Apophyseal Fractures. There is no standard method of treatment of fractures of the apophysis, because few such fractures have been described. Surgical treatment is indicated in situations where acceptable alignment cannot be achieved with closed methods. A recently published manuscript determined that fractures with more than 4 mm of displacement or with a noncongruent intra-articular surface should be treated surgically to achieve a better reduction and surgical outcome.[82] With mild to moderately displaced fractures, if a satisfactory closed reduction can be obtained, percutaneous pinning will stabilize the reduction. This can allow for casting in flexion, which is often better tolerated. For fractures with significant displacement, treatment is usually open reduction with internal fixation using a combination of axial pins and tension-band wiring (Fig. 13-57).[35,77,98] Gortzak et al.[34] described a technique of open reduction using percutaneously placed Kirschner wires and absorbable sutures instead of wires for the tension band. The percutaneously placed wires are subsequently removed 4 to 5 weeks postoperatively, eliminating the need for implant removal. Most stress injuries respond to simple rest from the offending activity. However, a chronic stress fracture can result in a symptomatic nonunion. Use of a compressive screw alone across the nonunion often is sufficient,[54] but supplemental bone grafting may be necessary to achieve union.[48,75]

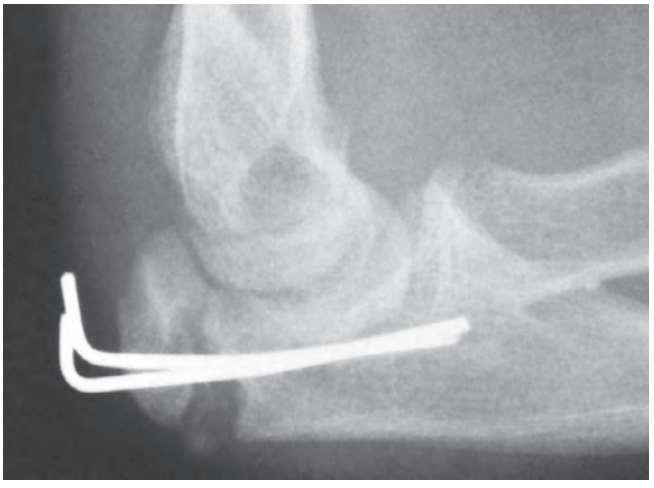
FIGURE 13-57 Operative treatment of an apophyseal fracture. **A:** Postoperative radiograph of the fracture shown in Figure 11-40D, which was stabilized with small Steinmann pins alone. **B:** Five months later, growth has continued in the traction center and the articular center is ossified (*arrow*).



C

D

FIGURE 13-57 (*continued*) **C:** One year after injury, the apophysis was partially avulsed a second time. The two secondary ossification centers are now fused. **D:** Three months after the second fracture, the fracture gap has filled in, producing a normal olecranon.

Metaphyseal Olecranon Fractures

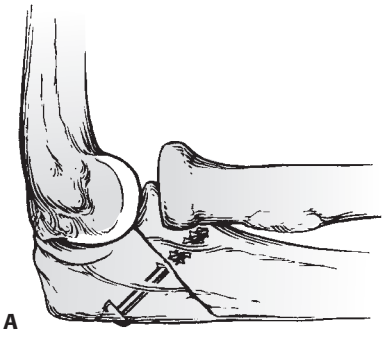
Flexion Injuries. If the fracture is significantly displaced or comminuted, open reduction with internal fixation usually is required. Recommended fixation devices vary from catgut or absorbable suture[56] to an axial screw,[55] tension-band wiring with axial pins,[26,35,56,89,91,98] or a plate.[105] Internal fixation allows early motion.

Extension Injuries. Treatment of extension injuries requires both adequate realignment of the angulation of the olecranon and treatment of the secondary injuries. Occasionally, in extension fractures, complete separation of the fragments requires open reduction and internal fixation (Fig. 13-56).

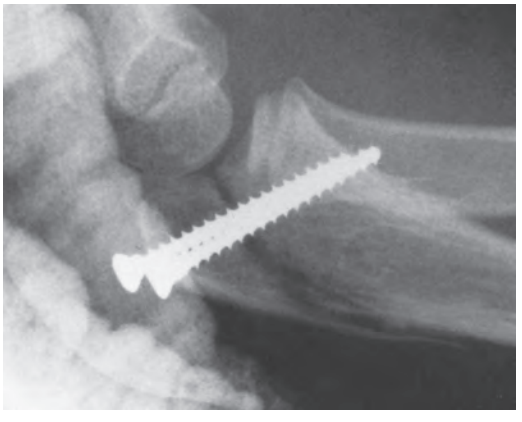
Shear Injuries. For anterior shear fractures, the key to management is recognition that the distal fragment is displaced anteriorly and the posterior periosteum remains intact. The intact posterior periosteum can serve as an internal tension band to facilitate reduction. If the periosteum is torn or early motion is desirable, Zimmerman[126] advocated internal fixation of the two fragments with an oblique screw perpendicular to the fracture line (Fig. 13-58).

Closed Reduction and Percutaneous Pinning

Preoperative Planning. To adequately prepare for this technique, we must carefully assess the fracture pattern and determine that an attempt at closed reduction is feasible. It is good practice to also prepare for the possibility that this technique may need to be abandoned and transitioned to an open procedure in the event that an adequate closed reduction is not attainable. Accordingly the patient, family, and operating room team should all be informed of these possibilities. The OR table, positioning of the patient, and equipment necessary for both closed and open procedures should be identified and available before beginning the surgery. Equipment needed for a potential open procedure can be left unopened in the sterile packaging, but should be visually accounted for and immediately available (Table 13-20).



A



B

FIGURE 13-58 Operative treatment of extension shear fractures. **A:** If the periosteum is insufficient to hold the fragments apposed, an interfragmentary screw can be used. **B:** An extension shear type of fracture secured with two oblique interfragmentary screws.

TABLE 13-20 Closed Reduction and Percutaneous Pinning of Fractures Involving the Proximal Apophysis and Olecranon Metaphysis

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Smooth Kirschner wires; power drill; tension-band equipment available
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet

Positioning. Same as for instrument-assisted closed reduction of proximal radius fractures.

Surgical Approach(es). A percutaneous approach is utilized starting at the subcutaneous border of the tip of the olecranon.

Technique. Simple steel K-wires are appropriate to use for this technique. Size will range from 2 to 2.7 mm based on the size of the child. Fluoroscopy is used to localize the fracture site and intended entry site of the wire. The fracture is then reduced with simultaneous elbow extension and thumb pressure over the olecranon. Once the fracture reduction is achieved, percutaneous K-wires are driven from the tip of the olecranon, across the fracture site, and exiting the far cortex. Fracture stability and pin configuration are then assessed with fluoroscopy. The pins are then cut and bent outside of the skin. We prefer placing a sterile felt pad between the cut pins and the skin, followed by a long-arm cast for immobilization. The pins are then removed in the office after the fracture has healed, typically 3 to 4 weeks (Table 13-21).

Open Reduction and Tension-Band Fixation

Preoperative Planning. Once it has been determined that satisfactory reduction is not achievable by closed methods, an open reduction is indicated. The preparation for this procedure includes ensuring proper OR table, fluoroscopy, patient positioning, and necessary equipment (Table 13-22).

TABLE 13-21 Closed Reduction and Percutaneous Pinning of Fractures Involving the Proximal Apophysis and Olecranon Metaphysis

Surgical Steps

- Attempt closed reduction
- Assess reduction with fluoroscopy
- Assess stability
  - If stable: Immobilize in long-arm cast
  - If unstable: Antegrade K-wire fixation
- Percutaneous insertion of K-wires to stabilize fracture
- Bend, cut wires outside skin

Positioning. The positioning for this procedure is the same as for the closed reduction and percutaneous pinning technique described above.

Surgical Approach(es). A standard posterior approach to the proximal ulna is used, with the incision spanning from 1 to 2 fingerbreadths proximal to the tip of the olecranon to 2 to 3 cm distal to the fracture site. The subcutaneous location of the ulna in this location allows for quick access to the fracture site. However, particularly close attention needs to be paid to delicate handling of the soft tissue envelop as there is commonly a fair amount of soft tissue trauma locally from the injury. It is recommended to shape the incision in a curvilinear fashion proximally to avoid placing the scar directly over the bony prominence of the olecranon.

Technique. Once the fracture is exposed a reduction can be performed with a bone reduction forceps. The reduction maneuver can be facilitated by first placing a small unicortical drill hole distal to the fracture site along the diaphysis of the ulna. Then with one tine of the forceps in the drill hole and the other tine at the tip of the olecranon, applying gentle compression with the forceps will help reduce and stabilize the fracture.

With the fracture now reduced two K-wires are driven in an antegrade fashion, parallel to each other, starting near the tip of the olecranon and coursing obliquely to cross the fracture site and exit the cortex of the anterior ulna. The fracture reduction and K-wire position are then assessed with fluoroscopy. The K-wires are then bent and cut in preparation for capture of the tension band. The wires are pulled back 3 to 4 mm at this time so that when fully impacted later they will not protrude too far beyond the anterior ulnar cortex.

In preparation for tension band application, a transverse tunnel is created in the ulnar diaphysis1 to 2 cm distal to the fracture site. It is critical to leave an intact cortical bridge of bone along the posterior aspect of the ulna superficial to the tunnel. A drill is used to perforate the medial and lateral cortex

TABLE 13-22 Open Reduction and Tension-Band Fixation of Fractures Involving the Proximal Apophysis and Olecranon Metaphysis

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Smooth Kirschner wires; tension-band equipment
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet

TABLE 13-23 Open Reduction and Tension-Band Fixation of Fractures Involving the Proximal Apophysis

Surgical Steps

- Expose proximal ulna
- Reduce fracture and provisionally stabilize with reduction clamp
- Assess reduction with fluoroscopy
- Insert two parallel antegrade K-wires in preparation for tension band
- Bend the proximal tip for later impaction
- Prepare bone tunnel in distal fragment for tension band
- Pass tension-band material through bone tunnel and around K-wires
- Stabilize fracture by securing the tension band
- Impact the proximal K-wires into the olecranon

of the ulna at the desired level of tunnel creation. A towel clip can then be inserted into these two pilot drill holes to finish creating the ulnar bone tunnel.

The tension-band material is then selected, either 18 to 20 gauge wire, or large absorbable or nonabsorbable suture. We frequently utilize no. 2 polyethylene core braided polyester suture (FiberWire, Arthrex, Naples FL) or no. 1 polydioxanone suture (PDS) instead of wire. The tension band is then passed through the ulnar bone tunnel and around the previously placed K-wires. Twisting the wires or tying the sutures tightens the tension band. At this point, the reduction clamp is removed and fracture stability assessed with elbow flexion/extension and fluoroscopy. The previously cut/bent K-wires are then impacted into the olecranon, finalizing the capture of the tension band (Table 13-23).

Open Reduction and Compression Screw Fixation

Preoperative Planning. The preparation for this procedure is the same as for the above tension-band technique with the exception of equipment/implant differences needed (Table 13-24).

TABLE 13-24 Open Reduction and Compression Screw Fixation of Fractures Involving the Proximal Apophysis and Olecranon Metaphysis

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Large fragment set (4.5- and 6.5-mm screws); smooth Kirschner wires; tension-band equipment
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet

TABLE 13-25 Open Reduction and Compression Screw Fixation of Fractures Involving the Proximal Apophysis

Surgical Steps

- Expose proximal ulna
- Reduce fracture and provisionally stabilize with reduction clamp
- Assess reduction with fluoroscopy
- Insert antegrade guide wire for appropriate size screw
- Starting point at tip of olecranon
- Drill/tap over guide wire
- Place appropriate-sized screw over guide wire

Positioning. The positioning for this procedure is the same as for the closed reduction and percutaneous pinning technique described above.

Surgical Approach(es). The approach for this procedure is the same as for the tension-band technique described above.

Technique. Once the fracture is exposed a reduction can be performed with a bone reduction forceps. The reduction maneuver can be facilitated by first placing a small unicortical drill hole distal to the fracture site along the diaphysis of the ulna. Then with one tine of the forceps in the drill hole and the other tine at the tip of the olecranon, applying gentle compression with the forceps will help reduce and stabilize the fracture.

With the fracture now reduced the guide pin from the cannulated screw system can be placed in an antegrade fashion starting near the tip of the olecranon, across the fracture site, and into the intramedullary canal of the ulna. Most commonly a 6.5-mm cancellous bone screw is selected. The screw tract is then drilled and tapped over the guide wire, followed by placement of the appropriate-sized screw. The alignment and stability are then assessed with elbow flexion/extension and fluoroscopy (Table 13-25).

Author's Preferred Treatment for Fractures of the Proximal Ulna

Apophyseal Fractures and Nondisplaced Fractures

For apophysitis and nondisplaced stress fractures, we ask the patient to cease the offending activity. During this period of rest, the patient should maintain upper extremity strength with a selective muscle exercise program as well as maintain cardiovascular conditioning. When a persistent nonunion of the olecranon in an adolescent does not demonstrate healing after a reasonable period of simple rest, we place a cannulated compression screw across the apophysis to stimulate healing.

Displaced Fractures

With minimal displacement of the fracture, satisfactory closed reduction can be obtained with the elbow extended. We usually

immobilize the elbow in a long-arm cast in extension. Percutaneous pinning will stabilize the reduction if there is any concern about loss of reduction. Completely displaced fractures are treated operatively using a tension-band technique. In young children, we use small Steinmann or Kirschner pins. Patients with large ossification centers are treated with a compression screw similar to those with metaphyseal fractures.

Metaphyseal Olecranon Fractures

We use a classification based on the mechanism of injury in choosing the method of treatment (Table 13-15).

Flexion Injuries

Nonoperative

We immobilize most nondisplaced flexion injuries with the elbow in 5 to 10 degrees of flexion for approximately 3 weeks. It is important to obtain radiographs of these fractures after approximately 5 to 7 days in the cast to ensure that there has not been any significant displacement of the fragment.

Operative: Tension Band

To determine which injuries need internal fixation, we palpate the fracture for a defect and flex the elbow to determine the integrity of the posterior periosteum. If the fragments separate with either of these maneuvers, they are unstable and are fixed internally so that active motion can be started as soon as possible.

We prefer a modification of the tension-band technique. Originally we used the standard AO technique with axial Kirschner wires or Steinmann pins and figure-of-eight stainless steel as the tension band (Fig. 13-59A). Because removal of the wire often required reopening the entire incision, we now often use an absorbable suture for the figure-of-eight tension band. no. 1 PDS suture, which is slowly absorbed over a few months, is ideal (Fig. 13-59B). When rigid internal fixation is applied, rapid healing at the fracture site produces internal stability before the PDS absorbs. We prefer Kirschner wires in patients who are very young and have very little ossification of the olecranon apophysis (Fig. 13-57). If the axial wires become a problem, we remove them through a small incision. Most recently, we have used a combination of an oblique cortical screw with PDS as the tension band (Fig. 13-59C, D) and are pleased with the results. In the past, we had to remove almost all the axial wires; very few of the screws cause enough symptoms to require removal. Occasionally, we use the tension-band wire technique with 16- or 18-gauge wire in a heavier patient.

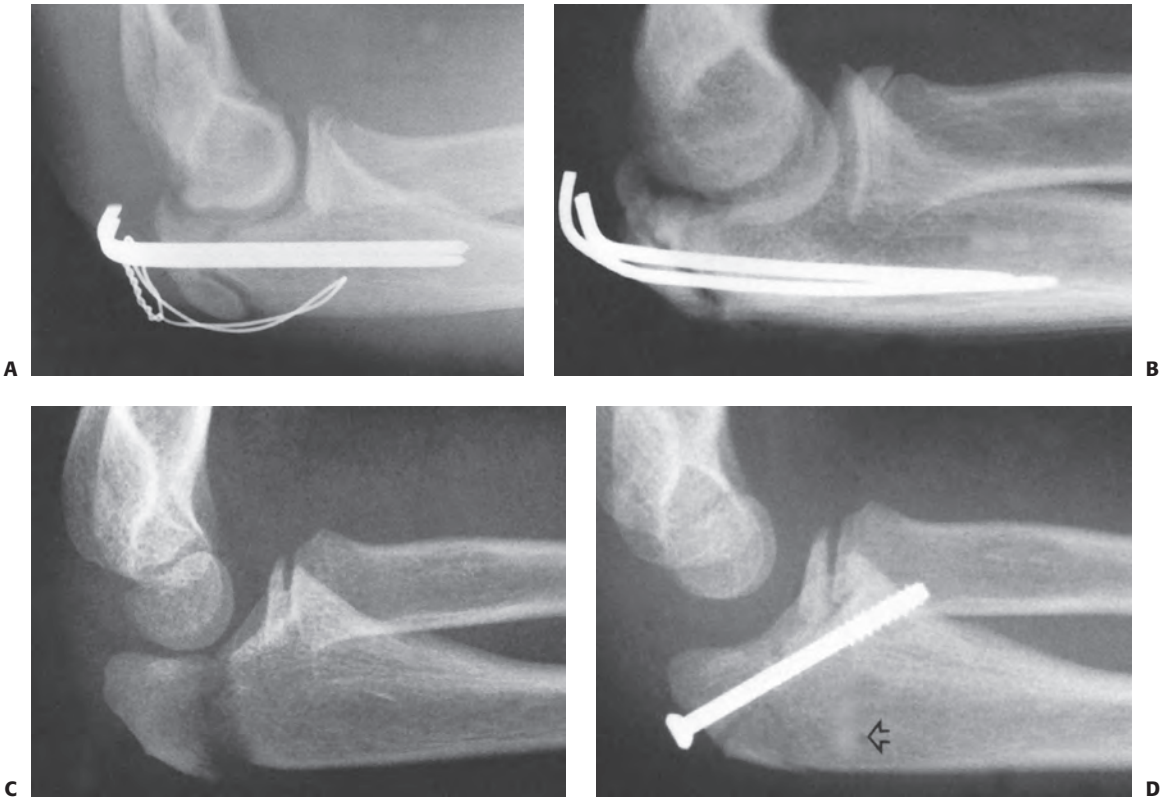


FIGURE 13-59 Internal tension-band techniques. **A:** Standard AO technique with stainless steel wire. The wire can be prominent in the subcutaneous tissues. **B:** Axial wires plus polydioxanone sutures (PDSs) 6 weeks after surgery. **C:** A displaced flexion-type injury in an 11-year-old male. There is complete separation of the fracture fragments. **D:** A cancellous lag screw plus PDS. The screw engages the anterior cortex of the coronoid process. The PDS passes through a separate drill hole in the olecranon (*open arrow*) and crosses in a figure-of-eight manner over the fracture site and around the neck of the screw.

Extension Injuries

For extension injuries, we anesthetize the patient to allow a forceful manipulation of the olecranon while it is locked in its fossa in extension. Because this is a greenstick fracture, we slightly overcorrect to prevent the development of reangulation. These fractures may require manipulation/remanipulation in 1 to 2 weeks if the original angulation recurs. Associated fractures are treated as if they were isolated injuries.

Shear Injuries

Most shear fractures can be treated nonoperatively. We usually immobilize them in enough flexion to hold the fragments together, if the posterior periosteum is intact (Fig. 13-60). If the periosteum is torn, an oblique screw is an excellent way to secure the fracture (Fig. 13-58). If considerable swelling prevents the elbow from being hyperflexed enough to use the posterior periosteum as a tension band, an oblique screw is a good choice.

Postoperative Care

A critical advantage of surgical management is the ability to allow and encourage early motion. Accordingly, with stable fixation, a brief period of immobilization postoperatively is in order. Typically this would entail 10 to 14 days of immobilization, to allow for wound healing, followed by active measures geared toward resumption of elbow/forearm range of motion.

Potential Pitfalls and Preventative Measures

Murphy et al.[63] compared the failure of various fixation devices under rapid loading: (a) Figure-of-eight wire alone, (b) cancellous screw alone, (c) AO tension band, and (d) cancellous screw

FIGURE 13-60 Shear injuries. **A:** Flexion pattern: Radiograph of the patient seen in Figure 11-45A after the elbow was flexed. The intact posterior periosteum acted as a tension band and held the fracture reduced. **B:** Radiograph taken 4 weeks after surgery shows new bone formation under the intact periosteum (*arrows*) on the dorsal surface of the olecranon. **C:** Extension pattern: Radiograph of patient with an extension shear injury showing an increase in the fracture gap (*arrows*) (see also Fig. 11-45B). **D:** Because the dorsal periosteum and cortex were intact, the fracture gap (*arrows*) closed with flexion of the elbow.

TABLE 13-26 Proximal Ulna Apophyseal and Metaphyseal Olecranon Fractures: Potential Pitfalls and Preventions

Pitfall	Preventions

Nonunion	Consider bone grafting Compression techniques
Loss of reduction in extension type	Reduce in extension, "over" reduce Pin if stability questionable

with a figure-of-eight wire combination. The cancellous screw alone and figure-of-eight wire alone were by far the weakest. The greatest resistance to failure was found in the combination of a screw plus figure-of-eight wire, followed closely by the AO tension-band fixation. In their clinical evaluation of patients, comparing the AO tension band and combination of screw and figure-of-eight wire, they found more clinical problems associated with the AO technique.[64] The main problem with the AO technique is the subcutaneous prominence of the axial wires[53,73] To prevent proximal migration of these wires, Montgomery devised a method of making eyelets in the proximal end of the wires through which he passed the figure-of-eight fixation wire.

Zimmerman[126] reported that the original angulation tends to redevelop in some extension type olecranon fractures. If a varus force produced the fracture, the proximal ulna or olecranon may drift back into varus, which can cause a painful subluxation of the radial head. A secondary osteotomy of the proximal ulna or olecranon may be necessary if the angulation is significant (Table 13-26).

Treatment-Specific Outcomes

There are no validated outcome measures on this population in the current literature. In general, the limited studies available report good-to-excellent outcomes with the techniques described above.

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures of the Proximal Ulna

Spur Formation. Overgrowth of the epiphysis proximally may produce a bony spur. Symptomatic spurs can be treated with surgical excision.

Nonunion. Nonunion is a rare event in these fractures, most likely occurring in the apophysitis/overuse type injuries. Bone grafting the nonunion and ensuring stable fixation with compression is the most efficacious method of treatment. Nonunion is unusual and should not be confused with congenital pseudarthrosis of the ulna, which is rare (Fig. 13-61). In the latter condition, there is no antecedent trauma.

FIGURE 13-61 Congenital pseudarthrosis of the olecranon in a 9-year-old female who had limited elbow extension and no antecedent trauma. The edges of the bone were separated by thick fibrous tissue. (Courtesy of Michael J. Rogal, MD.)

Apophyseal Arrest. Apophyseal arrest appears to have no significant effect on elbow function (Fig. 13-62). There has been concern that applying compressive forces across the apophysis might cause premature growth arrest. In our experience, fusion of the apophysis to the metaphysis is accelerated. Apophyseal fractures usually occur when the physis is near natural closure. The growth proximally is appositional rather than lengthwise across the apophyseal plate itself. As a result, we have not found any functional shortening of the olecranon because of the early fusion of the apophysis to the metaphysis (Fig. 13-57D). In practice, the use of a compression screw across an ossified olecranon fracture causes no loss of ulnar length. Children who sustain injuries before the development of the secondary ossification center may develop a deformity that is visible on radiographs (Fig. 13-62). Although there may be shortening of the olecranon, it does not appear to produce functional problems. There are no reports of the effects of this injury in very young children or infants.

Irreducibility. An and Loder reported inability to reduce the fracture in one of their patients because the proximal fragment was entrapped in the joint.

Delayed Union. Delayed radiographic union usually is asymptomatic.[56] In Mathews's series,[56] one fracture treated with suture fixation ultimately progressed to a nonunion. Despite this, the patient had only a 10-degree extension lag and grade 4 triceps strength. An accessory ossicle, such as a patella cubiti, is not a nonunion.

Compartment Syndrome. Mathews[56] described one patient with Volkmann ischemic contracture after an undisplaced linear fracture in the olecranon.

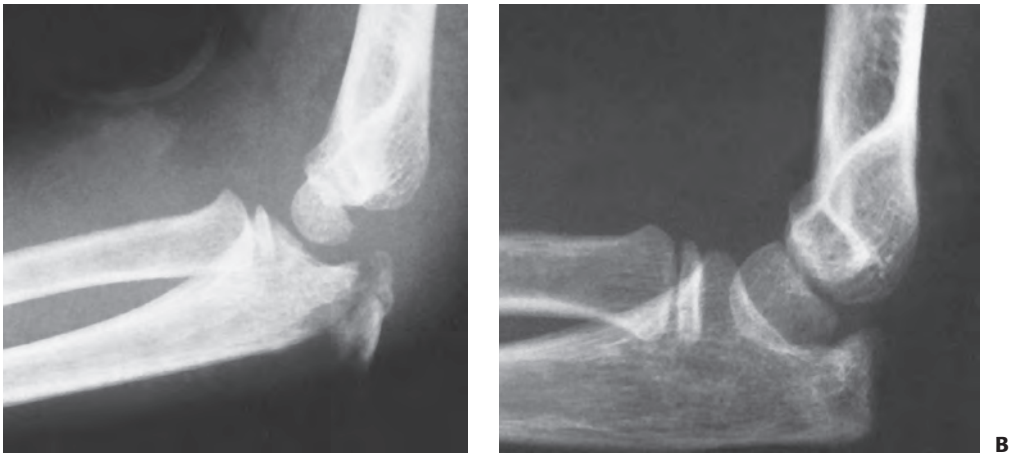

FIGURE 13-62 Preosseous apophyseal arrest. **A:** Comminuted fracture of the proximal olecranon from a direct blow to the elbow in an 8-year-old male. This fracture was treated nonoperatively. **B:** Radiograph 18 months later shows cessation of the proximal migration of the metaphyseal margin and a lack of development of a secondary ossification center. Despite this arrest of the apophysis, the patient had a full range of elbow motion.

Nerve Injuries. Zimmerman[126] reported ulnar nerve neurapraxia from the development of a pseudarthrosis of the olecranon where inadequate fixation was used.

Elongation. Elongation of the tip of the olecranon may complicate healing of a fracture. Figure 13-63 illustrates a delayed union in which the apophysis became elongated to the point that it limited extension. This proximal overgrowth of the tip of the apophysis has occurred in olecranon fractures after routine open reduction and internal fixation.[71]

Loss of Reduction. Apparently stable fractures treated with external immobilization may lose reduction, which results in a significant loss of elbow function (Table 13-27, Fig. 13-64).

Operative Treatment of Fractures of the Coronoid Process in Fractures of the Proximal Ulna

Indications/Contraindications

Regan and Morrey[84] found that the elbow often was unstable in type III fractures, and they secured these fractures with internal fixation. They had satisfactory results with type I and II fractures, but in only 20% of type III fractures were the results

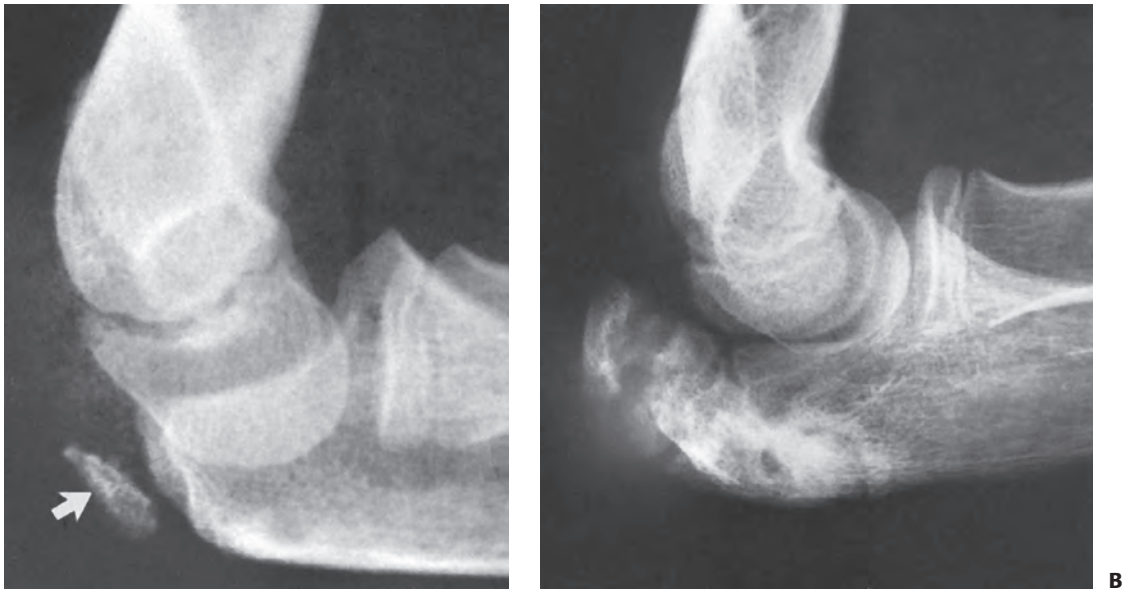

FIGURE 13-63 **A:** Injury film showing partial avulsion of the tip of the olecranon apophysis (*arrow*). **B:** Radiograph taken 4 years later shows a marked elongation and irregular ossification of the apophysis. (Courtesy of Joel Goldman, MD.)

TABLE 13-27 Proximal Ulna Apophyseal and Metaphyseal Olecranon Fractures: Common Adverse Outcomes and Complications

TABLE 13-28 ORIF of Coronoid Fractures

Preoperative Planning Checklist

- OR table: Standard with radiolucent hand table
- Position/positioning aids: Turn table 90 degrees, bring patient to edge of table toward hand table. Secure head with blanket/towel and tape. Safety strap over torso
- Fluoroscopy location: In line with affected extremity, perpendicular to OR table
- Equipment: Minifragment set (2–2.75-mm screws); dental picks
- Tourniquet (sterile/nonsterile): Nonsterile tourniquet

satisfactory that were treated nonoperatively. These indications were further supported by Aksu et al.[1], who recommends surgical management for all type III injuries.

The presence of a coronoid fracture alerts us to be especially thorough in looking for other injuries. In children, surgery is rarely necessary. If there is a large fragment and marked displacement, open reduction is indicated.

Open Reduction and Internal Fixation of Coronoid Fractures

Preoperative Planning. The preparation for ORIF of the coronoid process starts with ensuring familiarity with the local anatomy and anterior approach to this region. In addition, the surgeon needs to prepare for dealing with a relatively small-sized fracture fragment that will require significant precision for reduction and screw placement (Table 13-28).

Positioning. The positioning for this technique is the same as described previously in the apophyseal and metaphyseal fracture section.

Surgical Approach(es). This procedure is performed through a Henry anterior approach to the elbow. The anatomic plane of the deep dissection lies between the brachioradialis and brachialis. The radial nerve lies within this interval, and needs to be protected. The fracture fragment will likely have at least partial attachment of the brachialis.

Technique. As a result of the confined space anatomically in this location, the use of fracture reduction forceps will be challenging if not impossible. Accordingly, dental picks are very useful in obtaining reduction of this fracture. Once reduced, the fragment is fixed with a minifragment screw or sewn in place through two drill holes in the posterior aspect of the ulna. If there is significant comminution or the fragment is small, the pull through suture technique is superior (Table 13-29).

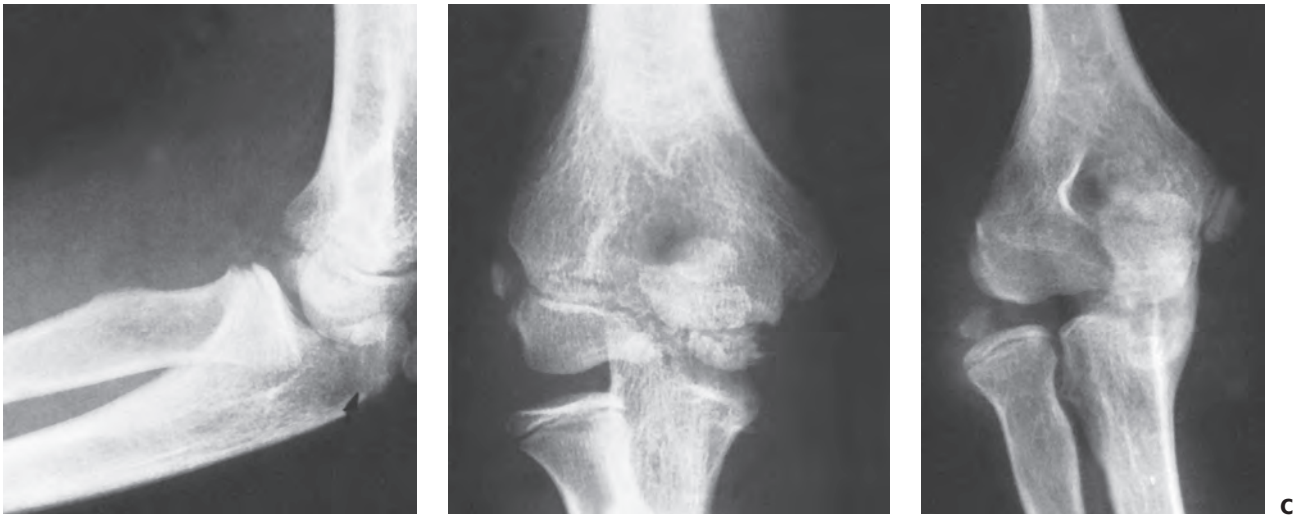

FIGURE 13-64 Loss of reduction. **A:** Lateral radiograph of what appeared to be a simple undisplaced fracture (*arrow*) of the olecranon in a 13-year-old female. **B:** On the anteroposterior film, the fracture also appears undisplaced. The mild lateral subluxation of the radial head was not recognized. **C:** Radiographs taken 5 months later showed further lateral subluxation with resultant incongruity of the elbow joint. (Courtesy of Richard W. Williamson, MD.)

TABLE 13-29 ORIF of Coronoid Fractures

Surgical Steps

- Expose proximal ulna via anterior Henry approach
- Protect the radial nerve
- Reduce fracture fragment using dental picks
- Fix fracture with appropriate size minifragment screw

Author's Preferred Treatment for Fractures of the Proximal Ulna

We usually treat coronoid fractures with early motion, much as we do elbow dislocations. The presence of a coronoid fracture alerts us to be especially thorough in looking for other injuries. In children, surgery is rarely necessary. If there is a large fragment and marked displacement, open reduction is done through a Henry anterior approach to the elbow. The fragment is fixed with a minifragment screw or sewn in place through two drill holes in the posterior aspect of the ulna.

Postoperative Care

A short period of immobilization, 10 to 14 days, followed by active range of motion is preferred. However, tenuous fixation may be encountered when treating these injuries. Intraoperative assessment of fixation and stability is warranted, and depending on the assessment, the postoperative care may need to be adjusted accordingly.

Potential Pitfalls and Preventative Measures (Table 13-30)

TABLE 13-30 Coronoid Fractures: Potential Pitfalls and Preventions

Pitfall	Preventions
Loss of fixation	Assess intraoperatively Cast longer if fixation tenuous
Elbow instability	Treat type III injuries operatively
Fragment comminution	Be prepared for pull through suture technique

Treatment-Specific Outcomes

As noted previously, Regan and Morrey[84] found that the elbow often was unstable in type III fractures, and they secured these fractures with internal fixation. They had satisfactory results with type I and II fractures, but in only 20% of type III fractures were the results satisfactory that were treated nonoperatively.

Management of Expected Adverse Outcomes and Unexpected Complications

Because of the high association of these injuries with elbow dislocations, postinjury stiffness is a concern. Accordingly, treatment modalities are selected to allow for early range of motion when possible. Complications are rare. In fractures with a large fragment (type III), the elbow may be unstable and prone to recurrent dislocations. Nonunion with the production of a free fragment in the joint occurs rarely in children (Table 13-31).[72]

TABLE 13-31 Coronoid Fractures: Common Adverse Outcomes and Complications

Elbow stiffness

Recurrent elbow instability

Summary, Controversies, and Future Directions Related to Fractures of the Proximal Radius and Ulna

A large portion of proximal radius and ulna fractures in children can be treated successfully by nonoperative methods. The surgical techniques described in this chapter are effective in achieving fracture union and good clinical results. However, the current literature is deficient in the area of functional outcome instruments for fractures of the proximal ulna and radius in children. The previously published studies on the outcomes of these fractures have used descriptive assessments that are currently nonvalidated techniques. Elbow range of motion after these injuries continues to be a driver of functional outcomes. As such, there is a definite need for both accurate methods of measuring range of motion as well as validated techniques for reporting the results.

14 MONTEGGIA FRACTURE-DISLOCATION IN CHILDREN

Apurva S. Shah and Peter M. Waters

Introduction to Monteggia Fracture-Dislocations

Monteggia fracture-dislocations are a rare but complex injury usually involving a fracture of the ulna associated with proximal radioulnar joint dissociation and radiocapitellar dislocation. These injuries comprise less than 1% of all pediatric forearm fractures and typically affect patients between 4 and 10 years of age.[77,156] The annual incidence of Monteggia fracture-dislocations in children is less than 1 in 100,000.[77] In 1814, Giovanni Battista Monteggia, a surgical pathologist and public health official in Milan, Italy, first described a variation of the injury that now bears his name as "a traumatic lesion distinguished by a fracture of the proximal third of the ulna and an anterior dislocation of the proximal epiphysis of the radius."[91,107,114] In 1967, Jose Luis Bado,[8,10] while director of the Orthopedic and Traumatology Institute in Montevideo, Uruguay, published his classic monograph on the classification of Monteggia lesions. Bado[8,10] described a Monteggia lesion as a radial head fracture or dislocation in association with a fracture of the middle or proximal ulna. Over the last century, numerous authors have made significant contributions on pathoanatomy, classification, diagnosis, treatment, and complications.[7,21,32–34,37,38,48,52,55,65,70,81,83,88,89,99,106,116,119,127,131,160]

Despite the increased understanding of Monteggia lesions, the injury continues to represent a challenge for the orthopedic surgeon. In 1943, Sir Watson-Jones wrote that "no fracture presents so many problems; no injury is beset with greater difficulty; no treatment characterized by more general failure."[158] Unfortunately, despite the increased awareness and understanding of Monteggia lesions, the initial diagnosis is still missed by qualified radiologists, emergency room physicians, and orthopedic surgeons amongst others.[18,42,43,48,50,60,81,84,108,119,121,127,131,151,160,163] In addition, less than optimal treatment of recognized but unstable injuries has also resulted in chronic Monteggia lesions.[34,38,48,57,62,70,74,116,118,119,161] A chronic Monteggia lesion can result in substantial morbidity, and is far more complex in terms of surgical decision making and management than an acute injury.[18,29,33,43,50,60,66,84,121,125]

Assessment of Monteggia Fracture-Dislocations

Classification of Monteggia Fracture-Dislocations

Bado Classification

Bado's[8,10] original classification has stood the test of time with minimal modifications except for the addition of various equivalent lesions (Fig. 14-1). The classification system is based upon the direction of the radial head dislocation and the apex of the associated ulna fracture. Bado's[8,10] four true Monteggia types are as follows:

Bado Type I

A Bado type I lesion is an anterior dislocation of the radial head associated with an apex anterior ulnar diaphyseal fracture at any level. This is the most common Monteggia lesion in children and represents approximately 70% to 75% of all injuries.[38,53,81,119,156]

Bado Type II

A Bado type II lesion is a posterior or posterolateral dislocation of the radial head associated with an apex posterior ulnar diaphyseal or metaphyseal fracture. This pattern is the most common Monteggia lesion in adults, but is relatively rare in children.[105,106,119] Type II lesions account for 6% of Monteggia lesions in children,[77] and are usually found in older patients[105] who have sustained significant trauma.[41,116,117]

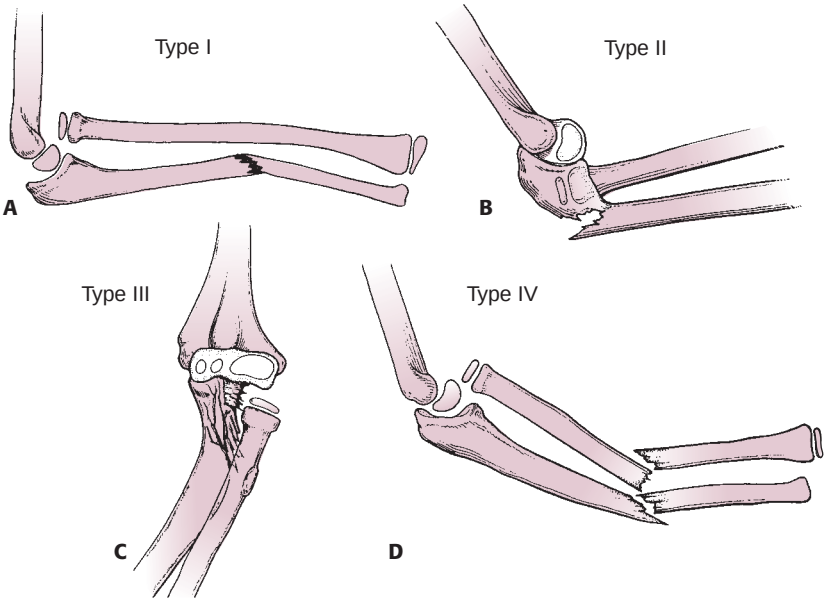

FIGURE 14-1 Bado classification. **A:** Type I (anterior dislocation): The radial head is dislocated anteriorly and the ulna has a short oblique or greenstick fracture in the diaphyseal or proximal metaphyseal area. **B:** Type II (posterior dislocation): The radial head is posteriorly or posterolaterally dislocated; the ulna is usually fractured in the metaphysis in children. **C:** Type III (lateral dislocation): There is lateral dislocation of the radial head with a greenstick metaphyseal fracture of the ulna. **D:** Type IV (anterior dislocation with radial shaft fracture): The pattern of injury is the same as with a type I injury, with the inclusion of a radial shaft fracture distal to the level of the ulnar fracture.

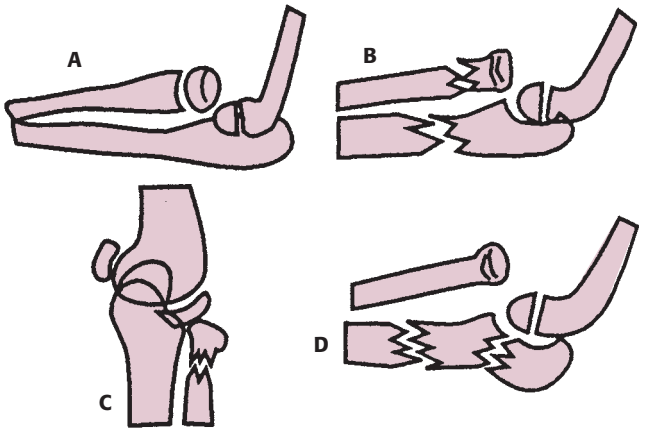

FIGURE 14-2 Type I equivalents. **A:** Isolated anterior radial head dislocation. **B:** Ulnar fracture with fracture of the radial neck. **C:** Isolated radial neck fractures. **D:** Elbow (ulnohumeral) dislocation with or without fracture of the proximal radius.

Bado Type III

A Bado type III lesion is a lateral dislocation of the radial head associated with a varus (apex lateral) fracture of the proximal ulna. This is the second most common pediatric Monteggia lesion.[13,48,98,103,160] When an injury is characterized by an olecranon fracture and a lateral or anterolateral radiocapitellar dislocation but no radioulnar dissociation, the injury is not a true Monteggia lesion.[63,118,146]

Bado Type IV

A Bado type IV lesion is an anterior dislocation of the radial head associated with fractures of both the ulna and the radius. The original description was of a radial fracture at the same level or distal to the ulna fracture. Type IV lesions are relatively rare in children.

Expansion of the Bado Classification: Monteggia Equivalent Lesions

Bado[8,10] classified certain injuries as equivalents to true Monteggia lesions because of their similar mechanisms of injury, radiographic appearance, or treatment methods. Since his original publication, the list of equivalent lesions has expanded case report by case report.

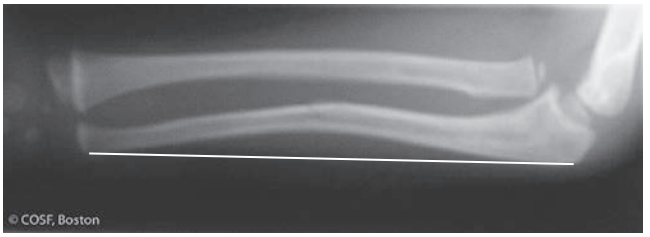

FIGURE 14-3 The ulnar bow line. This line, drawn between the distal ulna and the olecranon, defines the ulnar bow. The ulnar bow sign is deviation of the ulnar border from the reference line by more than 1 mm.

Type I Equivalents

Bado type I equivalents (Fig. 14-2) include isolated anterior dislocations of the radial head without ulnar fracture. This subclassification includes a "pulled elbow" or "nursemaid's elbow" because the mechanism of longitudinal traction, pronation, and hyperextension is similar to a true type I lesion. In nursemaid's elbow cases, the radiographs are normal. In type I equivalent lesions, the radial head is malaligned in its relationship to the capitellum and proximal ulna. However, the ulnar bow sign (Fig. 14-3) is normal as opposed to subtle plastic deformation of the ulna which will have a concave ulnar bow and can be misdiagnosed as a type I equivalent when the injury is really a Bado I lesion. This distinction can be critical in terms of operative decision making in that the type I equivalent lesion requires only open repair of the displaced ligament while the Bado type I lesion with plastic deformation requires correction of the ulnar deformity. Other type I equivalents (Fig. 14-2) include anterior dislocation of the radial head with ulnar metaphyseal or diaphyseal fracture and radial neck fracture; anterior dislocation of the radial head with radial diaphyseal fracture more proximal to ulnar diaphyseal fracture; anterior radial head dislocation with ulnotrochlear dislocation (Fig. 14-4)[119];

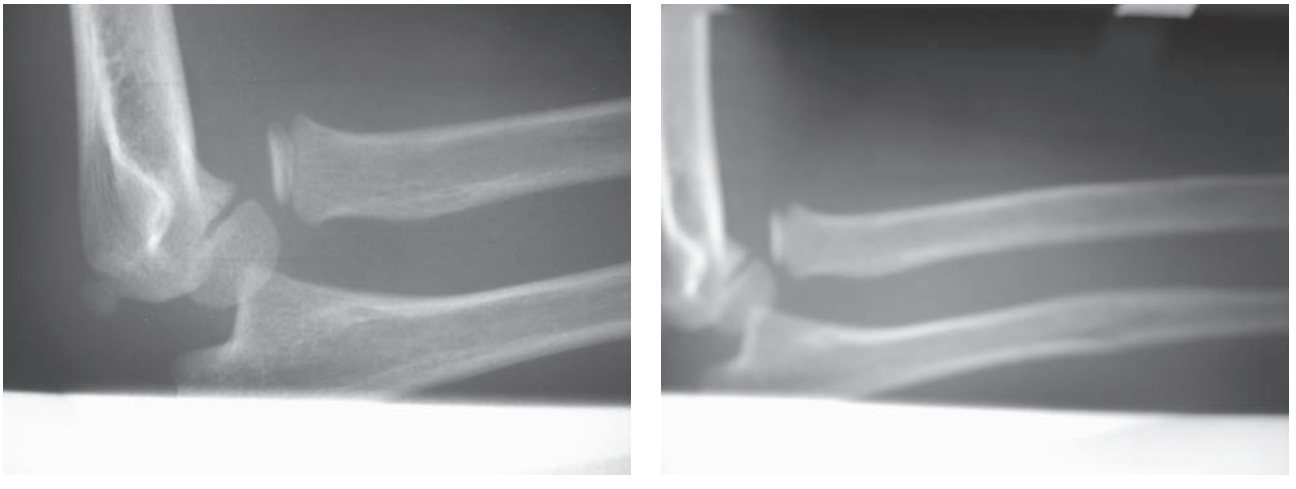

FIGURE 14-4 Type I equivalent that includes elbow subluxation in addition to the radioulnar dislocation.

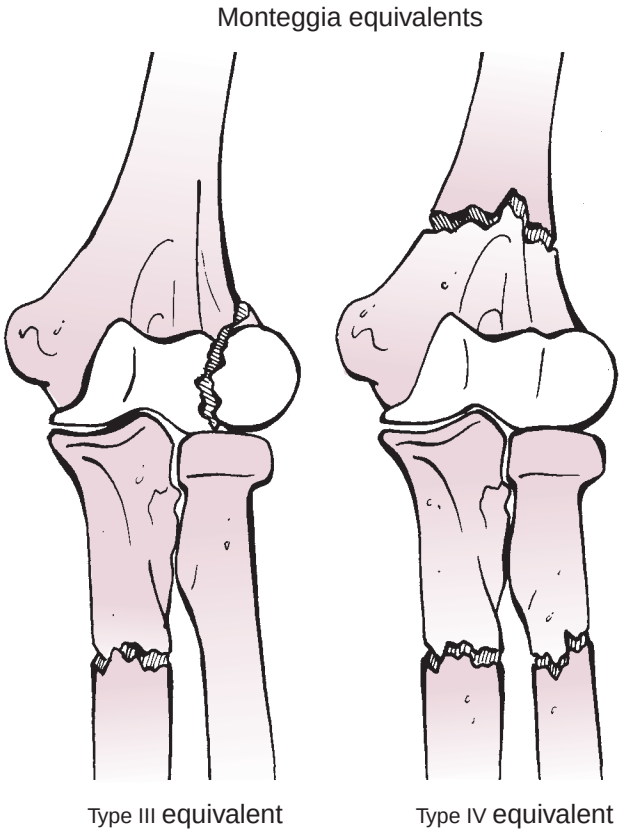

FIGURE 14-5 Type III equivalent described by Ravessoud[115]: An oblique fracture of the ulna with varus alignment and a displaced lateral condylar fracture. Type IV equivalent described by Arazi[5]: Fractures of the distal humerus, ulnar diaphysis, and radial neck.

and anterior dislocation of the radial head with segmental ulna fracture.[2,53,63,110,123,146] More case reports will probably expand this subclassification over time. The type I equivalents have been shown to have poorer outcomes and require more frequent operative intervention than true Monteggia lesions.[53,98] Poor outcomes may relate to intra-articular injury, coronoid fracture, comminution of the ulna fracture, and comminution of the radial head fracture.[126]

Type II Equivalents

Bado[8,10] described type II equivalents to include posterior radial head dislocations associated with fractures of the proximal radial epiphysis or radial neck.

Type III and Type IV Equivalents

Bado[8,10] did not have equivalent lesions for the true type III and type IV lesions. Because mechanism of injury allows for this subclassification, case reports have emerged over time to include fractures of the distal humerus (supracondylar, lateral condylar) in association with proximal forearm fractures (Fig. 14-5).[5,16,17,36,46,51,53,54,86,95,110,115,120,123,129]

Letts Classification

Letts et al.[81] have described an alternate classification schedule for pediatric Monteggia fracture-dislocations based both on direction of radial head dislocation and the type of ulnar fracture (Fig. 14-6). Letts types A, B, and C are analogous to Bado type I lesions and are characterized by anterior dislocation of the radial head with an associated ulnar fracture. In a type A lesion there is plastic deformation of the ulna; in a type B lesion there is an incomplete or greenstick ulnar fracture, and in a type C lesion there is a complete ulnar fracture. Letts type D lesions are equivalent to Bado type II injuries and are characterized by posterior radial head dislocation. Letts type E lesions are equivalent to Bado type III injuries and are characterized by lateral radial head dislocation.

Author's Preferred Classification

Ring, Jupiter, and Waters[118,119] defined a Monteggia lesion as a proximal radioulnar joint dislocation in association with a forearm fracture. In this classification system, it is the character of the ulnar fracture, more so than the direction of the radial head dislocation, that is most useful in determining the optimal treatment of Monteggia fracture-dislocations in both adults and children. Stable anatomic reduction of the ulnar fracture almost always results in anatomic, stable reduction of the radial head, proximal radioulnar joint, and radiocapitellar joint in the acute

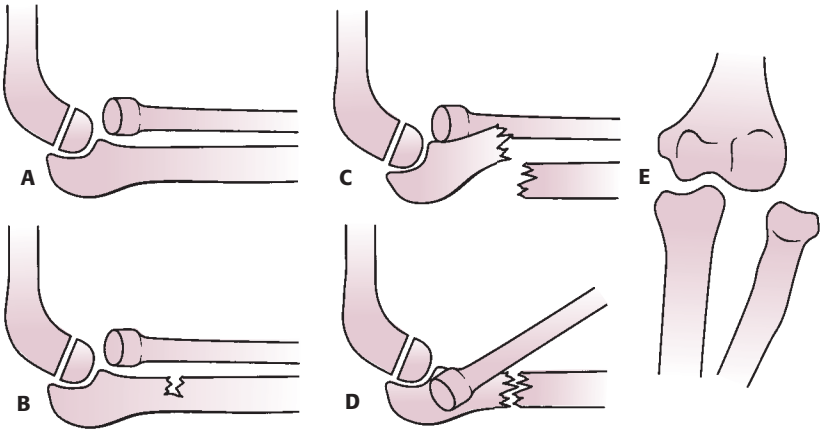

FIGURE 14-6 Pediatric Monteggia fracture-dislocation classification by Letts et al.[81] **A:** Anterior dislocation of the radial head with plastic deformation of the ulna. **B:** Anterior dislocation of the radial head with greenstick fracture of the ulna. **C:** Anterior dislocation of the radial head with complete fracture of the ulna. **D:** Posterior dislocation of the radial head with fracture of the ulnar metaphysis. **E:** Lateral dislocation of the radial head and metaphyseal greenstick fracture of the ulna.

TABLE 14-1 Author's Classification of Monteggia Fracture-Dislocations

Type	Dislocation	Fracture
True lesions		
I	Anterior	Metaphysis–diaphysis
II	Posterior	Metaphysis–diaphysis
III	Lateral	Metaphysis
IV	Anterior	Radial diaphysis, ulnar diaphysis
Hybrid lesion	Anterior, posterior, or lateral	Metaphysis or olecranon

Type	Description
Equivalent lesions	
I	Isolated dislocation of radial head Radial neck fracture (isolated) Radial neck fracture in combination with a fracture of the ulnar diaphysis Radial and ulnar fractures with the radial fracture above the junction of the middle and proximal thirds Fracture of ulnar diaphysis with anterior dislocation of radial head and an olecranon fracture
II	Posterior dislocation of the elbow
III	Ulnar fracture with displaced fracture of the lateral condyle
IV	None described

setting. The ulnar fracture is defined similarly to all pediatric forearm fractures: Plastic deformation, incomplete or greenstick fractures, and complete fractures. Complete fractures are further subdivided into transverse, short oblique, long oblique, and comminuted fractures. Treatment directly relates to the fracture type: Closed reduction for plastic deformation and greenstick fractures; intramedullary fixation for transverse and short oblique fractures; and open reduction and internal fixation with plate and screws for long oblique and comminuted fractures (Table 14-1).

Mechanisms of Injury for Monteggia-Fracture Dislocations

Type I Mechanism of Injury

Three separate mechanisms of type I lesions have been described: direct trauma,[10,22,27,42,96,113,116,131,151] hyperpronation, and hyperextension.[22,116]

Direct Blow Theory

The first theory proposed in English literature was the direct blow mechanism described by Speed and Boyd[131] and endorsed by Smith (Fig. 14-7).[127] This theory was actually proposed by Monteggia,[91] who noted that the fracture occurs when a direct blow on the posterior aspect of the forearm first produces a fracture through the ulna. Then, either by continued deformation or direct pressure, the radial head is forced anteriorly with respect to the capitellum, causing the radial head to dislocate. Monteggia[91] explained that these injuries sometimes resulted from a blow by a staff or cudgel on the forearm raised to protect the head.

The parry fracture, another term for the Monteggia fracture-dislocation, has been mentioned in the literature. During the American Civil War, Monteggia fractures were frequent because of direct blows on the forearm received while attempting to parry the butt of a rifle during hand-to-hand combat. The major argument against this theory as the mechanism is that in the usual clinical situation, there rarely is evidence of a direct blow to the posterior aspect of the forearm, such as a contusion or laceration.[42,151]

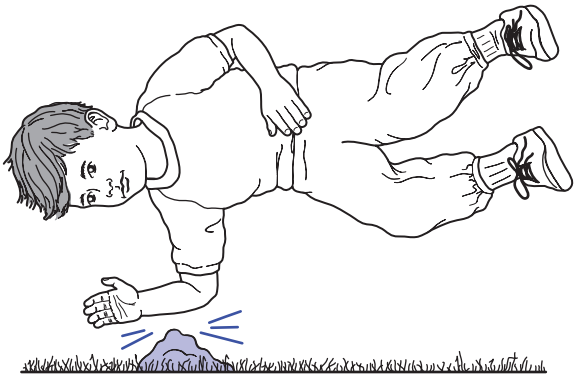

FIGURE 14-7 Mechanism of injury for type I Monteggia lesions: Direct blow theory. The fracture-dislocation is sustained by direct contact on the posterior aspect of the forearm, either by falling onto an object or by an object striking the forearm. The continued motion of the object forward dislocates the radial head after fracturing the ulna.

Hyperpronation Theory

In 1949, Evans[42] published his observations regarding anterior Monteggia fracture-dislocations. Previous investigators had based their direct blow theory on hypothesis and clinical observation, but Evans used cadaveric investigation to support his hyperpronation theory. He demonstrated that hyperpronation of the forearm produced a fracture of the ulna with a subsequent dislocation of the radial head. He postulated that during a fall, the outstretched hand, initially in pronation, is forced into further pronation as the body twists above the planted hand and forearm (Fig. 14-8). This hyperpronation forcibly rotates the radius over the middle of the ulna, resulting in either anterior dislocation of the radial head or fracture of the proximal third of the radius, along with fracture of the ulna. In actual patients reported on by Evans, the ulnar fractures demonstrated a pattern consistent with anterior tension and shear or longitudinal compression. His cadaveric investigation, however, showed the ulnar fracture pattern to be consistent with a spiral or rotational force. The hyperpronation theory was also supported by Bado.[9]

Two arguments have been used to dispute the hyperpronation mechanism.[151] First, the ulnar fracture rarely presents clinically in a spiral pattern; it is often oblique, indicating an initial force in tension with propagation in shear rather than rotational. Second, the Evans experiments, which were performed on totally dissected forearms,[42] did not take into consideration the dynamic muscle forces at play during a fall on an outstretched hand.

Hyperextension Theory

In 1971, Tompkins[151] analyzed both theories and presented good clinical evidence that type I Monteggia fracture-dislocations were caused by a combination of dynamic and static forces. His study postulated three steps in the fracture mechanism: Hyperextension, radial head dislocation, and ulnar fracture (Fig. 14-9). The patient falls on an outstretched arm with forward momentum, forcing the elbow joint into hyperextension. The radius is first dislocated anteriorly by the violent reflexive contracture of the biceps, forcing the radius away from the capitellum. Once the proximal radius dislocates, the weight of the body is transferred to the ulna. Because the radius is usually the main load-bearing bone in the forearm, the ulna cannot handle the transmitted longitudinal force and, subsequently, fails in tension. This tension force produces an oblique fracture line or a greenstick fracture in the ulnar diaphysis or at the diaphyseal–metaphyseal junction. In addition to the momentum of the injury, the anterior angulation of the ulna results from the pull of the intact interosseous membrane on the distal fragment, causing it to follow the radius. The brachialis muscle causes the proximal ulnar fragment to flex.

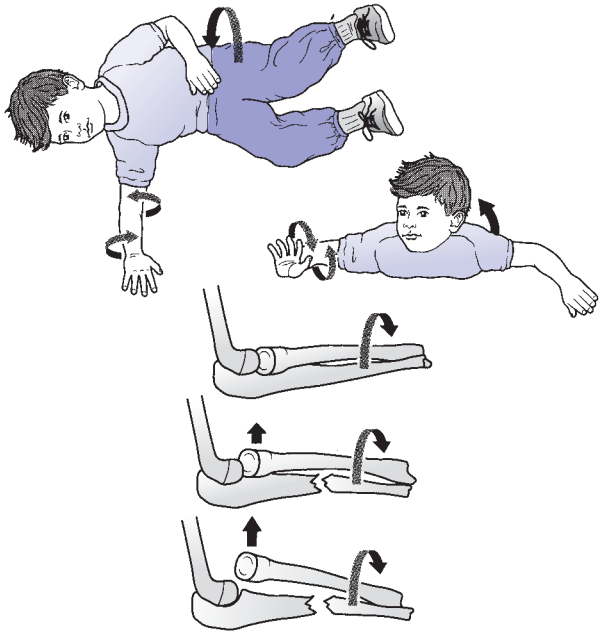

FIGURE 14-8 Mechanism of injury for type I Monteggia lesions: Hyperpronation theory (Evans).[42] Rotation of the body externally forces the forearm into pronation. The ulnar shaft fractures with further rotation, forcibly dislocating the radial head.

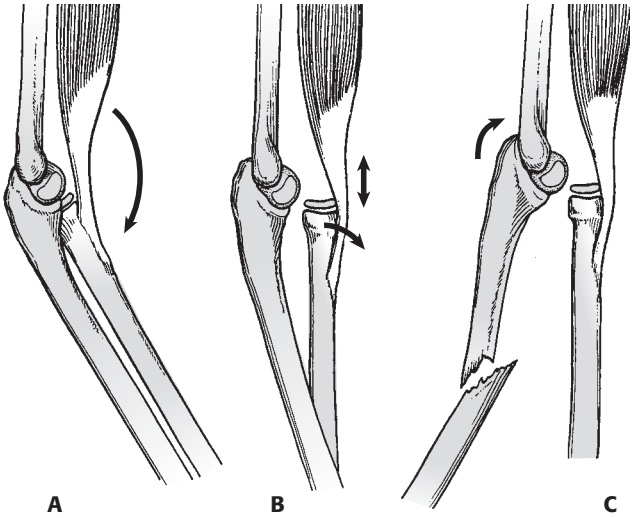

FIGURE 14-9 Mechanism of injury for type I Monteggia lesions: Hyperextension theory (Tompkins).[151] **A:** Forward momentum caused by a fall on an outstretched hand forces the elbow into hyperextension. **B:** The biceps contracts, forcibly dislocating the radial head. **C:** Continued forward momentum causes the ulna to fracture because of tension on the anterior surface.

Summary of Type I Mechanism of Injury

The type I lesion can probably be caused by any of the three proposed mechanisms, but the most common mechanism is a fall on an outstretched hand that forces the elbow into complete extension, locking the olecranon into the humerus. The forearm is in a rotational position of neutral to midpronation. As the proximal ulna locks into the distal humerus, the bending force stresses the proximal radioulnar joint. Because of the relatively pronated position of the joint, the ligamentous restraints are lax, providing only tenuous stability for the radial head. The anterior bending force, combined with a reflexive contraction of the biceps, violently dislocates the radial head

anteriorly. The radioulnar joint and its ligamentous complex are at risk because of the ligamentous laxity and the decreased contact area between the proximal radius and ulna created by the rotation of the forearm. At midrotation, the short axis of the elliptical radial head is perpendicular to the ulna, causing the annular ligament and the dense anterior portion of the quadrate ligament to be relaxed. The contact area of the proximal radioulnar joint, because of the shape of the radial head, is also decreased, further reducing the stability of the joint. The ulna, now the main weight-bearing structure of the forearm, is loaded by a continued bending moment, causing tension on the anterior cortex and producing failure. The force at the site of failure is propagated in shear at approximately 45 degrees to the long axis of the ulna. This mechanism may produce plastic deformation with an anterior bow, a greenstick fracture, or an oblique fracture pattern, all of which are observed clinically. As the anterior bending movement continues, the vector of the biceps changes and acts as a tether and resists any further advance of the proximal radius. The distal fragment of the ulna continues to advance, acting as a fulcrum against the radial shaft. The anteriorly directed force of the distal ulnar fragment, combined with the retrograde resistance of the biceps, may create a fracture of the radius, or a type IV lesion.

Type II Mechanism of Injury for Monteggia-Fracture Dislocations

The cause of the type II Monteggia lesion is subject to debate. Bado[10] thought the lesion was caused by direct force and sudden supination. Penrose[108] analyzed seven fractures in adults and noted that a proximal ulnar fracture was the typical pattern. He postulated that the injury occurred by longitudinal loading rather than by direct trauma.[131] Olney and Menelaus[98] reported four type II lesions in their series of pediatric Monteggia fractures. Three of these patients had proximal ulnar fractures and one had an oblique midshaft fracture, suggesting two different mechanisms of injury.

The mechanism proposed and experimentally demonstrated by Penrose[108] was that type II lesions occur when the forearm is suddenly loaded in a longitudinal direction with the elbow in approximately 60 degrees of flexion. This investigation demonstrated that a type II lesion occurred consistently if the ulna fractured; otherwise, a posterior elbow dislocation was produced (Fig. 14-10). The difference in bone strength of the ulna may explain the reason for the high incidence of type II Monteggia lesions in older adults and their rarity in children. Penrose[108] further noted that the rotational position of the forearm did not seem to affect the type of fracture produced.

Haddad et al.[58] described type II injuries caused by low-velocity injuries in six adults, five of whom were on long-term corticosteroid therapy. They suggested that this supports the theory that the type II Monteggia injury is a variant of posterior elbow dislocation, in that it occurs when the ulna is weaker than the ligaments surrounding the elbow joint, resulting in an ulnar fracture before the ligament disruption required for dislocation.

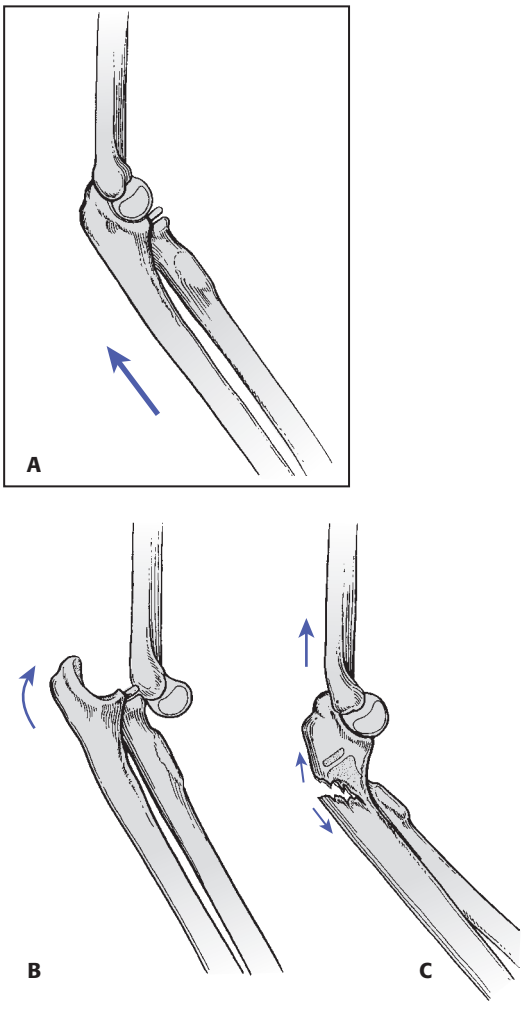

FIGURE 14-10 Mechanism of injury for type II Monteggia lesions. **A:** With the elbow flexed approximately 60 degrees; a longitudinal force is applied, parallel to the long axis of the forearm. **B:** This force may result in a posterior elbow dislocation. **C:** If the integrity of the anterior cortex of the ulna is compromised, a type II fracture-dislocation occurs.

Type III Mechanism of Injury for Monteggia-Fracture Dislocations

Wright[163] studied fractures of the proximal ulna with lateral and anterolateral dislocations of the radial head and concluded that the mechanism of injury was varus stress at the level of the elbow, in combination with an outstretched hand planted firmly against a fixed surface (Fig. 14-11). This usually produces a greenstick ulnar fracture with tension failure radially and compression medially. The radial head dislocates laterally, rupturing the annular ligament. Hume[63] suggested that type III lesions may be the result of hyperextension of the elbow combined with pronation of the forearm. Other authors confirmed the mechanism of varus force at the elbow as the cause of type III injuries.[10,38,93,106,146] The direction of the radial head dislocation is probably determined by the rotational and angular force applied simultaneously to the varus moment at the elbow.[93]

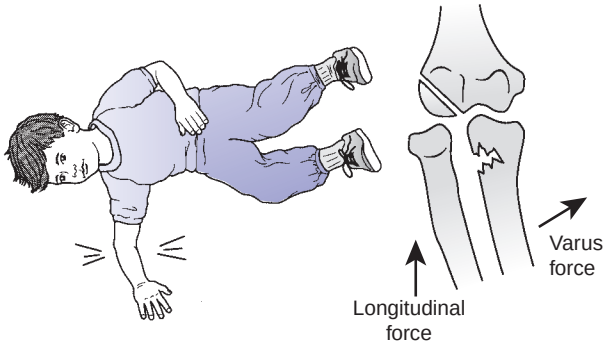

FIGURE 14-11 Mechanism of injury for type III Monteggia lesions. A forced varus stress causes a greenstick fracture of the proximal ulna and a true lateral or anterolateral radial head dislocation.

Type IV Mechanism of Injury for Monteggia-Fracture Dislocations

Bado[8] proposed that a type IV lesion is caused by hyperpronation. Of the case reports discussing the mechanism of injury, both hyperpronation[48] and a direct blow[120] have been postulated. Olney and Menelaus[98] reported a single type IV lesion in their series but did not discuss the mechanism. Type IV lesions appear to be caused by the mechanism described for type I lesions.

Associated Injuries with Monteggia Fracture-Dislocations

Monteggia lesions have been associated with fractures of the wrist and the distal forearm,[10] including distal radial and ulnar metaphyseal and diaphyseal fractures.[10,64,66,120] Galeazzi fractures may also occur with Monteggia lesions.[10,27,28,80] Radial head and neck fractures are commonly associated with type II fractures[10,77] but may occur with other types.[1,45,49,141] With a type II lesion, the radial head fracture is usually at the anterior rim.[41,105] Strong et al.[140] reported two type I equivalent lesions consisting of a fractured radial neck and midshaft ulnar fracture. This injury pattern is notable because of significant medial displacement of the distal radial fragment. Obtaining and maintaining reduction of the radius proved difficult with a closed technique.

Fractures of the distal humerus lateral condyle have also been associated with Monteggia fractures.[31,106] Ravessoud[115] reported an ipsilateral ulnar shaft lesion and a lateral condylar fracture without loss of the radiocapitellar relation, suggesting a type II equivalent (Fig. 14-5). Kloen et al.[72] reported a bilateral Monteggia fracture-dislocation and described the operative technique for its treatment. Despite surgical and rehabilitative challenges, excellent results were obtained in both elbows. In essence, any fracture about the elbow and forearm should be inspected for an associated Monteggia lesion.

Signs and Symptoms of Monteggia Fracture-Dislocations

Type I Clinical Findings

Bado,[8,10] in his original description, provided an accurate clinical picture of Monteggia fracture-dislocations. In general, there is fusiform swelling about the elbow. The child has significant pain and has limitations in elbow flexion and extension as well as forearm pronation and supination. Usually, an angular change in the forearm itself is evident, with the apex shifted anteriorly and mild valgus apparent. There may be tenting of the skin or an area of ecchymosis on the volar aspect of the forearm. It is imperative to check for an open fracture wound. The child may not be able to extend the fingers at the metacarpophalangeal joints or retropulse the thumb secondary to a posterior interosseous nerve palsy. Later, as the swelling subsides, anterior fullness may remain in the cubital fossa for the typical type I lesion. However, this finding may be subtle because children will usually have an elbow flexion posture following injury. If the injury is seen late, there will be a loss of full flexion at the elbow and a palpable anterior dislocation of the radial head. The radial head–distal humerus impingement that occurs may be a source of pain with activities. There is usually loss of forearm rotation with late presentation. Progressive valgus may occur if the anterior radial head dislocation worsens.

Type II Clinical Findings

Similar to type I lesions, the elbow region is swollen but exhibits posterior angulation of the proximal forearm and a marked prominence in the area posterolateral to the normal location of the radial head. The entire upper extremity should be examined because of the frequency of associated injuries.[74,105]

Type III Clinical Findings

Lateral swelling, varus deformity of the elbow, and significant limitation of motion (especially supination) are the hallmarks of type III Monteggia fracture-dislocations. Again, these signs can be subtle and missed by harried clinicians. Injuries to the radial nerve, particularly the posterior interosseous branch, occur more frequently with type III lesions than other Monteggia fracture-dislocations.[13,119,134]

Type IV Clinical Findings

The appearance of the limb with a type IV lesion is similar to that of a type I lesion. However, more swelling and pain can be present because of the magnitude of force required to create this complex injury. Particular attention should be given to the neurovascular status of the limb, anticipating the possible increased risk for a compartment syndrome.

Clinical Findings in Monteggia Equivalents and Associated Injuries

In a Monteggia equivalent injury, clinical findings are similar to those for the corresponding Bado lesion, with the common triad of pain, swelling, and deformity. Given the frequency of associated skeletal injuries, a careful examination of the entire upper extremity should be performed. This involves careful inspection of the skin and palpation of the distal humerus lateral condyle, the distal radius, and the distal radioulnar joint. Given the high frequency of radial nerve injuries with Monteggia fracture-dislocations,[13,14,63,96,119,127,134] a careful examination of neurologic examination should be performed. Because the posterior interosseous branch is most commonly injured,

FIGURE 14-12 Type I lesion. **A:** The AP forearm radiograph demonstrates an ulnar fracture and an apparently located radial head. **B:** However, the lateral view reveals anterior dislocation of the radial head. Note the disruption of the radiocapitellar line.

the clinician should routinely examine motor function of the extensor digitorum comminus and the extensor pollicis longus. Failure to extend the fingers at the metacarpophalangeal joints or retropulse the thumb are concerning for a posterior interosseous nerve palsy.

Imaging and Other Diagnostic Studies for Monteggia-Fracture Dislocations

The standard evaluation of a Monteggia fracture-dislocation includes anteroposterior (AP) and lateral radiographs of the forearm and elbow. Any disruption of the ulna, including subtle changes in ulnar bowing, should alert the clinician to look for disruption of the proximal radioulnar joint.[30,32,68,70,83] Unfortunately, the dislocated radial head is all too often missed in the acute setting. It must be stressed that every forearm and elbow injury requires close scrutiny of the radial head–capitellar relationship. In cases where plain radiographs are concerning but equivocal, fluoroscopic imaging or cross-sectional imaging such as magnetic resonance imaging (MRI) or ultrasound scan should be strongly considered. The goal for every radiologist, orthopedist, and emergency department physician should be to never miss a Monteggia lesion in the acute setting.

Type I Radiographic Evaluation

The radiographic alignment of the radial head and capitellum is particularly important and is best defined by a true lateral view of the elbow. In a type I Monteggia fracture-dislocation, the radiocapitellar relationship may appear normal on an AP radiograph despite obvious disruption on the lateral view (Fig. 14-12). If there is any doubt regarding the radiocapitellar alignment, further radiographic evaluation must be obtained. Smith[127] and later Storen[138] noted that a line drawn through the center of the radial neck and head should extend directly through the center of the capitellum. This alignment should remain intact regardless of the degree of flexion or extension of the elbow (Fig. 14-13). In some instances, there is disruption of the radiocapitellar line in a normal elbow. Miles and Finlay[90] pointed out that the radiocapitellar line passes through the center of the capitellum only on a true lateral projection.

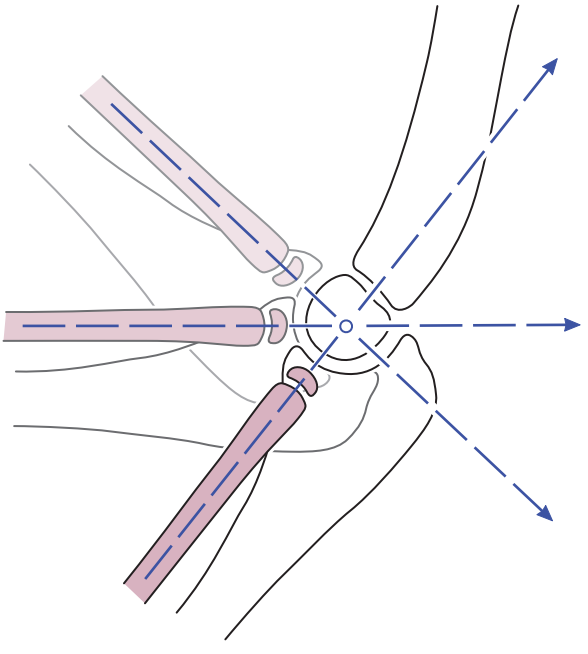

FIGURE 14-13 Radiocapitellar line. A composite drawing with the elbow in various degrees of flexion. A line drawn down the long axis of the radius bisects the capitellum of the humerus regardless of the degree of flexion or extension of the elbow.

They reported five patients in whom the elbow was clinically normal but the radiocapitellar line appeared disrupted. In analyzing the radiographs, they found that the radiographic projection of the elbow was usually an oblique view or that the forearm was pronated in the radiograph. If this disruption appears on radiographs in a child with an acute injury, however, it is the treating surgeon's responsibility to ensure that it is an insignificant finding.

As John Hall often said, "Monteggia lesions are not like throwing horse shoes; being close does not count." It is still too frequent an occurrence that a highly qualified, distraught, orthopedic surgeon will call for referral of a chronic Monteggia lesion that was missed acutely. With late presentation of a chronic Monteggia injury, an MRI scan may be useful to determine the congruency of the radial head and capitellum. If the radial head is no longer centrally concave or the capitellum is no longer symmetrically convex, surgical reduction may fail to improve pain or restore motion.

Type II Radiographic Evaluation

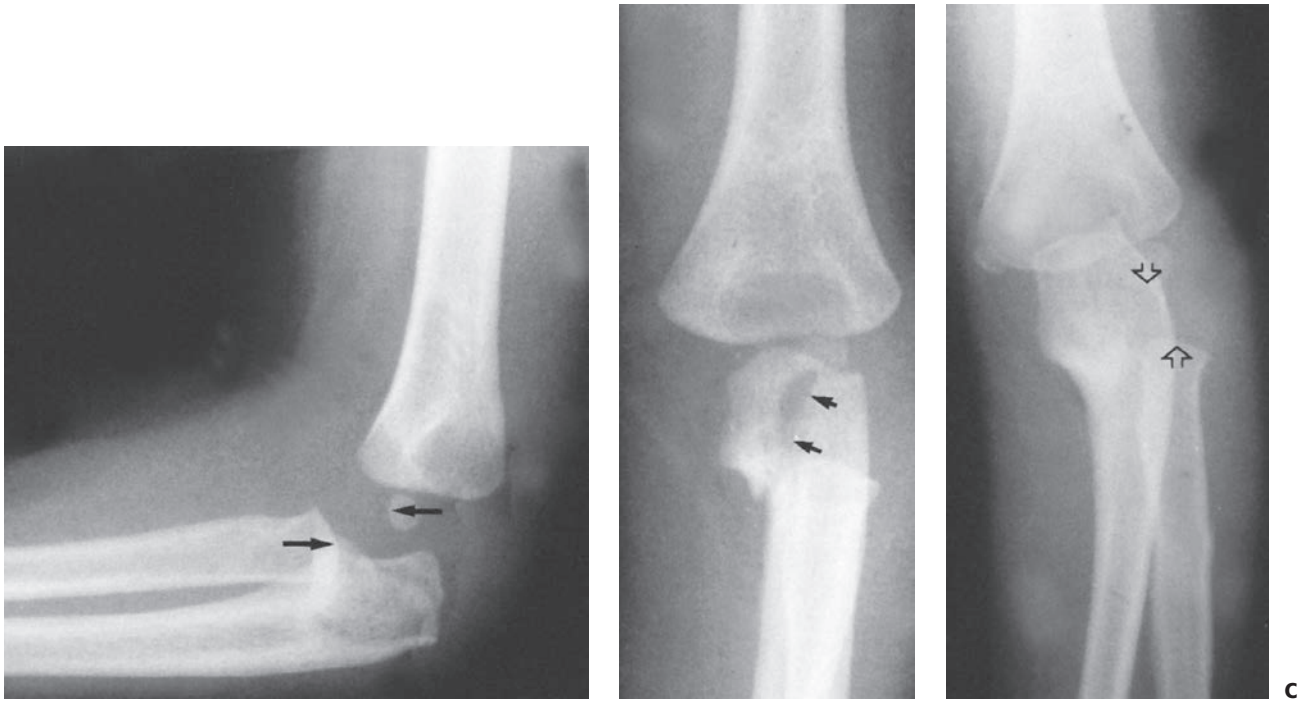
Standard AP and lateral radiographs of the forearm demonstrate the pertinent features for classifying type II Monteggia fracture-dislocations. The typical findings include a proximal metaphyseal fracture of the ulna, with possible extension into the olecranon (Fig. 14-14).[41,98,147] Oblique diaphyseal ulnar fractures can also result in a type II Monteggia lesion.[8,41,98] The radial head is dislocated posteriorly or posterolaterally[10] and should be carefully examined for other injuries. Accompanying fractures of the anterior margin of the radial head have been noted.[41,105] Initially, these rim fractures are subtle in children but can lead to progressive subluxation and make late reconstruction difficult. Cross-sectional imaging, such as an MRI or ultrasound scan, should be obtained if further characterization of the injury pattern is deemed warranted.

Type III Radiographic Evaluation

In type III lesions, the radial head is displaced laterally or anterolaterally,[104,106] which is best visualized on the AP radiograph (Fig. 14-15). The ulnar fracture often is in the metaphyseal region,[10,13,63,69,92,119,163] but it can also occur more distally.[10,11,47,162] Varus deformity is common to all ulna fractures, regardless of the level. Radiographs of the entire forearm should be obtained because of the association of distal radial and ulnar fractures with this complex elbow injury.[147] As with all Monteggia injuries, the acute lesion can be missed if proper radiographs are not obtained and careful evaluation of the studies is not performed.

Type IV Radiographic Evaluation

In a type IV Monteggia fracture-dislocation, the anterior radial head dislocation is similar to that in a type I lesion (Fig. 14-16). The radial and ulnar fractures generally are in the middle third of the shaft,[39] with the radial fracture typically distal to the ulnar fracture. The fractures may be incomplete or complete. Although this injury pattern is uncommon in adults and rare in children, the radiocapitellar joint should be examined in



A, B C

FIGURE 14-14 Type II lesion. The typical radiographic findings include **A:** A posterior dislocation of the radial head (*arrows*) and **(B)** A proximal metaphyseal fracture, which may extend into the olecranon (*arrows*). **C:** The radial head dislocation also may be posterolateral (*arrows*).

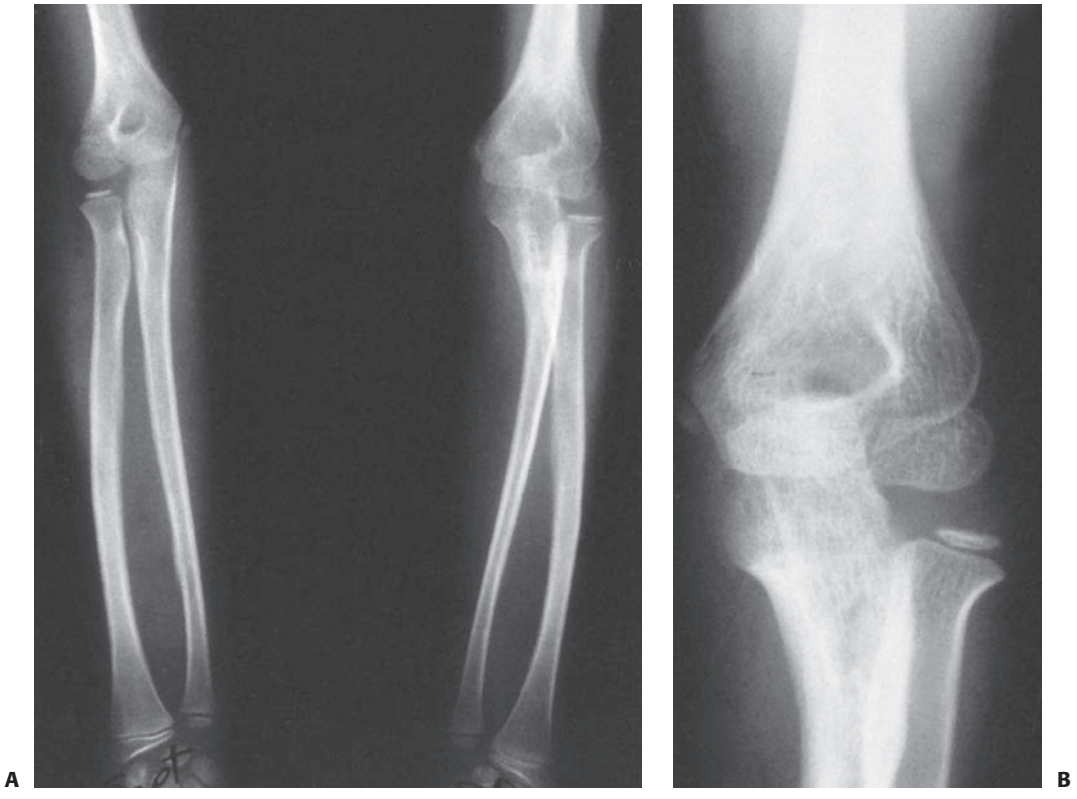


FIGURE 14-15 Type III lesion. **A:** AP radiographs of the bilateral forearms demonstrate residual bow of the proximal ulna after an incompletely reduced type III lesion (persistent varus deformity). **B:** The persistent bow resulted in symptomatic lateral subluxation of the radial head.

all midshaft forearm fractures to avoid missing the proximal radioulnar joint disruption (Fig. 14-17). Failure to recognize the radial head dislocation is the major complication of this fracture.[12]

Radiographic Evaluation of Monteggia Equivalents

As with the true Bado types, careful radiographic study should be made with at least two orthogonal views of the elbow in addition to standard views of the forearm. Special views such as obliques should be obtained to clearly delineate the associated injuries (e.g., radial head or neck fracture, distal humerus lateral condyle fracture) and allow adequate pretreatment planning. Cross-sectional imaging, such as an MRI or ultrasound scan, should be obtained as needed if further characterization of the injury is required.

Traumatic Versus Congenital Dislocation

Distinguishing between traumatic and congenital radial head dislocations can be challenging. When radiocapitellar alignment is disrupted radiographically, evaluation of the shape of

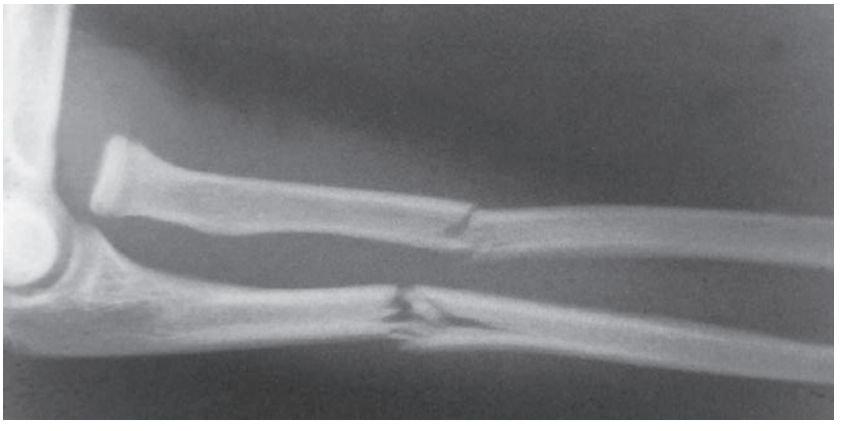

FIGURE 14-16 Type IV lesion. There is an anterior dislocation of the radial head. The radial and ulnar fractures are usually in the middle third of the shaft, with the radial fracture distal to the ulnar fracture.

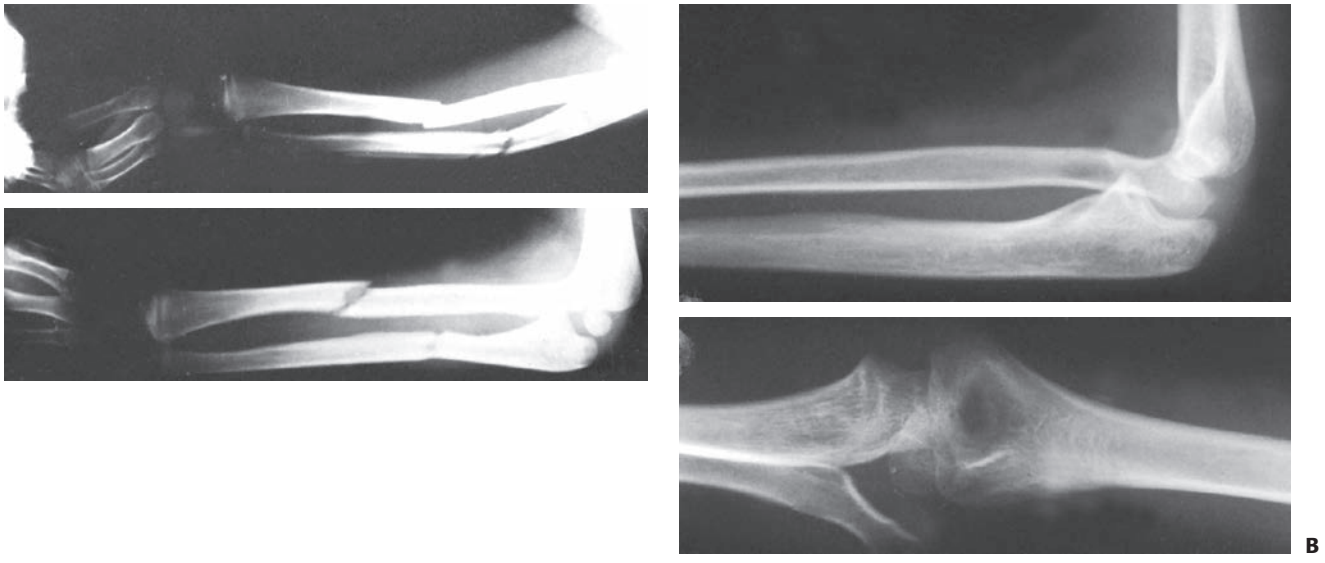

FIGURE 14-17 Type IV lesion. **A:** Anterior dislocation of the radial head with fracture of the proximal third of the radial shaft and an apex anterior ulnar fracture. The dislocation of the radial head was not recognized. **B:** Five years later, the radial head remained dislocated and was visibly misshapen and prominent. Full range of motion was present, with the exception of a loss of 10 degrees of full supination. The patient had no pain, but generalized weakness was noted in the extremity, especially during throwing motions.

the radial head and capitellum can help determine the cause of the disruption, especially if there is no history of trauma or the significance of the trauma is questioned. The presence of a hypoplastic capitellum and a convex deformed radial head suggests a congenital etiology (Fig. 14-18).[87] True congenital radial head dislocations are usually (but not always) posterior, may be bilateral, and can be associated with various syndromes such as Ehlers–Danlos and nail–patella.[3,84] To avoid missing the diagnosis of an acute Monteggia fracture-dislocation, all anterior radial head dislocations should be at least suspected of having a traumatic origin.[3,26,84]

Outcome Measures for Monteggia-Fracture Dislocations

To assess recovery and patient outcome following closed or open treatment of Monteggia lesions, the clinician should carefully measure union rate, time to union, pain, patient satisfaction, elbow flexion and extension, and forearm rotation. Common treatment complications must be accurately recorded, especially because acute Monteggia injuries continue to be missed or inadequately treated, resulting in the development of chronic Monteggia lesions. An improved understanding of return to sports and functional outcomes is critical. The disabilities of the arm, shoulder, and hand (DASH) score can be used to measure the disability following Monteggia fracture-dislocations, but has not been validated in children. Joint-specific outcome measures have been developed for the elbow, but many of these measures would benefit from further research into their validity, reliability, and applicability in children.[128] For pediatric patients, the pediatric outcomes data collection instrument (PODCI) offers a validated tool, but its upper limb disability measurement is broad and not joint or disease specific. The development and validation of pediatric upper limb outcome measures is needed.

Pathoanatomy and Applied Anatomy Relating to Monteggia Fracture-Dislocations

Understanding the anatomy of the proximal radioulnar joint, radiocapitellar joint, and proximal forearm is critical to understanding the treatment of acute and chronic Monteggia lesions. The bony architecture, joint contour, and periarticular ligaments provide stability to the proximal forearm and elbow. The muscle insertions and origins affect stability and determine surgical exposure along with the neighboring neurovascular structures.

Ligaments

Annular Ligament

The annular (or orbicular) ligament (Fig. 14-19) is one of the prime stabilizers of the proximal radioulnar joint during forearm rotation. The annular ligament encircles the radial neck from its origin and insertion on the proximal ulna. Because of the shape of the radial head, the annular ligament tightens in supination. The annular ligament is confluent with the remainder of the lateral collateral ligamentous complex which provides stability to the radiocapitellar and proximal radioulnar joints and resists varus stress. Displacement of the annular ligament occurs in a Monteggia lesion.[144]

FIGURE 14-18 Congenital versus traumatic dislocation. **A:** AP elbow radiograph of a 7-year old who presented with limited forearm rotation. **B:** Lateral elbow radiograph of the elbow of the same child. Note dysplastic radial head, anterior dislocation, and a hypoplastic capitellum. All of these findings are consistent with congenital radial head dislocation. **C:** AP elbow radiograph of a child with radioulnar synostosis. **D:** Lateral elbow radiograph of radioulnar synostosis and posterior radial head dislocation. Note posterior bow of the ulna and hypoplasia of the capitellum. This is a case of congenital radioulnar synostosis.

Quadrate Ligament

The quadrate ligament[35,67,153] is just distal to the annular ligament and connects the proximal radius and ulna (Fig. 14-19). It has a dense anterior portion, thinner posterior portion, and even thinner central portion. The quadrate ligament also provides stability to the proximal radioulnar joint during forearm rotation. The anterior and posterior borders become taut at the extremes of supination and pronation, respectively.

Oblique Cord

The oblique cord (Fig. 14-20), also known as the Weitbrecht ligament, extends at a 45-degree angle from the ulna proximally to

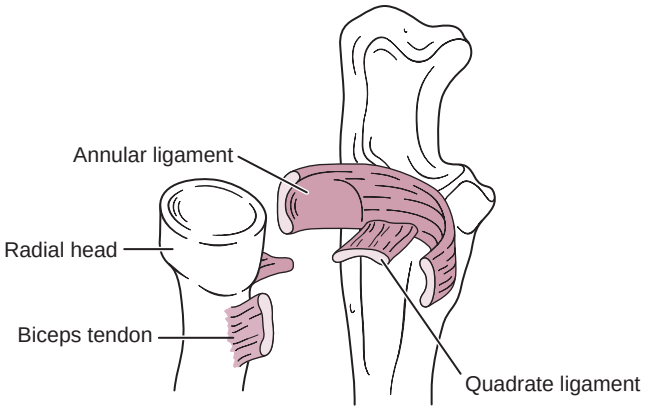

FIGURE 14-19 Ligamentous anatomy of the proximal radioulnar joint.

the radius distally and is present in approximately 53% of forearms.[152] The oblique cord originates just distal to the radial notch of the ulna and inserts just distal to the bicipital tuberosity of the radius. With supination, the oblique cord tightens and may provide a marginal increase in stability to the proximal radioulnar joint. The clinical relevance of this structure is uncertain.

Interosseous Ligament

The interosseous ligament (Fig. 14-20) is distal to the oblique ligament with its primary fibers running in the opposite direction (from radius proximally to ulna distally) to the oblique cord. However, similar to the oblique cord, it tightens in supination and provides further stability to the proximal radioulnar joint. The central band of the interosseous ligament is the stiffest stabilizing structure of the forearm.[159]

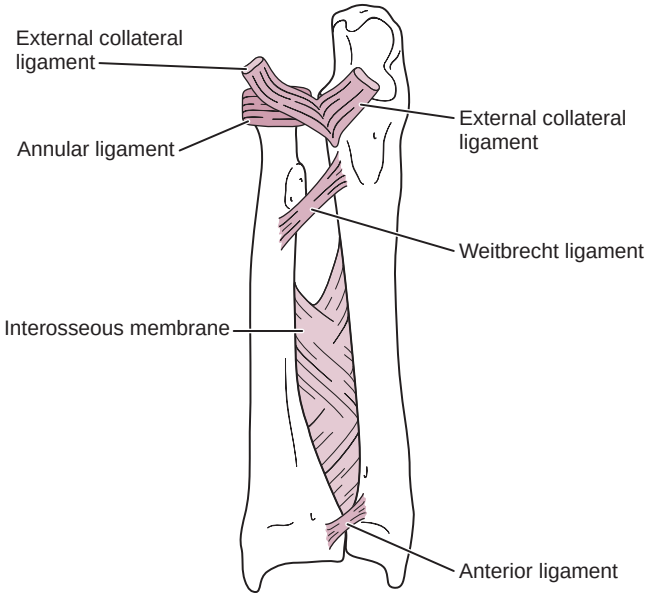

FIGURE 14-20 Ligaments of the forearm. In supination, the annular ligament, quadrate ligament, Weitbrecht ligament (oblique cord), and interosseous membrane are taut, providing increased stability to the proximal radioulnar joint.

Bony Architecture

The bony architecture of the elbow creates a relatively constrained hinge. The concave surface of the radial head matches the convex surface of the capitellum and provides stability to the radiocapitellar joint. In contrast, the bony geometry of the proximal radioulnar joint provides minimal inherent stability.

Radius

The shape of the radial head is generally elliptical in cross section (Fig. 14-21).[25] In supination, the long axis of the ellipse is perpendicular to the proximal ulna, causing the annular ligament and the anterior portion of the quadrate ligament to tighten and stabilize the proximal radioulnar joint. In addition, the contact area between the radius and the radial notch of the ulna increases in supination because of the broadened surface of the elliptical radial head proximal to distal in that position. This may provide some additional stability.

The radius "radiates" around the ulna. For this reason, the radius must have an anatomic bow to achieve full forearm rotation while maintaining stability at the proximal and distal radioulnar joints (Fig. 14-21). With the radius in supination,

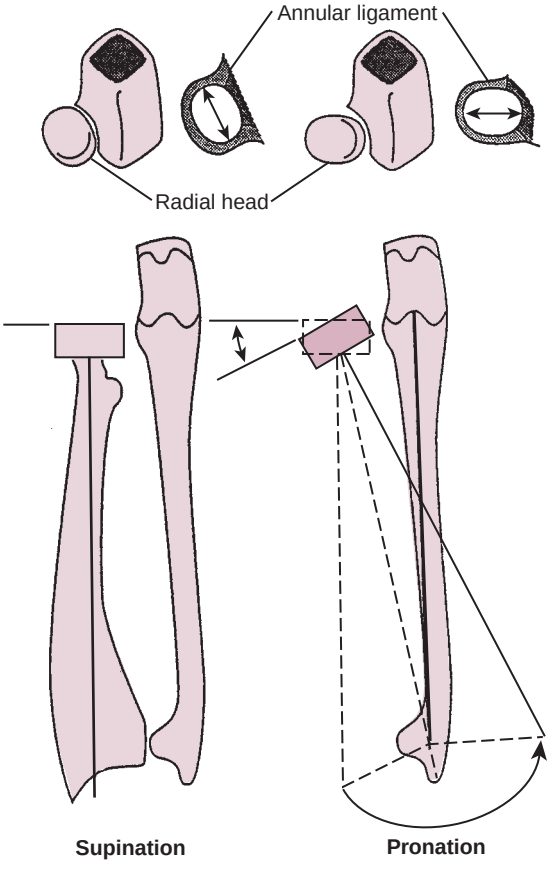

FIGURE 14-21 The radial head is an elliptical structure secured by the annular ligament, which allows movement while providing stability. Because of the shape of the radial head, the stability provided by the annular ligament is maximized in supination.

the bow tightens the oblique cord and interosseous ligament, thereby increasing stability of the proximal radioulnar joint.

Musculature

Biceps Brachii

The biceps brachii inserts into the bicipital tuberosity of the radius and acts as both flexor of the elbow and supinator of the forearm. The biceps acts as a deforming force in anterior Monteggia fracture-dislocations, pulling the radius anteriorly as the elbow is forcibly extended (Fig. 14-9).[151] During treatment of type I and type IV lesions, care is taken to maintain the elbow in flexion to prevent recurrent anterior subluxation of the radial head while the soft tissues heal.

Anconeus

The anconeus may act as a dynamic stabilizer of the elbow joint by providing a valgus moment at the joint during extension and pronation.[11,151] It may also act as a deforming force, along with the forearm flexors, on complete fractures of the ulna in a Monteggia lesion. Surgical exposure of the proximal radioulnar and radiocapitellar joints is usually performed through the anconeus–extensor carpi ulnaris interval.

Nerves

Posterior Interosseous Branch of the Radial Nerve

The radial nerve (Fig. 14-22) passes the distal humerus in the brachialis–brachioradialis interval. As the nerve descends into the forearm, it divides into the superficial radial sensory branch and the posterior interosseous motor branch. The posterior interosseous nerve passes under the Arcade of Frohse (Fig. 14-22) and between the two heads of the supinator, when present, or beneath the supinator when there is only one head. The nerve's close proximity to the radial head and neck makes it susceptible to injury with Monteggia fracture-dislocations.[70] Injuries to the posterior interosseous nerve occur more frequently with type III lesions than other types of Monteggia fracture-dislocations.[13,119,134] In chronic Monteggia lesions, the posterior interosseous nerve can be adherent to the dislocated radial head or, less commonly, entrapped in the radiocapitellar joint.[121] Care must be taken to avoid injury to the radial nerve in surgical reconstructions of the chronic anterior dislocation.

Ulnar Nerve

The ulnar nerve passes posterior to the medial intermuscular septum of the arm, through the cubital tunnel behind the medial epicondyle of the distal humerus, and then between both heads of the flexor carpi ulnaris into the forearm. The ulnar nerve is at risk for injury with type II Monteggia lesions because of the stretch associated with varus deformity and also with ulnar lengthening in chronic Monteggia reconstructions.

General Treatment Principles for Monteggia-Fracture Dislocations

Although most treatment algorithms for Monteggia fracture-dislocations are based on the Bado classification, Ring and Waters[119] recommended that treatment choices be based on the type of ulnar fracture rather than on the Bado type. They recommended plastic deformation of the ulna be treated with closed reduction of the ulnar bow to obtain stable reduction of the radiocapitellar joint. Incomplete (greenstick or buckle) fractures of the ulna are similarly treated with closed reduction and casting. In children, most type I Monteggia injuries with plastic deformation of the ulna or incomplete ulnar fractures are stable when immobilized in 100 to 110 degrees of elbow flexion and full forearm supination.

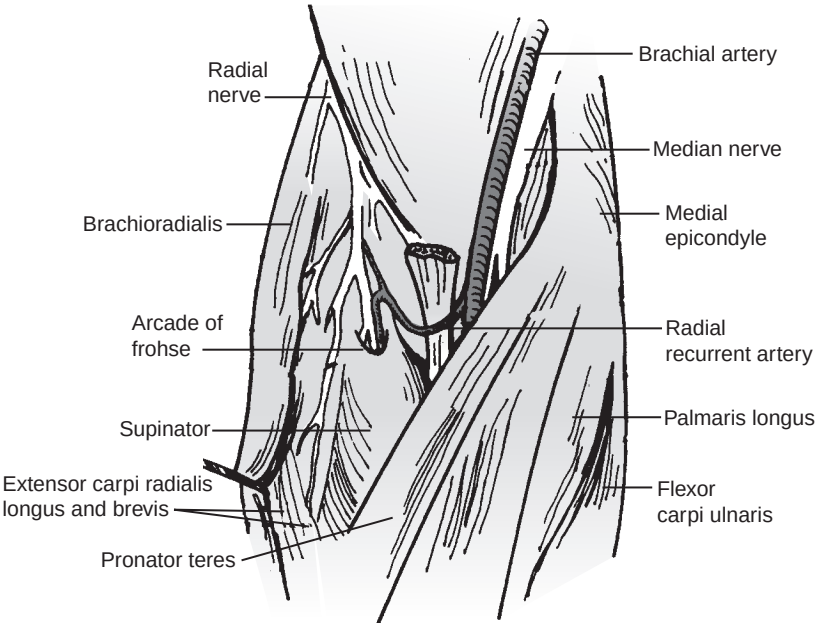

FIGURE 14-22 Dissection of the anterior elbow. Note the course of the radial nerve which emerges from the biceps–brachioradialis interval and then divides into the superficial radial sensory branch and the posterior interosseous branch. The posterior interosseous nerve then passes under the Arcade of Frohse.

However, any Monteggia lesion with a complete fracture of the ulna can be unstable after closed reduction. Therefore, with complete transverse or short oblique ulnar fractures or Monteggia lesions associated with a radial fracture (type IV lesions), intramedullary fixation is recommended. Long oblique or comminuted ulnar fractures, which can develop shortening and malalignment even with intramedullary fixation, are best stabilized with plate and screw fixation. Using this treatment protocol, Ring and Waters[119] reported excellent results in all 28 patients treated within 24 hours of injury.

As noted, successful treatment is dependent on three goals: Anatomical correction of the ulnar deformity, achieving a stable congruent reduction of the radiocapitellar joint, and maintenance of ulnar length and fracture stability. For plastic deformation and incomplete fractures, these goals can usually be achieved with closed reduction and cast immobilization. For complete fractures, fracture instability after closed reduction may lead to loss of anatomic ulnar length and redislocation of the radial head. These injuries are generally treated with internal fixation.

Treatment Options for Type I Monteggia-Fracture Dislocations

Nonoperative Treatment of Type I Monteggia Fracture-Dislocations

Indications/Contraindications

Closed reduction and cast immobilization is recommended as an initial treatment strategy for all type I Monteggia fracture-dislocations in which the ulna is plastically deformed or there is an incomplete fracture (greenstick or buckle). Operative intervention is recommended if there is a failure to obtain and maintain ulnar fracture reduction or a failure to obtain and maintain a congruent reduction of the radiocapitellar joint. In patients with complete transverse or oblique fractures of the ulna, closed reduction alone risks loss of reduction in a cast and development of a chronic Monteggia lesion. In these fractures, operative intervention is recommended to facilitate maintenance of ulnar alignment and the radiocapitellar reduction (Table 14-2).

TABLE 14-2 Monteggia Fracture-Dislocations

Nonoperative Treatment

Indications	Relative Contraindications
Plastic deformation of the ulna	Open fracture
Incomplete (greenstick or buckle) ulnar fracture	Unstable ulnar fracture pattern Transverse or short oblique ulnar fracture Long oblique or comminuted ulnar fracture Residual or recurrent loss of congruency at radiocapitellar joint

Closed Reduction and Immobilization in Type I Monteggia Fracture-Dislocations

Reduction of the Ulnar Fracture

The first step of the closed reduction is to reestablish the length of the ulna by longitudinal traction and manual correction of any angular deformity. The forearm is held in relaxed supination as longitudinal traction is applied with manual pressure directed over the apex of the deformity until the angulation is corrected clinically and radiographically (Figs. 14-23 and 14-24). With plastic deformation fractures, this may necessitate significant force that usually requires general anesthesia. With incomplete fractures, the correction of the ulnar deformity and radial head reduction can often be achieved with conscious sedation in the emergency room. Some papers have cited successful treatment of acute Monteggia lesions (defined as maintenance of the radiocapitellar reduction) with nonanatomic alignment of the ulnar fracture (Fig. 14-25).[48,111,113] However, anatomic reduction and healing of the ulna fracture is strongly advocated.

Reduction of the Radial Head

Once ulnar length and alignment have been reestablished, the radial head can be relocated. This is often accomplished by simply flexing the elbow to 90 degrees or more, thus producing spontaneous reduction (Fig. 14-26). Occasionally, posteriorly directed pressure over the anterior aspect of the radial head is necessary for reduction of the radial head. Flexion of the elbow to 110 to 120 degrees stabilizes the reduction. Once the radial head position is established, it should be scrutinized

radiographically in numerous views to ensure a concentric reduction. With a type I lesion, the optimal radiographic view is a true lateral of the elbow with the forearm held in supination. The longitudinal axis of the radius should pass directly through the center of the capitellum (Fig. 14-26).

Radiographic Evaluation and Immobilization

Once the concentric reduction of the radial head is confirmed, the elbow should be placed in approximately 110 to 120 degrees of flexion to alleviate the force of the biceps, which could redislocate the radial head. The forearm is placed in a position of midsupination to neutral rotation to alleviate the forces of the biceps, supinator muscle and the anconeus, as well as the forearm flexors, which tend to produce radial angulation of the ulna. After the fracture is reduced and the position of stability is established, a molded long arm splint or cast is applied to hold the elbow joint in the appropriate amount of flexion, usually 110 to 120 degrees. Once the casting is completed, careful radiographic assessment should establish the concentric reduction of the radial head with respect to the capitellum, as well as satisfactory alignment of the ulna (Fig. 14-27).

Postreduction Care

The patient is followed at 1- to 2-week intervals to confirm continued satisfactory reduction by radiography. At 4 to 6 weeks after the initial reduction, if there is radiographic evidence of consolidation of the ulnar fracture and stability of the radial head, the long-arm cast can be removed with progressive guarded return to full activity. A final set radiographs should be obtained when the patient has achieved full motion to be certain the radiocapitellar and proximal radioulnar joints remain anatomically aligned.

Outcomes of Nonoperative Treatment

In all series,[4,10,21,22,38,48,81,98,116,119,127,160] type I Monteggia lesions in children have uniformly good results when treated by manipulative closed reduction, if the radial head is properly aligned and the ulnar fracture is reduced with length preserved. These results most clearly apply to plastic deformation and incomplete fractures, which make up the majority of type I Monteggia lesions. No deterioration of results appears to occur at long-term.[79,101]

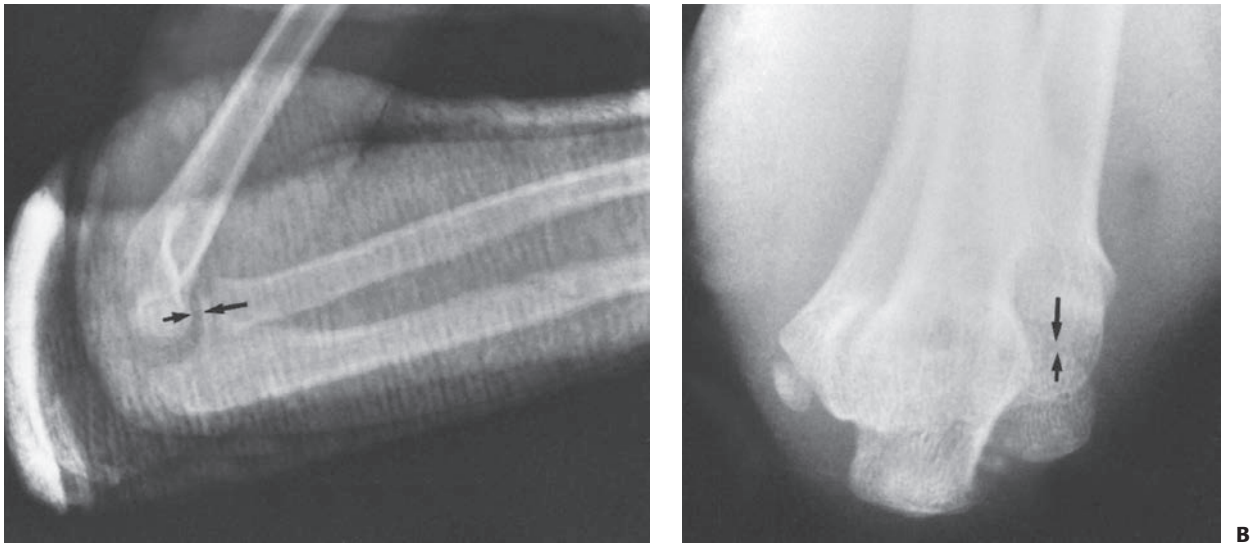

FIGURE 14-27 Once the close reduction is complete, radiographs should be analyzed for reestablishment of the radiocapitellar line (*arrows*) and ulnar alignment on both the lateral **(A)** and Jones **(B)** views.

Operative Treatment of Type I Monteggia Fracture-Dislocations

Indications

There are two principal indications for operative treatment of type I fracture-dislocations: Failure to obtain and maintain ulnar fracture reduction or a failure to obtain and maintain a congruent reduction of the radiocapitellar joint. The fractures most at risk for loss of reduction with nonoperative management are complete ulnar fractures. In these fractures, operative fixation of the ulna is recommended to facilitate maintenance of ulnar alignment and radiocapitellar reduction. In some cases, closed reduction of the radiocapitellar joint cannot be achieved, even after intramedullary or plate fixation of the ulna. It is important not to accept a nonanatomic reduction as an imperfect reduction which can result in further joint malalignment and the development of a chronic Monteggia lesion. In these cases, the annular ligament is almost always avulsed or entrapped.[144] There is a high likelihood that annular ligament and/or periosteal interposition is preventing congruent reduction of the radiocapitellar joint. In these situations, an open reduction of the radiocapitellar joint should be performed with restoration of the annular ligament to its normal position.[144,151] Routine preoperative planning is required before embarking on any of the operative treatment pathways described below (Table 14-3).

TABLE 14-3 Operative Treatment of Monteggia Fracture-Dislocations

Preoperative Planning Checklist

- Standard OR table with radiolucent arm board, table turned 90 degrees with operative limb pointing toward operating room
- Position: Patient supine with adequate padding of heels and other bony prominences
- Fluoroscopy location: Generally from below arm (medial to lateral)
- Equipment: Standard operating instruments, drill, K-wire or flexible titanium nail set, small fragment set, nonabsorbable 2–0 and 3–0 suture, splinting or casting supplies
- Tourniquet (sterile/nonsterile): Surgeon's preference, nonsterile tourniquet generally sufficient
- Standard preoperative verification

Intramedullary Fixation of Transverse or Short Oblique Ulnar Fractures

In patients with complete transverse or short oblique fractures, closed reduction alone can result in loss of reduction in a cast. In these cases, closed reduction and intramedullary fixation of the ulna is recommended to facilitate maintenance of ulnar alignment and length along with reduction of the radiocapitellar joint. The quality of the ulnar reduction affects the ability to reduce the radial head, which is of primary importance. If an ulnar fracture can be reduced but not maintained because of the obliquity of the fracture, internal fixation is also indicated.[48,98] Intramedullary fixation is standard in most series of Monteggia fracture-dislocations in children (Fig. 14-28).[8,10,38,47,48,76,78,85,98,112,119,122,138,160] Percutaneous intramedullary fixation reliably maintains alignment and preserves

length without the additional concerns of open surgery or implant retention. This method of fixation can be accomplished using image intensification and with a Kirschner wire (K-wire) or a flexible titanium nail (Synthes, West Chester, PA). K-wires have the advantage of being universally available and inexpensive. Their stainless steel composition and smooth tip also permit easy removal in the office without need for additional anesthesia. Note that K-wires may not be of sufficient length for use in older children with longer forearms. Entry can be through the apophysis or proximal metaphysis of the ulna, depending on the level of the fracture and surgeon's preference. For type I lesions, a closed reduction maneuver is performed as described above. At times, an intramedullary K-wire or nail in the proximal fragment can be used to joystick the reduction. Intraoperative fluoroscopy is utilized to confirm appropriate ulnar and radiocapitellar reduction, as well as proper interosseous placement of the intramedullary device. Because ulnar fractures heal rapidly in children, the intramedullary device can generally be bent and cut outside of the skin to facilitate subsequent office removal. Some surgeons prefer to leave the intramedullary rod

in a long time and therefore bury it beneath the skin. A long arm splint or bivalved cast is then applied with the elbow in 90 to 110 degrees of flexion and forearm supination, which provides additional stability to the radiocapitellar joint (Table 14-4).

Open Reduction and Plate Fixation of Long Oblique or Comminuted Ulnar Fractures

Although intramedullary fixation is preferred for transverse and short oblique fractures, long oblique and comminuted fractures may redisplace even with intramedullary fixation.[119] Plate and screw fixation (Fig. 14-29) is preferred with these rarer fractures.[78,104,109,119,148,154,162] A longitudinal incision, centered at the apex of the fracture, is made along the subcutaneous border of the ulna, at the extensor carpi ulnaris–flexor carpi ulnaris interval. An open reduction is performed, and a double-stacked one-third tubular plate or 3.5-mm dynamic compression plate (Synthes, West Chester, PA) is applied utilizing standard AO techniques. Four to six cortices of fixation is generally required both proximal and distal to the fracture. Intraoperative fluoroscopy is used to confirm appropriate ulnar and radiocapitellar reduction. The periosteum is repaired over the fracture site

TABLE 14-4 Intramedullary Fixation of Transverse or Short Oblique Ulnar Fractures

Surgical Steps

- Cortical entry through the apophysis or proximal metaphysis of the ulna
- Introduce appropriately sized intramedullary device (K-wire or flexible titanium nail)
- Perform closed reduction based on mechanism of injury
  - Intramedullary device can be used in the proximal fragment to joystick the reduction
- Stabilize fracture with the intramedullary device, utilize fluoroscopy to confirm appropriate ulnar and radiocapitellar reduction, as well as proper placement of the intramedullary device
- Bend and cut intramedullary K-wire outside of skin to facilitate subsequent removal in the office; titanium nails or buried wires need to be removed in day surgery unit
- Apply long arm splint or bivalved cast in a position of elbow flexion and supination appropriate for the specific Bado type

FIGURE 14-29 ORIF of Monteggia lesion in a 4-year-old male associated with a comminuted ulna fracture. **A, B:** Injury radiographs demonstrating the dislocated radial head and ulnar fracture pattern. **C, D:** Radiographs taken 3 months postoperatively, demonstrating a healed fracture and stable joint alignment. and implant. Again, a long arm splint or bivalved cast is then applied with the elbow in 90 to 110 degrees of flexion and forearm supination, which provides additional stability to the radiocapitellar joint (Table 14-5).

Open Reduction of the Annular Ligament

On occasion, a congruent closed reduction of the radiocapitellar joint cannot be achieved, even after intramedullary fixation or plate fixation of the ulna. In these situations, the position of the radial head may be improved, but the reduction remains imperfect. The surgeon may not feel a definitive clunk associated with an anatomic reduction, and instead may feel a soft or rubbery resistance during manipulation. This suggests soft tissue interposition of either the annular ligament and/or periosteum.[151,162] An open reduction of the radiocapitellar joint with restoration of the annular ligament to its normal position is recommended (Fig. 14-30). Soft tissue interposition more commonly occurs in type III lesions, but can also occur in type I lesions. Interposed cartilaginous or osteochondral fractures in the radiocapitellar joint or proximal radioulnar joint may also prevent complete reduction of the radial head.[151] Morris[92] described a patient in whom reduction of the radial head was obstructed by radial nerve entrapment between the radial head and ulna.

The most direct approach to the radiocapitellar joint is from the posterolateral aspect of the elbow. The interval between the anconeus and the extensor carpi ulnaris, using the distal portion of a Kocher incision, provides sufficient exposure of the radial head and the interposed structures.[56,139] This approach protects the posterior interosseous nerve when the forearm is pronated. A more extensile approach was described by Boyd (Fig. 14-31).[20] This exposure is begun by making an incision following the lateral border of the triceps posteriorly to the lateral condyle and extending it along the radial side of the ulna. The incision is carried under the anconeus and extensor carpi ulnaris in an extraperiosteal manner, elevating the fibers of the supinator from the ulna. This carries the approach down to the interosseous membrane, allowing exposure of the radiocapitellar joint, excellent visualization of the annular ligament, access to the proximal fourth of the entire radius, and approach to the ulnar fracture all through the same incision.[20,21,131] In addition, elevation of the extensor–supinator mass from the lateral epicondyle allows more proximal exposure of the dislocated radial head if entrapped behind the displaced capsule and annular ligament.

After obtaining adequate surgical exposure through either approach, a capsulotomy is performed and the elbow joint is inspected. Careful exploration is required to identify the annular ligament. The ligament is not typically torn in its midsubstance,

TABLE 14-5 Open Reduction and Plate Fixation of Long Oblique or Comminuted Ulnar Fractures

Surgical Steps

- Longitudinal incision over subcutaneous border of the ulna
- Develop interval between extensor carpi ulnaris and flexor carpi ulnaris
- Carefully incise periosteum and preserve for subsequent repair
- Perform open reduction
- Apply double-stacked one-third tubular plate or 3.5-mm dynamic compression plate
  - Four to six cortices of fixation both proximal and distal to the fracture
- Utilize fluoroscopy to confirm appropriate ulnar and radiocapitellar reduction, as well as proper placement of the plate and screws
- Repair periosteum over the fracture site and implant
- Layered wound closure
- Apply long arm splint or bivalved cast in a position of elbow flexion and supination appropriate for the specific Bado type

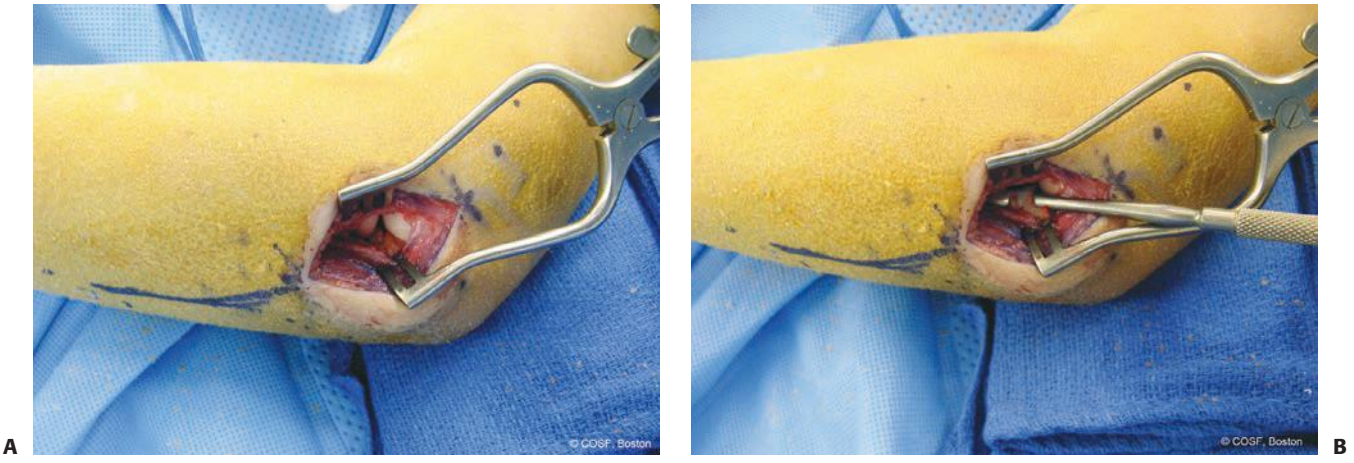

FIGURE 14-30 Open reduction of the radial head. **A:** Intraoperative photograph of a left elbow, depicting a dislocated radial head identified via a posterolateral approach. **B:** A Freer elevator has been placed into the middle of the annular ligament, which can then be reduced over the radial head and neck. (From Bae DS, Waters PM. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission)

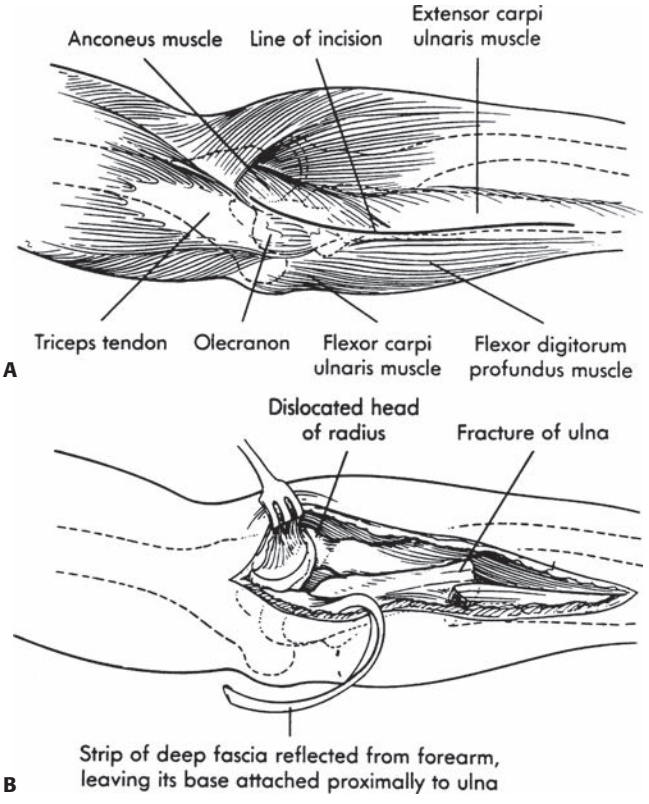

FIGURE 14-31 Boyd approach. **A:** The incision is carried under the anconeus and extensor carpi ulnaris to expose the radial head and annular ligament. **B:** The incision can be extended distally to allow exposure of the ulnar fracture and proximally to facilitate harvesting of a fascial strip for annular ligament reconstruction, if necessary.

but rather remains in continuity and tears of the ulna with a periosteal sleeve. Once the opening in the annular ligament is identified, a Freer elevator, forceps, soft tissue probe, or a small curette is used to reduce the annular ligament over the radial head. If a repair is required, 2-0 or 3-0 nonabsorbable sutures can be utilized. The congruency of the radiocapitellar reduction should be confirmed under direct visualization. Stability can then be confirmed by rotating the forearm under careful fluoroscopic imaging. If the radial head is still unstable, look for missed plastic deformation of the ulna. If present, closed reduction of the ulna, or at times opening wedge osteotomy of the ulna, is required to anatomically and stably reduce the radial head. A layered wound closure is performed, followed by application of a long arm splint or bivalved cast with the forearm in supination (Table 14-6).

TABLE 14-6 Open Reduction of Annular Ligament

Surgical Steps

- Posterolateral (Kocher) approach to the elbow under tourniquet control
- Develop interval between extensor carpi ulnaris and anconeus, maintain forearm in pronation to protect radial nerve from iatrogenic injury
- Perform elbow capsulotomy
- Identify annular ligament
  - Ligament typically in continuity, usually torn off the ulna with a periosteal sleeve (generally not torn midsubstance)
- Reduce annular ligament over the radius, repair as needed with 2–0 and/or 3–0 nonabsorbable suture
- Layered wound closure
- Apply long arm splint or bivalved cast in a position of elbow flexion and supination appropriate for the specific Bado type

Author's Preferred Treatment for Type I Monteggia-Fracture Dislocations

An anatomic, stable reduction of the ulnar fracture almost always leads to a stable reduction of the radiocapitellar joint (Fig. 14-32). This in turn leads to an excellent long-term outcome. Failure to obtain and maintain ulnar fracture and radiocapitellar reduction will lead to a chronic Monteggia lesion, which is a complex clinical and surgical problem with risk of

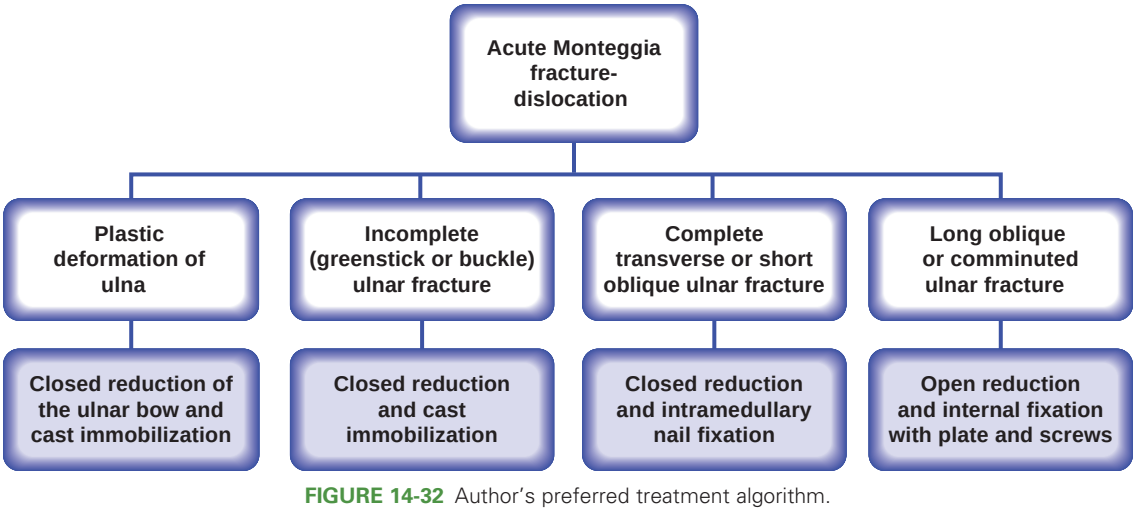

FIGURE 14-32 Author's preferred treatment algorithm.

TABLE 14-7 Monteggia Fracture-Dislocations

Potential Pitfalls and Preventions

Pitfall	Preventions
Failure to identify radial head dislocation leading to chronic Monteggia lesion	Always obtain dedicated elbow radiographs with forearm fractures to evaluate congruency of radiocapitellar reduction
Loss of radiocapitellar reduction leading to chronic Monteggia lesion	Intramedullary fixation or plate fixation for unstable ulnar fractures Regular postoperative radiographs every 1–2 weeks until fracture healing
Inadequate reduction of radial head leading to chronic Monteggia lesion	Never accept an imperfect reduction of the radial head, always perform an open reduction of radiocapitellar joint with restoration of the annular ligament to its normal position
Radial nerve palsy	During posterolateral approach to the elbow, pronate forearm to protect radial nerve from iatrogenic injury During chronic Monteggia reconstructions, identify and protect radial nerve
Compartment syndrome	Monitor high-energy injuries in hospital with frequent neurovascular monitoring Perform prophylactic volar and dorsal forearm fasciotomies during chronic Monteggia reconstructions Consider bivalving postoperative casts

a suboptimum outcome. Therefore, we are very aggressive in treatment of acute Monteggia fracture-dislocations. Percutaneous intramedullary fixation of complete transverse and short oblique ulna fractures is standard. Open reduction and internal fixation with plate and screws of the rarer long oblique and comminuted fracture is also standard. Any irreducible or unstable radial head after fracture reduction and stabilization is approached surgically to define and correct the cause. This usually involves reducing an interposed annular ligament. This aggressive approach avoids late complications.[119]

After closed or open reduction of the ulna fracture and closed or open reduction of the radial head, a bivalved long-arm cast is used for 4 to 6 weeks with the forearm in slight supination and the elbow flexed 90 to 110 degrees depending on the degree of swelling. Radiographs are obtained every 1 to 2 weeks until fracture healing. Intramedullary hardware is removed with fracture healing. Plate and screw fixation is removed after 6 to 12 months, only if resulting in discomfort. Home rehabilitation is begun at 6 weeks and return to sports is dependent on restoration of motion and strength (Table 14-7).

Treatment Options for Type II Monteggia-Fracture Dislocations

Indications for Treatment of Type II Monteggia Fracture-Dislocations

The indications for nonoperative and operative treatment of type II lesions are similar to type I lesions as the ulnar fracture pattern dictates initial decision making. Following ulnar fracture reduction, any residual lack of congruency at the radiocapitellar joint should be treated surgically.

Nonoperative Treatment of Type II Monteggia Fracture-Dislocations

As with type I injuries, incomplete type II fractures usually have a satisfactory result after closed reduction.[81,98,106,113,160] The ulnar fracture is reduced by longitudinal traction in line with the long axis of the forearm while the elbow is held at 60 degrees of flexion (Fig. 14-33). The radial head may reduce spontaneously or may require gentle, anteriorly directed pressure applied to its posterior aspect. The elbow is extended once the radial head is reduced; is immobilized in that position to stabilize the radial head and allow molding posteriorly to maintain the ulnar reduction.[38,106,155] If the ulnar alignment cannot be maintained, an intramedullary K-wire should be used.

Operative Treatment of Type II Monteggia Fracture-Dislocations

Treatment goals are stable concentric reduction of the radial head and alignment of the ulnar fracture. When there is an unstable, complete ulnar fracture, percutaneous intramedullary fixation or open reduction and internal fixation with plate and screws are used similar to type I Monteggia fracture-dislocations.[104,109] The radial head should be reduced by open technique if there is interposed soft tissue or the Monteggia lesion is accompanied by a fractured capitellum or radial head.

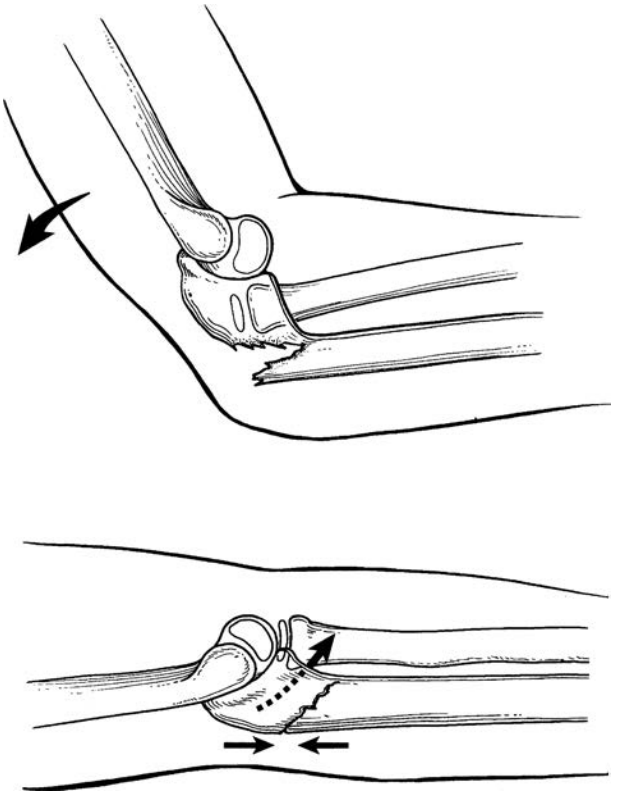

FIGURE 14-33 Schematic reduction maneuvers for type II lesion. Longitudinal traction and pronation of the forearm and immobilization in 60-degree flexion or complete extension.

Author's Preferred Treatment for Type II Monteggia Fracture-Dislocations

With incomplete fractures, ulnar length is reestablished by applying longitudinal traction and straightening the angular deformity (Fig. 14-33). The radial head may reduce spontaneously or with gentle, anteriorly directed force over the radial head. Once reduced, the position of the head can be stabilized by holding the elbow in extension. If the ulnar fracture is stable, it can be maintained by cast immobilization with the elbow in extension. However, if there is any doubt, percutaneous intramedullary fixation is preferred. Comminuted or very proximal fractures may require open reduction and internal fixation with plate and screws or tension band fixation. Postoperative radiographs are obtained approximately every 7 to 14 days to confirm continued reduction of the radial head.

The Boyd approach (Fig. 14-31) can be used to obtain reduction of the radial head if it cannot be obtained through closed manipulation. Management of the annular ligament is the same as described for type I Monteggia lesions. Associated compression fractures of the radial head require early detection to avoid late loss of alignment. Open reduction and internal fixation may be required to maintain radiocapitellar joint stability. Osteonecrosis and nonunion are complications of this rare injury pattern. Cast immobilization is continued until fracture and soft tissue healing, usually 6 weeks. Home rehabilitation is performed until restoration of motion and strength.[106]

Treatment Options for Type III Monteggia Fracture-Dislocations

Indications for Treatment of Type III Monteggia Fracture-Dislocations

Like type I lesions, there are two principal indications for operative treatment of type III fracture-dislocations: Failure to obtain and maintain ulnar fracture reduction or a failure to obtain and maintain a congruent reduction of the radiocapitellar joint. Soft tissue interposition more commonly occurs in type III lesions, and open reduction of the radial head may be required more frequently as a consequence.[13,63,119,145,162,163] Nonoperative treatment by manipulative closed reduction is usually effective in pediatric patients with metaphyseal, incomplete, or plastic deformation fractures.[10,38,50,63,81,93,98,106,146,160,163] However, the rate of operative treatment has been reported to be as high as 12%.[98]

Nonoperative Treatment of Type III Monteggia Fracture-Dislocations

Closed Reduction

A closed reduction is carried out by reversing the mechanism of injury.[38,93,106,147] The elbow is held in extension with longitudinal traction. Valgus stress is placed on the ulna at the fracture site, restoring anatomic realignment (Fig. 14-34). The radial head may spontaneously reduce or may need assistance with gentle pressure applied laterally (Fig. 14-35). Reduction of the radial head sometimes produces a palpable click.[147] Ulnar length and alignment must be nearly anatomic to ensure stability of the radial head.[48] Fluoroscopic radiographs are obtained to confirm radial head reduction.[90] Stability of the ulnar fracture is tested. Any malalignment of the radiocapitellar joint in any view implies the possibility of interposed tissue or persistent malalignment of the ulna fracture.

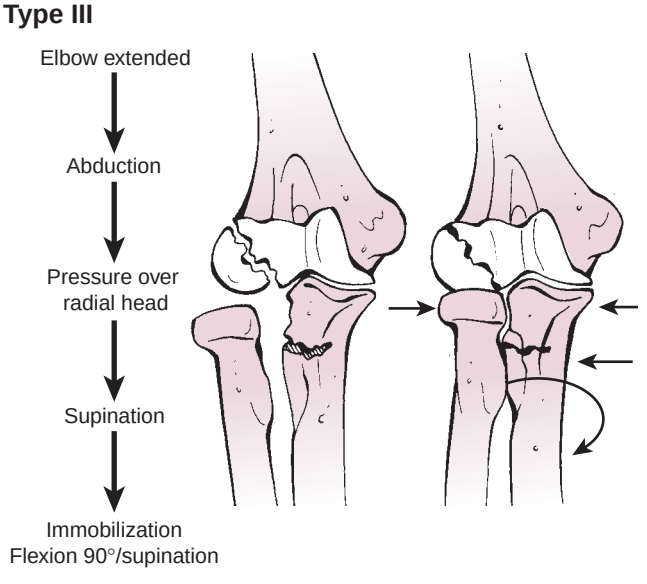

FIGURE 14-34 Schematic reduction maneuvers for type III lesion.

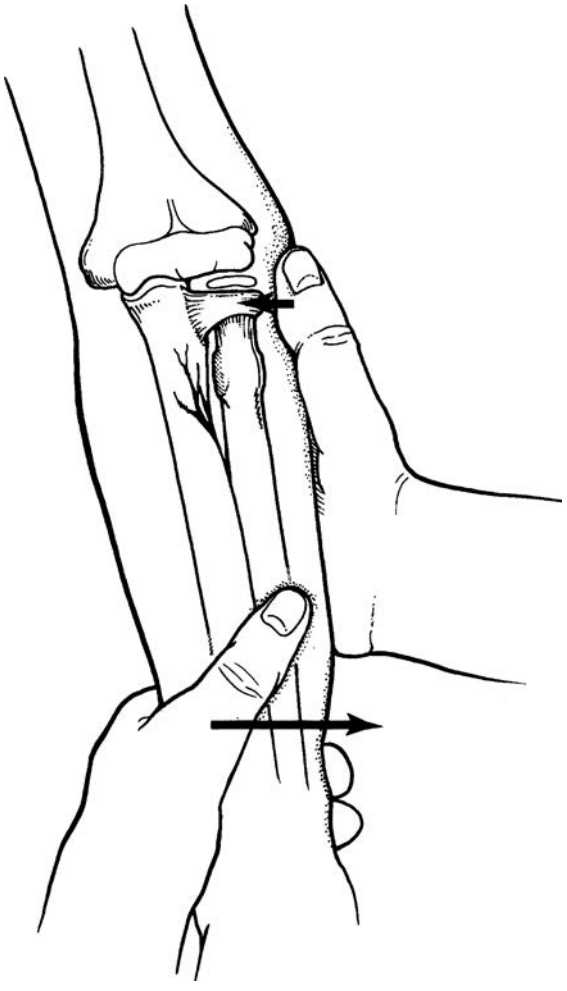

FIGURE 14-35 Reduction of type III lesion. Valgus stress is placed on the ulna at the fracture site (*arrows*), producing clinical realignment. The radial head may spontaneously reduce.

Radiographic Evaluation and Immobilization

Radiographs are taken in the AP and lateral planes to confirm the reduction of the radial head and assess the ulnar alignment. Up to 10 degrees of ulnar angulation is acceptable in younger children, provided the radial head reduction is concentric and stable. Range-of-motion testing of stability is appropriate and necessary with plastic deformation fractures because radiocapitellar alignment can be difficult to assess AP radiographs in the cast.

Reduction is maintained by the application of a long arm splint, cast or bivalved cast with a valgus mold and with the elbow in relative flexion. The degree of flexion varies depending on the direction of the radial head dislocation. When the radial head is dislocated in a straight lateral or anterolateral position, flexion to 100 to 110 degrees improves stability.[41,93,113,160] If there is a posterolateral component to the dislocation, flexion to 70 to 80 degrees has been recommended.[147] Forearm rotation in the cast is usually in supination, which tightens the interosseous membrane and further stabilizes the reduction.[10,38,93,160] Some have suggested positions of immobilization from pronation[146] to slight supination.[147] Ramsey and Pedersen[113] recommended neutral as the best position of rotation to avoid loss of motion; their patients showed no loss of reduction using this position. It must be emphasized that the ulnar fracture and radial head reduction need to be truly stable for closed treatment because postreduction radiographs in cast are difficult to interpret accurately.

Postreduction Care

Cast immobilization is continued until fracture and soft tissue healing, usually by 6 weeks. Home rehabilitation is performed until restoration of motion and strength. A final set of radiographs are obtained when the patient has achieved full motion and strength to be certain that there is continued anatomic reduction of the proximal radioulnar and radiocapitellar joints.

Operative Treatment of Type III Monteggia Fracture-Dislocations

As noted earlier, the goals of surgical intervention are reduction and stabilization of both the ulnar fracture and the radial head. If there is an inability to obtain and maintain anatomic alignment of the ulnar fracture, proximal radioulnar joint, or radiocapitellar joint, then operative treatment is clearly indicated.

Ulnar Stabilization

Ulnar malalignment may prevent anatomic relocation of the radial head. The ulnar fracture can usually be reduced closed, but internal fixation may be necessary if the ulnar fracture is unstable to prevent recurrent lateral dislocation of the radial head. Persistent varus alignment, particularly with oblique ulnar fractures, can lead to recurrent subluxation of the radial head, radiocapitellar incongruency and risk of a poor outcome (Fig. 14-15).[48,98] Anatomic reduction of the ulna and fixation with plates and screws[48] or intramedullary wires[8] will yield excellent results.

Open Reduction of the Annular Ligament

Failed closed reduction of the radial head with anatomic alignment of the ulna fracture implies interposition of soft tissue, which is repaired through a Boyd approach (Fig. 14-31).[20,162] This allows removal of the interposed tissues[151,162] and repair or reconstruction of the annular ligament and the periosteum of the ulna as necessary (Fig. 14-36),[14,23,48,50,131,145] The surgical technique is essentially the same as previously described for a type I Monteggia fracture-dislocation.

Author's Preferred Treatment for Type III Monteggia Fracture-Dislocations

As with any Monteggia lesion, treatment is primarily aimed at obtaining and maintaining reduction of the radial head, either by an open or closed technique. This is usually performed by anatomic, stable closed reduction of the ulnar fracture that in turn leads to a stable reduction of the proximal radioulnar and radiocapitellar joints.

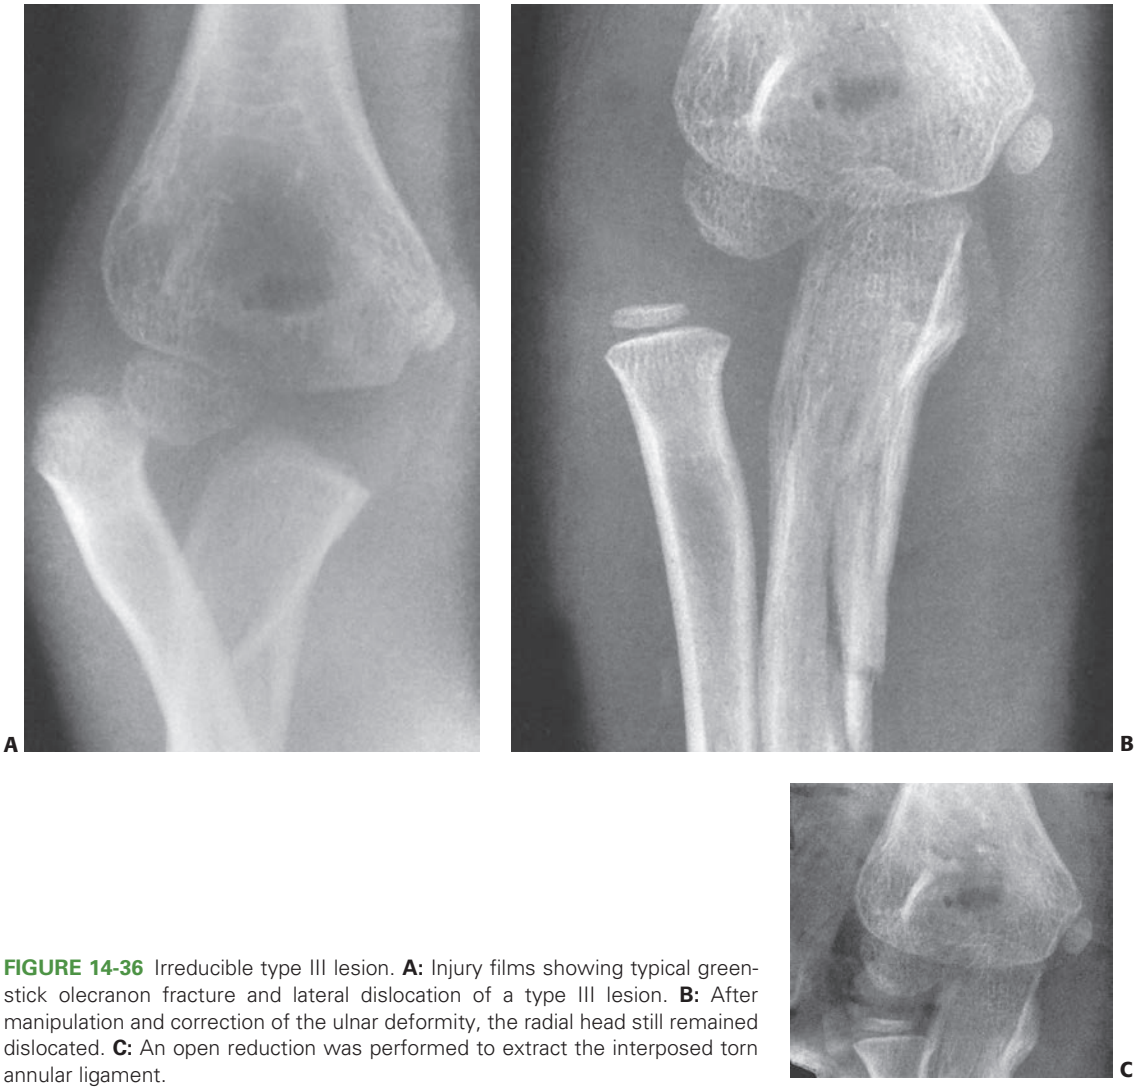

FIGURE 14-36 Irreducible type III lesion. **A:** Injury films showing typical greenstick olecranon fracture and lateral dislocation of a type III lesion. **B:** After manipulation and correction of the ulnar deformity, the radial head still remained dislocated. **C:** An open reduction was performed to extract the interposed torn annular ligament.

Treatment Options for Type IV Monteggia Fracture-Dislocations

Indications for Treatment of Type IV Monteggia Fracture-Dislocations

This complex lesion has been treated by both closed[98] and open[10] techniques. Percutaneous intramedullary fixation of the radial and ulnar fractures with flexible pins and closed reduction of the radial head also have been described.[51,120] The goals of treatment for a type IV Monteggia lesion are similar to those of other Bado types. The presence of the free-floating proximal radial fragment hampers the ability to reduce the radial head. Stabilization of the radial fracture converts a type IV lesion to a type I lesion, making treatment simpler.

Nonoperative Treatment of Type IV Monteggia Fracture-Dislocations

Closed reduction should be attempted initially, with the aim of transforming the type IV lesion to a type I lesion (Fig. 14-37), especially if the radial and ulnar fractures have greenstick patterns. Use of the image intensifier allows immediate confirmation of reduction, especially of the radial head. Closed treatment of unstable ulnar lesions should not be attempted. If the initial fracture reduction cannot be obtained, an anatomic stable reduction with either intramedullary or plate fixation is performed.

Operative Treatment of Type IV Monteggia Fracture-Dislocations

Type IV fractures are usually unstable and the reduction of the radial head is easier to obtain and maintain after stable fixation of the radius. In young patients, this may be achieved by intramedullary fixation. In children older than 12 years, plating of the radius through a volar Henry extensile approach[59] provides more rigid stabilization (Fig. 14-38). Once stability is achieved, a closed reduction of the radial head is attempted. This is usually successful, but any intra-articular obstruction can be removed through a Boyd approach (Fig. 14-31).

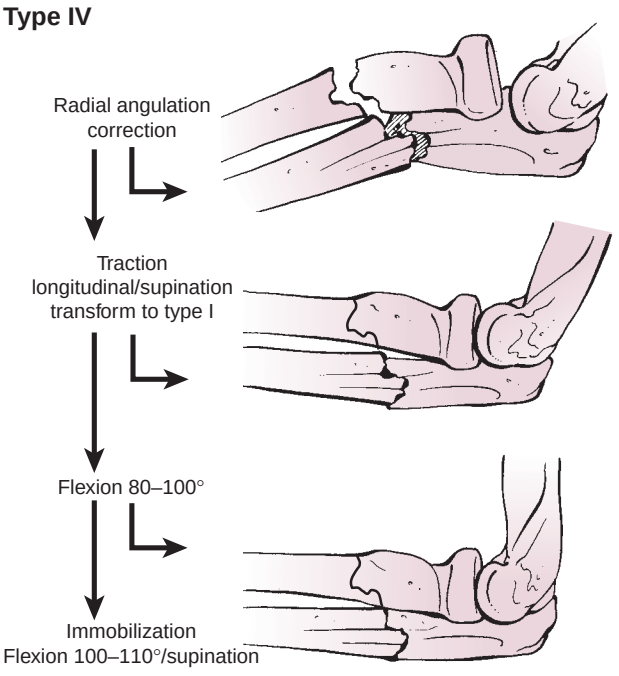

FIGURE 14-37 Schematic reduction maneuvers for type IV lesion.

Author's Preferred Treatment for Type IV Monteggia Fracture-Dislocations

As with any Monteggia lesion, treatment is primarily aimed at obtaining and maintaining reduction of the radial head, either by an open or closed technique. Percutaneous intramedullary fixation is frequently necessary because of inherent fracture instability. Following open treatment, the elbow is immobilized in a long-arm cast for 4 to 6 weeks in 110 to 120 degrees of flexion with the forearm in neutral rotation. A short-arm cast is used thereafter if additional fracture protection is necessary. Home rehabilitation is performed until restoration of motion and strength. Final radiographs are obtained with full restoration of motion and strength to be certain there is anatomic reduction of the proximal radioulnar and radiocapitellar joints.

Treatment Principles for Monteggia Equivalent Lesions

As with the true Bado types, treatment focuses on two general components of the lesion: Ulnar fracture alignment and radial head reduction. Associated injuries must be dealt with appropriately, and are discussed thoroughly in other sections of this chapter and book.

Management of Expected Adverse Outcomes and Unexpected Complications in Monteggia Fracture-Dislocations

TABLE 14-8 Monteggia Fracture-Dislocations

Common Adverse Outcomes and Complications
Chronic Monteggia lesion
Acute radial nerve palsy or posterior interosseous nerve palsy
Tardy radial nerve palsy
Acute ulnar nerve palsy
Acute anterior interosseous nerve palsy
Myositis ossificans
Compartment syndrome

Chronic Monteggia Fracture-Dislocations

A late presenting, previously undetected dislocation of the radial head is not as uncommon as we all would prefer (Table 14-8).[32,34,38,43,50,51,73,100,102,127,142] Isolated radial head dislocations with remote trauma have been mistaken for congenital radial head dislocations.[87] The shape of the ulna in patients with a seemingly isolated dislocation of the radial head usually indicates persistent plastic deformation or malunion of the ulna and a traumatic etiology to the radial head dislocation (Figs. 14-3 and 14-39).[83,90,127,138] Chronic Monteggia lesions have been diagnosed as early as several weeks after injury follow-up for a misdiagnosed, isolated ulnar fracture; or years later because of pain, restriction of motion, or extremity malalignment. Even a few weeks after injury, treatment becomes much more complicated than acute recognition and intervention. Proper recognition of a dislocated radial head at the time of injury can prevent the difficult problem of an untreated, chronic Monteggia lesion.

When a previously undetected proximal radioulnar and radiocapitellar dislocation is encountered (Fig. 14-40), there is controversy regarding subsequent care. At present there are limited levels of evidence and conflicting retrospective literature on this problem. Some reports indicate that the natural history of the untreated lesion is not problematic.[96,124,136]

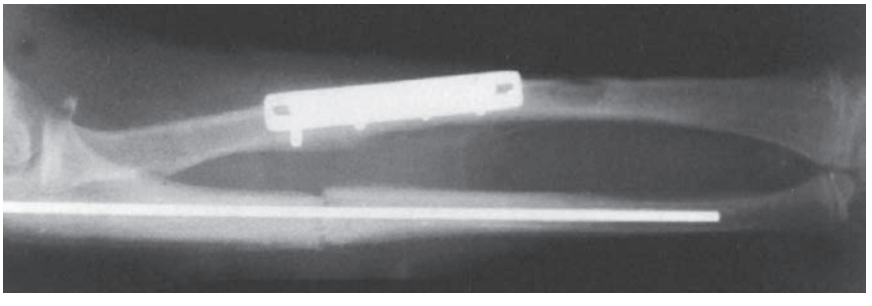

FIGURE 14-38 Operative treatment, type IV lesion. The initial goal is to stabilize the radius. In older children, a plate may be indicated. Intramedullary pinning usually is adequate.

FIGURE 14-39 Chronic Monteggia lesion with ulnar bow line. **A:** The injury radiograph of an 8-year-old girl who fell, spraining her arm. Note the anterior bow of the ulna (*black arrows*) and loss of the radiocapitellar relation (*open arrow*). The diagnosis of a Monteggia lesion was not established. **B:** Radiograph at time of late diagnosis. Note the persistent ulnar bow and overgrowth of radius.

Fahey[44] suggested that although persistent dislocations do well in the short-term, problems arise over time resulting in substantial patient morbidity. Other reports support the view that the natural history of persistent dislocation is not benign and is associated with restricted motion, deformity, functional impairment, pain, potential degenerative arthritis, and late neuropathy.[1,6,15,18,26,50,53,63,64,66,67,83] Kalamchi[66] reported pain, progressive valgus deformity, and restricted motion, especially loss of forearm rotation and elbow flexion. Tardy nerve palsies have been reported subsequent to long-standing, unrecognized Monteggia lesions.[1,6,61,84]

Indications for Treatment

Treatment indications have ranged from offering all patients with chronic Monteggia lesions surgical correction to limiting intervention to patients with pain, restricted motion, and functional disability. That wide spectrum of expert opinions makes individual case decisions difficult for patients, parents, and clinicians. Blount[19] and Fowles et al.[48] suggested that reconstruction provides the best results in patients who have had a dislocation for 3 to 6 months or less. Fowles et al.[48] reported successful relocations up to 3 years after injury; Freedman et al.[50] up to 6 years after injury. Throughout the literature, the appropriate age for radial head reduction seems to be younger than 10 years.[137] Hirayama et al.[60] suggested that the reduction of a chronically dislocated radial head should be avoided if there is significant deformation of the radiocapitellar joint architecture including permanent irregularity of the radial head or flattening of the capitellum. Seel and Peterson[125] suggested that the age of the patient and the duration of the dislocation are unimportant. Their criteria for surgical repair were (i) normal concave radial head articular surface and (ii) normal shape and contour of the ulna and radius (deformity of either correctable by osteotomy). They treated seven patients ranging in age from 5 to 13 years for chronic dislocations that had been present from 3 months to 7 years. All seven were fully active with no elbow pain or instability at an average of 4 years after surgery.

FIGURE 14-40 Chronic Monteggia lesion with a persistent anterior radial head dislocation and ossification of the displaced annular ligament.

Although they recommended surgical treatment of chronic Monteggia lesions in children because of the long-term sequelae, Rodgers et al.[121] cautioned that the results of reconstructive procedures can be unpredictable and associated with a number of complications including malunion of the ulnar shaft, recurrent radiocapitellar subluxation, and radial and ulnar neuropathy.

At present, most authors advocate surgical reconstruction of a chronic Monteggia when (i) the diagnosis is made early, (ii) there is preservation of the normal concave radial head and convex capitellum, (iii) especially when there is progressive deformity (i.e., valgus), loss of motion and pain, and (iv) the patient and family are well aware of the concerns with operative reconstruction.

Surgical Reconstruction

Descriptions of surgical reconstruction for pediatric chronic Monteggia lesions have been variable in terms of (i) annular

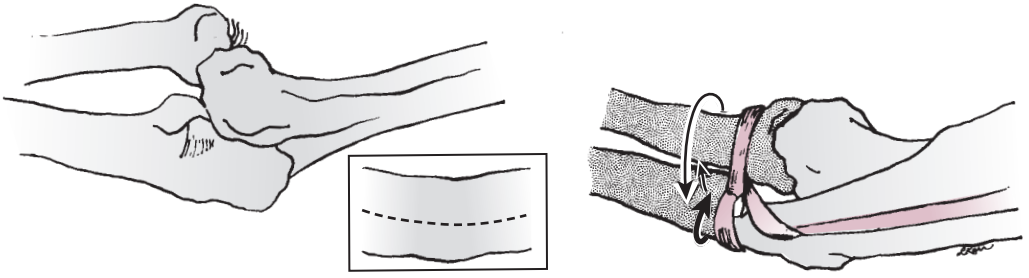

FIGURE 14-41 Bell-Tawse reconstruction. The central slip of the triceps is used to reconstruct an annular ligament in Bell-Tawse reconstruction. The direction of stability is posterior (*large arrow*).

ligament repair or reconstruction,[57] (ii) ulnar osteotomy alone[65,75] or in combination with ligament reconstruction,[34,62,94] and (iii) radial osteotomy.[33] The technique for delayed reduction of the radial head in a Monteggia fracture-dislocation is attributed to Bell-Tawse,[14] who used the surgical approach described by Boyd (Fig. 14-31).[20] Other surgical approaches have been developed.[56,139] Nakamura et al.[94] reported long-term clinical and radiographic outcomes in patients undergoing ulnar osteotomy with annular ligament reconstruction. At a mean follow-up of seven years, they reported excellent results in 19 out of 22 patients. Of concern, the radial head remained subluxated in five patients at the time of latest follow-up. Radiographic results did deteriorate when surgical reconstruction was performed more than 3 years after injury or in patients above 12 years of age.

Annular Ligament Repair or Reconstruction

Most but not all authors advocate surgical repair or reconstruction of the annular ligament in conjunction with an ulnar osteotomy for a pediatric chronic Monteggia lesion.[34,62,94,121] Annular ligament repair or reconstruction without an osteotomy is very rarely indicated.[24] Kalamchi[66] restored stability after open reduction and osteotomy by utilizing the native annular ligament. The native ligament is generally present, even years later. The central opening can be dilated with a probe and/or surgical hemostat or by radial incisions. The annular ligament is then brought back over the radial head and down to its anatomic location on the neck before repair to the proximal ulna periosteum. Bell-Tawse[14] used a strip of triceps tendon to reconstruct the annular ligament, as did Lloyd-Roberts[84] and Hurst.[64] Bell-Tawse[14] used the central portion of the triceps tendon passed through a drill hole in the ulna and around the radial neck to stabilize the reduction and immobilized the elbow in a long-arm cast in extension (Fig. 14-41). Bucknill[23] and Lloyd-Roberts[84] modified the Bell-Tawse procedure by using the lateral portion of the triceps tendon, with a transcapitellar pin for stability. The elbow was immobilized in flexion. Hurst and Dubrow[64] used the central portion of the triceps tendon but carried the dissection of the periosteum distally along the ulna to the level of the radial neck, which provided more stable fixation rather than stopping dissection at the olecranon as described by Bell-Tawse.[14] They also used a periosteal tunnel rather than a drill hole for fixation of the tendinous strip to the ulna. Other authors have used other soft tissues for reconstruction, including the lacertus fibrosus,[29] a strip of the forearm fascia (Fig. 14-31),[130] palmaris longus-free tendon graft,[157] and free fascia lata graft.[150]

Seel and Peterson[125] described the use of two holes drilled in the proximal ulna. The holes are placed at the original attachments of the annular ligament and allow repair of the annular ligament (frequently avulsed from one attachment and trapped within the joint) or reconstruction of the annular ligament with triceps tendon. This technique secures the radial head in its normal position from any dislocated position and allows osteotomy for correction of any accompanying deformity of the ulna or radius. Seel and Peterson[125] noted that the Bell-Tawse procedure tends to pull the radius posterolaterally (Fig. 14-42). A tight annular ligament reconstruction may constrict the neck of the radius, potentially limiting the growth of the radial neck ("notching") and reducing forearm rotation. Seel and Peterson[125] placed a single drill hole obliquely across the ulna to exit medially at the site of the medial attachment of the annular ligament on the coronoid process of the ulna (Fig. 14-42). The tendon was routed through the tunnel, brought around the neck, and sutured to the lateral side of the ulna. With this construct, the direction of stability was posteromedial. The use of two drill holes to secure the annular ligament or other reconstructive

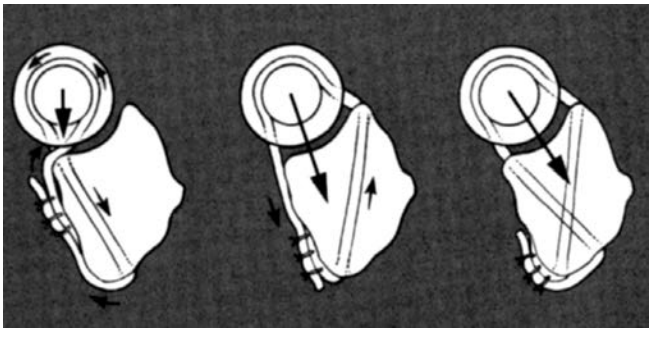

FIGURE 14-42 Drawings of transverse cuts of the proximal right radius and ulna (viewed distally) at the level of the radial head. **Left:** Route of the triceps tendon in Bell-Tawse reconstruction. The direction of stability is posterior (*large arrow*). **Center:** Drill hole placed obliquely to exit the ulna at the site of the medial annular ligament attachment. The direction of stability is posteromedial (*large arrow*). **Right:** Two drill holes exit the ulna at sites of medial and lateral annular ligament attachments. The direction of stability is anatomic (*arrow*).

tendon at both normal attachments of the annular ligament on the ulna achieved a more normal posteromedial holding force on the neck of the radius. Alternatives to holes drilled in the bone are small bone staples or bone-anchoring devices.

Ulnar Osteotomy

All surgeons advocate an ulnar osteotomy, with or without ligament repair or reconstruction, for a chronic pediatric Monteggia lesion. Various types of osteotomies have been used to facilitate reduction of the radial head and prevent recurrent subluxation (Fig. 14-43). Kalamchi[66] reported using a "drill hole" ulnar osteotomy to obtain reduction of the radial head in two patients. Minimal periosteal stripping with this technique allowed the osteotomy to heal rapidly. Hirayama et al.[60] used a 1-cm distraction ulnar osteotomy approximately 5 cm distal to the tip of the olecranon with plate and screw fixation, but complications with loosening and plate breakage occurred. Mehta[88,89] used an osteotomy of the proximal ulna stabilized with bone graft. In neither series was annular ligament repair performed.

Inoue and Shionoya[65] compared the results of simple corrective ulnar osteotomy in six patients with those of posterior angular (overcorrected) osteotomy in six others, and found that better clinical outcomes were obtained with the overcorrected, angular osteotomy. Tajima and Yoshizu,[143] in a series of 23 neglected Monteggia fractures, found that the best results were obtained by opening wedge osteotomy of the proximal ulna without ligament reconstruction.

Exner[43] reported that in patients with chronic dislocation of the radial head after missed type I Monteggia lesions, reduction was successfully obtained with ulnar corticotomy and gradual lengthening and angulation of the ulna using an external fixator. Another option for chronic type IV Monteggia lesion is a shortening osteotomy of the radius, usually indicated for angulation of the radius without angulation of the ulna.

Author's Preferred Treatment

In patients younger than 12 years of age with delayed diagnosis of a Monteggia lesion, reduction and stabilization of the radial head to its anatomic relationship with the capitellum is indicated if the radial head is still concave centrally. Even though the child may do well in the short-term without reduction of the radial head, problems usually develop in adolescence or adulthood when progressive instability, pain, weakness of the forearm, and restriction of motion are likely. There is also a risk of tardy radial or ulnar nerve palsies. The concavity of the radial head and convexity of the capitellum are assessed preoperatively, usually by MRI scan. Appropriate discussion with the patient and family regarding the risks and complications of surgery is performed. This is not an operation for the inexperienced surgeon or uninformed patient and family.

We perform an ulnar osteotomy and open reduction of the radial capitellar and radioulnar joints with annular ligament

reconstruction. The surgical approach is extensile (Fig. 14-44). The skin incision is curvilinear to allow for proximal triceps tendon harvesting, if necessary, and distally for an ulnar opening wedge osteotomy. Initially, only the proximal portion is opened. The radial nerve is identified between the brachialis and brachioradialis in the distal humerus. Dissection of the nerve is performed distally to its motor (posterior interosseous nerve) and sensory branches (Fig. 14-22). Generally, the posterior interosseous nerve is adherent to the dislocated radial head. The nerves are mobilized and protected throughout the remainder of the reconstruction.

Next, the anconeus–extensor carpi ulnaris (Kocher) interval is utilized to expose the joint. The joint exposure is carried proximal with elevation of the extensor–supinator mass and capsule as a single tissue plane off the distal humerus. This gives complete exposure of the elbow joint. The radial head is usually dislocated anteriorly and superiorly with a wall of interposed capsule and ligament blocking reduction. Pulvinar and synovitis are thoroughly debrided from the elbow joint. Particular attention is paid to a thorough debridement of the proximal radioulnar joint to allow the radial head to fit anatomically into place once reduced. At this stage, a decision needs to be made if the native annular ligament can be used for reconstruction. There is usually a central perforation in the capsular wall that separates the dislocated radial head from the joint. This perforation indicates the site of the opening of the original ligament. Dilatation and radial incisions extending from the center outward are made to enlarge this opening. This usually enables the native annular ligament to be reduced over the radial neck. Capsular adhesions are removed from the radial head to assist in reduction of the radial head and neck back into the joint. The native ligament usually detaches from the ulna with a large periosteal sleeve (the site of ossification on the radiographs of a chronic Monteggia lesion (Fig. 14-40)), and this can be the site for suture reattachment to the ulna of the native ligament. If the native ligament cannot be used, and most of the time it can, then it is thoroughly debrided in preparation for harvesting of triceps fascia for ligament reconstruction.

A radial head reduction is then attempted. The reduction is scrutinized for congruity between the radial head and the capitellum. If this is satisfactory, ligamentous repair or reconstruction alone can be done. This is exceedingly unusual. If the radius cannot be reduced, an ulnar osteotomy is made at the site of maximal deformity. This involves a more distal exposure to the ulna. Subperiosteal dissection is performed with fluoroscopic assistance at the site of maximal deformity. An opening wedge osteotomy is made with a laminar spreader to allow the radial head to align itself with the capitellum without pressure. Partial overcorrection of the ulnar alignment is the goal. A clever way to do this is to anatomically pin the radiocapitellar joint and allow the ulnar osteotomy to open the necessary amount for this reduction. When reduced anatomically, the ulnar osteotomy is then fixed partially proximally and distally with a plate and screws. Further testing of a complete stable arc of rotation of the radial head is performed in order to be certain that the correct level and degree of osteotomy were obtained to maintain radiocapitellar and radioulnar alignment. If a temporary radiocapitellar pin was used, it is removed for this testing. If correct, the fixation is completed. No bone graft is used, and the periosteum is repaired.

At this stage, the annular ligament repair or reconstruction is completed. If the native ligament is used, and it usually is in situations that are a year or less out from injury, then Ethibond mattress sutures (Ethicon, Somerville, NJ) are placed in the annular ligament and the ligament is repaired through ulnar periosteal tunnels. None of the radial sutures are tightened until all are placed. If reconstruction is necessary, a 6- to 8-cm strip of triceps fascia is developed from proximal to distal, carefully elevating the periosteum from the proximal ulna down to the level of the radial neck. Over the olecranon apophysis, this dissection will be delicate so as not to inadvertently amputate the fascia. The strip of tendon is then passed through the periosteum, around the radial neck, and then brought back and sutured to itself and the ulnar periosteum. The passage and securing in the periosteum is similar in design to the drill holes advocated by Seel and Peterson.[125] At this stage, the radial head and capitellum alignment should be anatomic throughout full rotation. Final closure involves repair of the capsule and extensor–supinator origin back to the lateral epicondylar region of the humerus. Final radiographs and fluoroscopic testing of a stable arc of motion in both flexion–extension and pronation–supination planes are gently tested before completion of closure. Prophylactic volar and dorsal forearm fasciotomies are carefully performed through the original incision with elevation of the skin and subcutaneous tissues and a long tenotomy scissors. Final inspection of the radial nerve is performed before subcutaneous and skin closure.

Radiocapitellar or radioulnar pin fixation is rarely needed if the osteotomy and soft tissue repair tension are correct. As mentioned at times, pin fixation is used intraoperatively for temporary stability to get the corrective ulnar osteotomy right; it is then removed to test the range of motion. If there is radial head deformity in very chronic reconstructions, pinning the joint is sometimes useful for 3 to 4 weeks postoperatively. In my experience, this has been occasionally necessary in repeat surgery for a chronic Monteggia lesion in which options are limited and the patient has pain and marked limitation of motion. Then, the radiocapitellar joint is secured by passing a smooth, transcapitellar pin through the posterior aspect of the capitellum into the radial head and neck with the elbow at 90 degrees and the forearm in supination. A pin of sufficient size is mandatory to avoid pin failure[71]; a small pin may fatigue and break. An alternative technique to secure the reduction of the radius is transversely pinning the radius to the ulna.[81]

After wound closure, a bivalved long-arm cast is applied with the forearm in 60 to 90 degrees of supination and the elbow flexed 80 to 90 degrees. The cast is maintained for 4 to 6 weeks and is then changed to a removable bivalved cast to allow active motion, especially pronation and supination. Elbow flexion and extension return more rapidly than rotary motion of the forearm which may take up to 6 months to improve, with pronation possibly limited, though minimally, permanently.[120] Final desired result is not determined until radiographs are anatomic with full restoration of motion.

Nerve Injuries

Radial Nerve

The literature reflects a 10% to 20% incidence of radial nerve injury, making it the most common complication associated with Monteggia fractures (Table 14-8).[63] It is most commonly associated with types I and III injuries.[14,96,127] The posterior interosseous nerve is most commonly injured because of its proximity to the radial head and its intimate relation to the Arcade of Frohse (Fig. 14-22). The arcade may be thinner and therefore more pliable in children than in adults.[132] In addition, the periosteum is much thicker in pediatric patients. This may account in part for the rapid resolution of the nerve injury in children. A radial nerve injury in a child is treated expectantly. Nerve function usually returns by 12 weeks after reduction, if not sooner.[133,135] A review of a series of pediatric Monteggia lesions[98] recommends waiting 6 months before intervention for a posterior interosseous nerve injury. Most series report 100% resolution in both fractures treated promptly and those treated late.[1,6,82]

Two reports[92,130] of irreducible Monteggia fractures caused by interposition of the radial nerve posterior to the radial head documented return of function approximately 4 months after the nerve was replaced to its normal anatomic position and the radial head was reduced. Morris,[92] in cadaver studies, showed that significant anterior dislocation of the radial head and varus angulation of the elbow allowed the radial nerve to slide posterior to the radial head and, with subsequent reduction of the radial head, become entrapped. If a chronic reconstruction is undertaken in the presence of a persistent radial nerve lesion, it is highly recommended that radial nerve exploration and decompression be performed before joint debridement. Rodgers et al.[121] cited a partial nerve injury during similar circumstances that was then microscopically repaired with full recovery. Rang[114] acknowledged the same experience in an open educational forum.

Ulnar Nerve

Bryan[22] reported one adult with an ulnar nerve lesion associated with a type II Monteggia lesion with spontaneous resolution. Stein et al.[135] reported three combined radial and ulnar nerve injuries, two of which underwent exploration and decompression for functional return of the nerve.

Median Nerve

Median nerve injuries are uncommon with Monteggia fractures, but injury to the anterior interosseous nerve has been reported.[157,160] Stein et al.,[135] in their report specifically examining nerve injuries in Monteggia lesions, reported no median nerve deficits. Watson and Singer[157] reported entrapment of the main trunk of the median nerve in a greenstick ulnar fracture in a 6-year-old girl. Completion of the fracture was necessary for release of the nerve. At 6 months after surgery, there was full motor recovery but the sensation was slightly reduced in the tips of the index finger and thumb.

Tardy Radial Nerve Palsy

Tardy radial nerve palsy associated with radial head dislocation has been infrequently reported.[1,6,61,82,164] Although reported treatment has varied, excision of the radial head with exploration and neurolysis of the nerve generally produced good results,[1,6] whereas exploration of the nerve alone produced variable results.[61,82] Yamamoto et al.[164] combined radial head resection and nerve exploration with tendon transfers, producing good results in two patients.

Periarticular Ossification

Two patterns of ossification after Monteggia fracture-dislocations have been noted radiographically: Ossification around the radial head and myositis ossificans. Ossification around the radial head and neck[14,63,82,84,136,138] appears as a thin ridge of bone in a cap-like distribution and may be accompanied by other areas resembling sesamoid bones (Table 14-8). This typically resorbs with time. Ossification may also occur in the area of the annular ligament,[40] including in a chronic Monteggia with a displaced annular ligament (Fig. 14-40). Elbow function generally is not affected by the formation of these lesions[14,63,84,136,138] as long as the radial head and neck are anatomically reduced.

The other form of ossification is true myositis ossificans, reported to occur in approximately 3% of elbow injuries and 7% of Monteggia lesions in adults and children.[97,149] Myositis ossificans has a good prognosis in patients younger than 15 years of age, appearing at 3 to 4 weeks after injury and resolving in 6 to 8 months. Its occurrence is related to the severity of the initial injury, association with a fractured radial head, the number of remanipulations during treatment, and passive motion of the elbow during the postoperative period.[97,149]

Summary, Controversies, and Future Directions Related to Monteggia Fracture-Dislocations

Adherence to several fundamental principles helps ensure a good outcome after Monteggia fracture-dislocations in children:

1. With a high index of suspicion and careful radiographic evaluation, acute Monteggia injuries can be accurately diagnosed. Evaluation of radiocapitellar alignment requires an AP and true lateral view of the elbow. All forearm fractures require careful inspection of the proximal radioulnar joint and the radiocapitellar joint before treatment.
2. The radiocapitellar line must be anatomic in all views.
3. If the radial head is dislocated, always look for ulnar fracture or plastic deformation. Conversely, if the ulna is fractured or plastically deformed, always look for a radial head subluxation or dislocation.
4. Stability of the ulnar reduction is required to maintain reduction of the radial head. Stability may be inherent to the fracture pattern (plastic deformation or incomplete fractures) or achieved by internal fixation (intramedullary fixation for short oblique and transverse fractures; plate and screw fixation for long oblique and comminuted fractures).
5. Radial head reduction confirmed by an intact radiocapitellar line must be achieved by open or closed means.
6. If the radial head is irreducible or unstable, removal of interposed soft tissue is required. An annular ligament repair or reconstruction may be required.

7. Treatment of an acute Monteggia lesion is more straightforward and much more successful than reconstruction of a chronic Monteggia lesion.
8. Reconstruction of a chronic Monteggia lesion is not an operation for the uninitiated. There is a high risk of recurrent or residual radial head subluxation and iatrogenic nerve injury.

Refining treatment recommendations for acute and chronic Monteggia lesions in the future will require prospective multicenter, scientific inquiry. To date, there are no prospective investigations with a large number of pediatric patients and sufficient duration of follow-up. The vast majority of published studies report limited outcomes data. Studies that report functional outcomes in addition to union rates, motion, and pain scores will permit surgeons to accurately counsel and monitor patient recovery and progress.

ACKNOWLEDGMENT

The authors wish to recognize contributions of the authors of previous editions of this chapter, Drs. Earl Stanley and Jose de la Garza.

15 EVALUATION OF PEDIATRIC DISTAL HUMERAL FRACTURES

James H. Beaty and James R. Kasser

INTRODUCTION TO EVALUATION OF PEDIATRIC DISTAL HUMERAL FRACTURES

At the end of the 19th century, Sir Robert Jones echoed the opinion of that era about elbow injuries: "The difficulties experienced by surgeons in making an accurate diagnosis; the facility with which serious blunders can be made in prognosis and treatment; and the fear shared by so many of the subsequent limitation of function, serve to render injuries in the neighborhood of the elbow less attractive than they might otherwise have proved."[37] These concerns are applicable even today. The importance of correct diagnosis was recently emphasized in a study of litigation against the National Health Service in England: over half of the cases involved missed or incorrectly diagnosed injuries, most of which were fractures about the elbow.[4] The difficulty in correctly diagnosing elbow injuries in children was shown by Shrader et al.,[55] who found that emergency room physicians accurately diagnosed elbow fractures in children only 53% of the time.

In other bones, good results can often be obtained with minimal treatment, but in the elbow, more aggressive treatment is often required to avoid complications. An understanding of the basic anatomy and radiographic landmarks of the elbow is essential in choosing appropriate treatment.

EPIDEMIOLOGY OF PEDIATRIC DISTAL HUMERAL FRACTURES

Because children tend to protect themselves with their outstretched arms when they fall, upper-extremity fractures account for 65% to 75% of all fractures in children. The most common area of the upper extremity injured is the distal forearm[8,41]; 7% to 9% of upper-extremity fractures involve the elbow.

The distal humerus accounts for approximately 86% of fractures about the elbow region. Supracondylar fractures are the most frequent elbow injuries in children, reported to occur in 55% to 75% of patients with elbow fractures. Lateral condylar fractures are the second most common, followed by medial epicondylar fractures. Fractures of the olecranon, radial head, and neck and medial condyle and T-condylar fractures are much less common.

Elbow injuries are much more common in children and adolescents than in adults.[14,63] The peak age for fractures of the distal humerus is between 5 and 10 years old.[32] Houshian et al.[34] reported that the average age of 355 children with elbow fractures was 7.9 years (7.2 years in boys and 8.5 years in girls). Contrary to most reports, these investigators found elbow fractures more frequent in girls (54%) than in boys. In a study of 450 supracondylar humeral fractures, Cheng et al.[17] found a median

age of 6 years (6.6 years in boys and 5 years in girls) and a predominance of injuries (63%) in boys. In a series of 1,297 consecutive supracondylar humeral fractures, including 873 type III fractures, Fletcher et al.[24] found that 18% occurred in children older than 8 years; these children had more open fractures from high-energy mechanisms than younger children. Stoneback et al.[61] reported that elbow dislocations were most frequent in those aged 10 to 19 years; 44% were sustained in sports.

Physeal injuries in most parts of the body occur in older children between the ages of 10 and 13; however, the peak age for injuries to the distal humeral physes is 4 to 5 years in girls and 5 to 8 years in boys. In most physeal injuries, the increased incidence with advanced age is believed to be due to weakening of the perichondrial ring as it matures (see Chapter 5). Thus, some different biomechanical forces and conditions must exist about the elbow to make the physis more vulnerable to injuries at an earlier age. (For more data on the relationship of fractures about the elbow to all types of fractures, see Chapter 1.)

Anatomy of Pediatric Distal Humeral Fractures

The elbow is a complex joint composed of three individual joints contained within a common articular cavity. Several anatomic concepts are unique to the growing elbow.

The Ossification Process of Pediatric Distal Humeral Fractures

The process of differentiation and maturation begins at the center of the long bones and progresses distally. The ossification process begins in the diaphyses of the humerus, radius, and ulna at the same time. By term, ossification of the humerus has extended distally to the condyles. In the ulna, it extends to more than half the distance between the coronoid process and the tip of the olecranon. The radius is ossified proximally to the level of the neck. The bicipital tuberosity remains largely unossified (Table 15-1).[26] Brodeur et al.[12] compiled a complete atlas of ossification of the structures about the elbow, and their work is an excellent reference source for finer details of the ossification process about the elbow.

TABLE 15-1 Sequence and Timing of Ossification in the Elbow

	Girls (y)	Boys (y)
Capitellum	1	1
Radial head	5	6
Medial epicondyle	5	7.5
Olecranon	8.7	10.5
Trochlea	9	10.7
Lateral epicondyle	10	12

Data from Cheng JC, Wing-Man K, Shen WY, et al. A new look at the sequential development of elbow-ossification centers in children. *J Pediatr Orthop.* 1998;18:161–167.

FIGURE 15-1 During the first 6 months, the advancing ossifying border of the distal humerus is symmetric.

Distal Humerus

Ossification of the distal humerus proceeds at a predictable rate. In general, the rate of ossification in girls exceeds that of boys.[23,26,30] In some areas, such as the olecranon and lateral epicondyle, the difference between boys and girls in ossification age may be as great as 2 years.[26] During the first 6 months, the ossification border of the distal humerus is symmetric (Fig. 15-1).

Lateral Condyle

On average, the ossification center of the lateral condyle appears just before 1 year of age but may be delayed as late as 18 to 24 months.[14] When the nucleus of the lateral condyle first appears, the distal humeral metaphyseal border becomes asymmetric. The lateral border slants and becomes straight to conform with the ossification center of the lateral condyle (Fig. 15-2). By the end of the second year, this border becomes well defined, possibly even slightly concave. The capitellar ossification center is usually spherical when it first appears. It becomes more hemispherical as the distal humerus matures,[13] and the ossific nucleus extends into the lateral ridge of the trochlea (Fig. 15-3). On the lateral view, the physis of the capitellum is wider posteriorly. This is a normal variation and should not be confused with a fracture.[13]

Medial Epicondyle

At about 5 to 6 years of age, a small concavity develops on the medial aspect of the metaphyseal ossification border. In this area, a medial epicondyle begins to ossify (Fig. 15-4).

Trochlea

At about 9 to 10 years of age, the trochlea begins to ossify. Initially, it may be irregular with multiple centers (Fig. 15-5).

FIGURE 15-2 Ossification at 12 months. As the ossification center of the lateral condyle develops (*arrow*), the lateral border of the metaphysis becomes straighter.

FIGURE 15-4 At about 5 or 6 years of age, a secondary center develops in the medial epicondylar apophysis (*white arrows*). At this same time, the ossification center of the radial head also develops (*open arrow*). Note that the physis of the proximal radius is widened laterally (*curved arrow*).

Lateral Epicondyle

The lateral epicondyle is last to ossify and is not always visible (Fig. 15-6). At about 10 years of age, it may begin as a small, separate oblong center, rapidly fusing with the lateral condyle.[13]

The Fusion Process in Pediatric Distal Humeral Fractures

Just before completion of growth, the capitellum, lateral epicondyle, and trochlea fuse to form one epiphyseal center. Metaphyseal bone separates the extra-articular medial epicondyle from this common humeral epiphyseal center (Fig. 15-7). The common epiphyseal center ultimately fuses with the distal humeral metaphysis. The medial epicondyle may not fuse with the metaphysis until the late teens.

Proximal Radius

The head of the radius begins to ossify at about the same time as the medial epicondyle (Fig. 15-4). The ossification center is present in at least 50% of girls by 3.8 years of age but may

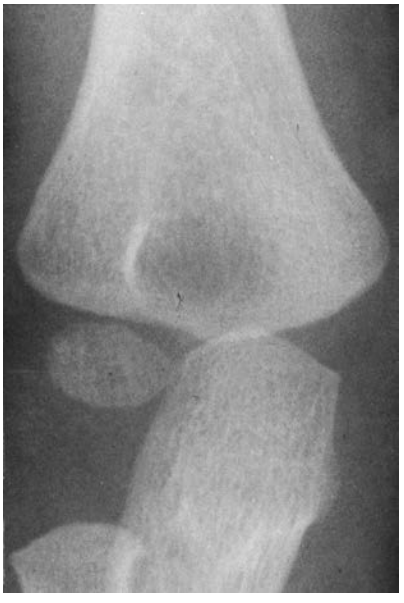

FIGURE 15-3 At 24 months, the oval-shaped secondary ossification center of the lateral condyle extends into the lateral crista of the trochlea. The lateral border of the neck (metaphysis) of the radius is normally angulated both anteriorly and laterally.

FIGURE 15-5 At about 9 years of age, the ossification of the medial crista of the trochlea may begin as two well-defined centers (*arrows*). These multiple centers can give the trochlea a fragmented appearance.

FIGURE 15-6 The apophysis of the lateral epicondyle ossifies as either an oblong or a triangular center (*arrows*). The wide separation of this center from the metaphyseal and epiphyseal borders of the lateral condyle is normal.

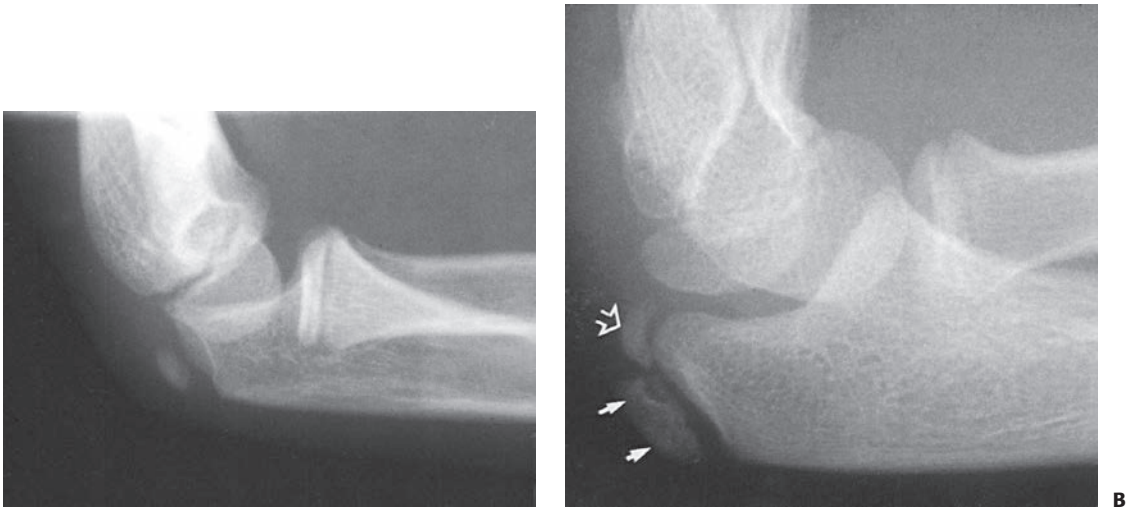
FIGURE 15-7 The secondary ossification centers of the lateral condyle, trochlea, and lateral epicondylar apophysis fuse to form one center (*white arrows*). This common center is separated from the medial epicondylar apophysis by advancing metaphyseal bone (*black arrows*).

not be present in the same proportion of boys until around 4.5 years.[23] Initially, the ossification center is elliptical, and the physis is widened laterally because of the obliquity of the proximal metaphysis. The ossification center flattens as it matures. At about age 12, it develops a concavity opposite the capitellum.[13]

Ossification of the radial head may be bipartite or may produce an irregularity of the second center. These secondary or irregular ossification centers should not be interpreted as fracture fragments.

Olecranon

There is a gradual proximal progression of the proximal ulnar metaphysis. At birth, the ossification margin lies halfway between the coronoid process and the tip of the olecranon. By about 6 or 7 years of age, it appears to envelop about 66% to 75% of the capitellar surface. The final portion of the olecranon ossifies from a secondary ossification center that appears around 6.8 years of age in girls and 8.8 years in boys (Fig. 15-8A). Peterson and Peterson[49] described two separate centers: one articular and the other a traction type (Fig. 15-8B). This secondary ossification center of the olecranon may persist late into adult life.[47]



A **B**

FIGURE 15-8 Ossification of the olecranon. **A:** Secondary ossification begins as an oblique oblong center at about 6 to 8 years of age. **B:** It may progress as two separate ossification centers: Articular (*open arrow*) and traction (*closed arrows*).

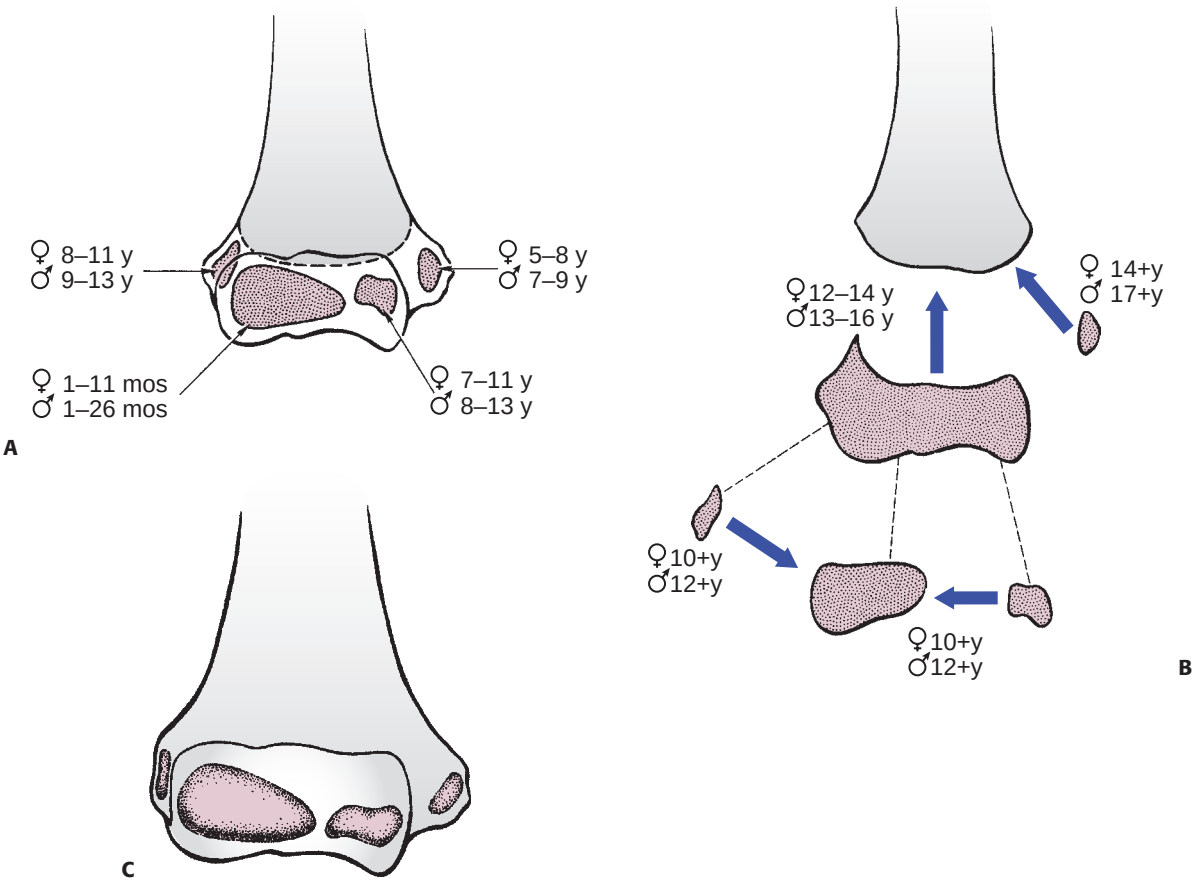


FIGURE 15-9 Ossification and fusion of the secondary centers of the distal humerus. **A:** The average ages for the onset of ossification of the various ossification centers are shown for both boys and girls. **B:** The ages at which these centers fuse with each other are shown for both boys and girls. (Modified and reprinted with permission from Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of intraosseous vasculature in distal humerus. *Acta Orthop Scand.* 1959;38:1–232.) **C:** The contribution of each secondary center to the overall architecture of the distal humerus is represented by the stippled areas.

Fusion of the Ossification Centers

The epiphyseal ossification centers of the distal humerus fuse as one unit and then fuse later to the metaphysis. The medial epicondyle is the last to fuse to the metaphysis. The ranges of onset of the ossification of various centers and their fusion to other centers or the metaphysis are summarized in Figure 15-9. Each center contributes to the overall architecture of the distal humerus (Fig. 15-9C).

Fusion of the proximal radial and olecranon epiphyseal centers with their respective metaphyses occurs at around the same time that the common distal humeral epiphysis fuses with its metaphysis (i.e., between 14 and 16 years of age).[9,12,53]

Noting that the pattern and ossification sequence of the six secondary ossification centers around the elbow were mainly derived from studies conducted more than 30 years ago, Cheng et al.[17] evaluated elbow radiographs of 1,577 Chinese children. They found that the sequence of ossification was the same in boys and girls—capitellum, radial head, medial epicondyle, olecranon, trochlea, and lateral epicondyle—but ossification was delayed by about 2 years in boys in all ossification centers except the capitellum (Table 15-1).

Blood Supply to Pediatric Distal Humerus

Extraosseous

There is a rich arterial network around the elbow (Fig. 15-10).[65] The major arterial trunk, the brachial artery, lies anteriorly in the antecubital fossa. Most of the intraosseous blood supply of the distal humerus comes from the anastomotic vessels that course posteriorly.

Three structural components govern the location of the entrance of the vessels into the developing epiphysis. First, there is no communication between the intraosseous metaphyseal vasculature and the ossification centers. Second, vessels do not penetrate the articular surfaces. The lateral condyle is nonarticular only at the origin of the muscles and collateral ligaments. Third, the vessels do not penetrate the articular capsule except at the interface with the surface of the bone. Thus, only a small portion of the lateral

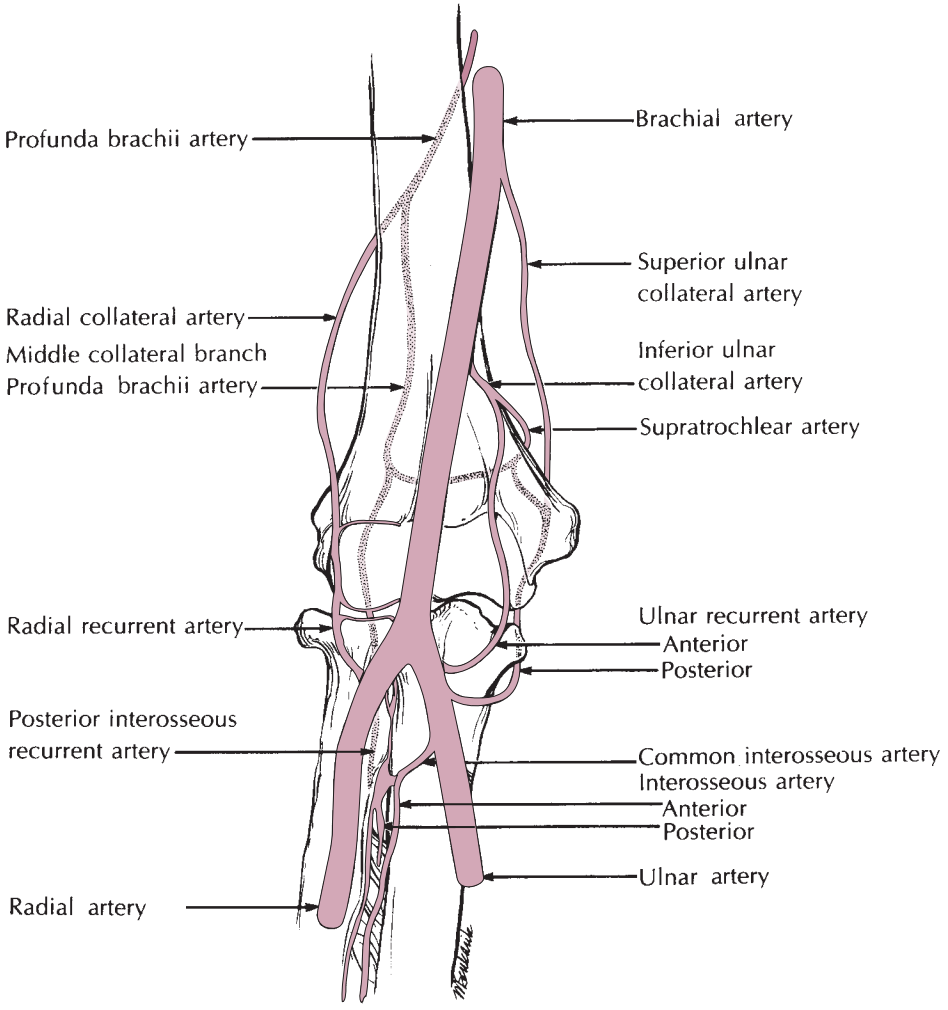

FIGURE 15-10 The major arteries about the anterior elbow.

pondyle posteriorly is both nonarticular and extracapsular (Fig. 15-11).[31]

Intraosseous

The most extensive study of the intraosseous blood supply of the developing distal humerus was conducted by Haraldsson[30,31] (Fig. 15-12A), who demonstrated that there are two types of vessels in the developing lateral condyle. These vessels enter the posterior portion of the condyle just lateral to the origin of the capsule and proximal to the articular cartilage near the origin of the anconeus muscle. They penetrate the nonossified cartilage and traverse it to the developing ossific nucleus. In a young child, this is a relatively long course (Fig. 15-12A). These vessels communicate with one another within the ossific nucleus but do not communicate with vessels in either the metaphysis or nonossified chondroepiphysis. Thus, for practical purposes, they are end vessels.

The ossification center of the lateral condyle extends into the lateral portion of the trochlea. Thus, the lateral crista or ridge of the trochlea derives its blood supply from these condylar vessels. The medial ridge or crista remains unossified for a

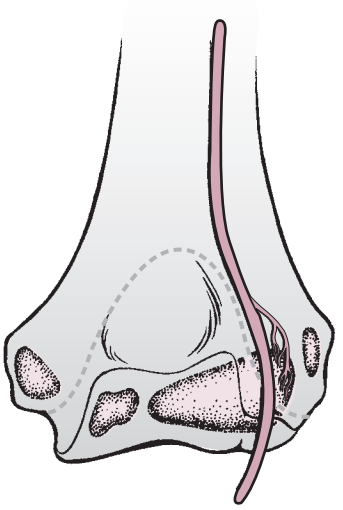

FIGURE 15-11 The vessels supplying the lateral condylar epiphysis enter the posterior aspect of the condyle, which is extra-articular. (Modified and reprinted with permission from Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of intraosseous vasculature in distal humerus. *Acta Orthop Scand.* 1959;38:1–232.)

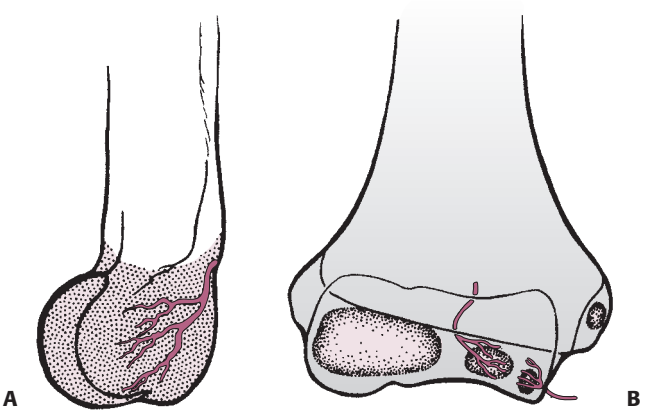

FIGURE 15-12 Intraosseous blood supply of the distal humerus. **A:** The vessels supplying the lateral condylar epiphysis enter on the posterior aspect and course for a considerable distance before reaching the ossific nucleus. **B:** Two definite vessels supply the ossification center of the medial crista of the trochlea. The lateral vessel enters by crossing the physis. The medial one enters by way of the nonarticular edge of the medial crista. (Modified and reprinted with permission from Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of intraosseous vasculature in distal humerus. *Acta Orthop Scand.* 1959;38:1–232.)

longer period of time. The trochlea is covered entirely by articular cartilage and lies totally within the confines of the articular capsule. The vessels that supply the nucleus of the ossific centers of the trochlea must therefore traverse the periphery of the physis to enter the epiphysis.

Haraldsson's[31] studies have shown two sources of blood supply to the ossific nucleus of the medial portion of the trochlea (Fig. 15-12B). The lateral vessel, on the posterior surface of the distal humeral metaphysis, penetrates the periphery of the physis and terminates in the trochlear nucleus. Because this vessel supplying the trochlea is an end vessel, it is especially vulnerable to injury by a fracture that courses through either the physis or the very distal portion of the humeral metaphysis. Injury to this vessel can markedly decrease the nourishment to the developing lateral ossific nucleus of the trochlea. The medial vessel penetrates the nonarticulating portion of the medial crista of the trochlea. This multiple vascular source may account for the development of multiple ossification centers in the maturing trochlea, giving it a fragmented appearance (Fig. 15-5). When growth is complete, metaphyseal and epiphyseal vessels anastomose freely. The blood supply from the central nutrient vessel of the shaft reaches the epicondylar regions in the skeletally mature distal humerus.[39]

Intra-Articular Structures of the Pediatric Distal Humerus

The articular surface lies within the confines of the capsule, but nonarticulating areas involving the coronoid and radial fossae anteriorly and the olecranon fossa posteriorly are also within the confines of the articular cavity.[64] The capsule attaches just distal to the coronoid and olecranon processes. Thus, these processes are intra-articular.[36] The entire radial head is intra-articular, with a recess or diverticulum of the elbow's articular

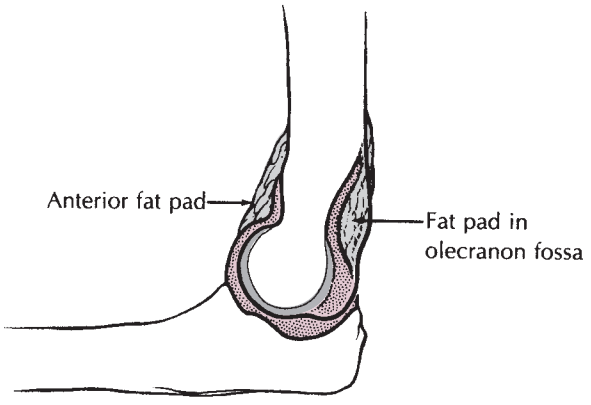

FIGURE 15-13 The elbow fat pads. Some of the coronoid fat pad lies anterior to the shallow coronoid fossa. The olecranon fat pad lies totally within the deeper olecranon fossa.

cavity extending distally under the margin of the orbicular ligament. The medial and lateral epicondyles are extra-articular.

The anterior capsule is thickened anteriorly. These longitudinally directed fibers are very strong and become taut with the elbow in extension. In hyperextension, the tight anterior bands of the capsule force the ulna firmly into contact with the humerus. Thus, the fulcrum of rotation becomes transmitted proximally into the tip of the olecranon in the supracondylar area. This is an important factor in the etiology of supracondylar fractures.

Fat Pads

At the proximal portion of the capsule, between it and the synovial layer, are two large fat pads (Fig. 15-13). The posterior fat pad lies totally within the depths of the olecranon fossa when the elbow is flexed. The anterior fat pad extends anteriorly out of the margins of the coronoid fossa. The significance of these fat pads in the interpretation of radiographs of the elbow is discussed later.

Ligaments

The pertinent ligamentous anatomy involving the orbicular and collateral ligaments is discussed in the sections on the specific injuries involving the radial neck, medial epicondyle, and elbow dislocations.

Radiographic Findings in Pediatric Distal Humeral Fractures

Because of the ever-changing ossification pattern, identification and delineation of fractures about the elbow in the immature skeleton may be subject to misinterpretation. The variables of ossification of the epiphyses should be well known to the orthopedic surgeon who treats these injuries.

Several studies have suggested that children with a normal range of elbow motion after elbow trauma do not require immediate radiographic evaluation. In a large multicenter prospective study, Appelboam et al.[3] found that of 780 children evaluated for elbow trauma, 289 were able to fully extend their elbow; among these, 12 (4%) fractures were identified, all at their first evaluation. Among the 491 children who could not fully extend their injured elbow, 210 (43%) had confirmed fractures. These

authors suggested that an elbow extension test can be used to rule out the need for radiographs, provided the physician is confident that an olecranon fracture is not present and that the patient can return for reevaluation if symptoms have not resolved in 7 to 10 days. Lennon et al.,[42] in a study involving 407 patients ranging in age from 2 to 96 years, proposed that patients aged no more than 16 years with a range of motion equal to the unaffected side do not require radiographic evaluation. Darracq et al.[19] found that limitation of active range of motion was 100% sensitive for fracture or effusion, whereas preservation of active range of motion was 97% specific for the absence of fracture. Other studies[20,40] have confirmed a high sensitivity (91% to 97%) of an inability to extend the elbow as a predictor of elbow fracture in both children and adults. More recently, however, Baker and Borland warned that in children with blunt trauma a normal range of motion does not rule out significant injury and should not be used as a screening tool. In their 177 patients, an abnormal range of motion had a negative predictive value of only 77%.[5]

Waters et al. described a subset of serious injuries to the pediatric elbow that they termed TRASH (The Radiographic Appearance Seemed Harmless) lesions (Table 15-2). These lesions represent predominantly osteochondral injuries in children younger than 10 years of age who have sustained high-energy trauma; the lesions are often associated with unrecognized, spontaneously reduced elbow dislocations (Fig. 15-14). Any elbow dislocation in a child younger than

TABLE 15-2 Elbow "TRASH" Lesions

- Unossified medial condylar humeral fractures
- Unossified transphyseal distal humeral fractures
- Entrapped medial epicondylar fractures
- Complex osteochondral elbow fracture-dislocation in a child younger than 10 years of age
- Osteochondral fractures with joint incongruity
- Radial head anterior compression fractures with progressive radiocapitellar subluxation
- Monteggia fracture-dislocations
- Lateral condylar avulsion shear fractures

10 years of age should raise concern about a displaced, intra-articular osteochondral fracture, especially with a high-energy mechanism of injury and more swelling than the seemingly benign radiograph demonstrates. A high index of suspicion and early additional imaging (ultrasound, arthrogram, or magnetic resonance imaging [MRI]) usually contribute to a more accurate diagnosis of these injuries.[62]

When radiographs are indicated, a number of anatomic landmarks and angles should be evaluated and measured, including any displacement of the fat pads about the elbow. It is important to be familiar with these landmarks and angles and to be aware of the significance of any deviation from normal.

Standard Views

The standard radiographs of the elbow include an anteroposterior (AP) view with the elbow extended and a lateral view with the elbow flexed to 90 degrees and the forearm neutral.

Jones View

It is often difficult for a child to extend the injured elbow, and an axial view of the elbow, the Jones view, may be helpful (Fig. 15-15). The distal humerus is normally difficult to interpret because of the superimposed proximal radius and ulna. There is often a high index of suspicion for a fracture, but none is visible on routine AP and lateral radiographs. In this case, internal and external oblique views may be helpful. This is especially true in identifying fractures of the radial head and coronoid process and judging displacement in lateral condylar fractures.

Measurement of Displacement of Pediatric Distal Humeral Fractures

The determination of the amount of fracture displacement is critical to the choice of treatment of medial epicondylar fractures. The general consensus among pediatric orthopedic surgeons seems to be that fractures with less than 2 mm of displacement can be treated nonoperatively, whereas those with more than 5 mm of displacement should be treated operatively.

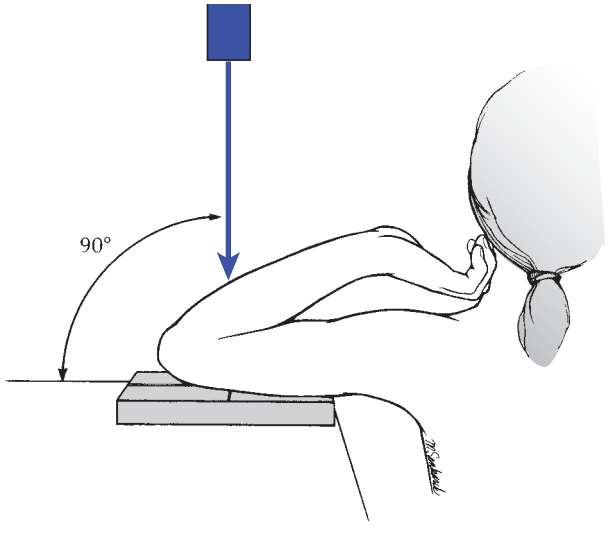

FIGURE 15-15 Jones axial radiographic view of the elbow.

A difference of 1 or 2 mm in the measurement of displacement can change the management of these fractures. To determine the reliability of displacement measurements, Pappas et al.[48] had radiographs of 38 children with fractures of the medial humeral epicondyle evaluated by five reviewers with different levels of orthopedic training. Pappas et al. found that the reviewers disagreed an average of 87% of the time about measurements on the lateral view, 64% of the time about measurements on the oblique view, and 54% about measurements on the AP view. The findings cast doubt on whether the amount of perceived displacement should be used as a criterion for choosing operative or nonoperative treatment of fractures of the medial epicondyle. Proposed methods for improving displacement measurement were (1) measuring displacement on AP views and (2) measuring displacement as the maximal distance between the fragment and the bone location from which it came (Fig. 15-16). In contrast, Edmonds[22] suggested that internal oblique views appear to best approximate the true anterior displacement. Comparison of measurements of displacement on

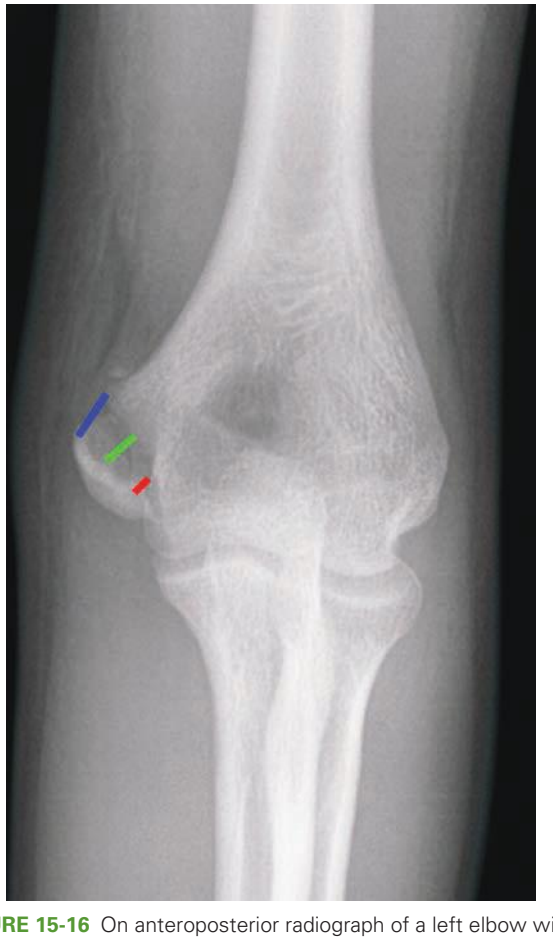

FIGURE 15-16 On anteroposterior radiograph of a left elbow with a medial epicondylar fracture, there are three different places where displacement could be measured. The *red line* represents 2 mm of displacement; the *green line,* 3 mm; and the *blue line,* 5 mm. (From Pappas N, Lawrence JT, Donegan D, et al. Intraobserver and interobserver agreement in the measurement of displaced humeral medial epicondyle fractures in children. *J Bone Joint Surg Am.* 2010;92:322–327.)

radiographs to those on three-dimensional computed tomography (CT) scans demonstrated that fractures that appear to be minimally displaced or nondisplaced on radiographs, especially AP and lateral views, may have more than 1 cm of anterior displacement by CT scan.

Anteroposterior Landmarks in Pediatric Distal Humerus Fractures

Baumann's Angle

In the standard AP view, the major landmark is the angulation of the physeal line between the lateral condyle and the distal humeral metaphysis. The ossification center of the lateral condyle extends into the radial or lateral crista of the trochlea (Fig. 15-9C). This physeal line forms an angle with the long axis of the humerus. The angle formed by this physeal line and the long axis of the humerus is the Baumann's angle (Fig. 15-17A).[6] The Baumann's angle is not equal to the carrying angle of the elbow in older children.[13] This is a consistent angle when both sides are compared, and the x-ray beam is directed perpendicular to the long axis of the humerus. Acton and McNally[1] reviewed the descriptions of the Baumann's angle in a number of commonly used textbooks and discovered three variations of measurement technique. They recommended that the angle should always be measured between the long axis of the humerus and the inclination of the capitellar physis, as Baumann described, and that it should be called the "shaft-physeal" angle to avoid confusion.

Caudad–cephalad angulation of the x-ray tube or right or left angulation of the tube by as much as 30 degrees changes the Baumann's angle by less than 5 degrees. If, however, the tube becomes angulated in a cephalad–caudad direction by more than 20 degrees, the angle is changed significantly and the measurement is inaccurate. In their cadaver studies, Camp et al.[15] found that rotation of the distal fragment or the entire reduced humerus can also alter the projection of the Baumann's angle. They found that to be accurate, the humerus must be parallel to the x-ray plate, with the beam directed perpendicular to the film as well. Thus, in the routine AP radiographs of the distal humerus, including the Jones view, the Baumann's angle is a good measurement of any deviation of the angulation of the distal humerus.[18,54,56,57]

Other Angles

Two other angles measured on AP radiographs are commonly used to determine the proper alignment of the distal humerus or carrying angle. The humeral–ulnar angle is determined by lines longitudinally bisecting the shaft of the humerus with the shaft of the ulna on an AP view (Fig. 15-17B).[7,35,48] The metaphyseal–diaphyseal angle is determined by a line that longitudinally bisects the shaft of the humerus with a line that connects the widest points of the metaphysis of the distal humerus (Fig. 15-17C).[46] The humeral–ulnar angle is the most accurate in determining the true carrying angle of the elbow. The

(Reprinted with permission from O'Brien WR, Eilert RE, Chang FM, et al. The metaphyseal–diaphyseal angle as a guide to treating supracondylar fractures of the humerus in children. Presented at: 54th Annual Meeting of AAOS; 1987; San Francisco, CA.)

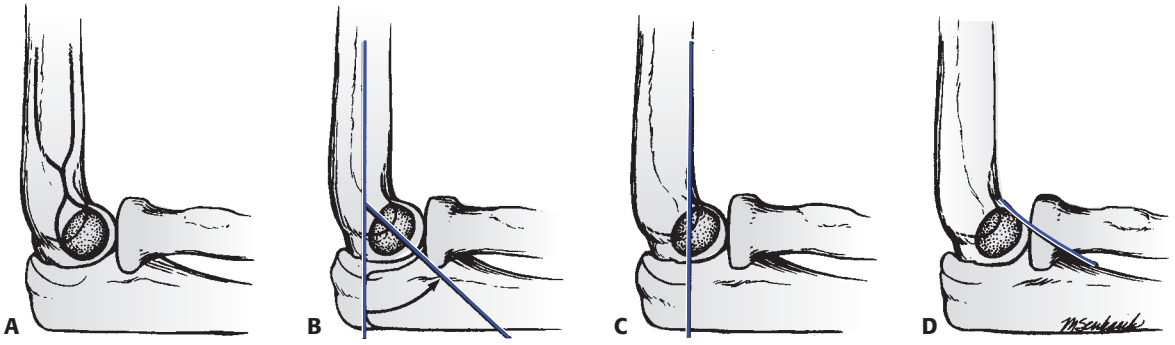

FIGURE 15-18 Lateral radiograph lines of the distal humerus. **A:** The teardrop of the distal humerus. **B:** The angulation of the lateral condyle with the shaft of the humerus. **C:** The anterior humeral line. **D:** The coronoid line.

Baumann's angle also has a good correlation with the clinical carrying angle, but it may be difficult to measure in adolescents in whom the ossification center of the lateral condyle is beginning to fuse with other centers. The metaphyseal–diaphyseal angle is the least accurate of the three.[60]

Lateral Landmarks in Pediatric Distal Humerus Fractures

Teardrop

The lateral projection of the distal humerus presents a teardrop-like shadow above the capitellum.[53] The anterior dense line making up the teardrop represents the posterior margin of the coronoid fossa. The posterior dense line represents the anterior margin of the olecranon fossa. The inferior portion of the teardrop is the ossification center of the capitellum. On a true lateral projection, this teardrop should be well defined (Fig. 15-18A).

Shaft-Condylar Angle

On the lateral radiograph, there is an angulation of 40 degrees between the long axis of the humerus and the long axis of the lateral condyle (Fig. 15-18B). This can also be measured by the flexion angle of the distal humerus, which is calculated by measuring the angle of the lateral condylar physeal line with the long axis of the shaft of the humerus.[51]

Anterior Humeral Line

If a line is drawn along the anterior border of the distal humeral shaft, it should pass through the middle third of the ossification center of the capitellum. This is referred to as the *anterior humeral line* (Fig. 15-18C). Passage of the anterior humeral line through the anterior portion of the lateral condylar ossification center or anterior to it indicates the presence of posterior angulation of the distal humerus. In a large study of minimally displaced supracondylar fractures, Rogers et al.[51] found that this anterior humeral line was the most reliable factor in detecting the presence or absence of occult fractures. Herman et al.,[33] however, found that the location of the anterior humeral line varied according to age: in almost half of children younger than 4 years of age the line passed through the anterior third of the capitellum, whereas in older children the anterior humeral line more consistently passed through the middle third.

Coronoid Line

A line directed proximally along the anterior border of the coronoid process should barely touch the anterior portion of the lateral condyle (Fig. 15-18D). Posterior displacement of the lateral condyle projects the ossification center posterior to this coronoid line.[51]

Lateral Humerocapitellar Angle

Shank et al.[52] described measurement of the lateral humerocapitellar angle (LHCA) using digital measurement tools and digital radiographs (Fig. 15-19). This angle measures the angular relationship between the humeral shaft and the

FIGURE 15-19 Lateral humerocapitellar angle (LHCA) on lateral radiograph of normal elbow. (From Shank CF, Wiater BP, Pace JL, et al. The lateral capitellohumeral angle in normal children: Mean, variation, and reliability in comparison to Baumann's angle. *J Pediatr Orthop*. 2011;31:266–271.)

capitellum as seen on the lateral view. In normal elbows, the LHCA averaged 51 degrees and was not affected by age, sex, or side. Its reliability was found to be inferior to that of the Baumann's angle but improved with increasing patient age. The correlation between the LHCA and clinical outcome is unclear, with some studies finding no correlation[44,45] and others reporting a strong correlation between the LHCA and loss of flexion at skeletal maturity.[25,58] Although the exact relationship between the LHCA and clinical outcome is unclear, the authors suggested that an LHCA of more than three standard deviations from normal (more than 69 degrees) should be accepted with reservation, especially in older patients, because some studies have suggested unpredictable remodeling of angular deformity.[25,27,58]

Pseudofracture

Some vagaries of the ossification process about the elbow may be interpreted as a fracture.[53] For example, the ossification of the trochlea may be irregular, producing a fragmented appearance (Fig. 15-5). This fragmentation can be misinterpreted, especially if the distal humerus is slightly oblique or tilted. These secondary ossification centers may be mistaken for fracture fragments lying between the semilunar notch and lateral condyle (Fig. 15-20).

On the lateral view, the physeal line between the lateral condyle and the distal humeral metaphysis is wider posteriorly. This appearance may give a misinterpretation that the lateral condyle is fractured and tilted.[13]

On the AP view before the radial head ossifies, there is normally some lateral angulation to the radial border of the neck of the radius that may give the appearance of subluxation (Fig. 15-3). The true position of the radial head can be confirmed by noting the relationship of the proximal radius to the ossification center of the lateral condyle on the lateral projection.[52]

FIGURE 15-20 Pseudofracture of the elbow. The trochlea with its multiple ossification centers may be misinterpreted as fracture fragments lying between the joint surfaces (*arrow*).

Fat Pad Signs of the Elbow

There are three areas in which fat pads overlie the major structures of the elbow. Displacement of any of the fat pads can indicate an occult fracture. The first two areas are the fat pads that overlie the capsule in the coronoid fossa anteriorly and the olecranon fossa posteriorly. Displacement of either or both of these fat pads is usually referred to as the *classic elbow fat pad sign*. A third accumulation of fat overlies the supinator muscle as it wraps around the proximal radius.

Olecranon (Posterior) Fat Pad. Because the olecranon fossa is deep, the fat pad here is totally contained within the fossa. It is not visible on a normal lateral radiograph of the elbow flexed to 90 degrees (Fig. 15-21A).

Distention of the capsule with an effusion, as occurs with an occult intra-articular fracture, a spontaneously reduced dislocation, or even an infection, can cause the dorsal or olecranon fat pad to be visible.[66]

Coronoid (Anterior) Fat Pad. Likewise, the ventral or coronoid fat pad may be displaced anteriorly (Fig. 15-21B).[11] Because the coronoid fossa is shallow, the fat pad in this area projects anterior to the bony margins and can be seen normally as a triangular radiolucency anterior to the distal humerus. Although displacement of the classic elbow fat pads is a reliable indication of an intra-articular effusion, there may be instances in which only one of the fat pads is displaced. Brodeur et al.[13] and Kohn[39] have shown that the coronoid fat pad is more sensitive to small effusions than the olecranon fat pad. The coronoid fat pad can be displaced without a coexistent displacement of the olecranon fat pad (Fig. 15-21C). Blumberg et al.[10] analyzed the radiographs of 197 consecutive patients with elbow trauma and found that 113 (57%) had normal anterior fat pads; of these, only two had fractures, giving a 98% negative predictive value to the presence of a normal anterior fat pad.

Supinator Fat Pad. A layer of fat on the anterior aspect of the supinator muscle wraps around the proximal radius. This layer of fat or fat pad may normally bow anteriorly to some degree. Brodeur et al.[13] stated that displacement may indicate the presence of an occult fracture of the radial neck. Displacement of the fat line or pad is often difficult to interpret; in a review of fractures involving the proximal radius, Schunk et al.[53] found it to be positive only 50% of the time.

Fat Pad Variations. For the fat pads to be displaced, the capsule must be intact. This can explain why there may be no displacement of the fat pads with an elbow dislocation that has spontaneously reduced because of capsule rupture. Murphy and Siegel[46] described other variations of classic fat pad displacement. If the elbow is extended, the fat pad is normally displaced from the olecranon fossa by the olecranon (Fig. 15-21D). Distal humeral fractures may cause subperiosteal bleeding and may lift the proximal portion of the olecranon fat pad without the presence of an effusion (Fig. 15-21E). These false-negative and false-positive determinations must be kept in mind when interpreting the presence or absence of a fat pad finding with an elbow injury.

To date, fat pad studies draw disparate conclusions. Corbett's[18] review of elbow injuries indicated that if a displacement of the

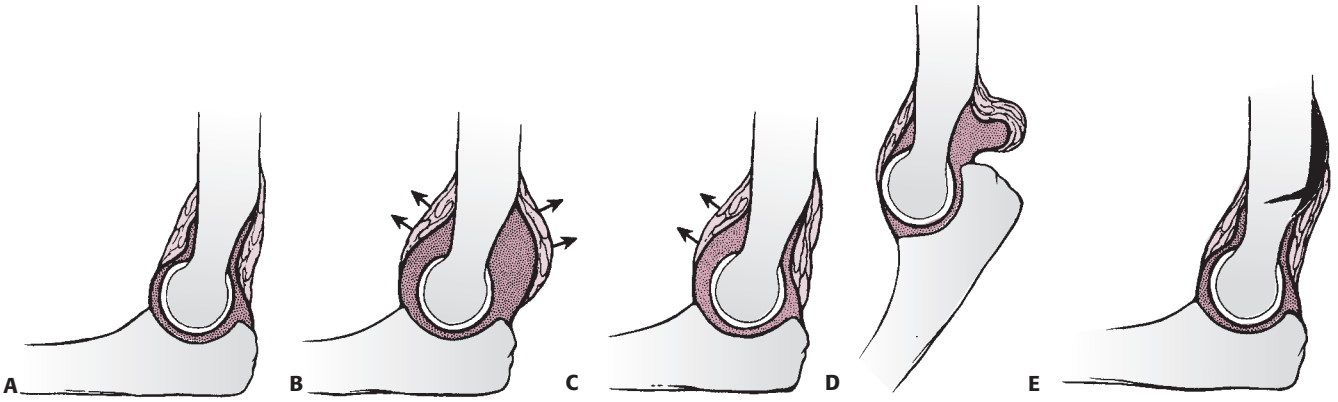

FIGURE 15-21 Radiographic variations of the elbow fat pads. **A:** Normal relationships of the two fat pads. **B:** Displacement of both fat pads (*arrows*) with an intra-articular effusion. **C:** In some cases, the effusion may displace only the anterior fat pad (*arrows*). **D:** In extension, the posterior fat pad is normally displaced by the olecranon. **E:** An extra-articular fracture may lift the distal periosteum and displace the proximal portion of the posterior fat pad. **F:** A radiograph showing displacement of both fat pads (*arrows*) from an intra-articular effusion. (Modified and reprinted with permission from Murphy WA, Siegel MJ. Elbow fat pads with new signs and extended differential diagnosis. *Radiology*. 1977;124:656–659.)

posterior fat pad existed, a fracture was almost always present. Displacement of the anterior fat pad alone, however, could occur without a fracture. Corbett[18] also determined that the degree of displacement bore no relation to the extent of the fracture. Skaggs and Mirzayan[59] reported that 34 of 45 children (76%) with a history of elbow trauma and an elevated posterior fat pad had radiographic evidence of elbow fractures at an average of 3 weeks after injury, though AP, lateral, and oblique radiographs at the time of injury showed no other evidence of fracture. They recommended that a child with a history of elbow trauma and an elevated fat pad should be treated as if a nondisplaced elbow fracture were present. Donnelly et al.,[21] however, found evidence of fracture in only 9 of 54 children (17%) who had a history of trauma and elbow joint effusion but no identifiable fracture on initial radiographs. Donnelly et al. concluded that joint effusion without a visible fracture on initial radiographs does not correlate with the presence of occult fracture in most patients (83%). Persistent effusion did correlate with occult fracture: 78% of those with occult fractures had persistent effusions, whereas effusions were noted in only 16% of those without fractures. More recently, in a prospective MRI study of 26 children with positive fat pad signs, Al-Aubaidi and Torfing[2] concluded that the presence of a positive fat pad sign is not synonymous with an occult fracture. All 26 children had a positive fat pad sign on lateral radiographs, but MRI scans obtained an average of 7 days later found occult fractures in only 6 patients, none of whom had a change in fracture treatment.

Comparison Radiographs of Pediatric Distal Humeral Fractures

Although it is often tempting to order comparison radiographs in a child with an injured elbow due to the difficulty evaluating the irregularity of the ossification process, the indications for ordering comparison radiographs are rare. Kissoon et al.[38] found that using routine comparison radiographs in children with injured elbows did not significantly increase the accuracy of diagnosis, regardless of the interpreter's training. Petit et al.[50] reviewed 3,128 radiographs of 2,470 children admitted to a pediatric emergency department for osteoarticular trauma and found that only 22% of the radiographs revealed abnormal findings; 33.3% of elbow radiographs revealed abnormalities. Fewer than half of clinically suspected fractures were confirmed by radiograph.

Magnetic Resonance Imaging for Pediatric Distal Humeral Fractures

Major and Crawford[43] used MRI to evaluate 7 children who had radiographs that showed effusion but no fractures; 4 of the children had fractures identified by MRI. These

investigators suggested that an occult fracture is usually present when effusion occurs, even if a fracture is not visible on radiograph. Griffith et al.[29] reviewed the radiographs and MRI scans of 50 children with elbow trauma. Radiographs identified effusions in 34% of the children and fractures in 52%; MRI identified effusions in 96% and fractures in 74%. Although MRI revealed a broad spectrum of bone and soft tissue injury beyond that shown on radiographs (bone bruising, muscle and ligament injuries, physeal injury, fracture), the additional information provided by MRI had little influence on patient treatment and no value in predicting clinical outcome. We have found MRI to be helpful in evaluating articular and osteochondral fractures to identify fracture pattern and extent, fragment position, and any interposed structure.

Other Imaging Modalities for Pediatric Distal Humeral Fractures

Sonography and arthrography can be useful in examining children with posttraumatic elbow effusions, but these can be painful and invasive. The use of CT in the young can be limited by the need for sedation. In adolescent T-condylar humeral fractures, CT is extremely helpful for planning operative intervention. The development of multidetector CT (MDCT) technology allows examinations to be completed in seconds, eliminating the need for sedation in most cases. Studies using MDCT can also be reformatted and evaluated in multiple planes, reducing the manipulation necessary for a series of radiographs. Chapman et al.[16] reported that, in a series of 31 children with posttraumatic elbow effusion and normal radiographs, MDCT depicted occult injuries in 52%. Besides the minimal manipulation required, making it relatively easy and pain free, and the speed with which the image is obtained, they cited as additional advantages of MDCT the lower radiation dose than conventional radiographs, its sensitivity (92%), specificity (79%), and high negative predictive value (92%). A limitation of this method may be its high cost compared to standard radiographic examination.

16 SUPRACONDYLAR FRACTURES OF THE DISTAL HUMERUS

David L. Skaggs and John M. Flynn

Introduction to Supracondylar Fractures of the Distal Humerus

Current evidence and consensus suggest displaced supracondylar fractures are best treated operatively with fixation.[3,90,140,187] Modern techniques for the treatment of supracondylar humerus (SCH) fractures in children have dramatically decreased the rates of malunion and compartment syndrome.[3,19,66,103,116,120,140,173] Discussion continues regarding the urgency of operative treatment and the management of the pulseless supracondylar. In some locations the treatment of supracondylar fractures in children is shifting to pediatric subspecialists. In New England in 1991, 37% of patients were treated by pediatric orthopedic specialists; by 1999 this figure rose to 68%.[99]

SCH fractures are the most common elbow fractures seen in children,[39,55,143] and the most common fracture requiring surgery in children. The peak age range at which most supracondylar fractures occur is 5 to 6 years.[37]

Principles of Management of Supracondylar Fractures of the Distal Humerus

Mechanism of Injury and Anatomy of Supracondylar Fractures of the Distal Humerus

Supracondylar fractures may be divided into extension and flexion types, depending on the direction of displacement of the distal fragment. Extension-type fractures, which account for approximately 97% to 99% of SCH fractures[121] are usually caused by a fall onto the outstretched hand with the elbow in full extension (Fig. 16-1). SCH fractures most frequently result from falling, commonly off playground equipment.[171] It has been reported that the overall safety of playground design can influence the likelihood of an SCH fracture, with children using the least safe playgrounds having almost five times the rate of SCH fracture as those using the safest playgrounds.[145]

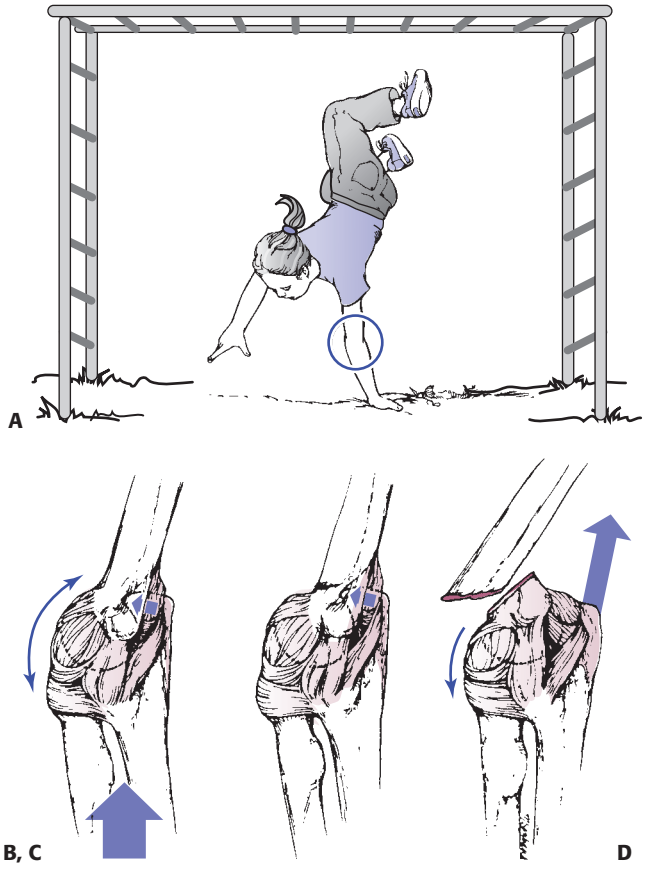

FIGURE 16-1 Mechanism of injury—elbow hyperextension. **A:** Most children attempt to break their falls with the arm extended, and the elbow then hyperextends. **B:** The linear applied force (*large arrow*) leads to an anterior tension force. Posteriorly, the olecranon is forced into the depths of the olecranon fossa (*small arrow*). **C:** As the bending force continues, the distal humerus fails anteriorly in the thin supracondylar area. **D:** When the fracture is complete, the proximal fragment can continue moving anteriorly and distally, potentially harming adjacent soft tissue structures such as the brachialis muscle, brachial artery, and median nerve.

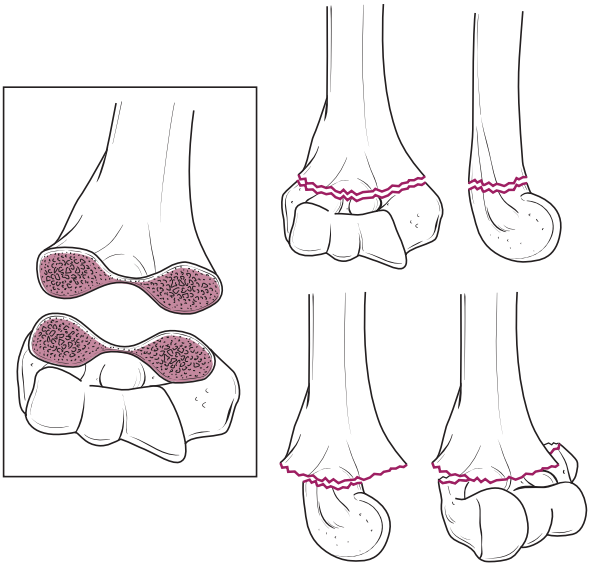

FIGURE 16-2 Supracondylar fractures occur through the thinnest portion of the distal humerus in the AP plane. The thin bone makes the fracture unstable.

The majority of this chapter is on extension-type fractures, with flexion-type fractures being covered at the end of the chapter. The medial and lateral columns of the distal humerus are connected by a thin segment of bone between the olecranon fossa posteriorly and coronoid fossa anteriorly resulting in a high risk of fracture to this area (Fig. 16-2). In a normal anatomic variant the olecranon fossa may be absent (Fig. 16-3). Another normal

FIGURE 16-3 Normal anatomic variant in which there is no bone in the olecranon fossa. Note the minimally displaced radial neck fracture. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

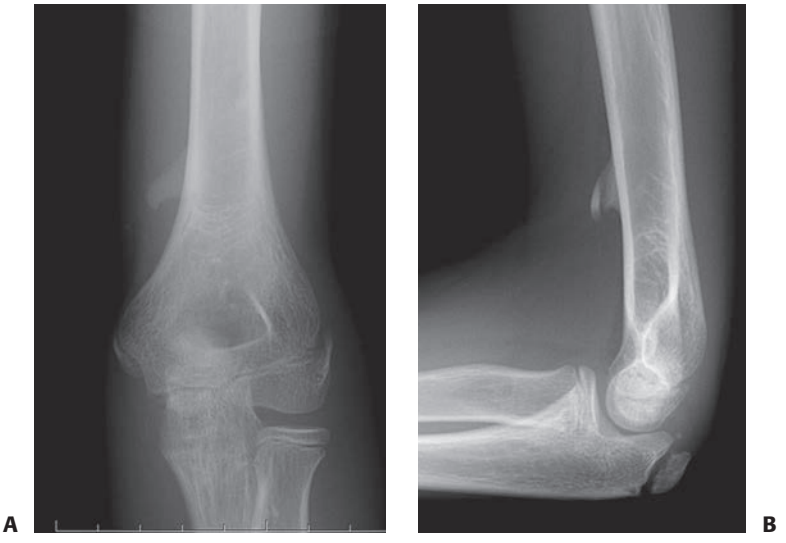

FIGURE 16-4 **A:** AP radiograph of the distal humerus demonstrating a supracondylar process, a normal anatomic variant. **B:** Lateral radiograph demonstrating a supracondylar process. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

anatomic variant is the supracondylar process which is present to some extent in about 1.5% of adult cadavers[51] and should not be mistaken for fracture pathology. However, this anatomic variant can be the site of median nerve compression (Fig. 16-4).

With forced elbow hyperextension, the olecranon forcefully pushes into the olecranon fossa and acts as a fulcrum, while the anterior capsule simultaneously provides a tensile force on the distal humerus at its insertion. The resulting injury is an extension-type SCH fracture. It has been postulated that ligamentous laxity with resulting elbow hyperextension may predispose to an SCH fracture[136] but this association is unclear.[128]

Posteromedial Versus Posterolateral Displacement of Extension-Type Supracondylar Fractures of the Distal Humerus

The periosteum plays a key role in regards to treatment. With extension-type injuries, the anterior periosteum is likely torn. The intact posterior periosteal hinge provides stability to the fracture and facilitates reduction with a flexion reduction maneuver. Many authors have described adding forearm pronation to assist in reduction, but this should not be automatic. The direction of fracture displacement often indicates whether the medial or lateral periosteum remains intact. With a posteromedially displaced fracture, the medial periosteum is usually intact. Elbow flexion and forearm pronation places the medial and posterior periosteum on tension, which corrects varus and extension malalignment and adds to stability of fracture reduction (Fig. 16-5). The medial periosteum however is often torn in a posterolaterally displaced fracture, in which case pronation may be counterproductive. Instead, in a posterolaterally displaced supracondylar fracture, forearm supination in addition to flexion may be better because the lateral periosteum is usually intact. If the posterior periosteal hinge is also disrupted, the fracture becomes unstable in both flexion and extension and this has been recently described as a multidirectionally unstable, modified Gartland type IV fracture.[118]

Generally, medial displacement of the distal fragment is more common than lateral displacement, occurring in approximately 75% of patients in most series. Whether the displacement is medial or lateral is important because it determines which soft tissue structures are at risk from the penetrating injury of the proximal metaphyseal fragment. Medial displacement of the

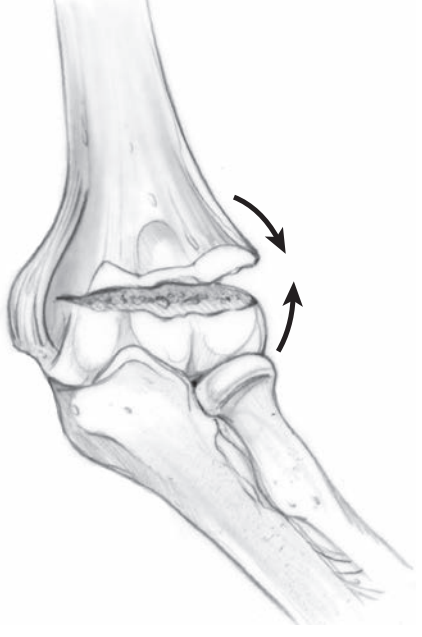

FIGURE 16-5 Laterally torn periosteum in a posteromedially displaced supracondylar humerus fracture. (From Skaggs DL. Closed reduction and pinning of supracondylar humerus fractures. In: Tolo VT, Skaggs DL, eds. *Masters Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007.)

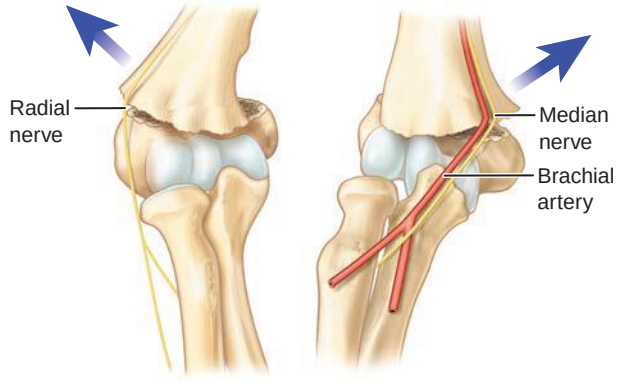

FIGURE 16-6 Relationship to neurovascular structures. The proximal metaphyseal spike penetrates laterally with posteromedially displaced fractures and places the radial nerve at risk; with posterolaterally displaced fractures, the spike penetrates medially and places the median nerve and brachial artery at risk. (From Choi PD, Skaggs DL. Closed reduction and percutaneous pinning of supracondylar fractures of the humerus. In: Wiesel S, ed. *Operative Techniques in Orthopaedic Surgery*. Philadelphia, PA: Lippincott William & Wilkins; 2010, with permission.)

distal fragment places the radial nerve at risk, and lateral displacement of the distal fragment places the median nerve and brachial artery at risk (Fig. 16-6).[119]

Radiographic Diagnosis of Supracondylar Fractures of the Distal Humerus

All patients with a history of a fall onto an outstretched hand as well as pain and inability to use the extremity should undergo a thorough radiologic evaluation. If physical examination does not localize the trauma to the elbow alone, this may include obtaining anteroposterior (AP) and lateral views of the entire upper extremity. Comparison views are rarely required by an experienced physician, but occasionally may be needed to evaluate an ossifying epiphysis. Beware that the emergency room physician's interpretation of elbow fractures in children has been reported to have an overall accuracy of only 53%.[167]

Radiographic examination begins with a true AP view of the distal humerus. (In contrast, an AP of an elbow in 90 degrees of flexion will give a roughly 45-degree angulated view of the distal humerus and proximal radius and ulna.) A true AP of the distal humerus allows a more accurate evaluation of the distal humerus and decreases the error in determining Baumann's angle. The lateral film should be taken as a true lateral with the humerus held in the anatomic position and not externally rotated (Fig. 16-7). Oblique views of the distal humerus occasionally may be helpful when a supracondylar fracture or occult condylar fracture is suspected but not seen on standard AP and lateral views, but should not be routinely ordered to evaluate for a supracondylar fracture.

Initial radiographs may be negative except for a posterior fat pad sign (Fig. 16-8). A series of patients with traumatic elbow pain and a posterior fat pad sign but no visible fracture found that 53% (18/34) had a SCH fracture, 26% (9/34) a fracture of the proximal ulna, 12% (4/34) a fracture of the lateral condyle, and 9% (3/34) a fracture of the radial neck.[176]

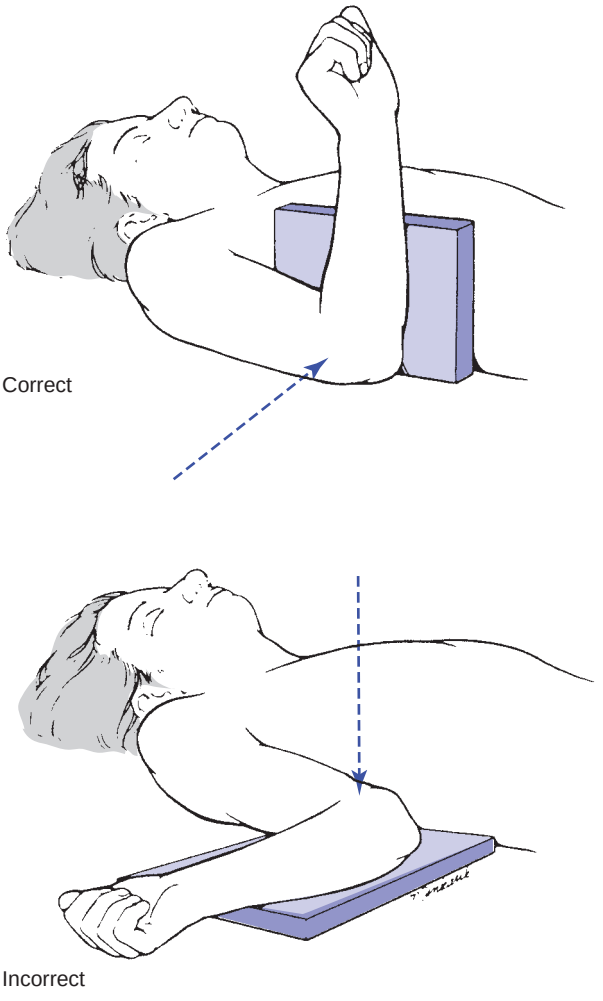

FIGURE 16-7 X-ray positioning. The correct method of taking a lateral view is with the upper extremity directed anteriorly rather than externally rotated.

Two main radiographic parameters are used to evaluate the presence of a supracondylar fracture. The anterior humeral line (AHL) should cross the capitellum on a true lateral of the elbow. Previous editions of this text and others have stated that in a normal elbow the AHL should pass through the middle third of the capitellum. However, it has been demonstrated in recent studies that in a normal elbow the AHL passes through the middle third of the capitellum only 52% of the time in children under 10 years of age, and in children younger than 4 years of age the AHL is equally likely to pass through the anterior third of the capitellum as the middle third (Fig. 16-9).[87] In an extension-type supracondylar fracture, the capitellum is posterior to this line. Note that the "hourglass" should be tilted slightly forward in a true lateral view of a normal elbow (Fig. 16-8A) and can help aid in the diagnosis of a type II SCH fracture.

Baumann's angle, also referred to as the humeral capitellar angle, is the angle between the long axis of the humeral shaft and the physeal line of the lateral condyle (normal range, about 9 to 26 degrees) (Fig. 16-10). Interpretation of Baumann's angle

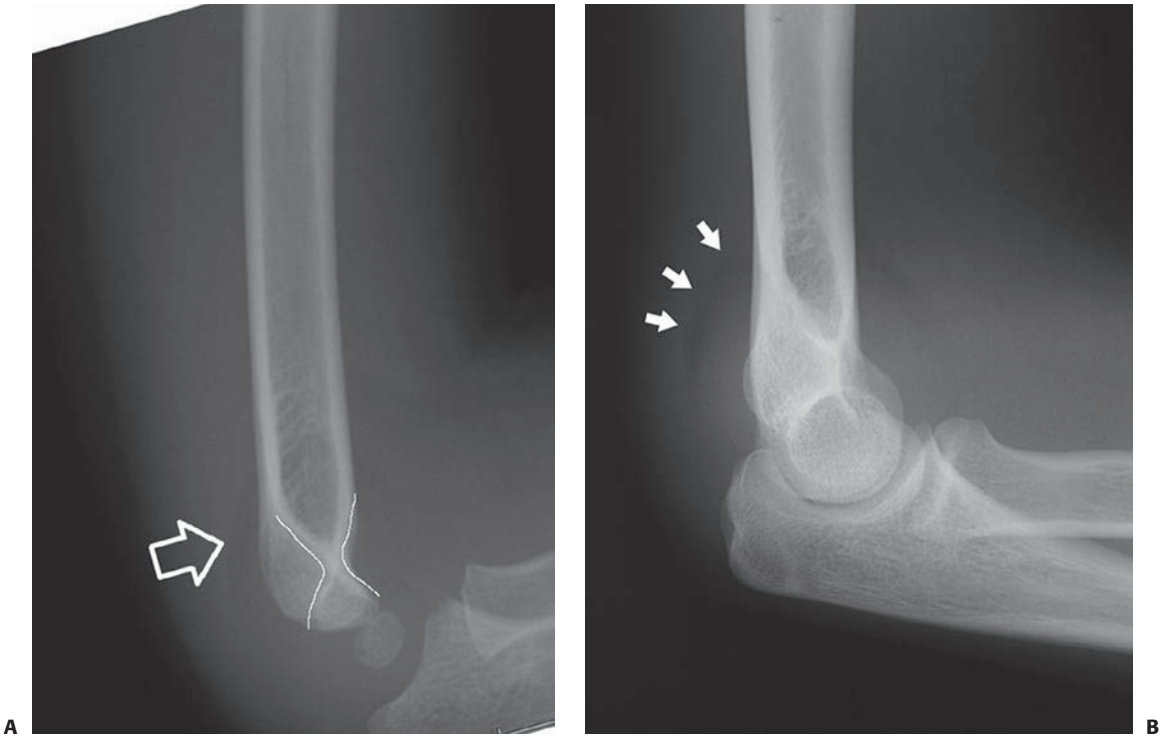

FIGURE 16-8 **A:** Lateral radiograph demonstrating an elevated posterior fat pad (*white arrow*) and a normal hourglass which is anteriorly tilted if there is not a displaced fracture. **B:** Another example of an elevated fat pad. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

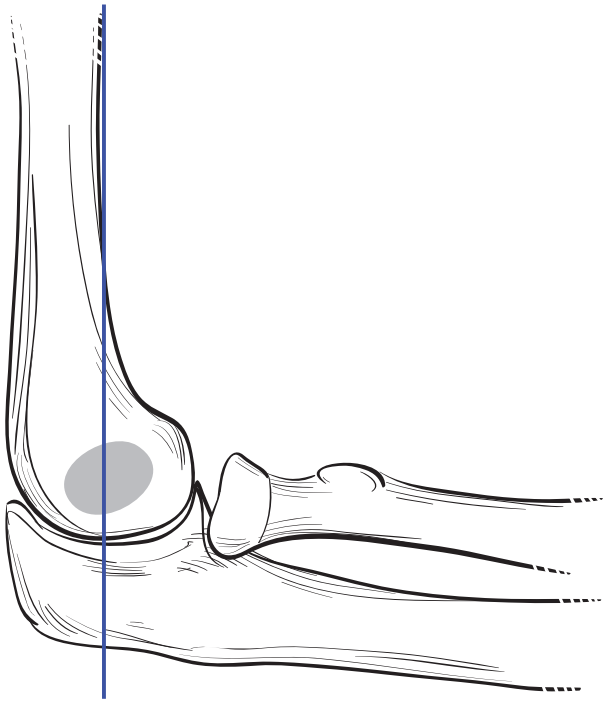

FIGURE 16-9 Anterior humeral line should cross the capitellum on a true lateral of the elbow, though not necessarily through the middle third of the capitellum as was previously believed. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics*. Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

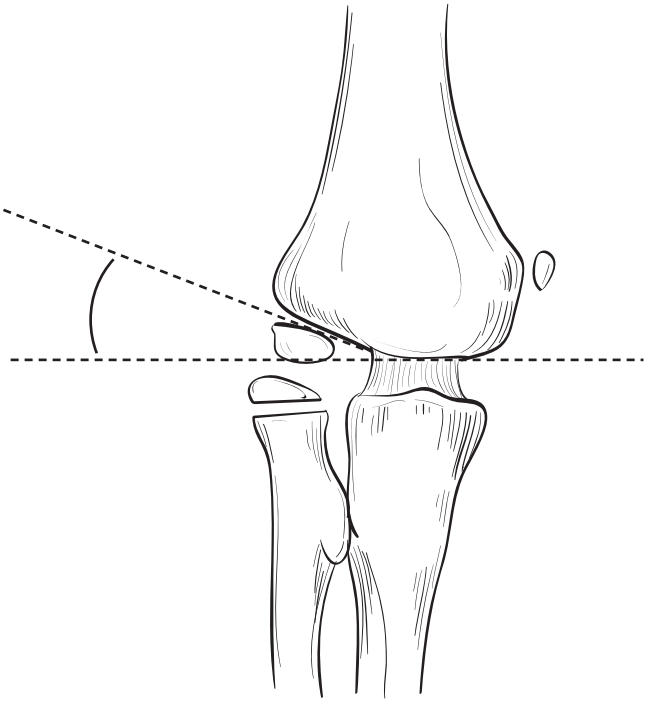

FIGURE 16-10 Baumann's angle is between the line perpendicular to the long axis of the humeral shaft and the physeal line of the lateral condyle. A decrease in Baumann's angle may indicate medial comminution. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics*. Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

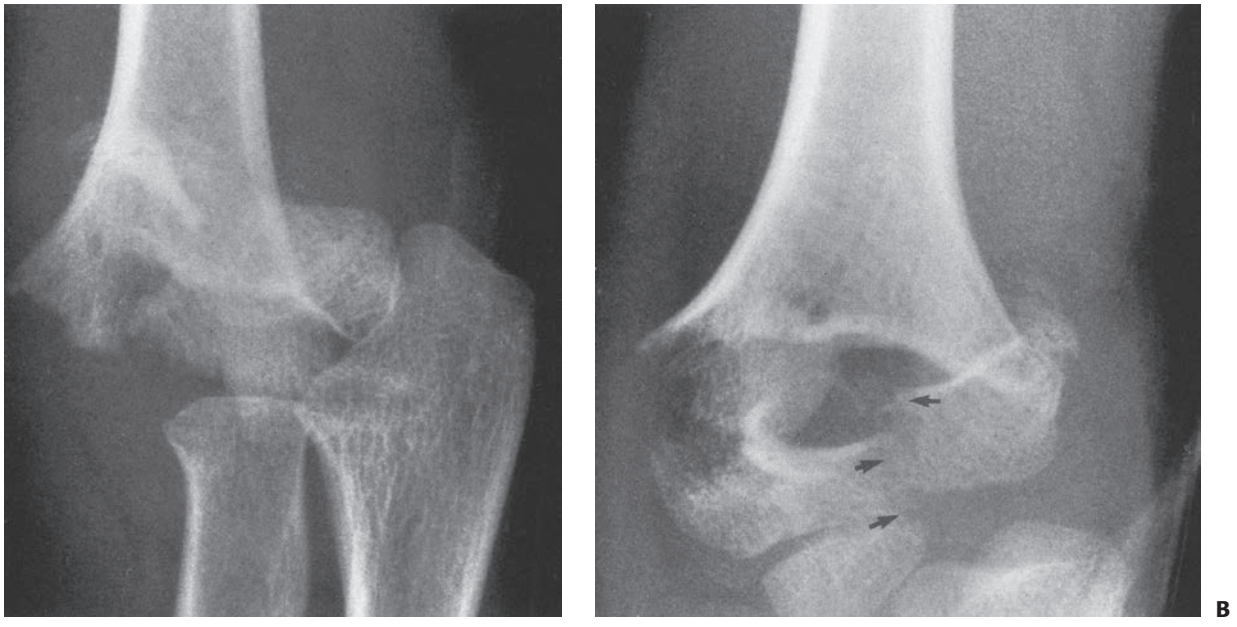

FIGURE 16-11 Occult T-condylar. **A:** Original x-rays appear to show a type III posteromedial supracondylar fracture. **B:** After manipulation, the vertical intercondylar fracture line (*arrows*) was visualized.

is open to variability. One study reports one of five observers measure Baumann's angle from the same radiograph greater than 7 degrees different from the other four observers.[169] A rule of thumb is that a Baumann's angle ≥10 degrees is OK. A decrease in Baumann's angle compared to the other side is a sign that a fracture is in varus angulation.

If the AP and lateral views show a displaced type II or III supracondylar fracture but do not show full detail of the distal humeral fragment, we usually obtain further x-ray evaluation to define the fracture anatomy with particular emphasis on (a) impaction of the medial column, (b) supracondylar comminution, and (c) vertical split of the epiphyseal fragment. T-condylar fractures (Fig. 16-11) can initially appear to be supracondylar fractures, but these generally occur in children over 10 years of age, in whom supracondylar fractures are less likely (see Chapter 17).

In a young child, an epiphyseal separation[215] can mimic an elbow dislocation. In an epiphyseal separation, the fracture propagates through the physis without a metaphyseal fragment. This fracture occurs in very young children with primarily chondral epiphyses. On physical examination, the patient appears to have a supracondylar fracture with gross swelling about the

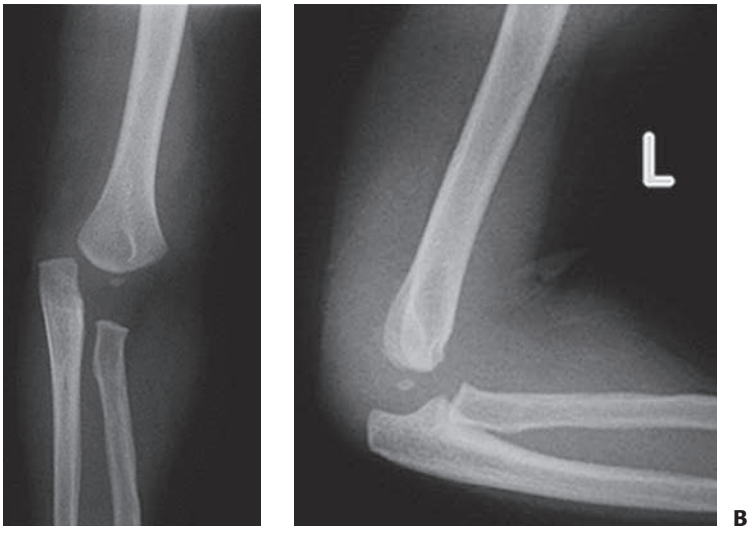

FIGURE 16-12 **A:** Twelve-month-old, Salter II fracture resulting from child abuse. Note the radius points to the capitellum in all views, so this is not a dislocation. **B:** Lateral view.

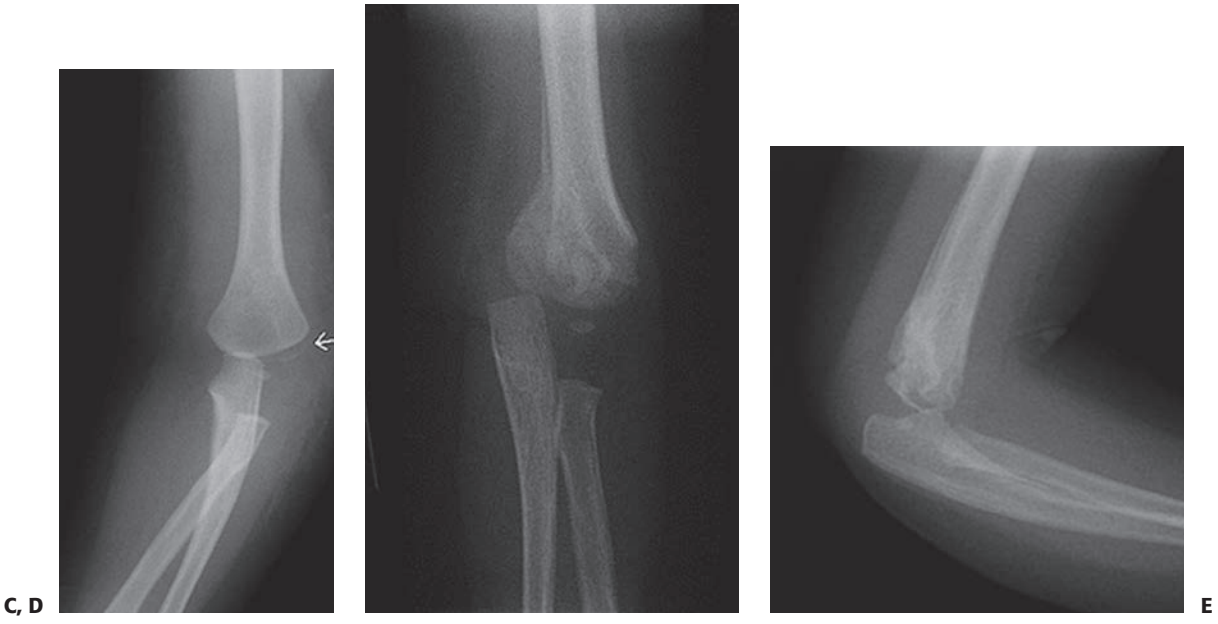

FIGURE 16-12 (*continued*) **C:** Oblique view shows the thin metaphyseal fragment, which defines this as a Salter II fracture. **D:** This fracture was not recognized at presentation to the emergency department. elbow and marked discomfort. The key to making the diagnosis and differentiating this injury from an elbow dislocation radiographically is seeing that the capitellum remains aligned with the radial head. Usually a thin metaphyseal fragment, which may make one think of a lateral condyle fracture can be seen, which technically makes this a Salter II fracture (Fig. 16-12). In such cases, more data is required to initiate treatment. An arthrogram may be helpful (Fig. 16-13). In selected patients, magnetic resonance imaging or ultrasonography[215] may also aid in evaluating the injury to the unossified epiphysis.

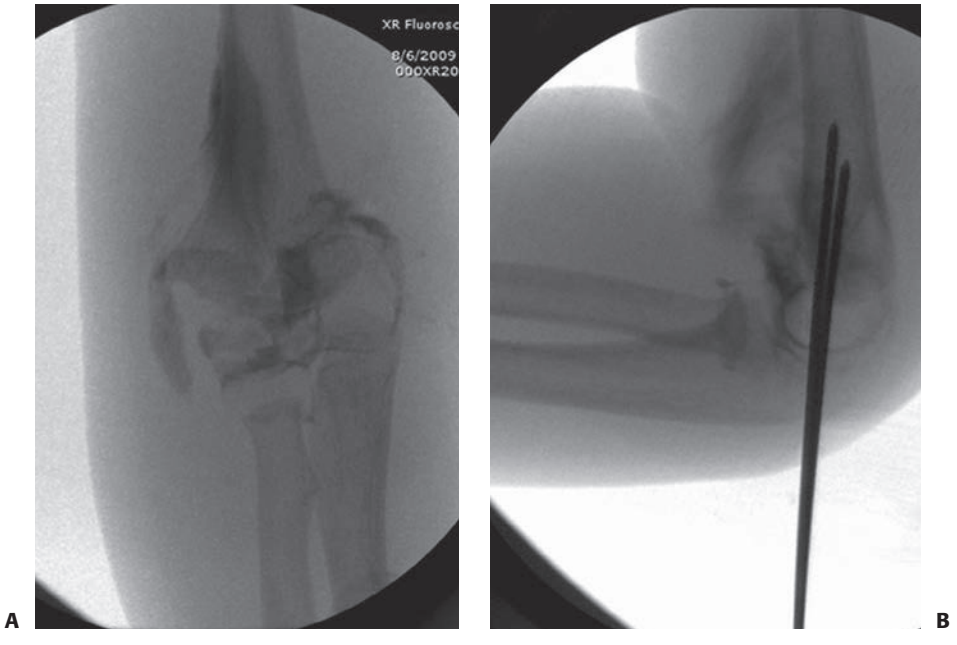

FIGURE 16-13 **A:** Salter II fracture in a 20-month-old is a bit easier to appreciate on arthrogram. **B:** Lateral view after reduction and pinning. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

TABLE 16-1 Modified Gartland Classification of Supracondylar Fractures

		Comments
Type I	Undisplaced	Fat pad present acutely
Type II	Hinged posteriorly	Anterior humeral line anterior to capitellum
Type III	Displaced	No meaningful cortical continuity
Type IV	Displaces into extension and flexion	Usually diagnosed with manipulation under fluoroscopic imaging
Medial comminution (not truly a separate type)	Collapse of medial column	Loss of Baumann's angle

Supracondylar Fractures of the Distal Humerus Classification (Table 16-1)

A modified Gartland classification of SCH fractures is the most commonly accepted and used system.[3,72,140,187] The modified Gartland classification had higher K values for intra- and interobserver variability than did fracture-classification systems previously studied according to a study by Barton et al.[18]

Type I

A Gartland type I fracture is a nondisplaced or minimally displaced (<2 mm) supracondylar fracture with an intact AHL. There may or may not be any evidence of osseous injury: The posterior fat pad sign may be the only evidence of fracture. There should be an intact olecranon fossa, no medial or lateral displacement, no medial column collapse, and a normal Baumann's angle. These fractures are stable.

Type II

A Gartland type II fracture is a displaced (>2 mm) supracondylar fracture with a presumably intact, yet hinged, posterior cortex. The AHL is usually anterior to the capitellum on a true lateral of the elbow (Fig. 16-14), though in mildly displaced fractures, the AHL may touch the capitellum (Fig. 16-15). Because of the intact posterior hinge there is generally little or no rotational deformity on an AP radiograph. In common usage, significant rotational deformity noted on an AP view, such as a loss of Baumann's angle, leads some to call the fracture a type III fracture. However, the presence of cortical contact technically means it is a worse type II but not a type III fracture.

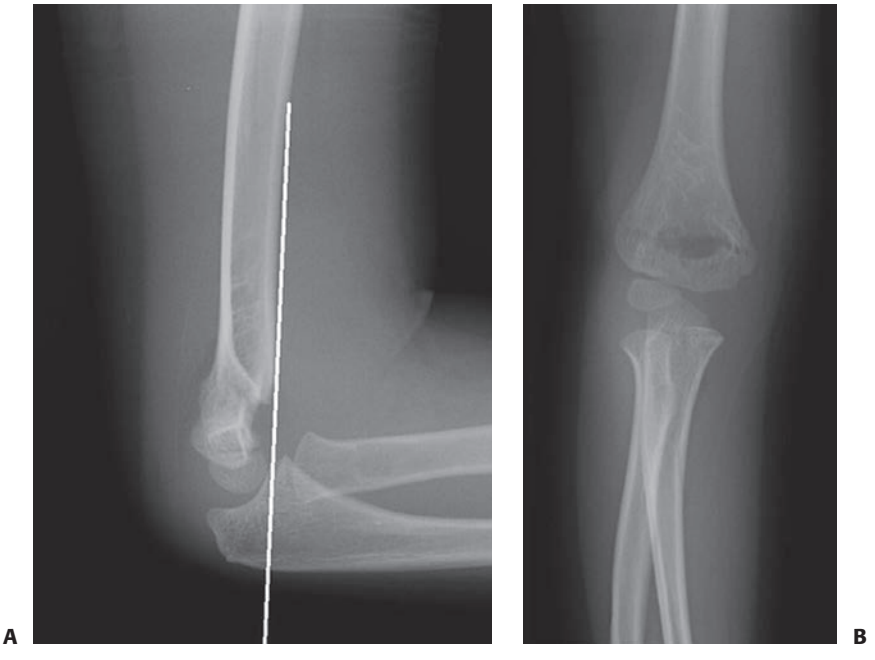

FIGURE 16-14 **A:** Type II SCH fracture with anterior humeral line anterior to the capitellum. **B:** AP radiograph of a type II SCH fracture in a 6-year-old girl. Note that Baumann's angle is intact.

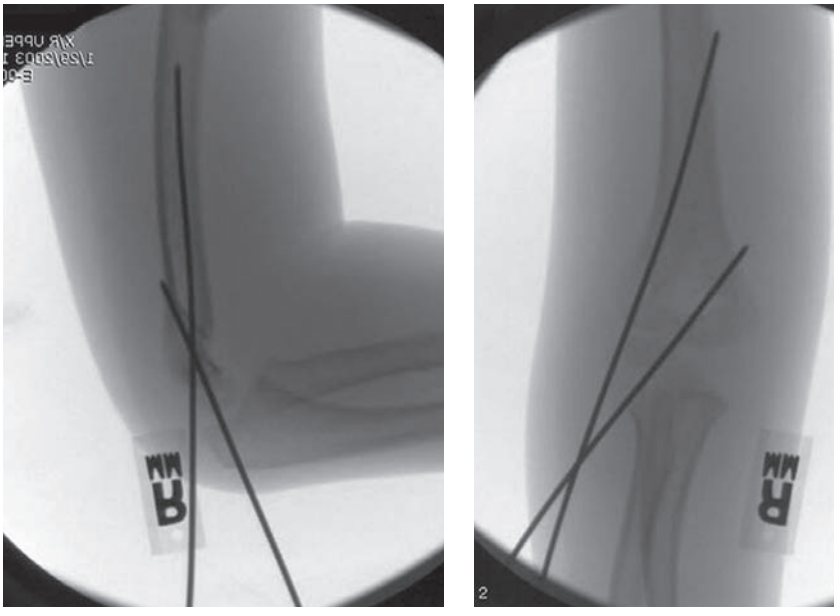

C D

FIGURE 16-14 (*continued*) **C:** In the reduced position the anterior humeral line crosses the capitellum. **D:** AP radiograph following reduction and pinning. FIGURE 16-15 Lateral radiograph of an elbow with a supracondylar humerus fracture (*black arrows*) and an elevated posterior fat pad (*white arrows*). The anterior humeral line (*thin white line*) passes through the capitellum, but not through the middle third, so some posterior angulation is present. This fracture may be considered borderline between a type II fracture (since there is some posterior angulation) and a type I fracture, as the anterior humeral line touches the capitellum. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

Type III

A Gartland type III fracture is a displaced supracondylar fracture with no meaningful cortical contact (Figs. 16-16 and 16-17). There is usually extension in the sagittal plane and rotation in the frontal and/or transverse planes. The periosteum is extensively torn, and soft tissue and neurovascular injuries often accompany this fracture.

FIGURE 16-17 Lateral view of fracture demonstrating no meaningful cortical continuity. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

Type IV

Leitch et al. retrospectively reviewed 297 displaced extension-type supracondylar fractures and described 9 of 297 (3%) with multidirectional instability. These fractures are characterized by an incompetent periosteal hinge circumferentially and defined by being unstable in both flexion and extension.[118] This multidirectional instability is usually determined under anesthesia at the time of operation when on a lateral view the capitellum is anterior to the AHL with elbow flexion, and posterior to the AHL with elbow extension (Figs. 16-18 and 16-19). This pattern of instability may be because of the initial injury sustained or may occur iatrogenically during repeated attempted reductions. Classifying this as a separate type of fracture is warranted as it has treatment implications, as discussed later in this chapter, and has gained wide acceptance.[3]

Alternative Classification System of Supracondylar Fractures of the Distal Humerus

An alternative classification system has been described in 2006 that could cause confusion as it unfortunately uses similar terms (type I to IV) as the established Gartland Classification, but with different definitions.[179] According to the Arbeitsgemeinschaft für Osteosynthesefragen (AO) Pediatric Comprehensive Classification, these fractures are classified with regard to the degree of displacement at four levels (I to IV): No displacement (type I), displacement in one plane (type II), rotation of the distal fragment with displacement in two planes (type III), and rotation with displacement in three planes (or no contact between bone fragments) (type IV).[179]

FIGURE 16-18 Intraoperative imaging demonstrates distal fragment falls into extension. (From Leitch KK, Kay RM, Femino JD, et al. Treatment of multidirectionally unstable supracondylar humeral fractures in children. A modified Gartland type-IV fracture. *J Bone Joint Surg Am.* 2006;88(5):980–985.)

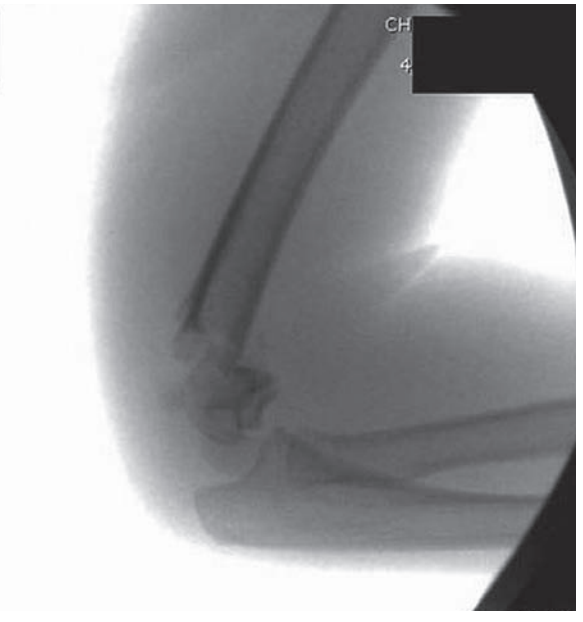

FIGURE 16-19 As the elbow is flexed the distal fragment falls into flexion, thus defining a Gartland type IV fracture. (From Leitch KK, Kay RM, Femino JD, et al. Treatment of multidirectionally unstable supracondylar humeral fractures in children. A modified Gartland type IV fracture. *J Bone Joint Surg Am.* 2006;88(5):980–985.)

FIGURE 16-20 Medial comminution is a subtle radiographic finding and indicates a more unstable variant which may collapse into varus if not treated appropriately. From Staying Out of Trouble in Pediatric Orthopaedics. (From Tolo VT, Skaggs DL, eds. *Masters Techniques in Orthopaedic Surgery: Pediatric Orthopaedics*. Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

The Special Case of Medial Comminution in Supracondylar Fractures of the Distal Humerus

A potential pitfall is to underappreciate the extent of loss of normal alignment in fractures with comminution and collapse of the medial column (Fig. 16-20). Medial collapse signifies malrotation in the frontal plane (which defines the injury as at least a type II fracture) and is associated with a loss of Baumann's angle and varus malalignment. The lateral view (Fig. 16-21) may show reasonable alignment, which may lull the inexperienced into not appreciating the seriousness of this fracture, which requires reduction and usually pin fixation to prevent late malunion.

Bahk et al.[16] reported that fractures with greater than 10 degrees of obliquity in the coronal plane or 20 degrees in the sagittal plane were more likely than fractures with less obliquity to result in malunion.

FIGURE 16-21 Note the lateral view does not show significant displacement. This view alone would suggest nonoperative treatment may be sufficient. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

Signs and Symptoms of Supracondylar Fractures of the Distal Humerus

An elbow or forearm fracture should be suspected in a child with elbow pain or failure to use the upper extremity after a fall. A careful examination of the entire arm should be performed, and any area with tenderness or swelling should have radiographs as multiple fractures (such as a supracondylar fracture and a radius/ulna fracture) are not uncommon (Fig. 16-22). In children with acute elbow pain and failure to use the upper extremity, the differential diagnosis should include fracture, nursemaid's elbow, inflammatory arthritis, and infection.

With a type I supracondylar fracture, there is tenderness about the distal humerus and restriction of motion, particularly lack of full elbow extension. X-rays may be negative except for a posterior fat pad sign. In type III fractures, gross displacement of the elbow is evident (Fig. 16-23).

An anterior pucker sign may be present if the proximal fragment has penetrated the brachialis and the anterior fascia of the elbow (Fig. 16-24). Skin puckering results from the proximal segment piercing the brachialis muscle and engaging the deep dermis. This is a sign of considerable soft tissue damage. If any bleeding from a punctate wound is present, this should be considered an open fracture.

Careful motor, sensory, and vascular examinations should be performed in all patients; this may be quite difficult in a

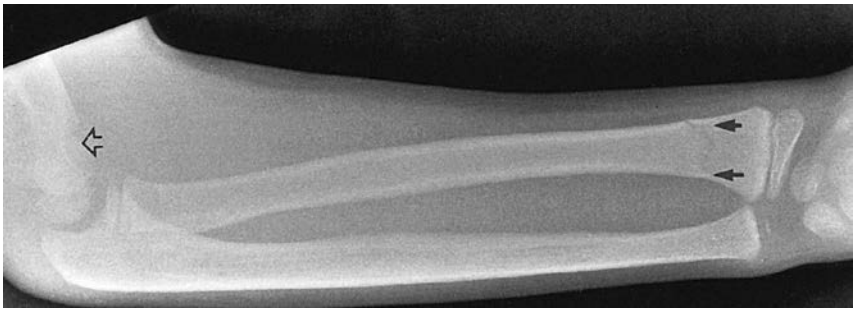

FIGURE 16-22 Occult ipsilateral fracture. Type II supracondylar fracture (*open arrow*) with an occult distal radial fracture (*solid arrows*). (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

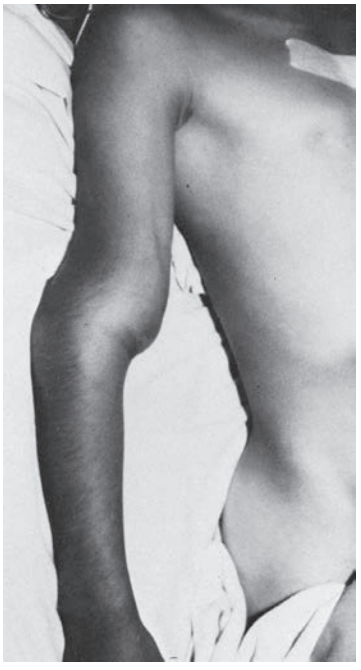

A

young child but should be attempted. Sensation should be tested in discrete sensory areas of the radial nerve (dorsal first web space), median nerve (palmar index finger tip), and ulnar nerve (ulnar side little finger tip). If a child is not cooperative or has altered mental status, a wet cloth may be wrapped around the hand and check for wrinkling of the skin, though in practice this is rarely done. Motor examination should include finger, wrist, and thumb extension (radial nerve), index finger distal interphalangeal flexion and thumb interphalangeal flexion (anterior interosseous nerve, or AIN), finger flexion

B

FIGURE 16-24 The pucker sign. This patient had penetration of the proximal fragment's spike into the subcutaneous tissue. In the AP view **(A),** there is a large puckering or defect in the skin where the distal fragment has pulled the skin inward. Laterally **(B)**, there is puckering of the skin (*arrow*) in the area where the spike has penetrated into the subcutaneous tissue.

strength (median), and interossei (ulnar nerve) muscle function. In young children the interosseous nerve may be tested by asking the child to pinch something with their thumb and first finger, while palpating the first dorsal interosseous for muscle contracture. If you cannot determine sensory and/or motor function accurately preoperatively, it should be recorded as such in the chart and communicated clearly to all caregivers. Misinformation preoperatively makes decision making postoperatively difficult when a nerve deficit is discovered.

The vascular examination should include determining the presence of pulse, as well as warmth, capillary refill, and color of the hand. Assessment of the vascular status is essential, as series report up to 20% of displaced fractures present with vascular compromise.[33,42,147,166] The vascular status may be classified into one of three categories.

I. Hand well perfused (warm and red), radial pulse present.
II. Hand well perfused, (warm and red) radial pulse absent.
III. Hand poorly perfused (cool and blue or blanched), radial pulse absent.

During the physical examination, a very high index of suspicion is needed in order not to miss a developing compartment syndrome in fractures with considerable swelling and/or ecchymosis, anterior skin puckering, and/or absent pulse, which are red flags for possible compartment syndrome. Tenseness of the volar compartment should be evaluated, and the amount of swelling about the elbow should be noted. Pain with passive finger extension and flexion should be tested and the findings should be accurately recorded. Recent studies show that increasing anxiety and need for pain medicine may be the earliest warning of compartment syndrome. (Pediatric patients with compartment syndromes often present with the 3 A's: Anxiety, agitation, and increasing analgesic requirement.) In the initial examination of a child with a severe supracondylar fracture with high parental and patient anxiety, it is easy to overlook vital information.

Treatment Options for Supracondylar Fractures of the Distal Humerus (Table 16-2)

Initial Management of Supracondylar Fractures of the Distal Humerus

Displaced supracondylar fractures requiring a reduction should be initially splinted with the elbow in a comfortable position of approximately 20 to 40 degrees of flexion, while avoiding tight bandaging or splinting. Excessive flexion or extension may compromise the limb's vascularity and increase compartment pressure.[20,124] The elbow and hand should then be gently elevated above the heart. A careful examination of the neurologic and vascular status is vital in all patients with a supracondylar fracture as well as an assessment of the potential for compartment syndrome. The remainder of the limb should be assessed for other injuries and radiographs should include any area which is tender, swollen, or lacks motion.

Urgency of Treatment of Supracondylar Fractures of the Distal Humerus

Several studies have concluded that delay of surgery of 8 to 21 hours did not have any deleterious effects on the outcomes of children with supracondylar fractures.[82,93,117,129,168] These studies were all retrospective and may have reported good results in large part because of the selection bias of experienced pediatric orthopedic surgeons selecting which fractures required urgent treatment. Although there is little published data to support our opinion, we and others believe that if conditions such as poor perfusion, an associated forearm fracture, firm compartments, skin puckering, antecubital ecchymosis, or very considerable swelling are present, operative treatment should not be delayed.[3,152]

How Late Can Fractures Be Reduced?

Little has been written about how long after injury a fracture can still be closed reduced. Silva et al. reported on 42 type II

TABLE 16-2 Current Treatment Options

	PRO	CON
Casting in situ	Good for type I fractures	Not for displaced fractures
Closed reduction and casting	No surgery	Cannot reliably hold reduction. Risks compartment syndrome if elbow flexed to hold reduction. X-rays difficult to interpret in flexed position.
Closed reduction and pinning	Predictable good outcome Few complications	Can be technically challenging to the inexperienced
Open reduction and pinning	Allows exposure and repair of neurovascular structures. Removes impediments to reduction.	Can make fracture less stable if periosteum is taken down with exposure. Scarring.
Traction	Salvage for rare severely comminuted fractures. Rarely if ever used at major centers.	Prolonged hospitalization Malunion

SCH fractures which were treated 7 to 15 days after injury. They found closed anatomic reduction was achieved in all fractures, with equal outcomes to fractures treated within 7 days of injury.[170] We would caution that in very young children reliable fracture reduction 2 weeks after injury as early callus formation is less likely. Two children closed reduced 8 days after injury developed avascular necrosis of the trochlea.[170] Though these numbers are small, this phenomena seems worthy of further study.

Closed Reduction and Casting

Closed reduction and casting is still performed in some orthopedic centers. Most pediatric orthopedic surgeons now reserve cast immobilization for stable, nondisplaced fractures (type I) and closed reduction with percutaneous pinning for all unstable, displaced fractures (types II and III). Mildly displaced fractures can be reduced closed, using the intact posterior periosteum as a stabilizing force and then holding reduction by flexing the elbow greater than 120 degrees. Less flexion increases the risk of loss of reduction. Immobilization techniques include collar and cuff sling or casting with careful antecubital fossa and olecranon relief and padding. The concern with closed reduction and flexion >120 degrees is the risk of vascular compromise and/or compartment syndrome in the presence of anterior swelling and compression. As mentioned, mild fractures treated closed (type II) need to be monitored closely for neurovascular compromise and loss of reduction. Follow-up radiographs can be difficult to interpret with elbow flexion >120 degrees. If necessary, rereduction or conversion to pinning needs to occur before full healing occurs so close radiographic follow-up is necessary in the first 3 weeks.

Closed Reduction and Pinning

This is the most common operative treatment of supracondylar fractures. An initial attempt at closed reduction is indicated in almost all displaced supracondylar fractures that are not open fractures. Under general anesthesia the fracture is first reduced in the frontal plane with fluoroscopic verification. The elbow is then flexed while pushing the olecranon anteriorly to correct the sagittal deformity and reduce the fracture. Criteria for an acceptable reduction include restoration of Baumann's angle (which is generally >10 degrees) on the AP view, intact medial and lateral columns on oblique views, and the AHL passing through the middle third of the capitellum on the lateral view. As there is considerable rotation present at the shoulder, minor rotational malalignment in the axial plane can be tolerated at the fracture site. However, any rotational malalignment is detrimental to fracture stability, so if present, be extra careful in assessing stability of reduction, and probably use a third pin.

The fracture reduction is held with two to three Kirschner wires (K-wires), as discussed later in this chapter. The elbow is immobilized in 40 to 60 degrees of flexion, depending on the amount of swelling and vascular status. If there is a considerable gap in the fracture site or the fracture is irreducible with a so-called rubbery feeling on attempted reduction, the median nerve and/or brachial artery may be trapped in the fracture site and an open reduction should be performed (Fig. 16-25).

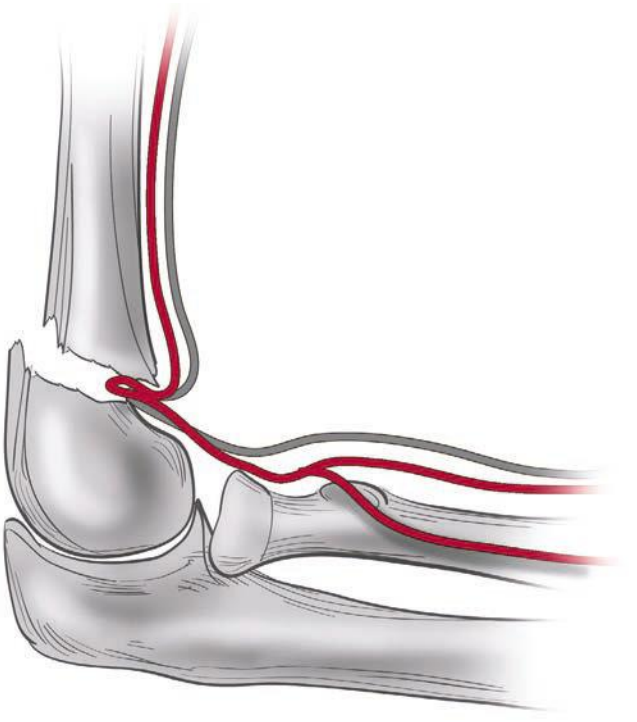

FIGURE 16-25 Brachial artery and median nerve may be trapped at the fracture site. If a reduction feels rubbery, and a gap at the fracture site is seen on imaging, entrapment is possible, especially in the setting of vascular compromise or median nerve or anterior interosseous nerve injury. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics*. Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

Crossed Pins Versus Lateral-Entry Pins

The two main issues with crossed pin versus lateral-entry pinning of SCH fractures are: (1) Risk of ulnar nerve injury and (2) risk of loss of reduction. Iatrogenic injury to the ulnar nerve with use of crossed pins has been reported to be as low as 0% but two large series of supracondylar fractures have shown the prevalence to be 5% (17 of 345) and 6% (19 of 331).[31,38,92,120,154,159,175,211] Others have reported that these injuries occur more commonly.[159,204]

Three recent meta-analysis have examined the issue of pin configuration and iatrogenic nerve injury. Slobogean et al.,[178] in 2010 reported on 32 trials with 2,639 patients and found there is an iatrogenic ulnar nerve injury for every 28 patients treated with crossed pins compared to lateral pinning. Babal et al.[13] in 2010 reported on a systematic review of 35 articles discussing medial and lateral pinning versus lateral-entry pinning and found that iatrogenic ulnar nerve injury occurred in 40 of 1,171 (3.4%) of cross pins and 5 of 738 (0.7%) of lateral-entry pins. Woratanarat et al. in 2012 included 18 studies and 1,615 SCH fractures. They reported the risk of iatrogenic ulnar nerve injury to be 4.3 times higher in cross pinning compared to lateral pinning. They found no difference in loss of fixation, late deformity, or Flynn criteria between the two types of pinning.[206]

In addition, several clinical studies reporting no difference in loss of reduction between lateral-entry pins and cross-pin

fixation,[73,121,208] or good results with lateral pins alone.[116,173] Although rare, radial nerve laceration by a medially inserted K-wire has been reported.[59] A prospective, surgeon-randomized study was performed on 104 children with type III SCH fractures, with surgeons using their preferred techniques of cross pins or lateral-entry pins. The authors found no statistical difference in the radiographic outcomes between lateral-entry and cross-pin techniques, but two cases of iatrogenic injury to the ulnar nerve occurred with medially placed pins.[73]

Zaltz et al.[211] reported that in children less than 5 years of age, when the elbow is flexed more than 90 degrees, the ulnar nerve migrated over, or even anterior to, the medial epicondyle in 61% (32/52) of children. Wind et al.[204] showed that the location of the ulnar nerve cannot be adequately determined by palpation to allow blind medial pinning. Unfortunately, even making an incision over the medial epicondyle to make certain the ulnar nerve is not directly injured by a pin does not ensure protection of the nerve.[175]

In a series of six cases of iatrogenic ulnar nerve injuries with early exploration, the nerve was directly penetrated by the pin in two of six cases (33.3%), with constriction of the cubital tunnel occurring in three of six cases (50%), and the nerve being fixed anterior to the medial epicondyle in one of six (16.7%) cases.[154] Thus even if direct penetration of the ulnar nerve is avoided, simply placing a medial epicondyle entry pin adjacent to the nerve may cause injury presumably by constriction of the cubital tunnel or kinking of the nerve. Iatrogenic ulnar nerve injuries usually resolve, but there have been several reports of permanent iatrogenic ulnar nerve injuries.[151,154,175]

Skaggs et al.[175] reported a series of 345 SCH fractures treated by percutaneous pinning and showed that the use of a medial pin was associated with a 4% (6/149) risk of ulnar nerve injury when the medial pin was placed without hyperflexion and 15% (11/71) if the medial pin was placed with hyperflexion. None of the 125 fractures treated with lateral-entry pins alone resulted in iatrogenic injury. This is consistent with the findings of Zaltz et al.[211] of anterior subluxation of the ulnar nerve with elbow flexion beyond 90 degrees. Thus one apparently undeniable conclusion is that if a medial pin is used, place the lateral pin(s) first, then extend the elbow and place the medial pin without hyperflexion of the elbow. Of course, the simplest way to avoid iatrogenic nerve injuries is not to place a medial pin. In a series of 124 consecutive fractures stabilized with lateral-entry pins, regardless of displacement or fracture stability, no iatrogenic ulnar nerve injuries were reported.[173]

The second issue with pin configuration is stability of pin configuration. Biomechanical studies of stability of various pin configurations have been somewhat misleading. Two studies evaluated the torsional strength of pin configurations and found crossed pins to be stronger than two lateral pins.[141,213] Unfortunately, in these studies the two lateral pins were placed immediately adjacent to each other and not separated at the fracture site as is recommended clinically for lateral-entry pins.[86,163,173] In synthetic humeri study, Srikumaran et al.[184] found cross pins to be stronger than two lateral-entry pins, but did not test three lateral-entry pins. Lee et al.[115] found that two divergent lateral pins separated at the fracture site were superior to crossed pins in extension loading and varus but were equivalent in valgus (Fig. 16-26). The greater strength seen with divergence of the pins was attributed to the location of the intersection of the two pins and greater divergence between the two pins, which would allow for some purchase in the medial column as well as the lateral column (Figs. 16-4 and 16-5).

Bloom et al.[26] reported three lateral divergent pins were equivalent to cross pinning and both were stronger than two lateral divergent pins. Another study with simulated medial comminution showed three lateral divergent pins had equivalent torsional stability to standard medial and lateral crossed pinning.[114] Feng et al.[60] reported that two and three lateral-entry pins had comparable construct stiffness to each other, and both were greater than crossed pins to all types of stress, except in valgus, in which cross pins had greater stiffness. Thus, contemporary biomechanical studies mostly support clinical recommendations of lateral-entry pins.[3,140,163,173]

In a biomechanical study of synthetic humeri, Gottschalk et al.[79] reported that construct strength increased when pin size was increased from 1.6 to 2 mm, but did not increase when a third pin was added. Srikumaran et al.[184] also reported increased stability with 2.8-mm pins compared with 1.6-mm pins in any configuration in synthetic humeri. The same group reported that in a clinical series of 159 patients larger pins led to less loss of fracture reduction in the sagittal plane. Simply, the bigger the pin, the more stable the fixation.[186]

Skaggs et al. demonstrated no malunions or loss of fixation in a series of 124 consecutive fractures treated with lateral-entry pins. From this successful series, combined with a failure analysis of eight fractures performed outside of this series they concluded the important technical points for fixation with lateral-entry pins are: (1) Maximize separation of the pins at the fracture site, (2) engage the medial and lateral columns

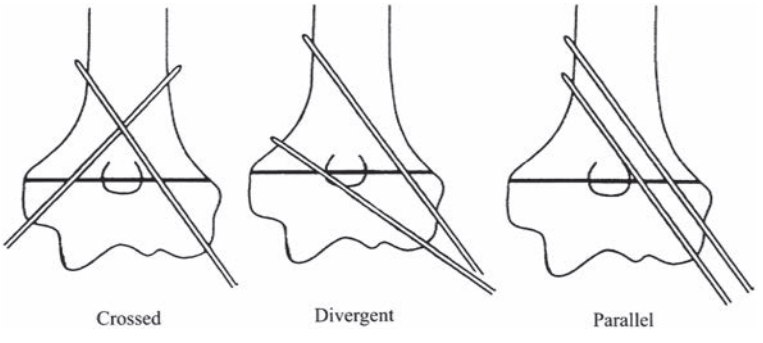

FIGURE 16-26 Three pinning techniques in study by Lee et al.[116] **A:** Crossed: One medial and one lateral pin. **B:** Divergent: Two divergent lateral pins. **C:** Parallel: Two parallel lateral pins.

proximal to the fracture, (3) engage sufficient bone in both the proximal segment and the distal fragment, and (4) maintain a low threshold for use of a third lateral-entry pin if there is concern about fracture stability or the location of the first two pins, and the use of three pins for type III fractures.[173] Gordon et al.[77] further validated this point by recommending two lateral pins initially for type III fractures then stressing the fixation under fluoroscopy to determine the need for an additional third lateral pin. Lee et al. reported 92% excellent clinical results using three lateral pins in 61 consecutive type II and II fractures. They found no loss of reduction of any fracture, no cubitus varus, no hyperextension or loss of motion, no iatrogenic nerve injury, no additional surgery, and one patient with a minor pin track infection.[116]

Intraoperative stability testing of lateral-entry pin fixation has been advocated. In a study of 21 children with type III fractures, after closed fracture reduction, two lateral-entry pins were inserted.[212] Stability was then assessed by comparing lateral fluoroscopic images in internal and external rotation. If the fracture remained rotationally unstable, a third lateral-entry wire was inserted, and images were repeated. A medial wire was used only if instability was demonstrated after the insertion of three lateral wires. Rotational stability was achieved with two lateral-entry wires in six cases, three lateral-entry wires in 10 cases, and with an additional medial wire in five cases. No patients required a reoperation using this protocol. The authors concluded that supracondylar fractures that are rotationally stable intraoperatively after wire fixation are unlikely to displace postoperatively. It is notable that they found 26% of these type III fractures were rotationally stable with two lateral-entry wires.

In a study of eight other cases of SCH fractures, which lost reduction, Sankar et al. reported loss of fixation in all cases was because of technical errors that were identifiable on the intraoperative fluoroscopic images and that could have been prevented with proper technique. They identified three types of pin-fixation errors: (1) Failure to engage both fragments with two pins or more, (2) failure to achieve bicortical fixation with two pins or more, and (3) failure to achieve adequate pin separation (>2 mm) at the fracture site.[163] A systematic review of 35 articles reported loss of reduction in 0 of 849 of crossed pins and 4 of 606 (0.7%) of lateral-entry pins.[29] Based upon this study and the previous series by Skaggs et al.,[173] we recommend a minimum of two pins for a type II fracture and three pins for a type III fracture.

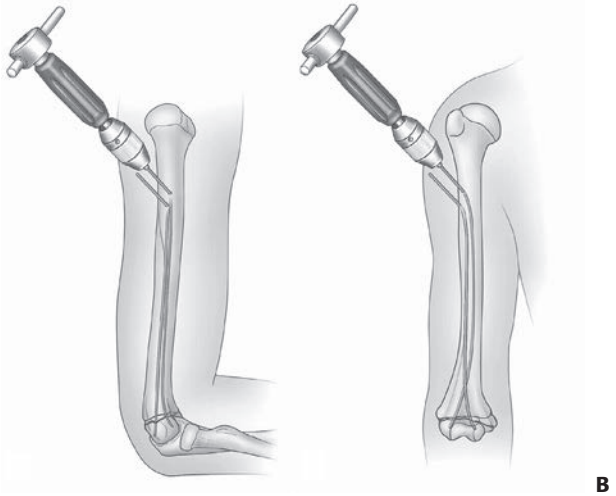
Two prospective randomized clinical trial comparing lateral- and cross-pinning techniques in the treatment of displaced SCH fractures showed no statistically significant difference between the two treatment groups in any radiographic or clinical outcome measures[103,192] including nerve injury. It is interesting that following the randomized clinical trial[103] the same eight surgeons who pretrial used cross pins in 59% of SCH fractures changed their practice to use cross pins in only 15% of cases posttrial.[122]

Dorgan's technique has been described in which cross pins are used, with the medial column pin placed from the lateral side, in a proximal–lateral to distal–medial direction, with the potential benefit being avoiding iatrogenic injury to the ulnar nerve. Potential downsides to this technique include iatrogenic injury to the radial nerve, technical difficulty of precise pin placement, and a higher reported infection rate (7%) than other techniques.[150]

An alternative technique using antegrade insertion of elastic intramedullary nailing has been described.[54] Using this technique, in a retrospective study of 127 patients, the authors reported 6% (7/127) had long-term functional loss of motion, 5% malunion (7/127) but no ulnar nerve injury and no secondary surgeries. The authors cite avoidance of iatrogenic ulnar nerve injury and not using a cast as advantages of this technique (Fig. 16-27).[110]

Open Reduction

Open reduction is indicated in cases of failed closed reduction, a loss of pulse or poorly perfused hand following reduction, and open fractures. In the past, open reductions led to concerns of elbow stiffness, myositis ossificans, ugly scarring, and iatrogenic neurovascular injury. However, several reports have shown the low rate of complications associated with open reduction, and this is in the setting of more severe soft tissue and bony injuries. Weiland et al.[198] reported on 52 displaced fractures treated with open reduction via a lateral approach. There was a 10% (5 of 52) rate of moderate loss of motion but no cases of infection, nonunion, or myositis ossificans. A series



A B

FIGURE 16-27 When the tips were being advanced into the metaphysis, the more distally implanted nail is rotated 180 degrees toward the medial column. Correspondingly, the tip of the most proximally inserted nail remained directed laterally. Both nails are advanced one at a time by T-handle or gentle hammer blows as far as a few millimeters proximal to the fracture line. Progression of the nails into the distal humerus is controlled under fluoroscopy and both implants reliably introduced into the distal fragment to impact the nails into the distal metaphyseal bone. (Adapted from Dietz HG, Schmittenbecher PP, Slongo T, et al. *AO Manual of Fracture Management: Elastic Stable Intramedullary Nailing in Children*. Stuttgart: Thieme Medical Publishers; 2006:53–62. Copyright and permission by AO Foundation, Davos, Switzerland.)

by Fleuriau-Chateau et al.[62] of 34 patients treated with open reduction via an anterior approach reported a 6% (2 of 34) unsatisfactory loss of motion but no cases of infection, myositis ossificans, malunion, or Volkmann contracture. Reitman et al.[156] reported that 8% of 862 consecutive supracondylar fractures were treated with open reduction. The reasons for open reduction rather than conventional closed reduction percutaneous pinning were irreducible fractures, vascular compromise, open fractures, and entrapped nerves. The open reduction was performed via the torn periosteum either anteromedial or anterolateral depending on direction of distal fragment displacement. Seventy-eight percent (51) of 65 patients had an excellent or good result according to the criteria of Flynn and Zink.[64] Loss of motion was reported in four cases. Ay et al.[12] found no loss of motion or clinical deformity in 61 patients treated with open reduction. In a prospective, randomized controlled study of 28 children, Kaewpornsawan[95] compared closed reduction and percutaneous pin fixation with open reduction (through a lateral approach); the patients treated with percutaneous pin fixation showed no differences with regard to cubitus varus, neurovascular injury, the range of motion, the infection rate, the union rate, or the criteria of Flynn et al. In older children with SCH fractures (8 to 14 years of age) Mollon et al.[133] reported a mean loss of 30 degrees of elbow flexion at final follow-up in those patients treated with open reduction internal fixation compared to those treated with closed reduction percutaneous pinning.

The direct anterior approach to the elbow is extremely useful for open reduction, particularly in cases of neurovascular compromise. The anterior approach has the advantages of allowing direct visualization of the brachial artery and median nerve as well as the fracture fragments. The exposure is through the torn periosteum and disrupted brachialis and therefore does not further destabilize the fracture. When performed through a relatively small (5 to 8 cm) transverse incision above the cubital fossa at the fracture site, the resulting scar is much more aesthetic than that of the lateral approach, and scar contraction limiting elbow extension is not an issue. A series of 26 patients treated with the anterior approach showed equivalent results to the traditional lateral or combined lateral with medial approach in terms of malunion, Flynn's criteria[64] and range of motion.

The posterior approach for an extended supracondylar fracture risks; (1) a higher rate of loss of motion; (2) further fracture instability with exposure through intact periosteum; and (3) more importantly the risk of avascular necrosis secondary to disruption of the posterior end arterial supply to the trochlea of the humerus (Fig. 16-28).[30,209]

Incidence of Complications Lessened

Open reduction has been increasingly accepted because there are relatively few complications with this method. Surgical experience[9,11,35,45,62,68,74,95,106,139,156] has dispelled the fears of infection, myositis ossificans, and neurovascular injury.[72,165,180,197] The incidence of neurovascular complications from the procedure itself was essentially zero. Four patients with myositis ossificans (1.4%) were reported, all in a single series.[76]

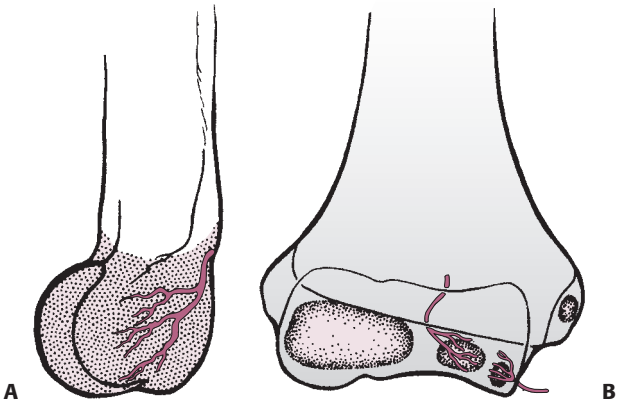


FIGURE 16-28 Intraosseous blood supply of the distal humerus. **A:** The vessels supplying the lateral condylar epiphysis enter on the posterior aspect and course for a considerable distance before reaching the ossific nucleus. **B:** Two definite vessels supply the ossification center of the medial crista of the trochlea. The lateral vessel enters by crossing the physis. The medial one enters by way of the nonarticular edge of the medial crista. (From Haraldsson S. On osteochondrosis deformans juvenilis capituli humeri including investigation of the intraosseous vasculature in the distal humerus. *Acta Orthop Scand.* 1959;38(Suppl):1–232, with permission.)

The most frequent complication of surgical management appears to be a loss of range of motion. One of the reasons given in the past for loss of motion was the use of a posterior approach. It has been stated that approaching the fracture through the relatively uninvolved posterior tissues induces added scar leading to stiffness. In earlier reported series using a posterior approach, loss of range of motion was significant. Preferred use of the anterior approach has resulted in a lower stiffness rate and complications similar to closed treatment. Most often the fractures treated with open reduction are the more severe fractures that are open, have vascular compromise, and/or an irreducible fracture because of soft tissue interposition. Residual cubitus varus occurred in as many as 33% of patients in some of the earlier series,[6,47,76,118] most because of inadequate surgical reduction. When good reduction was obtained, the incidence of cubitus varus deformity was low. Surgical intervention alone does not guarantee an anatomic reduction; the quality of the reduction achieved at the time of surgery is important.

Lal and Bhan[111] reported that delayed open reduction 11 to 17 days after injury, did not increase the frequency of myositis ossificans. If a supracondylar fracture is unreduced or poorly reduced, delayed open reduction and pin fixation appear to be justified. Agus et al.[4] showed that delay in reduction and pinning can be safely accomplished after skeletal traction and malreduction.

Open supracondylar fractures generally have an anterior puncture wound where the metaphyseal spike penetrates the skin (Fig. 16-29). Even if the open wound is only a small puncture in the center of an anterior pucker, open irrigation and debridement are indicated. The anterior approach, using a transverse incision with medial or lateral extension as needed, is recommended. The neurovascular bundle is directly under the skin and tented over the metaphyseal fragment, so care

FIGURE 16-29 Open supracondylar humerus fracture. The distal humerus metaphysis is completely protruding through the transverse open wound. Fortunately, the pulse was intact, and the hand was viable. (From Waters PW, Bae DS. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

should be taken in approaching this fracture surgically. The skin incision can be extended medially proximally and laterally distally if needed. However, usually only the transverse portion of the incision is required, which gives a better aesthetic result. The brachialis muscle is usually transected because it is a muscle belly to its insertion on the coronoid attachment and is highly vulnerable to trauma from the proximal metaphyseal fragment. The fracture surfaces are examined and washed, and a curette is used to remove any dirt or entrapped soft tissue. Once the debridement and washing are complete, the fracture is reduced by mobilizing the periosteum out of the way and flexing the distal humerus. Stabilization is with K-wires. All patients with open fractures are also treated with antibiotics: Generally, cefazolin for Gustilo types I, II, and IIIA injuries, with the addition of appropriate antibiotics to cover gram-negative organisms for type IIIB and C fractures.

Supracondylar Fractures of the Distal Humerus Treatment with Traction

Traction as definitive treatment for supracondylar fractures in children is largely of historic interest in most modern centers. Indications for traction may include severe comminution, lack of anesthesia, medical conditions prohibiting anesthesia, lack of an experienced surgeon, or temporary traction to allow swelling to decrease. Devnani[53] reported using traction in the gradual reduction of eight fractures with late presentation (mean of 5.6 days), though 18% of these children went on to a corrective osteotomy for malunion. Rates of cubitus varus from 9% to 33% have been reported in some series,[89,149] whereas others have reported excellent results.[47,70,181,210] Nevertheless, 11 to 22 days of inhospital traction is difficult to justify given the excellent results with closed reduction and pinning, which usually requires no more than one night hospitalization and is associated with a low rate of intraoperative complications. Advocates of traction in the treatment of supracondylar fractures describe use of overhead traction with use of an olecranon wing nut[14,144,207] (Fig. 16-30) as giving superior results to sidearm traction.

Supracondylar Fractures of the Distal Humerus Treatment by Fracture Type

Type I (Nondisplaced)

Simple immobilization with a posterior splint applied at 60 to 90 degrees of elbow flexion with side supports is all that is necessary.[36,202] If there is unequivocally no significant swelling about the elbow, circumferential or bivalved casts may be used, with education of the parents as to elevation and the signs and symptoms of compartment syndrome. The elbow should not be flexed greater than 90 degrees. Using Doppler examination of the brachial artery after supracondylar fractures, Mapes and Hennrikus[124] found that flow was decreased in the brachial artery in positions of pronation and increased flexion. Before the splint is applied, it should be confirmed that the pulse is intact and that there is good capillary refill with the amount of elbow flexion intended during immobilization. A sleeve sling or D-ring stockinette sling helps decrease torsional forces about the fracture.

X-rays are obtained 3 to 7 days after fracture to document lack of displacement. If there is evidence of significant distal fragment extension, as judged by lack of intersection of the AHL with the capitellum, the fracture should be treated with closed reduction and percutaneous pinning to secure the reduction.

An acceptable position is determined by the AHL transecting the capitellum on the lateral x-ray, a Baumann's angle of greater than 10 degrees or equal to the other side, and an intact olecranon fossa. The duration of immobilization for supracondylar fractures is 3 to 4 weeks, whether type I, II, or III. In general, no physical therapy is required after this injury. Patients may be seen 4 to 6 weeks after immobilization is removed to ensure that range of motion and strength are returning normally. As the outcome in type I fractures is predictably excellent if alignment is maintained at the time of early healing, follow-up visits are optional depending on family and medical circumstances.

Remember that the initial x-ray is a static representation of the actual injury that may involve soft tissue disruption much greater than one might expect from the minimal bony abnormality. Excessive swelling, nerve or vascular disruption, or excessive pain are indicative of a more significant injury that a type I fracture in which case periosteal disruption may render this fracture inherently unstable. Also, beware of any medial

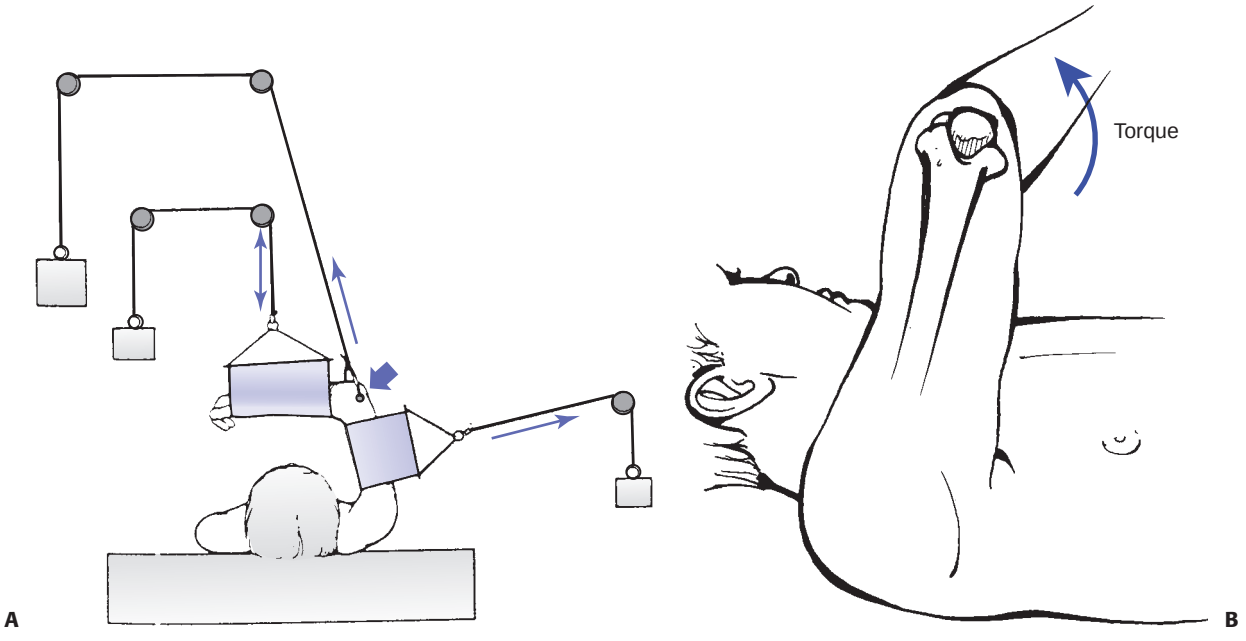

FIGURE 16-30 Overhead olecranon wing nut traction. The arm is suspended by a threaded wing nut through the olecranon (*short arrow*). The forces maintaining the reduction (*long arrows*) are exerted upward **(A)** through the pin and sideways through a counter-sling against the arm. The forearm is supported with a small sling (*double arrow*). By placing the traction rope eccentric to the screw's axis, a torque can be created to correct varus or valgus alignment **(B)**.

comminution that could allow the fracture to collapse into varus during immobilization.

Type II Fracture (Hinged Posteriorly, with Posterior Cortex in Continuity)

This fracture category encompasses a broad array of soft tissue injuries. Careful assessment of the soft tissue injury is critical in treatment decision making. As the posterior cortex is in continuity, good stability should be obtained with closed reduction.

Significant swelling, obliteration of pulse with flexion, neurovascular injuries, excessive angulation, and other injuries in the same extremity are indications for pin stabilization.

The optimal treatment of type II fractures has evolved to the current trend of operative intervention rather than cast immobilization. The distal humerus provides 20% of the growth of the humerus and thus has little remodeling potential. The upper limb grows approximately 10 cm during the first year, 6 cm during the second year, 5 cm during the third year, 3.5 cm during the fourth year, and 3 cm during the fifth year of life.[55] In toddlers (<3 years) some remodeling potential is present so the surgeon may accept nonoperative treatment of a type II fracture in which the capitellum abuts the AHL but does not cross it. Whereas, in a child who is 8 to 10 years old, there is only 10% of growth of the distal humerus remaining so adequate reduction and stabilization is essential to prevent malunion.

Three studies support the initial treatment of type II fractures with closed reduction and casting. Hadlow et al.[84] make the point that pinning all type II fractures in their series of initial closed reduction and casting meant that 77% (37 of 48) of patients would have undergone an unnecessary operative procedure. However, 23% (11 of 48) of the patients in that series lost reduction following closed reduction and underwent delayed operative fixation. Fourteen percent (2 of 14) that were followed had a poor outcome by Flynn criteria.[63] A retrospective review of 25 elbows treated with closed reduction and casting by Parikh et al. showed a 28% (7 of 25) loss of reduction, 20% (5 of 25) need for delayed surgery, and 2% (2 of 25) unsatisfactory outcome according to Flynn criteria.[63]

Similarly Fitzgibbons et al.[61] reported a 20% loss of reduction in the closed treatment of 61 type II fractures. They noted failure was more likely to occur in more displaced fractures in which the AHL did not touch the capitellum, and in those children with wider upper arms. They conclude that "a reasonable protocol might consist of urgent pinning for fractures in which the capitellum extends beyond the AHL, while less displaced fractures could be reduced, placed in a cast, and followed at 1-week intervals."[61] In a series of 155 type II SCH fractures treated nonoperatively, Camus et al.[34] reported fractures were found to have radiographic evidence of sagittal-plane (80% with abnormal AHL, decreased humerocapitellar angle), coronal-plane (47% with abnormal Baumann's angle), and rotational (44% with poor Griffet index) deformities.

In contrast, a consecutive series of 69 children with type II fractures treated with closed reduction and pinning reported

no radiographic or clinical loss of reduction, no cubitus varus, no hyperextension, and no loss of motion. There were no iatrogenic nerve palsies, and no patient required additional surgery.[173] In another study of type II fractures, 189 consecutive cases of closed reduction and percutaneous pinning were reviewed. There were 2% (4/189) pin tract infections, of which three were treated successfully with oral antibiotics and pin removal 1.5% (3/191) and one (0.5%: 1/191) had operative irrigation and debridement for a wound infection not involving the joint. There were no nerve or vascular injuries, and no loss of reduction, delayed unions, or malunions. The authors conclude that pinning type II supracondylar fractures leads to a high probability of satisfactory outcome compared with previous studies of closed reduction without pinning.[177]

Another reason for advocating operative treatment of these injuries is that the amount of hyperflexion needed to maintain reduction in unpinned type II fractures would predispose these patients to increased compartment pressures.[20] In a study by Mapes and Hennrikus[124] using Doppler examination, positions of pronation and increased flexion caused decreased flow in the brachial artery. They recommended a position of flexion and supination for "vascular safety." Pinning these fractures obviates the need for immobilization with considerable elbow flexion. To truly stabilize an extension fracture treated closed, greater than 120 degrees of flexion is required.[108] The basic concept is that any fracture that would require elbow flexion greater than 90 degrees to hold reduction increases the risk of neurovascular compromise and therefore, should instead have the reduction held by pins, and immobilized with the elbow in less flexion (usually about 45 to 70 degrees). If pinning is chosen, two lateral pins[163,173,175,191] through the distal humeral fragment, engaging the opposite cortex of the proximal fragment, are generally sufficient to maintain fracture alignment (Fig. 16-31) (Figs. 16-14C, D and 16-24) though in many series three pins are often used.[173] The posterior cortex and intact periosteum provide some degree of inherent stability. Cross pinning of a type II fracture is generally not needed. The techniques for crossed and lateral pinning are described later on in this chapter. If pin stabilization is used, the pins are left protruding through the skin and are removed at 3 to 4 weeks after fixation, generally without the need for sedation or anesthesia.

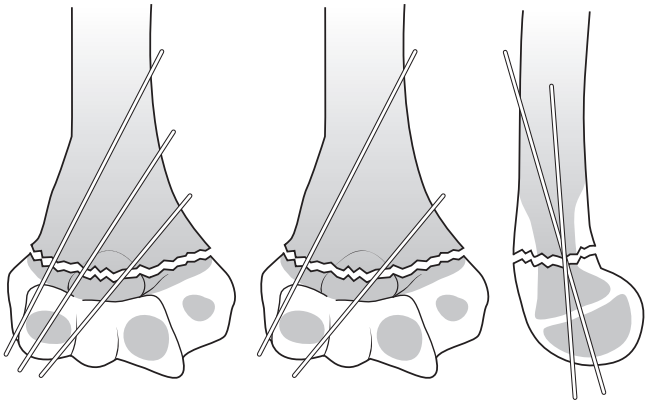

FIGURE 16-31 Properly placed divergent lateral-entry pins. On the AP view, there should be maximal pin separation at the fracture site, the pins should engage both medial and lateral columns just proximal to the fracture site, and they should engage an adequate amount of bone proximal and distal to the fragments. On the lateral view, pins should incline slightly in the anterior to posterior direction in accordance with normal anatomy. (From Skaggs DL, Cluck MW, Mostofi A, et al. Lateral-entry pin fixation in the management of supracondylar fractures in children. *J Bone Joint Surg Am.* 2004;86(4):702–707, with permission.)

Type III Fractures

If the child presents to the emergency room with the extremity in either extreme flexion or extension, carefully place the arm in 30 degrees of flexion to minimize vascular insult and compartment pressure. In type III fractures, the periosteum is usually torn, there is no cortical contact between the fragments, and soft tissue injury may accompany the fracture. Careful preoperative evaluation is mandatory. If circulatory compromise is indicated by absent pulse and a pale hand, or if compartment syndrome is suspected, urgent reduction and skeletal stabilization are mandatory. The standard of care in most modern centers for the treatment of type III fractures is operative reduction and pinning.

Cast immobilization techniques have been described as well. Because type III fractures are intrinsically unstable, the elbow must be held in extreme flexion to prevent the distal fragment from rotating; these fractures tend to rotate into extension with flexion of less than 120 degrees.[131] If the arm can be flexed to 120 degrees with an intact pulse, some believe casting can be used as primary treatment. Usually, however, severe swelling prevents the elbow from being kept in hyperflexion or compartment syndrome could result. In most series,[3,45,108,147,195] the results of type III fractures treated with closed reduction and cast immobilization are not as good as those treated with pinning. Hadlow et al.,[84] however, suggested that selective use of casting is beneficial, reporting that in their series, 61% of type III and 77% of type II fractures were successfully treated without pinning.

When a cast is used as primary treatment, it should be worn for 3 to 4 weeks. Although a number of historic series used casting as primary treatment, most recent reports favor pinning of this fracture because of concerns about vascular compromise, compartment syndrome, and malunion. It must be emphasized that flexion of the elbow with a type III (Fig. 16-32) supracondylar fracture up to 90 degrees or greater significantly increases the risk of compartment syndrome and should rarely, if ever, be done if modern operative facilities and an experienced surgeon are available.

The Special Case of Medial Column Comminution of Supracondylar Fractures of the Distal Humerus

Fractures with medial comminution may not have the dramatic displacement of most type III fractures, but must be treated with operative reduction because collapse of the medial column will lead to varus deformity in an otherwise minimally displaced supracondylar fracture (Fig. 16-20).[50] De Boeck

FIGURE 16-32 Figure-of-eight wrap. In the figure-of-eight cast, both the padding and the plaster are wrapped in a figure-of-eight manner (*arrows*). Flexion of a swollen elbow with a supracondylar fracture beyond 90 degrees increases the risk of compartment syndrome and is generally not recommended if operative treatment is available. (From Wilkins KE. The management of severely displaced supracondylar fractures of the humerus. *Tech Orthop*. 1989;4:5–24, with permission.)

et al. recommended closed reduction with percutaneous pinning when a fracture has medial comminution even in otherwise minimally displaced fractures to prevent cubitus varus. In this retrospective review, zero of six patients with medial comminution who underwent operative fixation had cubitus varus whereas four of seven (57%) patients who were treated nonoperatively developed cubitus varus.

Author's Preferred Treatment for Supracondylar Fractures of the Distal Humerus

Type I Fractures of Supracondylar Fractures of the Distal Humerus

These fractures are managed in a long-arm cast with approximately 60 to 90 degrees of elbow flexion for approximately 3 weeks. Follow-up x-rays at 1 week are recommended for assessment of fracture position.

Type II Fractures of Supracondylar Fractures of the Distal Humerus

We prefer closed reduction and pinning of most type II supracondylar fractures. Two lateral pins are chosen as the initial postreduction fixation method in nearly all cases (Fig. 16-14). If two lateral pins fail to provide acceptable fixation we do not hesitate to place a third lateral pin. We believe it is safer to hold a type II fracture reduced with pins, rather than flexing the elbow greater than 90 degrees. See below section for a detailed technique description (Table 16-3).

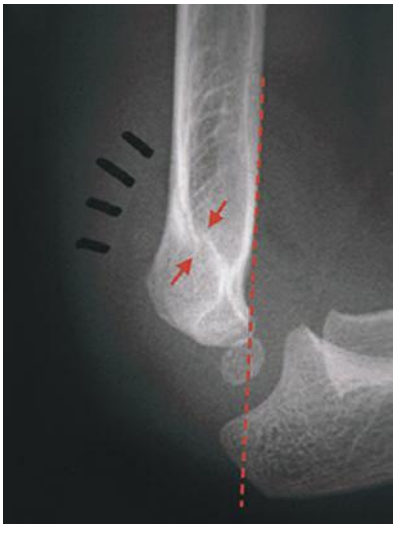
As a type I fracture is treated nonoperatively, and type II fractures are treated operatively, the lateral radiograph, which distinguishes these two fractures deserves special consideration. Below are some examples and authors' thoughts. Please assume the AP radiographs have a normal Baumann's angle.

Type III Fractures—Closed Reduction and Percutaneous Pinning of Supracondylar Fractures of the Distal Humerus

Once in the operating room, the patient receives a general anesthetic and prophylactic antibiotics. We prefer to have the

TABLE 16-3 Decision Making on Lateral X-Rays

This is a typical type I fracture. The anterior humeral line (AHL) clearly goes through the capitellum. Cast with no more than 90 degrees of elbow flexion.



(*continues*)

TABLE 16-3 Decision Making on Lateral X-Rays (*continued*)

This technically a type I fracture by definition as the AHL touches the capitellum. However, this fracture is at risk for displacement as the hourglass is not tilting forward, and the posterior cortex is broken as well. Initial treatment is casting at no more than 90 degrees of elbow flexion with the need for close follow-up stressed.

This is a typical type II fracture, with the AHL missing the capitellum and the distal fragment hinged posteriorly. This is treated with closed reduction and pinning.

As there is a hint of translation at the posterior cortex, this may be considered a type III fracture and should be reduced and pinned.

FIGURE 16-33 Positioning the fluoroscopy monitor on the opposite side of the bed allows the surgeon to easily see the images while operating. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

FIGURE 16-34 In small children, imaging of the elbow may be difficult if the arm is not long enough to reach the center of the fluoroscopy unit. By placing the child's head in the crack between the operating room table and the arm board, the elbow is more easily imaged, and the child's head is unlikely to be inadvertently pulled off the side of the bed during the procedure. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

fluoroscopy monitor opposite to the surgeon for ease of viewing (Fig. 16-33).

The patient is positioned supine on the operating table, with the fractured elbow on a short radiolucent arm board.[173] Some surgeons use the wide end of the fluoroscopy unit as the table, which is probably fine for type II fractures, but this set-up will not allow for rotation of the fluoroscopy unit to obtain lateral images of the elbow. In cases of unusual instability in which rotation of the arm risks loss of reduction, the child's shoulder needs to be flexible enough to allow for 90 degrees of external rotation to safely obtain a lateral of the elbow. It is essential that the child's arm is far enough onto the arm board that the elbow can be well visualized with fluoroscopy. In very small children this may mean having the child's shoulder and head on the arm board (Fig. 16-34).

The patient's arm is then draped and prepped. First, traction is applied with the elbow flexed at about 20 degrees to avoid the possibility of tethering neurovascular structures over an anteriorly displaced proximal fragment. For badly displaced fractures hold significant traction for 60 seconds to allow soft tissue realignment, with the surgeon grasping the forearm with both hands, and the assistant providing countertraction in the axilla (Fig. 16-35).

If it appears that the proximal fragment has pierced the brachialis, the "milking maneuver" is performed.[146] In this maneuver, the biceps are forcibly "milked" in a proximal to distal direction past the proximal fragment, often culminating in a palpable release of the humerus posteriorly through the brachialis (Fig. 16-36).

Next, with the elbow almost straight, varus and valgus angular alignment is corrected by movement of the forearm. Medial and lateral fracture translation is realigned with direct movement of the distal fragment by the surgeon with image confirmation. The elbow is then slowly flexed while applying anterior pressure to the olecranon with the surgeon's thumb(s) (Fig. 16-37).

Following a successful reduction, the child's elbow should sufficiently flex so that the fingers touch the shoulder. If not, the fracture is still likely not reduced and is in too much extension (Fig. 16-38).

If during the reduction maneuver the fracture does not stay reduced, and a "rubbery" feeling is encountered instead of the desired "bone-on-bone" feeling, the median nerve and/or brachial artery may be trapped within the fracture site (Fig. 16-25). If this occurs, an open reduction is generally necessary to remove the neurovascular structures from the fracture site.

FIGURE 16-35 Reduction maneuver: Traction with elbow flexed 20 to 30 degrees. Assistant provides countertraction against patient's axilla (*white arrow*) to allow for significant traction to be applied. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

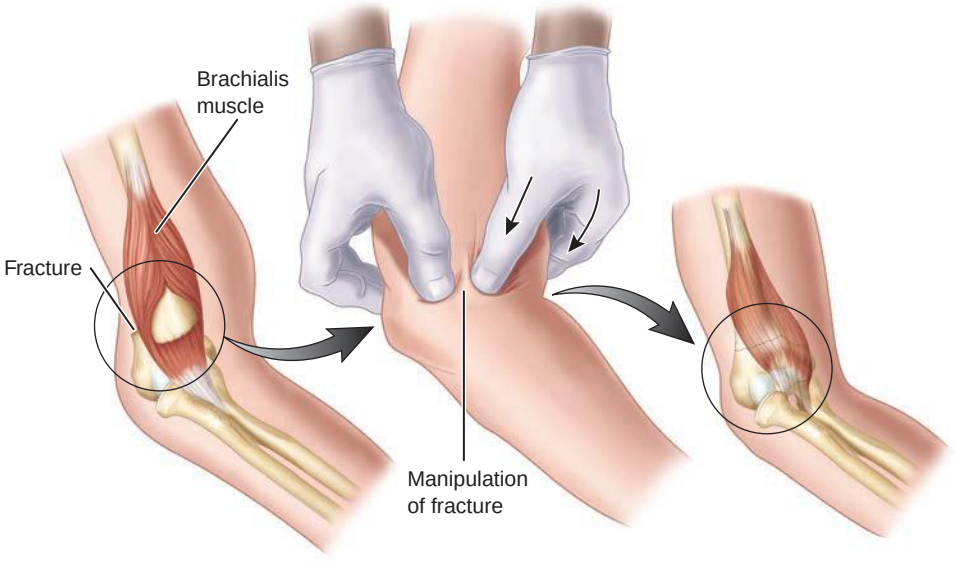


FIGURE 16-36 Brachialis muscle interposition is indicated on the left. The "milking maneuver" frees the brachialis muscle from its location in the fracture, allowing a closed reduction.

Many have described using pronation to assist in reduction, but this should not be automatic. In the most common posterior-medially displaced fracture the medial periosteum is usually intact. In this instance, pronation may assist in reduction by placing the medial periosteum in tension, and closing down the otherwise open lateral column (Fig. 16-5). However, the medial periosteum is often torn in a posterior laterally displaced fracture, and in which case pronation may be counterproductive and supination may be helpful.

The reduction is then checked by fluoroscopic images in AP, lateral, and oblique planes. Verify four points to check for a good reduction: (1) the AHL intersects the capitellum (Fig. 16-39), (2) Baumann's angle is greater than 10 degrees (Fig. 16-40), (3, 4) the medial and lateral columns are intact on oblique views (Figs. 16-41 and 16-42).

If difficulty is encountered maintaining fracture reduction when eternally rotating the shoulder for a lateral view of the elbow, consider moving the C-arm instead of the patient's arm (Fig. 16-43).

We will accept some translation of the distal fragment (up to perhaps 5 mm), as long as the above criteria are met.

Similarly, we will accept a moderate amount of persistent rotational malalignment, as long as the above criteria are met, as the shoulder joint has so much rotation it is highly unlikely to cause a functional problem. Once reduction is satisfactory, tape the elbow in the reduced position of elbow hyperflexion with elastic tape to prevent loss of reduction while pinning (Fig. 16-44).

The elbow is positioned on a folded towel. The surgeon then palpates the lateral humeral condyle. Most commonly, .062-in smooth K-wires are used (Zimmer, Warsaw, IN), though

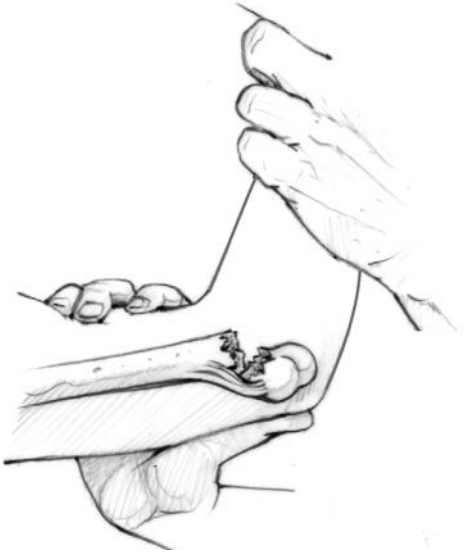

FIGURE 16-37 Reduction maneuver: Flex elbow while pushing anteriorly on olecranon with the thumb(s). (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics*. Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

FIGURE 16-38 If fingers cannot touch shoulder, flexion deformity may not be reduced.

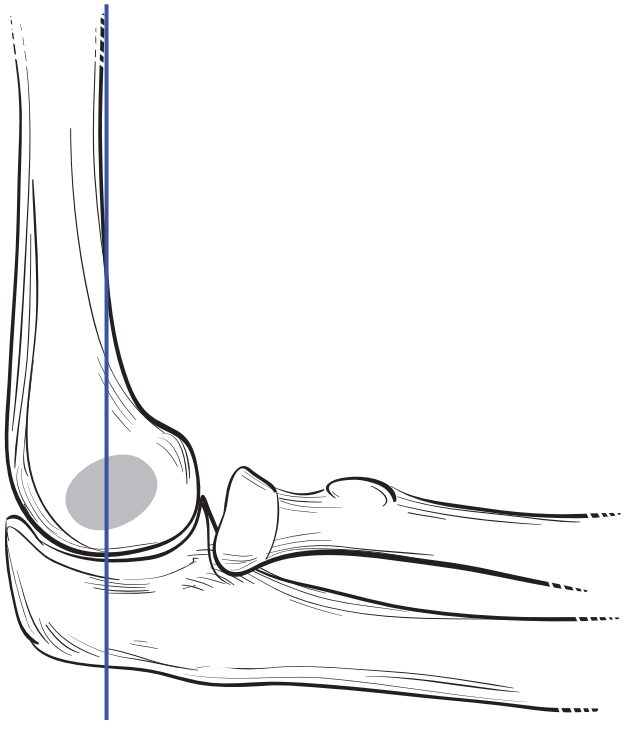

FIGURE 16-39 Anterior humeral line should cross the capitellum on a true lateral of the elbow. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

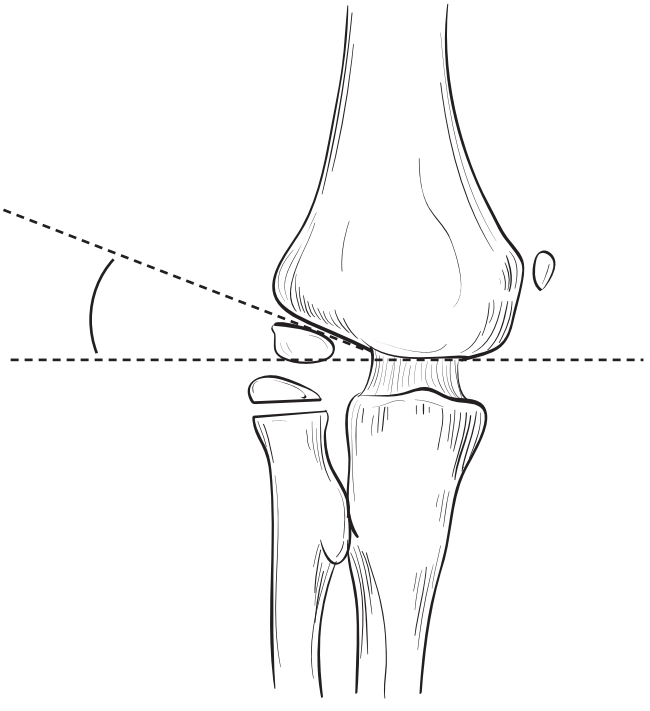

FIGURE 16-40 The Baumann's angle is between the line perpendicular to the long axis of the humeral shaft and the physeal line of the lateral condyle. A decrease in the Baumann's angle may indicate medial comminution. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

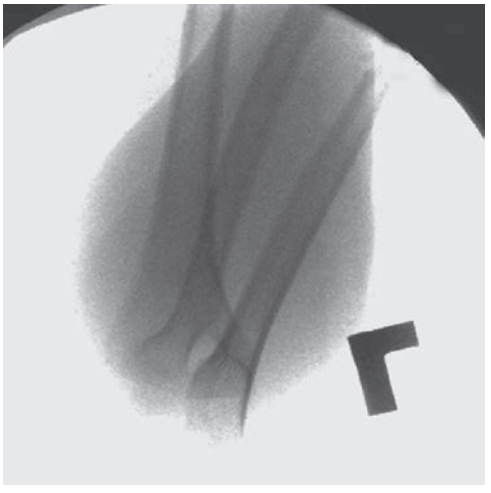

FIGURE 16-41 Oblique fluoroscopic view of the elbow demonstrating continuity of the medial column following adequate fracture reduction. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

at times smaller or larger sizes may be considered if the child is particularly small or large. The aim of pin placement is to maximally separate the pins at the fracture site to engage both the medial and lateral columns (Fig. 16-30). Whether the pins are divergent or parallel, or which pin is placed first is of little importance. Care must be taken to ensure there is sufficient bone engaged in the proximal and distal fragments. It is acceptable to cross the olecranon fossa which adds two more cortices to improve fixation, but note this means the elbow cannot be fully extended until the pins are removed. In the sagittal plane, to engage the most bone with the K-wire in the distal fragment the reduced capitellum lies slightly anterior to the plane of the fracture, thus the pin may start a bit anterior to the plane of the fracture and angulate about 10 to 15 degrees posteriorly to maximize osseous purchase. A key element to ensure a

FIGURE 16-42 Demonstration of lateral column continuity. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

FIGURE 16-43 In very unstable fractures, rotation of the shoulder into external rotation to obtain a lateral image of the elbow may lead to a loss of reduction. In these rare instances, rotation of the C-arm, rather than the elbow, is a useful trick. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007, with permission.)

correctly placed pin is to feel the pin go through the proximal cortex. If this feeling is not clearly appreciated, careful fluoroscopic imaging often reveals the pin did not engage the proximal fragment. As a general rule we recommend two pins for Gartland type II fractures, and three pins for Gartland type III fractures. Even though two good pins are probably sufficient, placing three pins increases the odds of actually having two good ones.

The K-wire is placed against the lateral condyle without piercing skin and checked under AP fluoroscopic guidance to assess the starting point. The K-wire is held free in the surgeon's hand at this point, not in the drill, to allow maximum

FIGURE 16-44 Fracture reduction is maintained by taping elbow in hyperflexed position. The wire may be pushed through the skin and into the cartilage, using the cartilage of the distal lateral condyle as a pincushion that will hold the K-wire in place while carefully examining the AP and lateral images. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

FIGURE 16-45 Assessment of sagittal alignment with lateral view. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

control. If the starting point and trajectory is correct, the wire may be pushed through the skin and into the cartilage, using the cartilage of the distal lateral condyle as a pincushion, (Fig. 16-43) that will hold the K-wire in place while you carefully examine the AP and lateral images. If imaging verifies correct pin placement, then advance the pin with a drill. Precise pin placement is an important part of the procedure that should not be rushed. We believe incorrect pin placement is the cause of loss of reduction in most fractures. Whether the pins are divergent or parallel are of little importance as long as the pins are well separated at the fracture site.

The reduction is again checked under fluoroscopy with lateral (Fig. 16-45), oblique (Fig. 16-46), and AP views (Fig. 16-47).

Stress should be applied in varus and valgus under fluoroscopy to ensure. If there is any instability, you want to know about it now, rather than a week later. If there is instability, we will add another lateral-entry pin (Fig. 16-48). In the exceptionally rare instance when three lateral pins do not stabilize the fracture, or there is an oblique fracture pattern preventing multiple lateral-entry pins, a medial pin may be considered. After placing lateral-entry pins, the elbow is fully extended to relax tension on the ulnar nerve and surrounding tissue, and the surgeon can palpate the medial epicondyle which is posterior to the center plane of the distal humerus. The entry site for medial pin placement is anterior on the medial epicondyle. A small incision

FIGURE 16-46 Both oblique views are checked to assess reduction of medial and lateral columns. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

is made to expose and protect the ulnar nerve. A drill guide is used to prevent binding of the perineural soft tissues that could kink the nerve. After desired pin placement is confirmed on fluoroscopy, the medial epicondyle and nerve are inspected to be certain there is no injury, impingement, or kinking of the nerve throughout flexion–extension arc of motion.

FIGURE 16-47 If the lateral and oblique views show good reduction, the tape is removed and reduction and pin placement are checked, in the AP view with elbow in relative elbow extension. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

We save the images in which the reduction looks the "worst," particularly if some translational or rotational malreduction is accepted, to have them for comparison during postoperative visits to determine if movement of the fracture occurred. Vascular status is assessed. The wires are bent and cut. Take care to leave the wires at least 1 to 2 cm off the skin after, to prevent migration of the wires under the skin. A sterile felt square with a slit cut into it is then placed around the wires to protect the skin (Fig. 16-49).

Foam is applied to the arm on the anterior and posterior aspects of the elbow to allow for swelling (Fig. 16-50). The cast is then applied in 45 to 70 degrees of elbow flexion, as flexion to 90 degrees may needlessly increase the risk of compartment

syndrome (Fig. 16-51). Remember that the pins, not the cast, are holding the fracture reduction. We use fiberglass casting material for its strength, weight, and radiolucency and feel that when properly applied, fiberglass does not lead to a tight cast.

If there is any question of perfusion following fracture reduction in the operating room, the surgical prep (betadine) may be removed to evaluate the skin color. In addition, a Doppler may be used to assess pulse. In the case of a poorly perfused hand following reduction, in a case where the hand was well perfused prior to reduction, one must assume the artery, or adjacent tissue is trapped in the fracture site. The pins should be immediately removed and allow the fracture to return to its unreduced position. If there is no pulse postoperatively in an arm that had no pulse preoperatively, but the hand is warm and well perfused, our preference is to observe the child in hospital for 48 hours with the arm mildly elevated (Fig. 16-52). This is especially true if there is associated neuropathy preoperatively.

FIGURE 16-49 Skin is protected from pins with felt squares. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

FIGURE 16-50 Sterile foam is placed directly on skin. If there is any circumferential dressing placed under the foam, it may be restricting. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007, with permission.)

The rich collateral circulation about the elbow is generally sufficient. The presence or absence of a pulse by Doppler does not change our management at this point, but will make us feel better if a pulse can be heard.

FIGURE 16-51 Cast with elbow flexion no more than 70 degrees and less flexion for very swollen elbows. (From Tolo VT, Skaggs DL, eds. *Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics.* Philadelphia, PA: Lippincott; 2007:1–15, with permission.)

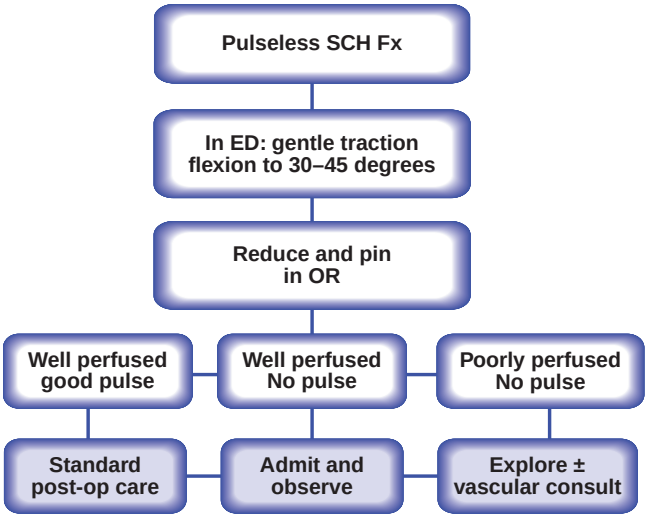

FIGURE 16-52 Author's preferred algorithm for management of the pulseless supracondylar humerus fracture.

Type IV Fractures of the Supracondylar Fractures of the Distal Humerus

Although this extremely unstable fracture could be treated with open reduction, we follow the protocol recommended by Leitch et al.[118] First place two K-wires into the distal fragment. Next, the fracture is reduced in the AP plane and verified by imaging. At this point, rather than rotating the arm for a lateral image as is commonly done in more stable fracture patterns, the fluoroscopy unit is rotated into the lateral view (Fig. 16-42). The fracture is then reduced in the sagittal plane, and the K-wires are driven across the fracture site. Often times the reduction is in midposition of flexion and extension (~60 degrees) and requires holding the reduction with distraction by the surgeon while the assistant places the first lateral-entry stabilizing pin.

Postoperative Care in Supracondylar Fractures of the Distal Humerus

Swanson et al.[188] reports acetaminophen is as effective as narcotic analgesics for providing pain control after supracondylar fracture surgery in children and Kay et al.[101] reports perioperative ketorolac (a nonsteroidal anti-inflammatory) does not increase the risk of complications following operative fracture care. We use acetaminophen and an NSAID as the first-line drugs for pain relief as narcotics are historically associated with more side effects.

Patients with minimal swelling felt to be at little risk for compartment syndrome may be discharged to home with appropriate postoperative instructions, but otherwise children are generally admitted overnight for elevation and observation. We recommend the elbow is elevated over the heart for at least 48 hours postoperatively. The patient customarily returns 5 to 7 days postoperatively at which time AP and lateral radiographs are obtained. In the unlikely event a loss of reduction were to occur, this would be noted in sufficient time for rereduction. This return visit is probably not necessary in most cases.[148] The cast is generally removed 3 weeks postoperatively, at which time radiographs are obtained out of the cast. The pins are removed in the outpatient setting at this time. Range-of-motion exercises are taught to the family, targeting gentle flexion and extension, to be started a few days after cast removal. The child returns 6 weeks postoperatively for a range of motion check, with no radiographs at that time.

Pearls and Pitfalls Related to Supracondylar Fractures of the Distal Humerus

- Aim to separate the pins as far as possible at the fracture site—this is more important than whether the pins are divergent or parallel.
- To optimize pin placement, think of the cartilaginous distal humerus as a pincushion. With the K-wires in your fingers (not the drill) push them into the cartilage in the exact location and trajectory you want. Verify with imaging, then advance the pin with a drill.
- In general, plan on a minimum of two pins for type II fractures and three pins for type III fractures.
- If the first pin is in between where you really wanted two pins, just leave it and place one on either side of it for a total of three pins.
- A small amount of translation or axial rotational malalignment may be accepted rather than doing an open reduction, but accept very little frontal or sagittal plane angular malalignment.
- Following reduction and fixation, stress the fracture under live imaging to the point where you are confident it will not fall apart postoperatively.
- Cast the elbow in significantly less than 90 degrees of flexion to avoid compartment syndrome, the pins are holding the reduction, not the cast.
- If you chose to place a medial pin, extend the elbow when placing the pin to keep the ulnar nerve posteriorly out of harm's way.

Open Reduction and Pinning in Supracondylar Fractures of the Distal Humerus

We prefer a transverse anterior incision above and parallel to the antecubital fossa at the fracture site about 4 to 5 cm long which allows access to the neurovascular structures and is aesthetic (Fig. 16-48C). If more visualization is needed, this incision can be extended medially or laterally based on displacement. Care must be taken in dissecting as the neurovascular bundle may be immediately superficial as it is pushed against the skin by the proximal fragment. Usually there is significant disruption of the brachialis muscle. The first major structure to be incised is the bicipital aponeurosis (lacertus fibrosus) which runs just superficial to the median nerve and brachial artery: From the biceps tendon it runs medially to the superficial flexors of the forearm. Just medial to the biceps tendon the brachial artery is noted, with the median nerve just medial to the artery. If the artery cannot be located in a patient presenting with a pulseless, poorly perfused hand search for the lacerated ends of the artery which may have retracted (Fig. 16-53).

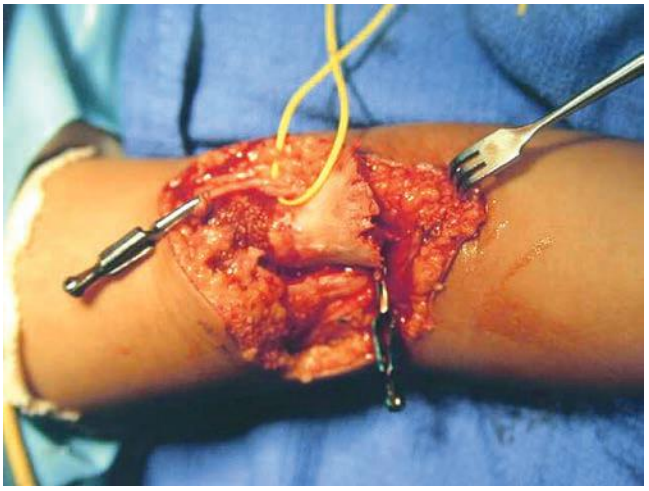

FIGURE 16-53 The brachial artery was lacerated by the proximal fragment. Bulldogs have been placed on each end of the artery to control bleeding, and the median nerve is within the vessel loop. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

Once the brachial artery and median nerve are identified, they should be retracted out of the fracture site. Reduction may be more challenging than one would imagine. One reduction technique is for the surgeon to push downward on the proximal fragment, while an assistant applies traction to the forearm with the elbow flexed at 90 degrees. Often the periosteum is also entrapped in the fracture site. A freerer can be used as a lever to elevate the periosteum and assist the reduction. Once a reduction has been obtained pinning may be accomplished in the same manner as in closed reduction with percutaneous pinning.

Complications in Supracondylar Fractures of the Distal Humerus

Vascular Injury in Supracondylar Fractures of the Distal Humerus

Preoperative Evaluation and Care

Approximately 1% to 15% of patients with supracondylar fractures present with an absent pulse but only a minority of these patients will require vascular repair.[37,42,56,81,119,147,164,166] At the initial evaluation the presence or absence of a pulse and perfusion of the hand should be determined. Perfusion of the hand is estimated by color, warmth, pulp turgor, and arterial capillary refill, but there is no clear evidence of the degree of reliability of these objective standards. Capillary refill by itself can be deceiving. For example after wrapping a rubber band around a finger there is instant venous capillary refill but no artery inflow or venous outflow, so this must be differentiated from normal arterial capillary refill. Generally accepted normal perfusion criteria (viable hand) are capillary refill equivalent to the opposite side and less than 3 to 5 seconds, normal pulp turgor and pink color. The clinician must distinguish between the nonviable and viable hand upon presentation and throughout care.

Hand perfusion, not presence or absence of a pulse, appears to be predictive of the need for arterial repair and risk of compartment syndrome. Choi et al.[42] reported on 25 pulseless patients whose hand was well perfused at presentation and none (0%) required vascular repair or developed a compartment syndrome. In contrast, of eight patients who presented with poor distal perfusion, compartment syndrome developed in 25% and 38% underwent vascular repair.

An absent radial pulse is not in itself an emergency, as collateral circulation may keep the limb well perfused in the short term and potentially even long term. In the case of a pulseless, perfused hand, urgent, but nonemergent, reduction with pinning in the operating room is indicated.[100,140,161,166] However, in the presence of an associated nerve injury, there is higher risk of a compartment syndrome and more cautious close observation until surgery is indicated.[134] If the arm is pulseless and also has signs of poor perfusion (white color, decreased turgor, and/or slow capillary refill), this is an emergency.[3] When a patient with a severely displaced supracondylar fracture presents to the emergency room and has compromised vascularity to the limb, the arm should be splinted with the elbow in approximately 20 to 40 degrees of flexion[100,140] to protect further injury as the patient progresses directly to surgery.

Fracture reduction should not be delayed by any waiting time for an angiographic study, as reduction of the fracture usually restores the pulse.[3,41] Several reports have shown angiography to be an unnecessary test that has no bearing on treatment.[43,147,164,166] Shaw et al.[166] reported on a series of 143 type III supracondylar fractures, 17 of which had vascular compromise. All underwent reduction and percutaneous pinning without preoperative angiogram. In 3 of the 17 (18%) patients, restored blood flow to the hand did not occur after reduction and required open exploration. In 14 of the 17 (82%) patients, restored blood flow to the hand occurred without complications. The authors concluded that prereduction angiography would add nothing to the management of these injuries. Another study utilized angiogram in 4 of 17 (24%) dysvascular SCH fractures and found that the angiogram did not alter the course of management in any of the cases.[43] Choi et al.[41] reported that of 25 patients presenting with a pulseless but well-perfused hand, 100% did well clinically without arterial repair—52% (11) had a palpable pulse following surgery, and 48% (10) remained pulseless but well perfused. Cheng et al.[37] in a series of 623 supracondylar fractures reported nine cases presenting with an absent radial pulse (1.4%), of which only one required exploration.

Operative Treatment of a White, Pulseless Hand in Supracondylar Fractures of the Distal Humerus

Closed Reduction, Percutaneous Pinning of Supracondylar Fractures of the Distal Humerus

Standard treatment for a pulseless hand is closed reduction and percutaneous pinning. After closed reduction and stabilization, the pulse and perfusion of the hand should be evaluated. Usually hand perfusion is restored. Most extension-type supracondylar fractures are reduced and pinned with the elbow in hyperflexion. With more than 120 degrees of elbow flexion, the radial pulse generally is lost, and the hand becomes pale, even

in patients with an initially intact pulse and a viable hand. Following pinning when the arm is extended, the pulse frequently does not return immediately. This is presumably secondary to arterial spasm, aggravated by swelling about the artery and decreased peripheral perfusion in the anesthetized, somewhat cool intraoperative patient.

Because of this phenomenon, up to 10 to 15 minutes should be allowed for recovery of perfusion in the operating room before any decision is made regarding the need for exploring the brachial artery and restoring flow to the distal portion of the extremity. Because most patients without a palpable pulse regain and maintain adequate distal perfusion, the absence of a palpable pulse alone is not an indication for exploring a brachial artery.

If there is a poor or absent pulse, and/or poor perfusion, there is a high risk of compartment syndrome, and a low threshold for intraoperative compartment pressure measurements and documentation. In cases of poor limb perfusion for over 6 hours, prophylactic forearm compartment release should be performed.

Postreduction White (Poorly Perfused), Pulseless Hand in Supracondylar Fractures of the Distal Humerus

Following reduction a poorly perfused pulseless hand requires urgent treatment.[3,140,187] If there was a pulse before fracture reduction, one must assume the artery or surrounding tissue is trapped at the fracture site, and pins should be pulled, and the artery explored. If there was not adequate perfusion before fracture reduction, and the hand remains poorly perfused, arterial exploration should be performed urgently.

Exploration through an anterior approach allows evaluation of arterial kinking by entrapped adjacent soft tissues or incarceration of the artery between the fracture fragments.[11,62] Once the artery is freed from the fracture, associated arterial spasm may be relieved by application of lidocaine, warming, and 10 to 15 minutes of observation. Following anatomic fracture reduction and decompression of the neurovascular bundle of a pulseless limb, if the hand remains poorly perfused, vascular reconstruction is indicated by an appropriate specialist.

Postreduction Pink (Perfused), Pulseless Hand in Supracondylar Fractures of the Distal Humerus

If the pulse does not return, but the hand is well perfused following reduction, treatment is controversial.[158,187] Our practice is to admit the child to the hospital with gentle arm elevation and careful observation for at least 48 hours. The patient should be observed for increasing narcotic requirements, increasing pain, and decreased passive finger motion. (The 3 A's of a pending pediatric compartment syndrome: Increasing anxiety, agitation, and analgesic requirement.) Multiple authors report good results with observation of the postreduction pink pulseless hand.[3,41,71,75,81] However, a very low threshold for returning to the operating room for vascular exploration, decompression, and/or reconstruction along with forearm fasciotomies must be maintained rather than assuming that perfusion from collaterals is sufficient. There are known disastrous cases of permanent impairment in this setting.

Alternatively, vascular reconstruction may be performed in the pink pulseless hand. There has been some variance of results of reconstruction long term. Sabharwal et al.[161] have shown that early repair of the brachial artery has a high rate of symptomatic reocclusion or residual stenosis and recommended a period of close observation with frequent neurovascular checks before more invasive correction of this problem is contemplated. Many other studies report good results following vascular repair[105,164,166] including an analysis of 19 studies with a patency rate of 91% in 54 patients with surgically repaired arteries.[200] Repair by microscopic techniques appear to have better long-term results.

Lally et al. reported on the long-term follow-up of 27 patients who had brachial artery ligation as a child for renal transplant. Decreased mean systolic pressure was noted in the affected limp in about 25% of patients and 67% had mildly decreased exercise tolerance. There was no significant difference in limb circumference or length. Perhaps most importantly, no patient specifically complained of problems with the ligated side.[113]

Vascular Studies of Supracondylar Fractures of the Distal Humerus

There is currently no generally accepted evidence that further vascular studies beyond pulse and perfusion lead to improved outcomes, though this is an area of active research. A review of articles subsequent to 1980 in the vascular surgical literature concludes: "Both angiography and color duplex ultrasound provide little benefit in the management of these patients. A child with a pink pulseless hand postfracture reduction can be managed expectantly unless additional signs of vascular compromise develop, in which exploration should be undertaken."[81] Similarly, some surgeons in the past have recommended pulse oximetry[155] for evaluating postreduction circulation, though this has not been shown to unequivocally discriminate the nonviable from the viable hand.

Special Case: Pulseless with Median Nerve Injury

If the arm is pulseless and has a median or AIN deficit special attention is warranted.[158] With injury to both the brachial artery and a nerve, we may assume that significant soft tissue damage has occurred, which places the child at higher risk for a compartment syndrome. The pain of a compartment syndrome may be masked by the nerve injury, so very careful assessment and monitoring for a compartment syndrome is needed throughout the perioperative period, with a low threshold for vascular exploration and/or compartment release.[134] Mangat et al.[123] reported on seven patients who were pulseless with a median or AIN injury, and all seven patients were found to have the brachial artery trapped or tethered at the fracture site. They recommend early exploration of the brachial artery in a Gartland type III supracondylar fracture in patients who present with an absent pulse and a coexisting anterior interosseous or median nerve palsy, as these appear to be strongly predictive of nerve and vessel entrapment. In contrast, they found only 20% of pulseless extremities without a nerve deficit had the artery trapped or tethered.

Exploration of the Brachial Artery

Often, during the open reduction of the fracture, release of a fascial band or an adventitial tether resolves the problem of obstructed flow. In some patients, however, a formal vascular repair and/or vein grafting is required, at which time many orthopedic surgeons will consult colleagues with vascular expertise. The brachial artery is approached through an anteromedial transverse incision at the level of the fracture above the antecubital fossa. Often this provides excellent exposure of the fracture site and neurovascular bundle. Distal and proximal extension can be performed with z-limbs if necessary as described in the author's preferred method for open reduction (Fig. 16-48C).

If the hand is still nonviable after reduction and pinning the fracture, care must be taken because the neurovascular bundle may be difficult to identify when it is surrounded by hematoma or lies in a very superficial position. At the level of the fracture, the artery may seem to disappear into the fracture site, covered with shredded brachialis muscle. This occurs when the artery is likely tethered by a fascial band or arterial adventitia attached to the proximal metaphyseal spike pulling the artery in the fracture site. Dissection is often best accomplished proximally to distally, along the brachial artery, identifying both the artery and the median nerve. Arterial injury is generally at the level of the supratrochlear artery (Fig. 16-54), which provides a tether, making the artery vulnerable at this location. Arterial transection or direct arterial injury can be identified at this level.

If arterial spasm is the cause of inadequate flow, and collateral flow is not sufficient to maintain the hand, attempts to relieve the spasm may be tried. Once the artery is no longer kinked or tethered, direct application of papaverine or local anesthetic to the artery has been found to be beneficial. Sympathetic block with a stellate ganglion block may prolong the vasodilatory effect. If these techniques do not relieve the spasm, and if collateral flow is insufficient to maintain a viable hand, there most likely is an intimal injury and occlusion. In these rare situations, the injured portion of the vessel is excised and a reverse vein graft of appropriate size is inserted, usually from the same extremity. Prophylactic release of forearm fascia is indicated in cases of prolonged ischemia to prevent a reperfusion compartment syndrome. When flow is restored, the wound is closed, the patient is placed in a splint with the elbow in approximately 60 degrees of flexion, and the forearm in neutral pronation and supination. Postoperative monitoring should include temperature, pulse oximetry, and frequent examinations of perfusion and for signs of compartment syndrome or ischemia. Although injecting urokinase has been suggested to increase flow,[32] we no longer advocate that technique because of systemic risks.

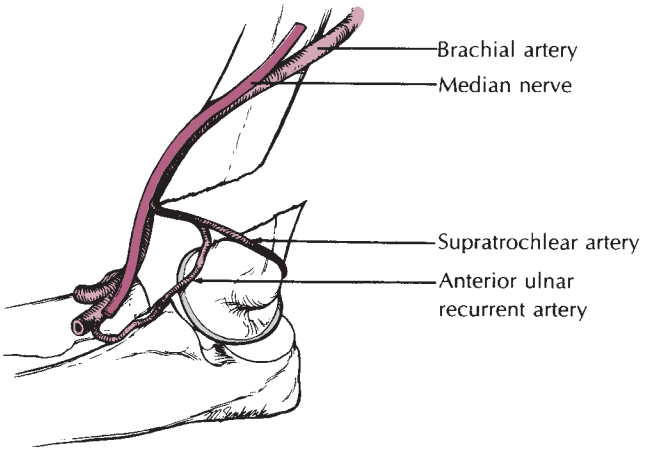

FIGURE 16-54 Arterial pathology. The supratrochlear branch that arises from the anterior ulnar recurrent artery may bind the main trunk of the brachial artery against the sharp end of the proximal fragment. (From Rowell PJW. Arterial occlusion in juvenile humeral supracondylar fracture. *Injury*. 1974;6:254–256, with permission.)

There is a single case report of a 6-year-old boy who developed a brachial artery pseudoaneurysm following an SCH fracture.[78] The patient presented with a type III SCH extension-type fracture with a pulseless, well-perfused hand. Following fracture reduction and pinning the radial pulse was palpable. At 5-week follow-up the patient had diminished sensation and strength in the radial nerve distribution, accompanied by diminished radial pulse, and swelling in the antecubital fossa. Ultrasound revealed a large pseudoaneurysm of the left brachial artery which was treated with an interposition vein graft.

Compartment Syndrome (see Chapter 6 for More In-Depth Discussion of Compartment Syndrome and Surgical Technique)

The prevalence of compartment syndrome in the setting of a supracondylar fracture is estimated to be 0.1% to 0.5%.[19,20] The classic five "P's" for the diagnosis of compartment syndrome – pain, pallor, pulselessness, paresthesias, and paralysis – are poor indicators of a compartment syndrome in children. Bae et al. report increasing analgesia requirement in combination with other clinical signs are more sensitive and earlier indicators of compartment syndrome in children. They found 10 children with access to patient-controlled or nurse-administered analgesia had increasing requirement for pain medication.[15] Resistance to passive finger movement and dramatically increasing pain after fracture are clinical signs of compartment syndrome of the forearm. Special attention must be paid to supracondylar fractures with median nerve injuries, as the patient will not feel pain in the volar compartment.[134] A compartment syndrome of the forearm may occur with or without brachial artery injury and in the presence or absence of a radial pulse.

If the supracondylar fracture's mechanism of injury is high energy as evidenced by crushing or associated fractures there is an increased risk for compartment syndrome. Blakemore et al.[24] found a 7% incidence of forearm compartment syndrome (3 of 33 patients) with the combined injury of supracondylar fracture and radial fracture. Ring et al.[157] found 6 of 10 pediatric floating elbows with pending or true compartment syndromes and recommend pinning of both distal radius and SCH fractures. An arterial injury in association with multiple injuries or crush injury further diminishes blood flow to the forearm musculature and increases the probability of a compartment syndrome.

In a multicenter review Ramachandran et al.[152] identified 11 cases in which children with supracondylar fracture developed compartment syndrome despite presenting with closed,

low-energy injuries and no associated fractures or vascular compromise. This series is disturbing as it demonstrates that compartment syndrome still occurs with modern treatment, even in children who may be thought to be at low risk. They found that in 10 of 11 patient's charts, excessive swelling was noted at time of presentation. The 10 cases with severe elbow swelling documented at presentation had a mean delay until surgery of 22 hours. This study suggests excessive swelling combined with delay in treatment is a risk factor for development of compartment syndrome. The authors also noted that even if distal pulse is found by palpation or Doppler examination, an evolving compartment syndrome may be present.

If one is concerned that a compartment syndrome may be evolving, initial management includes removing all circumferential dressings. Battaglia et al.[20] documented the relationship between increasing elbow flexion above 90 degrees and increasing volar compartment pressure, so the elbow should be extended to a position well below 90 degrees. The volar compartment should be palpated, and the elbow should be extended. We believe that the fracture should be immediately stabilized with K-wires to allow proper management of the soft tissues.

Another factor that contributes to the development of compartment syndrome is warm ischemic time after injury. When blood flow is compromised and the hand is pale with no arterial flow, muscle ischemia is possible, depending on the time of oxygen deprivation. After fracture reduction and flow restoration, the warm ischemic time should be noted. If this time is more than 6 hours, compartment syndrome secondary to ischemic muscle injury is likely. Prophylactic volar compartment fasciotomy can be performed at the time of arterial reconstruction. The exact indication for prophylactic fasciotomy in the absence of an operative revascularization is uncertain. Even when the diagnosis is delayed or if the compartment syndrome is chronic, fasciotomy has been shown to be of some value.

Blakey et al.[25] report on the experience of their specialized center over a 21-year period. At a mean of 3 months after sustaining an SCH fracture, 23 children with ischemic contractures of the forearm were referred. The authors recommend that urgent exploration of the vessels and nerves in a child with a "pink pulseless hand" following fracture reduction with persistent and increasing pain suggest critical ischemia. No further conclusions regarding acute care of patients with a pink pulseless hand that does not have increasing pain suggestive of ischemia can be drawn from this retrospective study of established ischemic contractures.

Neurologic Deficit in Supracondylar Fractures of the Distal Humerus

A meta-analysis of 3,457 extension-type SCH fractures found an overall neuropraxia rate of 13%, with the AIN (5%) being the most common, followed by the radial nerve 4%.[13] AIN palsy presents as paralysis of the long flexors of the thumb and index finger without sensory changes. Complete median nerve injury has also been described with these fractures because of contusion or transection of the nerve at the level of the fracture and presents with sensory loss in the median nerve distribution as well as motor loss of all muscles innervated by the median nerve.[182,186] Nerve transections are rare and almost exclusively involve the radial nerve.[17,46,125,126]

The direction of the fracture's displacement determines the nerve most likely to be injured. If the distal fragment is displaced posteromedially, the radial nerve is more likely to be injured. Conversely, if the displacement of the distal fragment is posterolateral, the neurovascular bundle is stretched over the proximal fragment, injuring the median nerve or AIN or both. In a flexion type of supracondylar fracture, which is rare, the ulnar nerve is the most likely nerve to be injured (Fig. 16-6).

Open reduction and exploration of the injured nerve is not necessarily indicated in cases of nerve injury in a closed fracture. Neural recovery, regardless of which nerve is injured, generally occurs with observation after 2 to 2.5 months, but may take up to 6 months.[31,100]

Culp et al.[46] reported identification of eight injured nerves in five patients in which spontaneous recovery did not occur by 5 months after injury. Neurolysis was successful in restoring nerve function in all but one patient. Nerve grafting may be indicated for nerves not in continuity at the time of exploration. Decompression and neurolysis for perineural fibrosis is generally successful in restoring nerve function. There is no indication for early electromyographic analysis or treatment other than observation for nerve deficit until 3 to 6 months after fracture.

In their series of radial nerve injuries with humeral fractures, Amillo et al.[7] reported that of 12 injuries that did not spontaneously recover within 6 months of injury, only one was associated with a supracondylar fracture. Perineural fibrosis was present in four patients, three nerves were entrapped in callus, and five were either partially or totally transected.

In the supracondylar area, nerve compression and perineural fibrosis appears to be the most common cause of prolonged nerve deficit. Although nerve injury is related to fracture displacement, a neural deficit can exist with even minimally displaced fractures. Sairyo et al.[162] reported one patient in whom radial nerve palsy occurred with a slightly angulated fracture that appeared to be a purely extension-type fracture on initial x-rays. Even in patients with mild injuries, a complete neurologic examination should be performed before treatment. An irreducible fracture with nerve deficit is an indication for open reduction of the fracture to ensure that there is no nerve entrapment. Chronic nerve entrapment in healed callus can give the appearance of a hole in the bone, Metev's sign.

Iatrogenic injury to the ulnar nerve has been reported to occur in 1% to 15% of patients with supracondylar fractures.[31,57,92,154,159,175] In a large series of type III supracondylar fractures, the rate of iatrogenic injury to the radial nerve was less than 1%. The course of the ulnar nerve through the cubital tunnel, between the medial epicondyle and the olecranon, makes it vulnerable when a medial pin is placed. Rasool[154] demonstrated with operative exploration that the pin usually did not impale the ulnar nerve, but more commonly constricted the nerve within the cubital tunnel by tethering adjacent soft tissue. These findings were later confirmed by an ultrasonographic study by Karakurt et al.[98] Zaltz et al.[211] reported that in children less than 5 years of age, when the elbow is flexed more than

90 degrees, the ulnar nerve migrated over, or even anterior to, the medical epicondyle in 61% (32/52) of children. It has been suggested that placement of lateral-entry pins first, followed by elbow extension to relax tension on the ulnar nerve and subsequent placement of a medial pin could decrease the risk of iatrogenic nerve injury. Using this technique these authors reported a 1.1% (2/187) rate of iatrogenic ulnar nerve injury with medial pins.[57]

If an iatrogenic ulnar nerve injury occurs following placement of a medial pin, there is a lack of literature on which to base treatment. Lyons et al.[120] reported on 17 patients with iatrogenic ulnar nerve injuries presumably due to a medial pin. All 17 patients had complete return of function, though many not until 4 months. Only 4 of the 17 (24%) had the medial pins removed. This study demonstrates ulnar nerve function can eventually return without pin removal. Brown and Zinar[31] reported four ulnar nerve injuries associated with pinning of supracondylar fractures, all of which resolved spontaneously 2 to 4 months after pinning. Rasool[154] reported six patients with ulnar nerve injuries in whom early exploration was performed. In two patients, the nerve was penetrated, and in three, it was constricted by a retinaculum over the cubital tunnel, aggravated by the pin. In one patient, the nerve was subluxed and was fixed anterior to the cubital tunnel by the pin. Full recovery occurred in three patients, partial recovery in two, and no recovery in two. Royce et al.[159] reported spontaneous recovery of ulnar nerve function in three patients. One nerve that was explored had direct penetration, and the pin was replaced in the proper position. Two patients had late-onset ulnar nerve palsies discovered during healing, and the medial pin was removed.

If an immediate postoperative neural injury is documented, we prefer to explore the ulnar nerve and to replace the pin in the proper position or convert to a lateral pin construct. Common sense suggests that removal of the causative factor (the medial pin) earlier rather than later may lead to a quicker recovery of the nerve. Routine exploration of the ulnar nerve is not recommended.[31,63,154,211]

Preventing ulnar nerve injury is obviously more desirable than treating ulnar neuropathy. Because of the frequency of ulnar nerve injury with crossed pinning, most surgeons prefer to use two or three lateral pins if possible and no medial pin. Successful maintenance of alignment of type III supracondylar fractures with lateral pins has been reported in many series.[38,103,173,175,191] In our opinion the only technique for avoiding iatrogenic ulnar nerve injury across is to use lateral-entry pins, and avoid the use of cross pins. However, one meta-analysis of 3,457 extension-type fractures reported an iatrogenic neurapraxia rate of 1.9% for laterally placed pins.[13] As 97% of these patients were studied retrospectively, we suspect that many if not most of these "iatrogenic" nerve injuries were really due to inaccurate preoperative neurologic examinations.[13]

Elbow Stiffness in Supracondylar Fractures of the Distal Humerus

Clinically significant loss of motion after extension-type supracondylar fractures is rare in children. In a study of 45 children with SCH fractures who did not undergo physical therapy, 90% range of motion (ROM) returned at 30 days for extension and 39 days for flexion.[196] In another report of 63 patients with closed reduction percutaneous pinning of supracondylar fractures of the humerus stabilized with either two or three lateral-entry pins, elbow ROM returned to 72% of contralateral elbow motion by 6 weeks after pinning and progressively increased to 86% by 12 weeks, 94% by 26 weeks, and 98% by 52 weeks.[214] Pins were removed by 3 to 4 weeks. No patient participated in formal physical therapy.

Although most children do not require formal physical therapy, we generally teach the parents range-of-motion exercises to be performed at home following pin and cast removal at about 3 to 4 weeks. A follow-up appointment to assess range of motion is scheduled about 4 to 8 weeks later, and if motion is not nearly normal at that time, a physical therapy to improve elbow motion is begun.

Significant loss of flexion can be caused by a lack of anatomic fracture reduction: Either posterior distal fragment angulation, posterior translation of the distal fragment with anterior impingement, or medial rotation of the distal fragment with a protruding medial metaphyseal spike proximally (Fig. 16-55). In young children with significant growth potential, there may be significant remodeling of anterior impingement, and any corrective surgery should be delayed at least 1 year. Although anterior impingement can significantly remodel, there is little remodeling of persistent posterior angulation or hyperextension.

Pin Tract Infections

The reported prevalence of pin tract infections in SCH fractures ranges from less than 1% to 2.5% with closed reduction and standard pinning techniques.[19,38,173] In a retrospective review of 622 operative treated patients, one patient developed a deep infection with septic arthritis and osteomyelitis (0.2%). Five additional patients had superficial skin infections and were treated with oral antibiotics for a total infection rate of 6 of 622 patients (1%).[19]

Pin tract infections generally resolve with pin removal and antibiotics. Fortunately, by the time a pin tract infection develops the fracture is usually stable enough to remove the pin without loss of reduction. However, an untreated pin tract infection can result in a septic joint and should thus be treated as soon as is recognized or suspected.

Pin Migration

In one retrospective series of 622 patients, the most common complication was pin migration necessitating unexpected return to the operating room for pin removal in 11 patients (1.8%). This complication can be minimized by both bending at least 1 cm of pin at a 90-degree angle, at least 1 cm from the skin, and protecting the skin with thick felt over the pin (Fig. 16-48A) or using commercially available pin covers.

Myositis Ossificans in Supracondylar Fractures of the Distal Humerus

Myositis ossificans is a remarkably rare complication of supracondylar fractures, but it can occur (Fig. 16-56). This complication has been described after closed and open reduction,

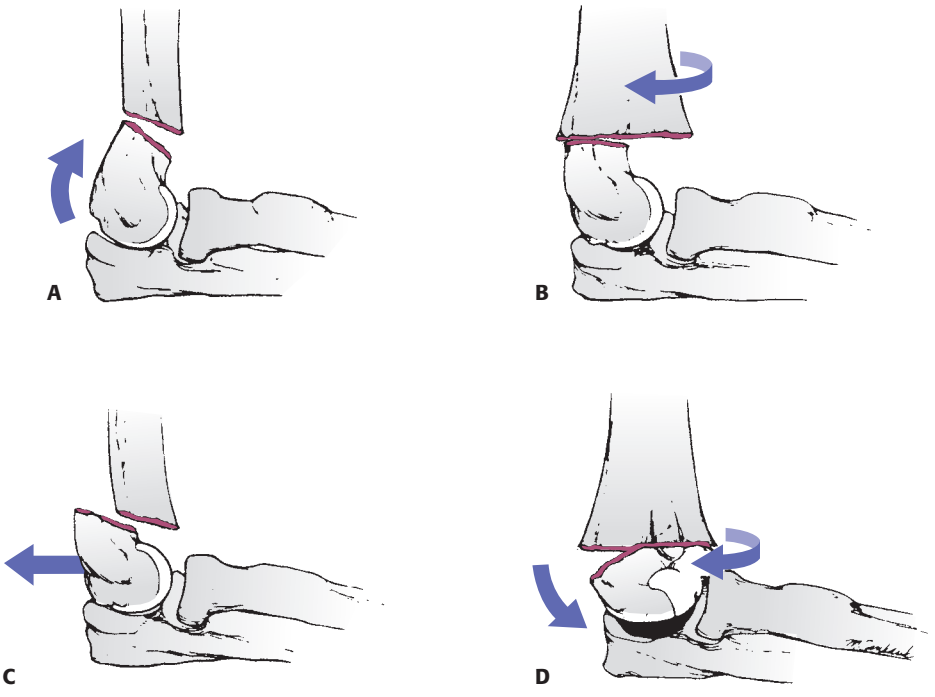

FIGURE 16-55 Distal fragment rotation. **A:** Posterior angulation only of the distal fragment. **B:** Pure horizontal rotation without angulation. **C:** Pure posterior translocation without rotation or angulation. **D:** Horizontal rotation with coronal tilting, producing a cubitus varus deformity. Les fractures de l'extremite inferieure de l'humerus chez l'enfant. *Rev Chir Orthop.* 1962;48:337–413, with permission **[C, D].**)

but vigorous postoperative manipulation or physical therapy is believed to be the most commonly associated factor.[107,147]

In a report of two patients with myositis ossificans after closed reduction of supracondylar fractures, Aitken et al.[5] noted that limitation of motion and calcification disappeared after 2 years. Postoperative myositis ossificans can be observed with the expectation of spontaneous resolution of both restricted motion and the myositis ossificans. There is no indication for early excision. O'Driscoll[137] reported a single case of myositis ossificans associated with sudden onset of pain posttrauma in which a 1-year-old lesion of myositis ossificans was fractured. With excision, the pain was relieved, and full range of motion returned.

Nonunion of Supracondylar Fractures of the Distal Humerus

The distal humeral metaphysis is a well-vascularized area with remarkably rapid healing, and nonunion of a supracondylar fracture is rare, with only a single case described by Wilkins and Beaty[201] after open reduction. We have not seen nonunion of this fracture. With infection, devascularization, and soft tissue loss, the risk of nonunion would presumably increase.

Avascular Necrosis in Supracondylar Fractures of the Distal Humerus

Avascular necrosis of the trochlea after supracondylar fracture has been reported. The blood supply of the trochlea's ossification center is fragile, with two separate sources. One small artery is lateral and courses directly through the physis of the medial condyle. It provides blood to the medial crista of the trochlea. If the fracture line is very distal, this artery can be injured, producing avascular necrosis of the ossification center and resulting in a classic fishtail deformity. Kim et al.[102] identified 18 children with trochlear abnormalities after elbow injuries, five of which were supracondylar fractures. MRI indicated low-signal intensity on T2 indicative of cartilage necrosis. Cubitus varus deformity developed in all cases.

Symptoms of avascular necrosis of the trochlea do not occur for months or years. Healing is normal, but mild pain and occasional locking develop with characteristic radiologic

FIGURE 16-57 Avascular necrosis of the trochlea developed following open reduction through a posterior approach. The child had limited motion and symptoms of occasional catching. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

findings and motion may be limited depending on the extent of AVN. An important risk for AVN of the trochlea is following an open reduction of a supracondylar fracture through a posterior approach which presumably disrupts the blood supply of the trochlea (Fig. 16-57).

Loss of Reduction in Supracondylar Fractures of the Distal Humerus

Sankar et al.[163] in a series of 322 fractures reported 2.9% had postoperative loss of fixation. All eight were Gartland type III fractures treated with just two pins (seven lateral entry and one cross pin). In all cases, loss of fixation was due to technical errors that were identifiable on the intraoperative fluoroscopic images and that could have been prevented with proper technique. They identified three types of pin-fixation errors: (1) Failure to engage both fragments with two pins or more, (2) failure to achieve bicortical fixation with two pins or more, and (3) failure to achieve adequate pin separation (>2 mm) at the fracture site (Fig. 16-58).

Clinical experience of a series of 124 consecutive SCH fractures including completely unstable fractures has taught us that lateral-entry pins, when properly placed, are usually strong enough to maintain reduction of even the most unstable SCH fracture.[173]

Cubitus Varus

Cubitus varus, also known as a "gunstock deformity" has a characteristic appearance in the frontal plane (Fig. 16-59). The malunion also includes hyperextension, which leads to increased elbow extension and decreased elbow flexion (Figs. 16-60 and 16-61). The appearance of cubitus varus deformity is distinctive upon x-ray. On the AP view, the angle of the physis of the lateral condyle (Baumann's angle) is more horizontal than normal (Fig. 16-62). On the lateral view, hyperextension of the distal fragment posterior to the AHL goes along with the clinical findings of increased extension and decreased flexion of the elbow (Fig. 16-63).

Some authors have proposed that unequal growth in the distal humerus causes cubitus varus deformity,[91,144] though this is unlikely as there is not enough growth in this area to cause cubitus varus within the time it is recognized. The most common reason for cubitus varus in patients with supracondylar fractures is likely malunion rather than growth arrest.[10,33,47,63,198] Cubitus varus can be prevented by making certain Baumann's angle is intact at the time of reduction and remains so during healing. Pirone et al.[147] reported cubitus varus deformities in 8 of 101 (7.9%) patients treated with cast immobilization compared to 2 of 105 (1.9%) patients with pin fixation, with ages ranging from 1.5 to 14 years (mean of 6.4 years). A decrease in frequency of cubitus varus deformity after the use

FIGURE 16-59 Five-year-old girl with cubitus varus of right elbow following a malunion of a supracondylar humerus fracture. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

of percutaneous pin fixation has been reflected in other recent series,[27,28,63,64,97,130,147] with one large retrospective[73] and one prospective study[104] reporting no cases of cubitus varus.

The distal humerus growth is 20% of that of its overall length. In a 5-year-old, therefore, the amount of distal humeral growth in 1 year is approximately 2 mm, making it unlikely that growth asymmetry is a significant cause of varus deformity that occurs within the first 6 to 12 months after fracture. Avascular necrosis of the trochlea or medial portion of the distal humeral fragment can result in progressive varus deformity, however. In a series of 36 varus deformities reported by Voss et al.,[194] only four patients had medial growth disturbance and

FIGURE 16-60 Hyperextension of right elbow. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

FIGURE 16-61 Decreased flexion of right elbow. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

distal humeral avascular necrosis as a cause of progressive varus deformity.

Treatment for cubitus varus has in the past been considered for cosmetic reasons only. However, there are several consequences of cubitus varus such as an increased risk of lateral condyle fractures, pain, and tardy posterolateral rotatory instability,

FIGURE 16-62 AP radiograph of the girl in preceding clinical photos. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, CA.)

FIGURE 16-63 Lateral radiograph shows overlapping of the distal humerus with the olecranon (*arrow*) producing the typical crescent sign. Note the anterior humeral line is anterior to the capitellum.

which may be indications for an operative reconstruction with a supracondylar humeral osteotomy.[1,2,22,48,127,137,183] Our experience suggested many patients have elbow discomfort with significant cubitus varus. Takahara et al.[190] reported nine patients with distal humeral fractures complicating varus deformity. Supracondylar fractures as well as epiphyseal separations were included in these nine fractures. Further problems complicating varus deformity involved the shoulder. Tardy ulnar nerve palsy has also been associated with varus and internal rotational malalignment.[83,132]

Cubitus varus deformity is also associated with a significant increase in late ulnar nerve palsies, as reported in the Japanese literature.[2,23,193] With a cubitus varus deformity, the olecranon fossa moves to the ulnar side of the distal humerus,[138] and the triceps shifts a bit ulnar ward. Investigators theorized that this ulnar shift might compress the ulnar nerve against the medial epicondyle, narrowing the cubital tunnel and resulting in chronic neuropathy. In a recent report,[2] a fibrous band running between the heads of the flexor carpi ulnaris was thought to cause ulnar nerve compression.

Treatment of Cubitus Varus Deformity. As for the treatment of any posttraumatic malalignment, options include: (a) Observation with expected remodeling, (b) hemiepiphysiodesis and growth alteration, and (c) corrective osteotomy. Observation is generally not appropriate because hyperextension may remodel to some degree in a young child (Fig. 16-64). In an older child, little remodeling occurs even in the joint's plane of motion.

Hemiepiphysiodesis of the distal humerus may rarely be of value, but only to prevent cubitus varus deformity from developing in a patient with clear medial growth arrest or trochlear

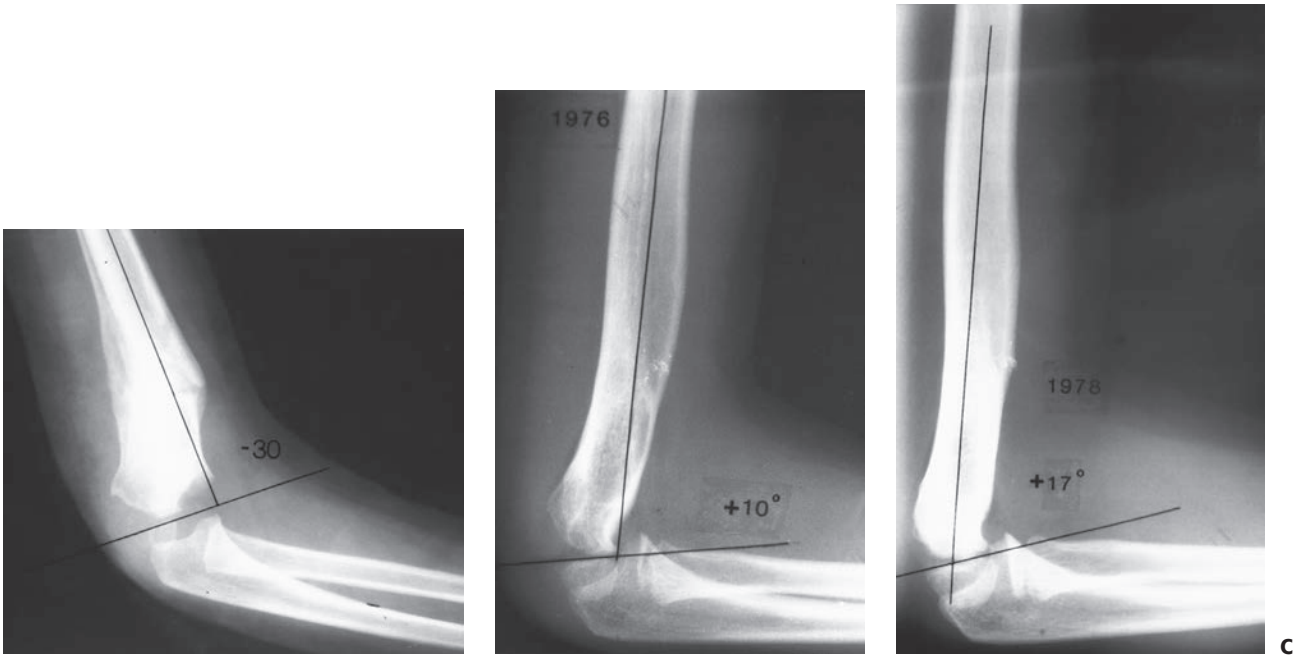

FIGURE 16-64 A hyperextension deformity in the distal humerus may remodel somewhat, whereas varus and valgus deformity do not. Hyperextension deformity in the distal humerus after fracture **(A)**. Four years later **(B)**, a more normal distal humeral anatomy is seen with remodeling of the hyperextension deformity; 2 years later, **(C)**, a normal distal humeral anatomy is reconstituted.

avascular necrosis. If untreated, medial growth disturbance will lead to lateral overgrowth and progressive deformity. Lateral epiphysiodesis will not correct the deformity, but will prevent it from increasing. Voss et al.[194] used hemiepiphysiodesis with osteotomy in two patients with growth arrest and varus deformity. The humerus varies in length by a few centimeters from one individual to another, but in general, it is about 30 cm long at skeletal maturity. Approximately 65% of the length of the humerus is achieved by age 6 years. A 6-year-old child has approximately 10 cm of growth left in the entire humerus, with only approximately 2 cm provided by the distal physis. Growth arrest, in the absence of avascular necrosis or collapse, will be a very slowly evolving phenomenon, and epiphysiodesis in a child older than 6 years will have little effect on longitudinal growth. In general, prevention of increasing deformity from medial growth arrest is the only role for lateral epiphysiodesis. Because of the slow growth rate in the distal humerus, we do not believe there is any role for lateral epiphysiodesis in correcting a varus deformity in a child with otherwise normal physis.

Osteotomy. Osteotomy is the only way to correct a cubitus varus deformity with a high probability of success. High complication rates in historic series have led to some controversy about the value of a distal humeral corrective osteotomy for cubitus varus deformity. In a review of 41 patients undergoing distal humeral osteotomies for malunions following SCH fractures at two major pediatric centers, Weiss et al.[199] reported a complication rate of 53% with a 32% return to the operating room in surgeries performed between 1987 and 1997. However, in surgeries performed from 1998 to 2002, the complication rate was 14% with a 0% reoperation rate. This group found when lateral-entry pins were used to fix the osteotomy there were significantly less complications.[199]

Because malunion is the cause of most cubitus varus deformities, the angular deformity usually occurs at the level of the fracture. Rotation and hypertension may contribute to the deformity, but varus is the most significant factor.[40] Hyperextension can produce a severe deformity in some patients. An oblique configuration (Fig. 16-65) places the corrective osteotomy's center of rotation as close to the actual level of the deformity as possible. On an AP x-ray of the humerus with the forearm in full supination, the size of the wedge and the angular correction needed are determined. An "incomplete" lateral closing wedge osteotomy may be performed, leaving a small medial hinge of bone intact. The osteotomy usually is fixed with two K-wires placed laterally. In the absence of an intact medial hinge, two lateral wires probably are not sufficient to secure this osteotomy.[194] Wilkins and Beaty[201] recommended crossed wires in this situation. In general, an oblique lateral closing wedge osteotomy with a medial hinge will correct the varus deformity, with minimal correction of hyperextension.[8,21,44,67,69,80,94,96,109,189,194,205] A transverse lateral closing wedge has more risk of a lateral bump with poor aesthetics. Residual rotational deformity was not found to be a significant problem in studies by Voss et al.[194] and Oppenheim et al,[142] which is logic given the amount of rotation available from the shoulder. The French osteotomy[67] aims to enable axial rotational correction as well, but does so at the expense of stability and we do not use this osteotomy.

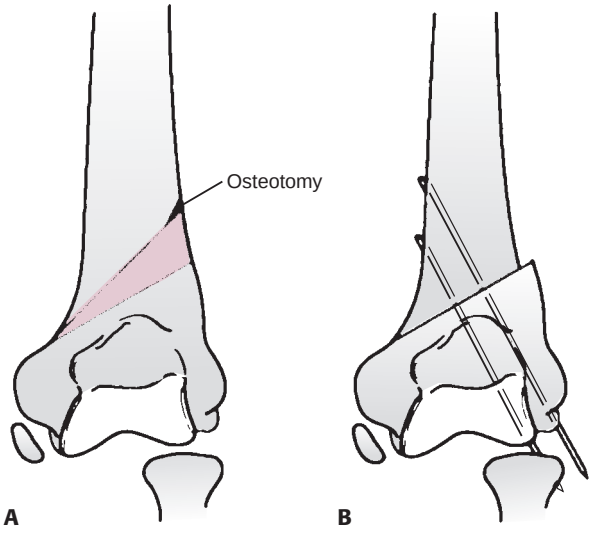

FIGURE 16-65 **A:** By moving the apex of the closing wedge distally, the osteotomy's center of rotation is moved closer to the deformity. **B:** Upon closing a distally based wedge osteotomy, there is less translational effect than in a more proximally based osteotomy.

Japanese surgeons[88] described a dome osteotomy in which a curved osteotomy is made in the supracondylar area. Proponents of this osteotomy suggest that multiplane correction is possible without inducing translation in the distal fragment and that rotation can be corrected. DeRosa and Graziano[52] described a step-cut osteotomy in which the distal fragment is slotted into the proximal fragment and the osteotomy is secured with a single screw. Functional outcomes are generally good, but the preoperative functional deficit is nearly always minor in patients with cubitus varus deformities.

Hyperextension deformity may remodel over time (Fig. 16-62), but correction is slow and inconsistent. In one series,[194] hyperextension deformities remodeled as much as 30 degrees in very young children, but in older children, there was no significant remodeling in the flexion/extension plane. If hyperextension appears to be a major problem, osteotomy should also be directed at this deformity rather than simple correction of the varus deformity; this situation requires a multiplane osteotomy.

Author's Preferred Treatment for Supracondylar Fractures of the Distal Humerus

We prefer to use a Wiltse type osteotomy, similar to that described by DeRosa but with the complete cut distal as possible, just superior to the olecranon fossa, to have the axis of rotation of the osteotomy as close as possible to the deformity (Fig. 16-66).[174] Preoperative templating is performed to determine the angle of correction required for correction of the varus and, if necessary, for correction of any extension deformity.

FIGURE 16-66 This osteotomy can address frontal and sagittal plane malalignment, and offer some inherent bony stability, while not producing a lateral bump which occurs with simple closing wedge osteotomies. *Hollow arrows* show triangles of bone that are removed, *solid arrow* shows rotation of fragment.

Templating is based on AP of bilateral upper extremities centered on the elbow combined with clinical examination comparing one arm to the other in terms of frontal plane appearance and arc of motion. For example, if the affected arm has 20 degrees more extension and 20 degrees less flexion than the contralateral arm, a 20-degree wedge is planned in the sagittal plane.

A longitudinal incision measuring approximately 6 cm is made over the lateral distal humerus. The antebrachial cutaneous nerve and its branches may be identified and protected. The radial nerve is generally proximal to the field of dissection. Dissection is carried out in the interval between the brachioradialis and triceps. Subperiosteal dissection is performed to expose the distal humerus. There is sometimes scarring from fracture healing about the area of fracture. Posterior dissection is continued to the olecranon fossa as a landmark, but not distal to it to prevent harming the blood supply to the trochlea. Chandler retractors are used for circumferential protection with special care medially near the ulnar nerve. An osteotomy is performed just above the olecranon fossa perpendicular to the shaft of the humerus. The proximal humerus is delivered out of the wound, to allow the more complex part of the osteotomy to be performed with maximal visualization and protection. At this second cut, the osteotomy is angled correctly to account for sagittal malalignment. On average, about a 20-degree anterior closing wedge is performed, but this may be adjusted as needed to make certain the postfixation image demonstrates the AHL is through the midthird of the capitellum. A small lateral portion of the proximal fragment is left intact and a similarly shaped area with a 90-degree angle is made in the lateral portion of the distal fragment using a rongeur to allow the pieces to fit together for added stability. This technique is adopted from the osteotomy described by Wiltse.[203] This prevents excessive lateral translation of the distal fragment, keeps the axis of rotation near the site of deformity, and has some inherent stability if done correctly. Once correction is achieved, bony contact is maximized by further cuts if needed. Three .062-in or 2-mm Kirschner wires are then placed across the osteotomy site from lateral to medial. A goniometer is used to measure alignment. Elbow flexion and extension are then checked to ensure that fingers can touch the ipsilateral shoulder and full extension is achieved. The wound is irrigated, a small amount of local bone graft from the excised wedge is packed around the osteotomy site but making certain bone graft is not in the olecranon fossa. After closure, flexion and extension are checked under live imaging to ensure that there is no motion at the osteotomy site. A long-arm cast is applied in 60 to 80 degrees of flexion with the arm at neutral in regards to supination and pronation. The cast is removed when good callus is demonstrated on radiographs, usually approximately 4 weeks postoperatively, and the pins are removed in clinic at that time. In eight cases performed by one of us with this technique there has been full frontal and sagittal plane correction with no complications (Figs. 16-67 to 16-70).[174]

Controversies Related to Supracondylar Fractures of the Distal Humerus

Flexion-Type Supracondylar Fractures of the Distal Humerus

Flexion-type supracondylar humeral fractures account for about 2% of humeral fractures.[121] A flexion pattern of injury may not be recognized until reduction is attempted because

FIGURE 16-67 AP radiograph of elbow of 5-year-old girl in cubitus varus with Baumann's angle about 0 degrees. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

FIGURE 16-68 Lateral radiograph demonstrates capitellum is posterior to the anterior humeral line. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

initial radiographs are inadequate. A key to recognizing a flexion-type supracondylar fracture is that it is unstable in flexion, whereas extension-type fractures generally are stable in hyperflexion. A laterally displaced supracondylar fracture may actually be a flexion-type injury.

Etiology and Pathology of Supracondylar Fractures of the Distal Humerus

The mechanism of injury is generally believed to be a fall directly onto the elbow rather than a fall onto the outstretched hand with hyperextension of the elbow (Fig. 16-71). The distal fragment is displaced anteriorly and may migrate proximally in a totally displaced fracture. The ulnar nerve is vulnerable in this fracture pattern,[65,85,121,160] and it may be entrapped in the fracture or later in the healing callus.[112] A meta-analysis of 146 flexion-type SCH fractures found an overall neuropraxia rate of 15%, with the ulnar nerve injury as the most common nerve injured (91%).[13]

FIGURE 16-69 Intraoperative AP image demonstrates restoration of Baumann's angle after Wiltse type osteotomy. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

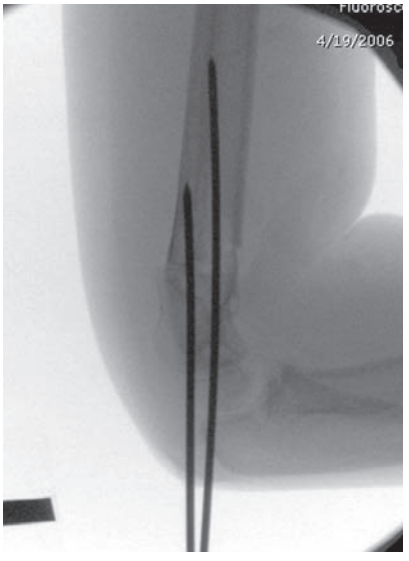

FIGURE 16-70 Lateral intraoperative image demonstrates the anterior humeral line now intersects the capitellum. Postoperatively a normal arc of elbow flexion and extension was restored. (Reproduced with permission from Children's Orthopaedic Center, Los Angeles, CA.)

X-Ray Findings of Supracondylar Fractures of the Distal Humerus

The x-ray appearance of the distal fragment varies from mild angular deformity to complete anterior displacement. Anterior displacement may be accompanied by medial or lateral translation. Associated fractures of the proximal humerus and radius can occur and any tenderness in these areas mandate full x-ray evaluation of the upper extremity. Fracture classification is similar to extension-type supracondylar fractures[72]: Type I, nondisplaced fracture; type II, minimally angulated with cortical contact; and type III, totally unstable displaced distal fracture fragment.

Treatment of Supracondylar Fractures of the Distal Humerus

In general, type I flexion-type supracondylar fractures are stable nondisplaced fractures that can simply be protected in a long arm cast.[58,135,153] If mild angulation, as in a type II fracture, requires some reduction in extension, the arm can be immobilized with the elbow fully extended. X-ray evaluation with the elbow extended is easily obtained and accurate in determining the adequacy of reduction. Reduction is assessed by evaluating Baumann's angle, the AHL intersecting the lateral condyle and

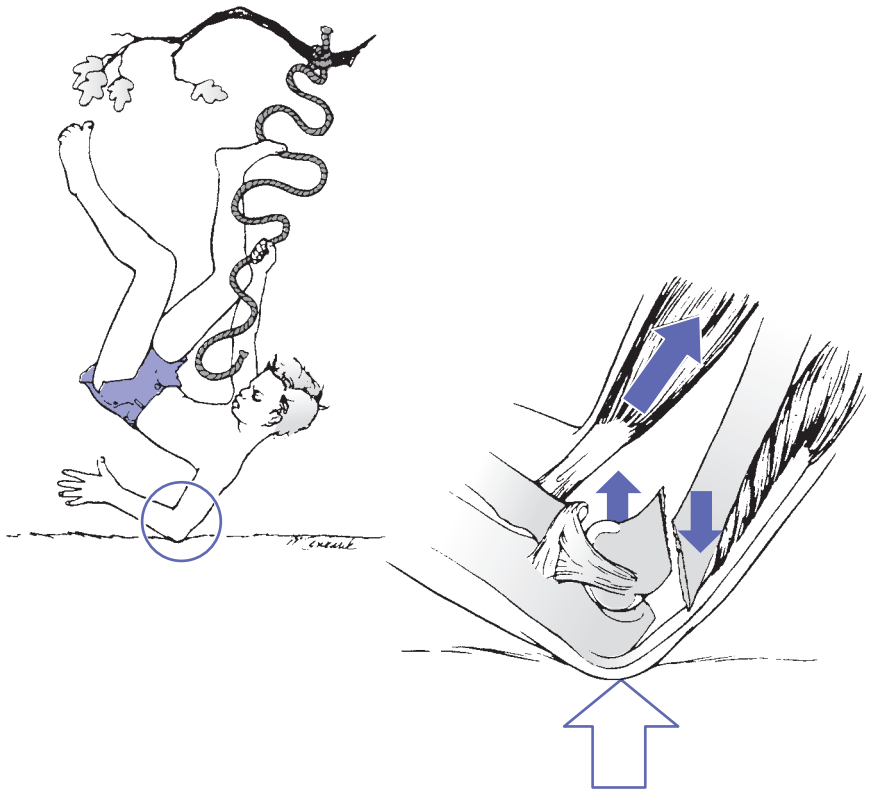

FIGURE 16-71 Flexion mechanism. Flexion-type fractures usually result from a blow to the posterior aspect of the elbow. The obliquity of the fracture line may be opposite that of an extension type. The large *white arrows* demonstrate the usual direction of fragment displacement.

the integrity of the medial and lateral columns at the olecranon fossa. If reduction cannot be obtained, as is often the case, or if rotation persists, soft tissue interposition, possibly the ulnar nerve, should be suspected. De Boeck[49] studied 22 flexion-type supracondylar fractures. He found cast treatment to be satisfactory in nondisplaced cases. In the other 15 cases, closed reduction and percutaneous pinning was successful in most patients.

A problem with type III flexion supracondylar fractures is that reduction is not easy to achieve and when achieved, the elbow is usually in extension, making it technically challenging to stabilize the distal fragment using pins.

Type I and II fractures (Figs. 16-72 and 16-73) are generally reduced if any angular displacement is seen on fluoroscopic intraoperative evaluation. Type II fractures can be immobilized in an extension cast with the elbow fully extended (Fig. 16-73). The cast is removed at 3 weeks. If closed reduction is performed without skeletal stabilization, follow-up x-rays usually are taken at 1 week and when the cast is removed at 3 weeks. True lateral x-rays in a fully extended cast are important, and may require a few attempts or use of live fluoroscopy.

Pinning is generally required for unstable type II and III flexion supracondylar fractures. The pinning technique described for extension-type supracondylar fractures is not appropriate for this fracture, because its instability in flexion precludes pinning with the elbow hyperflexed. In a flexion-type supracondylar fracture the posterior periosteum is torn, so reduction can be obtained in extension which places tension across the intact anterior periosteum. In general, a slightly less than anatomic reduction can be accepted as long as (a) there is no soft tissue interposition of tissue, (b) Baumann's angle is close to the other side, and (c) neither flexion nor extension is seen on the lateral view. Although

FIGURE 16-72 Type I flexion injury. A type I flexion supracondylar fracture pattern (*arrows*) in a 6-year-old below-the-elbow amputee. There is only about a 10-degree increase in the shaft condylar angle. The patient was treated with a simple posterior splint.

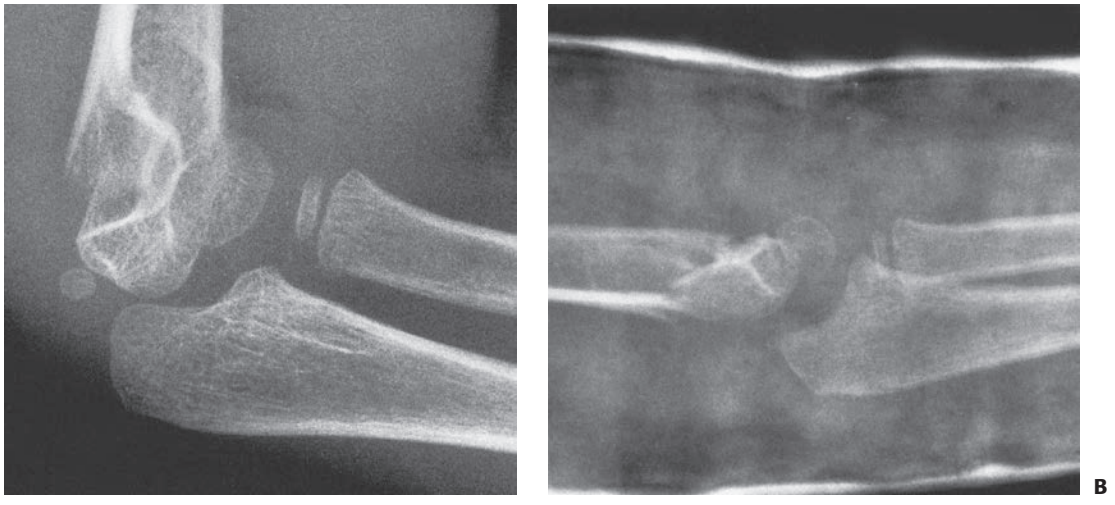

FIGURE 16-73 Closed reduction, extension cast. **A:** A 5-year-old girl sustained a type II flexion pattern. **B:** She was manipulated into extension and found to be stable, and thus was maintained in a long-arm cast in extension.

rotating the arm is often possible for a lateral view of extension supracondylar fracture, the C-arm must be moved to obtain satisfactory x-ray results when pinning a flexion-type supracondylar fracture, because they are often rotationally unstable even when reduced (Fig. 16-43).

Pinning is generally performed with the elbow in approximately 30 degrees of flexion, holding the elbow in a reduced position. If closed reduction can be obtained, pinning can be accomplished in this position. Placing two lateral-entry pins in the distal fragment first, allows them to be used as a joy stick and help manipulate the fracture into a reduced position, at which time the pins may be driven across the fracture site (Fig. 16-74).

If the fracture is held in anatomic position with pins, a flexed-arm cast can be used to provide better patient comfort, but a cast with the elbow in almost full extension is acceptable.

Open reduction may be required for flexion-type supracondylar fractures. Open reduction is best performed through an anteromedial or posterior approach, rather than an anterior approach, as is used for extension-type supracondylar fractures. With flexion-type fractures, brachialis remains intact and must be retracted to expose the fracture, necessitating a medial extension to the anterior approach. To ensure that the ulnar nerve is not entrapped in the fracture site, exploring the ulnar nerve or at least identification is probably advisable with this fracture, which is another reason for a medial approach to open reduction.

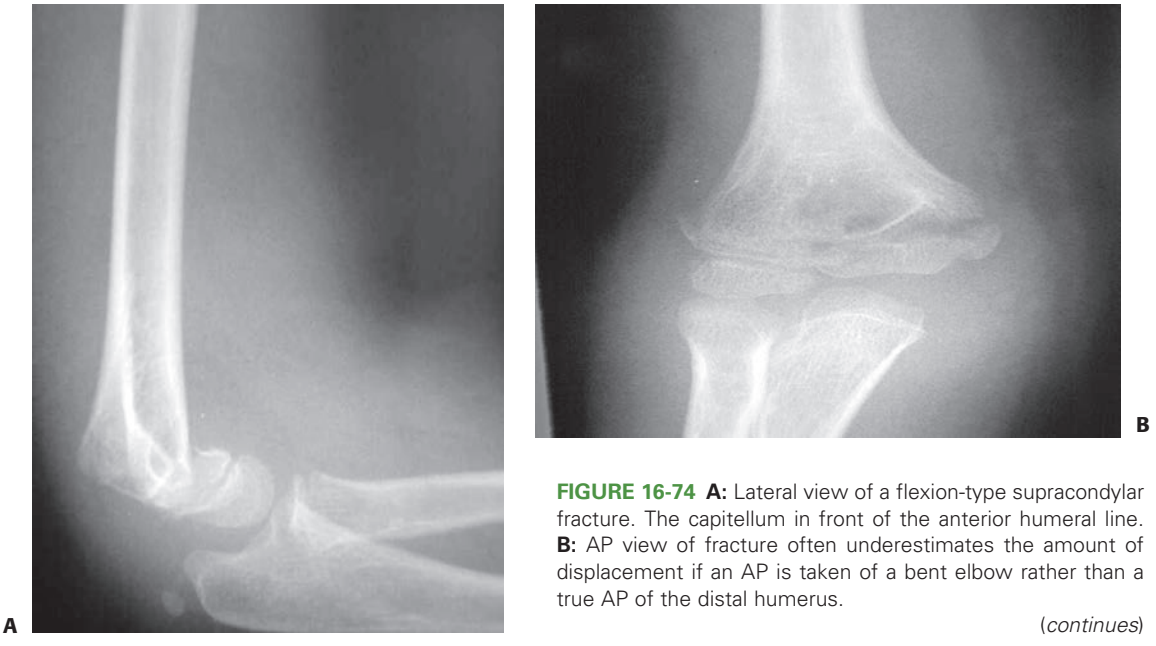

FIGURE 16-74 **A:** Lateral view of a flexion-type supracondylar fracture. The capitellum in front of the anterior humeral line. **B:** AP view of fracture often underestimates the amount of displacement if an AP is taken of a bent elbow rather than a true AP of the distal humerus.

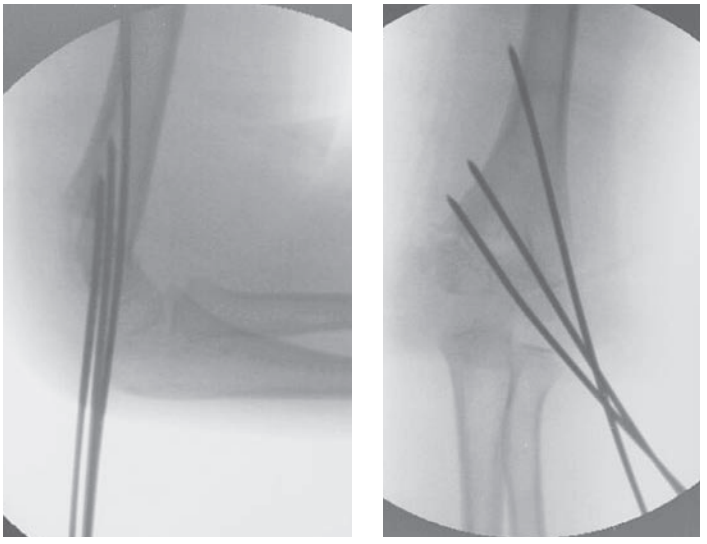
(*continues*)



C D

FIGURE 16-74 (*continued*) **C:** Intraoperative view shows anatomy has been restored, with the anterior humeral line crossing the middle third of the capitellum. **D:** AP view demonstrates three well-placed lateral pins with maximal separation at fracture site, with all pins engaging solid bone.

Anteromedial Open Reduction of Flexion-Type Supracondylar Fractures

The surgeon makes a transverse incision across the antecubital fossa, curving proximally posterior to the neuromuscular bundle. Dissection is carried down to the level of the superficial fascia of the forearm and antecubital fossa. The neurovascular bundle is identified and retracted medially. The brachialis and biceps tendons are retracted laterally to expose the fracture site and facilitate reduction. If there is medial soft tissue impingement or a question of ulnar nerve entrapment within the fracture, the dissection should be carried around posterior to the medial epicondyle, so the ulnar nerve and fracture can be identified.

Postoperative immobilization is maintained for 3 or 4 weeks until good callus formation is present. Pins are generally left out through the skin and removed in the office without the need for anesthetic. No immediate rehabilitation is given, but the patient is encouraged to begin gentle activities with the arm and to begin regaining motion without a stressful exercise program.

Author's Preferred Treatment

In general, we treat type I flexion supracondylar fractures with a splint or cast with the elbow flexed for comfort. Minimally displaced type II fractures that reduce in extension are treated in an extension cast. Unstable types II and III fractures are pinned. Open reduction through an anteromedial or posterior approach is used if an anatomic closed reduction cannot be obtained. If a posterior approach is used care is taken to avoid posterior soft tissue dissection of distal fragment to avoid injuring the blood supply to the trochlea. The ulnar nerve is identified and protected throughout the exposure and fracture stabilization.

17 T-CONDYLAR DISTAL HUMERUS FRACTURES

Benjamin Shore and Peter M. Waters

INTRODUCTION TO T-CONDYLAR DISTAL HUMERUS FRACTURES

In T-condylar fractures, the fracture line originates in the central groove of the trochlea and courses proximal to the olecranon and coronoid fossae, where it divides and separates the medial and lateral bony columns of the distal humerus. If the proximal fracture lines are oblique, the fracture may be termed *Y-condylar.* T- and Y-condylar fractures are rare injuries in skeletally immature children and are often a transitional fracture seen in adolescents at the end of skeletal development.

Incidence of T-Condylar Distal Humerus Fractures

The early modern literature reflects only reports by Blount[5] and Zimmerman,[33] who each described a case of a T-condylar distal humerus fracture in an 11-year-old patient. The average age of pediatric patients reported in four major case series[15,18,23,25] was 12.8 years. Three studies have found that the nondominant arm is more likely to be injured 2.5 times greater than the dominant arm.[20,22,25] Thus, Maylahn and Fahey,[21] who reported six patients near skeletal maturity, were accurate when they said, "the fractures (T-condylar) take on the characteristics of an adult fracture and should be treated as such."

The actual incidence in younger children is certainly low, but it may be underdiagnosed because it is often confused with other fractures, such as those involving the lateral condylar physis or total distal humeral physis. Special imaging studies such as arthrograms or MRI scans may be necessary to demonstrate the intracondylar aspects in young children. The combination of an increased awareness of the possibility of this injury and a more aggressive diagnostic approach may result in more cases being recognized acutely and appropriately treated in this younger age group.

ASSESSMENT OF T-CONDYLAR DISTAL HUMERUS FRACTURES

Mechanisms of Injury of T-Condylar Distal Humerus Fractures

The primary mechanism of this injury is the direct wedge effect of the articular surface of the olecranon on the distal end of the humerus. The sharp edge of the semilunar notch or coronoid process acts as a wedge to break the trochlea and split the condyles, which in turn separates the two columns of the distal humerus. Flexion and extension types of injuries have been described.

The most common mechanism producing a flexion injury is a direct blow to the posterior aspect of the elbow, usually when

the child falls directly on the flexed elbow. This flexion mechanism in young children contributes to its rarity because most upper-extremity injuries in children result from a fall on an outstretched hand and have a component of elbow hyperextension. In these flexion injuries, the wedge effect is produced at the apex of the trochlea by the central portion of the trochlear notch. The condylar fragments usually lie anterior to the shaft in these flexion injuries (Fig. 17-1A, B).

A T-condylar fracture may also be caused by a fall on the outstretched arm with the elbow in only slight flexion. This extension mechanism has been suggested by patients in their description of the dynamics of the fall and indirectly by the position of the distal fragments in relation to the diaphyses of the humerus—in other words, lying posterior (Fig. 17-1C, D). In the extension type of injury, the coronoid portion of the semilunar notch produces the wedge effect.

FIGURE 17-1 **A–D:** Mechanism patterns. **A, B:** The more common flexion pattern in which the condylar fragments are situated anterior to the distal shaft. **C, D:** An extensor pattern in which the condylar fragments are situated posterior to the distal shaft. The muscle origins on the respective condyles cause them to diverge in the coronal plane (*arrows*) and flex in the sagittal plane.

It has been suggested that contraction of the forearm flexor and extensor muscles may play a role in the displacement pattern of this fracture. Because of their origins on the epicondyles, they accentuate both the separation in the coronal plane and the forward displacement in the sagittal plane. This displacement pattern is often evident on the injury films (Fig. 17-1C, D).

Associated Injuries with T-Condylar Distal Humerus Fractures

Very little has been written on the type of associated injuries seen with T-condylar distal humerus fractures in children. In general, these are high-velocity injuries which are typically the result of high-energy mechanisms, such as motor vehicle collisions, high-speed sporting accidents or falls from significant heights.[14] Open wounds, other ipsilateral upper limb injuries, and general systemic injury can occur because of the heightened energy of the trauma that occurs.

Signs and Symptoms of T-Condylar Distal Humerus Fractures

The history should focus on the mechanism and time of injury and the identification of other sites of injury. It is important to recognize any prior elbow injury or upper extremity surgery. Rounding out the history would include gathering information on pre-existing medical conditions, medication, and hand dominance.

In addition to a complete physical examination, a detailed head-to-toe trauma assessment should be completed, to rule out significant concomitant injuries to the axial and appendicular skeleton. Focused examination of the injured extremity should include inspection for bruising, swelling, deformity, and evidence of any open injuries. A thorough circumferential inspection of the elbow is critical to avoid missing open wounds, which commonly occur on the posterior aspect.[20] Careful examination of distal vascular status is performed, inspecting the distal extremity for color, turgor, and palpating the radial and ulnar pulses. If there is a questionable pulse in the setting of gross malalignment of the arm, gentle longitudinal traction can be used to realign the limb and often restore the distal pulse. A detailed distal neurologic examination including motor function, hand sensibility, and two-point discrimination (median and ulnar nerves) should be performed to identify injury to the median, ulnar, radial, anterior, and posterior interosseous nerve. At the conclusion of the examination, the arm is splinted for comfort in a padded posterior, above-elbow splint.

Imaging and Other Diagnostic Studies for T-Condylar Distal Humerus Fractures

Clinically, these fractures are most often confused with extension-type supracondylar fractures. The extended position of the elbow, along with the massive swelling, is almost identical to that of the displaced extension type of supracondylar fracture.

Plain radiographs are the cornerstone to the diagnosis. In older children, the differentiation must be made from that of a comminuted supracondylar fracture. Sometimes, the diagnosis is not obvious until the fragments have been partially reduced, which allows the vertical fracture lines splitting the trochlea to become more evident. In younger children, the diagnosis is much more difficult because the articular surface is cartilaginous and not visible on plain radiographs. In addition, because of its rarity, the possibility of a T-condylar fracture may not be considered in this age group.

The diagnosis must exclude common fracture patterns of either the isolated lateral or medial condyles and complete separation of the distal humeral physis. In these latter fractures, an important sign is the presence of a medial or lateral Thurston–Holland fragment in the metaphysis.[4] The key differential for the T-condylar fracture is the presence of a vertical fracture line extending down to the apex of the trochlea.

If the diagnosis is suspected after a careful evaluation of the static radiographs, it can be confirmed with a preoperative CT scan for adolescent children, MRI in younger children, or varus/valgus stress films made while the patient is under general anesthesia.[4] The use of contrast medium in the form of an arthrogram intraoperative can also be helpful to distinguish fracture lines and aid in the assessment of the quality of the articular reduction.

Classification of T-Condylar Distal Humerus Fractures

Fracture Pattern

The fracture pattern in adolescents is similar to that in adults. The condylar fragments are often separated, with the articular surface completely disrupted. In addition to separation of the condylar fragments by the force of the original injury, the muscles that originate on these condylar fragments rotate them in both the coronal and sagittal planes (Fig. 17-1C, D). In the sagittal plane, the position of the condylar fragments in relation to the humeral shaft and metaphysis can either be anterior (flexor mechanism; Fig. 17-1B) or posterior (extension mechanism; Fig. 17-1D).

In skeletally immature patients, the central portions of the condylar fragments are usually separated, but the articular surface may remain intact because of its large cartilage component (Fig. 17-2).[23] Thus, the disruption and displacement are primarily in the osseous supracondylar area. The elasticity of the cartilage of the distal end of the humerus often acts as an opening hinge but protects the articular surface from being completely disrupted.

Classification

Various classifications[15,27] for adult T-condylar fractures have been proposed, but there are problems with applying these classifications to children's injuries. For example, the number of young children with this fracture is so small that it limits the experience of any one clinician in treating all types of fracture patterns. In addition, there is no useful classification for younger patients, in whom the unossified intact articular cartilage is not visible on plain radiographs. Toniolo and Wilkins[30] proposed a simple classification based on the degree of displacement and comminution of the fracture fragments for pediatric T-condylar fractures. Type I fractures are minimally displaced (Fig. 17-3A, B, C).

FIGURE 17-2 Intact articular surface. In this T-condylar fracture in a 7-year-old boy, the thick articular cartilage remains essentially intact, preventing separation of the condylar fragments. This fracture was secured with simple percutaneous pins.

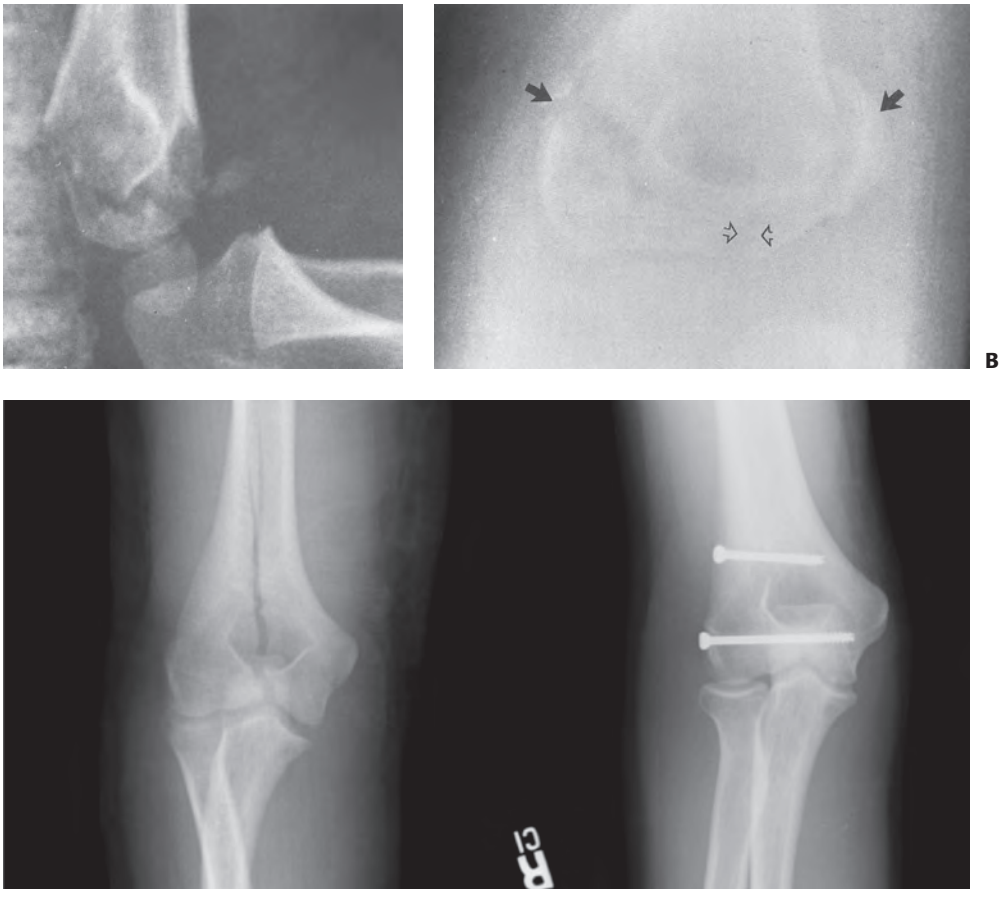

FIGURE 17-3 Examples of Type I T-condylar fractures. **A:** Lateral view of Type I undisplaced T-condylar fracture in a 6-year-old. **B:** AP of the t-Condylar fracture line (*open arrows*) was not appreciated until it healed. There are both medial and lateral Thurstan–Holland fragments (*solid arrows*) (Courtesy of Ruben D. Pechero, MD). **C:** Pre- and postoperative x-rays of minimally displaced intra-articular Type I T-condylar fracture in a 16-year-old boy treated with closed reduction and percutaneous screw fixation.

A

B

FIGURE 17-4 Type II displaced T-condylar factures. **A:** Type II displaced T-condylar fracture with very little metaphyseal comminution. **B:** Pre- and postoperative images of displaced Type II T-condylar fracture with significant displacement but no comminution, treated with olecranon osteotomy and bicolumn rigid fixation to facilitate early range of motion.

Type II fractures are displaced but do not have comminution of the metaphyseal fragments (Fig. 17-4AB). Type III fractures are displaced fractures with comminution of the metaphyseal fragments (Fig. 17-5A-F).

In a child, the integrity of the articular surface may be difficult to determine without using arthrography or MRI. Because disruption of the articular surface is rare, this factor was not used in those general classification schemes. However, it is imperative to know the status of articular alignment pre- and posttreatment.

In adolescents aged 12 years or older, classification and treatment follow similar patterns to those for adults. In general intra-articular humerus fractures are defined by column (medial, lateral, or both) and degree of comminution. The Arbeitsgemeinschaft für Osteosynthesefragen (AO) classification is used most often (Fig. 17-6). T-condylar fractures in the adolescent are usually AO C1 and C2 injuries.[25] Fortunately C3 injuries with marked comminution is rare in the adolescent. Metaphyseal–diaphyseal fractures are separate entities and need to be recognized as such for proper treatment and fixation decisions.[10]

Outcome Measures for T-Condylar Distal Humerus Fractures

Common clinical outcomes recorded in T-condylar distal humerus fractures include, time to union, range of motion, and elbow strength as measured through Cybex testing. Functional outcome scores for both operative and nonoperative treatments such as the Objective Functional Elbow Index[6] and the Disability of the Arm, Shoulder, and Hand[8] (DASH) are frequently used to measure functional improvement after upper extremity surgery.

Pathoanatomy and Applied Anatomy Relating to T-Condylar Distal Humerus Fractures

The elbow is a complex joint composed of three individual joints contained within a common articular cavity. Ossification of the distal humerus proceeds at a predictable rate. However, the rate of ossification in girls generally exceeds that of boys.[9,11,12] In some areas, such as the olecranon and lateral epicondyle, the difference between boys and girls in ossification age may be as great as 2 years.[11] Knowledge of the sequence and timing of ossification in the elbow will aide the treating physician in differentiating true intercondylar pathology from normal anatomic variant.

The bone of the distal humerus is triangular in shape. The medial and lateral columns of the distal humerus form the supracondylar region and are characterized by sharp and thin ridges of bone, respectively.[3] At the base of the triangle lies the trochlea, which represents the most distal portion of the humerus. It is important to realize that the lateral column of the distal humerus curves anteriorly along with the anteriorly translated articular surface of the distal humerus, but the medial column is straight in line with the humeral diaphysis. The spatial

FIGURE 17-5 Type III T-condylar fractures with significant displacement and comminution. **A, B:** Type III—two views of markedly comminuted T-condylar fracture with multiple displaced fragments (*arrows*) in a 12-year-old. **C–F:** Pre-, intra-, postoperative, and final healed radiographs of a 12-year-old girl with displaced and severely comminuted distal humerus and ipsilateral distal radius fracture, treated with a combination of transarticular screw and cross-wire fixation. At 1 year she has made a complete recovery with comparable range of motion to her contralateral elbow.

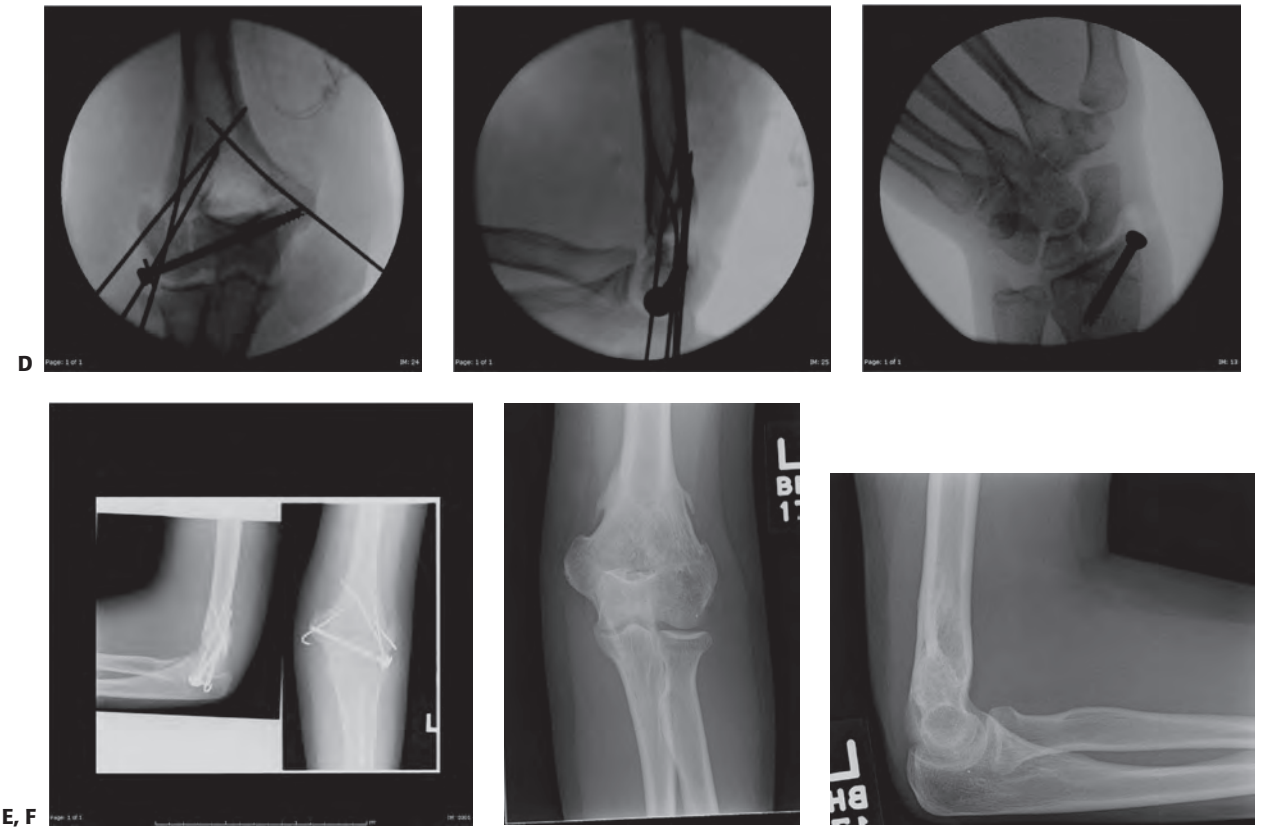

FIGURE 17-5 (*continued*)

relationship between the medial column, lateral column, and trochlea are conceptually similar to a spool of thread being held between the thumb and index finger.[16]

The surgical approach for distal humerus fractures most widely accepted is an extensile posterior incision through which all aspects of the elbow can be exposed including the anterior structures.[24] The ulnar nerve is frequently a structure that needs to be identified and protected during open reduction and internal fixation. It passes through the cubital tunnel just posterior to the medial epicondyle and is held in close proximity to the distal elbow by Osborne's fascia. Higher on the lateral side the radial nerve pierces the intermuscular septum where it is vulnerable to injury by a fracture or surgical exposure.

Treatment Options for T-Condylar Distal Humerus Fractures

Because of the rarity of this injury, treatment recommendations are based on isolated case or small retrospective case series and/or the application of adult treatment principles.[1,4,15,18,23,25,26,31] Regardless of the treatment method, certain basic principles must be considered in dealing with these fractures.

A treatment plan must be individualized for the specific fracture and the surgeon's level of expertise and experience. The following principles must be considered in planning a treatment method:

- The T-condylar fracture is an articular fracture, so the first goal is to restore and stabilize the joint surface.
- Stability depends on the integrity of the lateral and medial supracondylar columns.
- Elbow articular mobility depends on articular congruity, correct alignment of the axis of motion, and debris- and bone-free fossae.
- Closed methods alone usually cannot produce an acceptable result because the muscle forces applied to the fragments make the fracture unstable.
- Most patients are adolescents with minimal potential for bone remodeling and should be treated with bicolumn open reduction and internal fixation similar to an adult.
- Although surgical reduction may produce an acceptable reduction on radiograph, it may add to the already extensive damage to soft tissues; this in turn can contribute to postoperative stiffness. Stable internal fixation that allows for immediate postoperative movement is important in reducing the risk of contracture development.

Nonoperative Treatment of T-Condylar Distal Humerus Fractures

Indications/Contraindications

The majority of T-condylar distal humerus fractures are best treated with some form of open reduction and internal fixation. However, there is a narrow range of fractures that are indicated for management of these injuries with closed reduction and

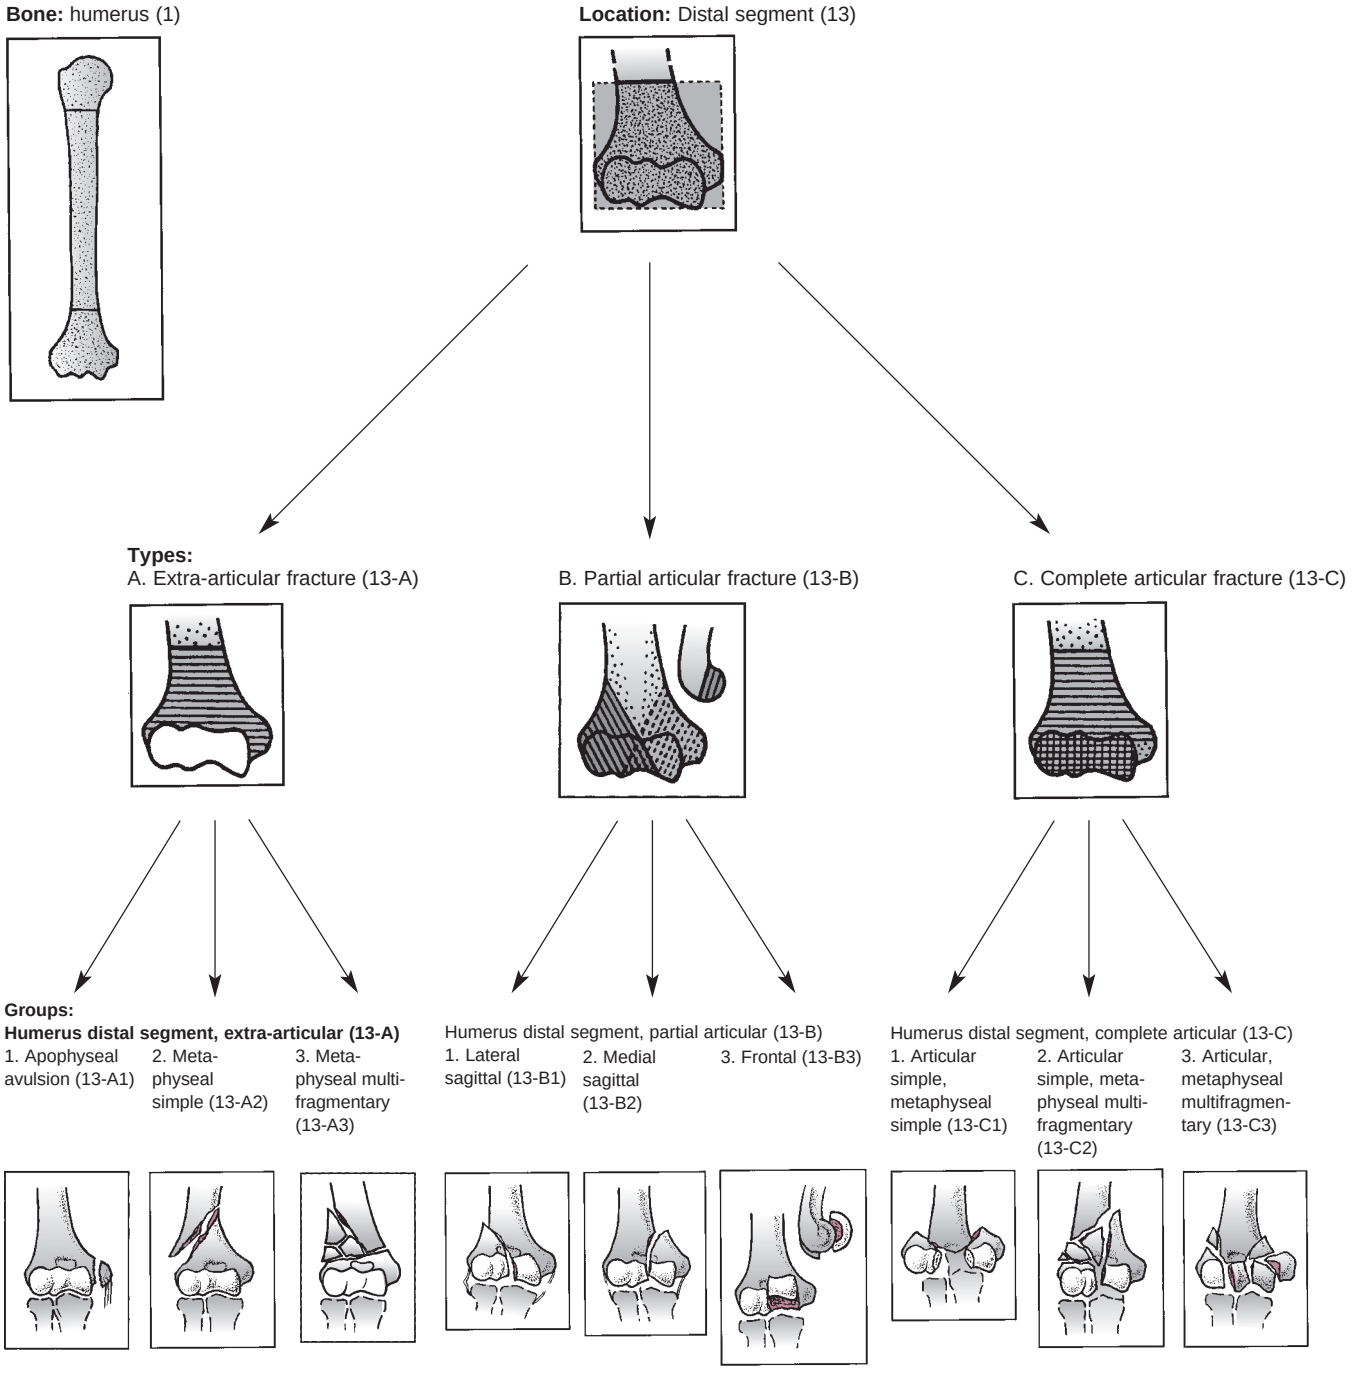

FIGURE 17-6 The AO classification of distal humerus fractures—fractures are classified as extra-articular, partial articular, and complete articular fracture and treatment can be tailored based on fracture classification. (Redrawn from Marsh JL, Slongo TF, Agel J, et al. Fracture and dislocation classification compendium—2007: Orthopaedic Trauma Association classification, database, and outcomes committee. *J Orthop Trauma* 2007;21(suppl 10):S1–133, with permission.)

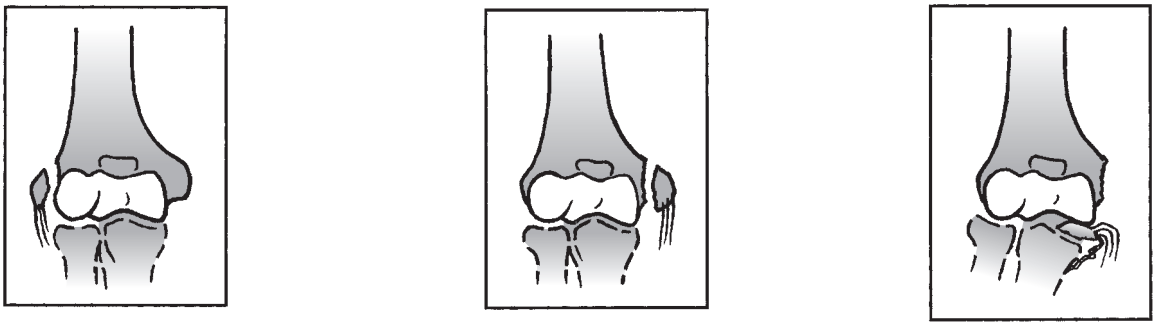
Subgroups and Qualifications:

Humerus, distal, extra-articular apophyseal avulsion (13-A1)

1. Lateral epicondyle (13-A1.1)
2. Medial epicondyle, nonincarcerated (13-A1.2)
   (1) nondisplaced
   (2) displaced
   (3) fragmented
3. Medial epicondyle, incarcerated (13-A1.3)

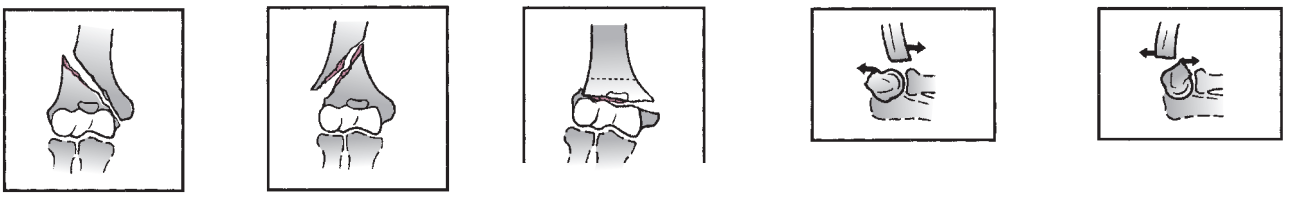
A1



Humerus, distal, extra-articular metaphyseal simple (13-A2)

1. Oblique downward and inward (13-A2.1)
2. Oblique downward and outward (13-A2.2)
3. Transverse (13-A2.3)
   (1) transmetaphyseal
   (2) juxtaepiphyseal with posterior displacement (Kocher I)
   (3) juxtaepiphyseal with anterior displacement (Kocher II)

A2



Humerus, distal, extra-articular metaphyseal multifragmentary (13-A3)

1. With intact wedge (13-A3.1)
   (1) lateral
   (2) medial
2. With fragmented wedge (13-A3.2)
   (1) lateral
   (2) medial
3. Complex (13-A3.3)

A3

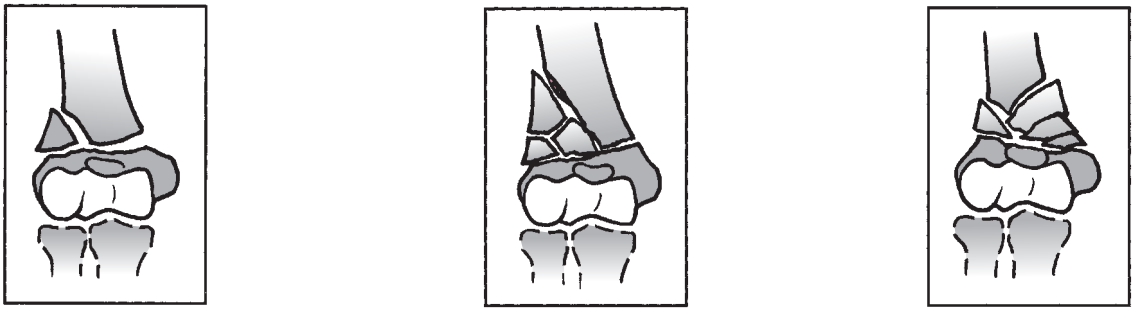


FIGURE 17-6 (*continued*)

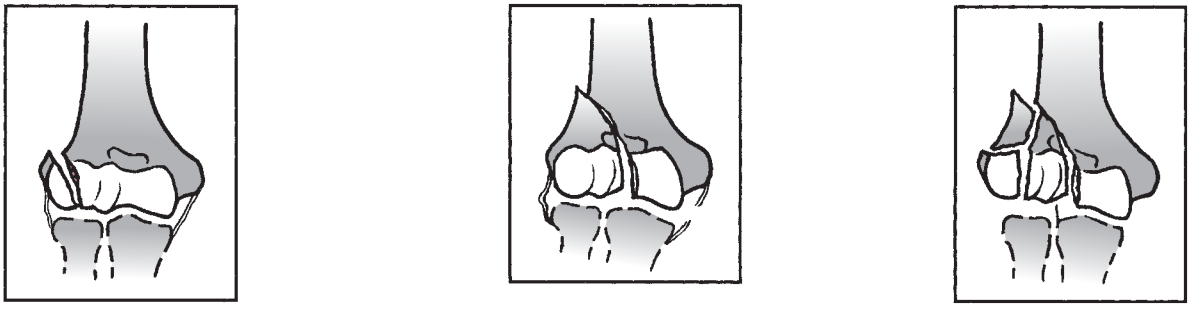
Humerus, distal, partial articular, lateral sagittal (13-B1)

1. Capitellum (13-B1.1)
(1) through the capitellum (Milch I)
(2) between capitellum and trochlea

2. Transtrochlear simple(13-B1.2)
(1) medial collateral ligament intact
(2) medial collateral ligament ruptured
(3) metaphyseal simple (classic Milch II) lateral condyle
(4) metaphyseal wedge
(5) metaphysio-diaphyseal

3. Transtrochlear multifragmentary (13-B1.3)
(1) epiphysio-metaphyseal
(2) epiphysio-meta-physeal-diaphyseal

B1



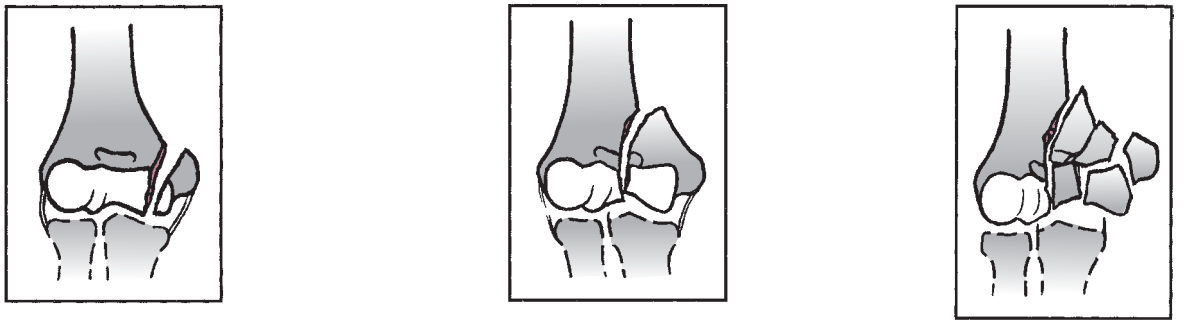
Humerus, distal, partial articular, medial sagittal (13-B2)

1. Transtrochlear simple, through medial side (Milch I) (13-B2.1)

2. Transtrochlear simple, through the groove (13-B2.2)

3. Transtrochlear multifragmentary (13-B2.3)
(1) epiphysio-metaphyseal
(2) epiphysio-metaphyseal-diaphyseal

B2



Humerus, distal, partial articular, frontal (13-B3)

1. Capitellum (13-B3.1)
(1) incomplete (Kocher-Lorenz)
(2) complete (Hahn-Steinthal 1)
(3) with trochlear component (Hahn-Steinthal 2)
(4) fragmented

2. Trochlea (13-B3.2)
(1) simple
(2) fragmented

3. Capitellum and trochlea (13-B3.3)

B3

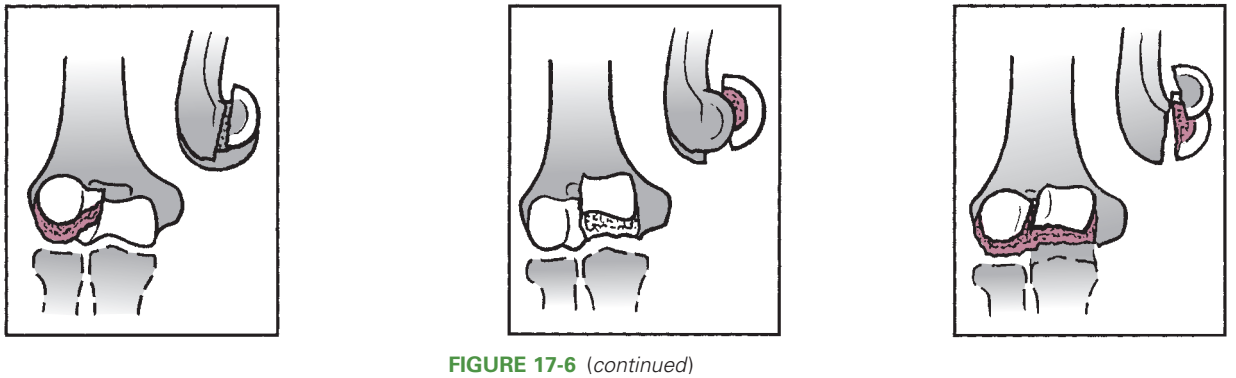


FIGURE 17-6 (*continued*)

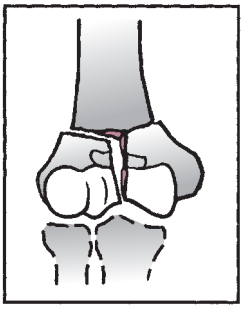
Humerus, distal complete, articular simple, metaphyseal simple (13-C1)

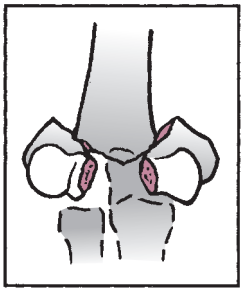
1. With slight displacement (13-C1.1)
(1) Y-shaped
(2) T-shaped
(3) V-shaped

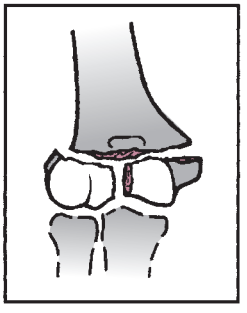
2. With marked displacement (13-C1.2)
(1) Y-shaped
(2) T-shaped
(3) V-shaped

3. T-shaped epiphyseal (13-C1.3)

C1







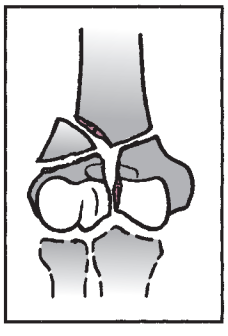
Humerus, distal, complete articular simple metaphyseal multifragmentary (13-C2)

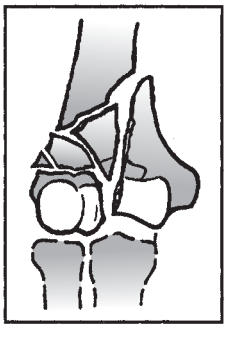
1. With intact wedge (13-C2.1)
(1) metaphyseal lateral
(2) metaphyseal medial
(3) metaphysio-diaphyseal-lateral
(4) metaphysio-diaphyseal-medial

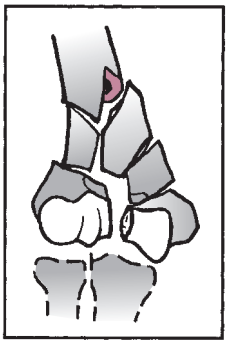
2. With a fragmented wedge (13-C2.2)
(1) metaphyseal lateral
(2) metaphyseal medial
(3) metaphysio-diaphyseal-lateral
(4) metaphysio-diaphyseal-medial

3. Complex (13-C2.3)

C2







Humerus, distal, complete multifragmentary (13-C3)

1. Metaphyseal simple (13-C3.1)

2. Metaphyseal wedge (13-C3.2)
(1) intact
(2) fragmented

3. Metaphyseal complex (13-C3.3)
(1) localized
(2) extending into diaphysis

C3

TABLE 17-1 T-Condylar Distal Humerus Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Young children <8 yrs with intact periosteum	Fracture displacement >2 mm
Simple fractures without comminution, displacement, and angulation	Fracture comminution Ipsilateral arm injuries

casting. Children who are under 8 years of age with robust periosteum and essentially nondisplaced fractures are good candidates for closed reduction and casting (Table 17-1).

Techniques

A very small number of T-condylar distal humerus fractures can potentially be treated with immobilization exclusively. Nondisplaced fractures can be splinted or casted until healing with close radiographic follow-up. An above-elbow cast is applied for at least 3 weeks with repeat x-rays on a weekly interval to detect interval displacement. Some clinicians perform a closed reduction for very minimally displaced fractures. Reduction under conscious sedation or anesthesia with in-line traction and live fluoroscopy is necessary to ensure that acceptable reduction is maintained. Review of reduction may be necessary with three-dimensional (3D) imaging in the form of CT or MRI. To be honest, we rarely treat fractures with any displacement closed. If a reduction is required, we view this as an unstable injury and at a minimum, will utilize three percutaneous pins to stabilize the anatomic alignment of the articular surface and both columns.

Outcomes

The majority of T-condylar distal humerus fractures are treated operatively, and therefore it is very difficult to tease out the results of nonoperative management of these fractures. In our review of several series, only 4 of 48 combined fractures were treated nonoperatively.[18,23,25] In these limited cases, all patients achieved a full arc of motion without complications from their fracture or treatment.

Operative Treatment of T-Condylar Distal Humerus Fractures

Indications/Contraindications

Adolescents with T-condylar distal humerus fractures are usually treated with bicolumn open reduction and internal fixation similar to an adult. Indications for open reduction and internal fixation include all displaced extra-articular fractures, displacement of the articular surface greater than 2 mm, comminution of the distal humerus with greater than two fracture fragments, and ipsilateral fracture(s) of the upper extremity. Open fractures, pending compartment syndromes, and avascular limbs are surgical emergencies. However, the majority of T-condylar distal humerus fractures can be treated electively within 72 hours from the initial injury.

In adolescents, the majority of T-condylar distal humerus fractures are C1 according to the AO classification (Fig. 17-6). Therefore, choosing either a triceps splitting or triceps reflecting approach is sufficient to facilitate access for open reduction and internal fixation. In the rare circumstances of C2 or C3 fractures, especially in the setting of anterior comminution, an olecranon osteotomy is warranted to facilitate visualization and fixation of the articular surface.

Closed Reduction and Percutaneous Pin/Screw Fixation

In young children (<8 years) with robust periosteum, the T-condylar distal humerus fracture may represent isolated hinging of the periosteum with minimal displacement of the intercondylar fracture. Careful preoperative imaging will demonstrate merely hinging of the articular surface without significant displacement. In younger children with minimal displacement, it is not unreasonable to perform a fluoroscopic guided reduction and stabilization with multiple percutaneous pins. Generally three smooth, appropriate-sized wires are used: One horizontally from the lateral to medial to stabilize the joint surface and two to stabilize the medial and lateral columns. These pins can either be divergent lateral entry or both medial and lateral entry pins.

In older children with minimal displacement, especially single column intra-articular fractures, percutaneous reduction and cannulated column screw fixation is acceptable. This, to some degree violates standard adult principles of open reduction internal fixation. However, if anatomic articular alignment and stable internal fixation can be achieved percutaneously, then less invasive treatment is appropriate. It is critical to have superior fluoroscopic images intraoperatively to prevent the realization of persistent fracture fragment displacement and/or inadvertent screw malposition with the first set of postoperative radiographs.

Preoperative Planning. Surgical planning includes decisions on percutaneous pin versus screw fixation and patient positioning in the operative room. Careful scrutiny of preoperative radiographs and 3Dimaging (usually CT scans) is imperative. Sometimes, intraoperative fluoroscopy images with traction realignment are essential in final decision making about surgical approach and fixation methods. Percutaneous treatment should only be chosen if anatomic reduction and stable fixation can be achieved with limited postoperative immobilization to lessen the risk of elbow contracture.

Similar principles for displaced adult distal humerus intra-articular fractures are employed, with reduction and stabilization of the articular surface first, followed by stabilization of the medial and lateral columns. If percutaneous reduction and fixation is performed, a large, external bone holding the reduction clamp is used to facilitate interfragmentary reduction and compression of the joint, prior to pin or screw fixation. Accurate placement of a transverse pin to hold the articular segments in an anatomic position is critical. Depending on the degree of displacement and fracture fragment configuration, provisional or definitive fixation can be achieved with standard medial and lateral column pins as in a supracondylar humerus fracture. As

TABLE 17-2 CRPP of T-Condylar Distal Humerus Fractures

Preoperative Planning Checklist

- OR Table: Flat Jackson with addition of radiolucent hand table
- Position/positioning aids: Supine on hand table
- Fluoroscopy location: C-arm can come in from the head or foot of the bed when necessary
- Equipment: Large AO pelvic reduction clamps, c- or K-wires, cannulated screws (4 or 4.5 mm)
- Tourniquet (sterile/nonsterile): Sterile tourniquet can be used but not necessary

noted above, in limited scenarios, these fractures can be treated definitively with closed reduction and percutaneous fixation using either smooth wires or cannulated screws (Table 17-2).

Positioning. Percutaneous fixation of T-condylar distal humerus fractures is usually performed in the supine position, but can be facilitated also in the lateral or prone position. Most commonly the patient is positioned supine with arm on a hand table. The arm is elevated on a stack of towels to facilitate easier screw insertion. Bringing the shoulder into abduction and elbow into extension can improve the quality of visualization of the fracture with C-arm imaging. Generally the young have enough rotatory motion about the shoulder to allow for proper visualization in the supine position.

An alternative approach is to position the patient in the lateral position with an axillary roll to protect the brachial plexus on the nonoperative limb. In this position a large bump is fashioned or a specialized arm holder is used to hold the arm in internally rotated position at the shoulder with 90 degrees of flexion at the elbow. The C-arm machine can obtain acceptable images coming from the head or feet parallel to the bed. Finally, patients can be positioned in the prone position with the operative limb exposed on a separate small arm board/table or hanging off the side of the bed. In this position bolsters are used in a standard fashion similar to a spinal procedure to decompress the abdomen and protect the neurovascular structures. The arm is held similar to the lateral position, with internal rotation of the shoulder and 90 degrees of flexion at the elbow with minimal tension. Again, C-arm imaging is accessible from the head or foot of the bed. Prone positioning is most useful in obese patients.

Surgical Approach(es). In closed reduction and percutaneous pin/screw fixation, limited surgical exposure is performed. In some settings, small stab incisions are made to ensure that the large bone reducing forceps are able to be placed directly on bone (medial and lateral epicondyles most commonly) to generate the desired compressive effect. In general, wires are placed percutaneously from the lateral column of the distal humerus. On the medial side, small 1- to 2-cm incisions can be made to prevent inadvertent injury to the ulnar nerve. In addition, the arm is placed in a semi-extended position when passing wires/screws from the medial to lateral, to decrease the risk of iatrogenic ulnar nerve injury.

Technique (Table 17-3)

TABLE 17-3 CRPP of T-Condylar Distal Humerus Fractures

Surgical Steps

- Begin with performance of accurate AP/lateral and oblique fluoroscopic images of the distal humerus
- Make small stab incisions, to facilitate bone clamp application
- Under dynamic fluoroscopy verify that fracture reduction is being achieved with dynamic compression
- Once the fracture is in an acceptable position
  - Place appropriate wires to achieve provisional stability
    - Fix the articular fragment first
    - Address column stability second
- Once the wires are in the correct position, confirm with live fluoroscopy to ensure adequate reduction and wire placement
- Measure screw lengths when appropriate and then overdrill guide wires
- Place the screw across the articular fragment first and then stabilize the medial/lateral columns
- Test stability with flexion and extension

Open Reduction Internal Fixation

Preoperative Planning. The surgical treatment of T-condylar distal humerus fractures involves consideration of three critical components: (1) Surgical approach—triceps splitting, triceps elevating, paratricipital, or olecranon osteotomy; (2) Type of fixation—single column, bicolumn orthogonal or parallel plating or rarely three plates; (3) Body positioning—prone, lateral decubitus, or supine (Table 17-4).

TABLE 17-4 ORIF of T-Condylar Distal Humerus Fractures

Preoperative Planning Checklist

- OR Table: Flat Jackson with fluoroscopic arm board extension
- Position/positioning aids: Prone position on bolsters to decompress abdomen and protect neurovascular structures
- Fluoroscopy location: C-arm can come in from the head or foot of the bed when necessary
- Equipment: Large AO pelvic reduction clamps, K-wires, cannulated screws and precontoured distal humerus plates or pelvic reconstruction plates
- Tourniquet (sterile/nonsterile): Sterile tourniquet used but can be let down if necessary because of timing
- Cautery: Monopolar and bipolar cautery to facilitate dissection of the ulnar nerve
- Penrose drain/Vessel loop: Used to isolate the ulnar nerve during the case

Positioning. Fixation of distal humerus fractures can be facilitated in the supine, lateral, or prone positions with the choice determined primarily based on the anticipated exposure, presence of concomitant injuries, and surgeon experience.

In the setting of polytrauma, patients may be positioned in supine/sloppy lateral position with a large bump placed under the ipsilateral shoulder. Surgery can be performed with the arm across the chest, held in place by an assistant or a towel clamp. Bringing the arm into abduction and extension can aid with visualization of the fracture and improve the quality of C-arm imaging.

An alternative approach is to position the patient in the lateral position with an axillary roll to protect the brachial plexus on the nonoperative limb. In this position a large bump is fashioned or a specialized arm holder is used to hold the arm in internally rotated position at the shoulder with 90 degrees of flexion at the elbow. The C-arm machine can obtain acceptable images coming from the head or feet parallel to the bed.

Finally, patients can be positioned in the prone position with the operative limb exposed on a separate small arm board/table. In this position bolsters are used in standard fashion similar to a spinal procedure to decompress the abdomen and protect neurovascular structures. The arm is held similar to the lateral position, with internal rotation of the shoulder and 90 degrees of flexion at the elbow with minimal tension. Again, C-arm imaging is accessible from the head or foot of the bed.

Surgical Approach(es)

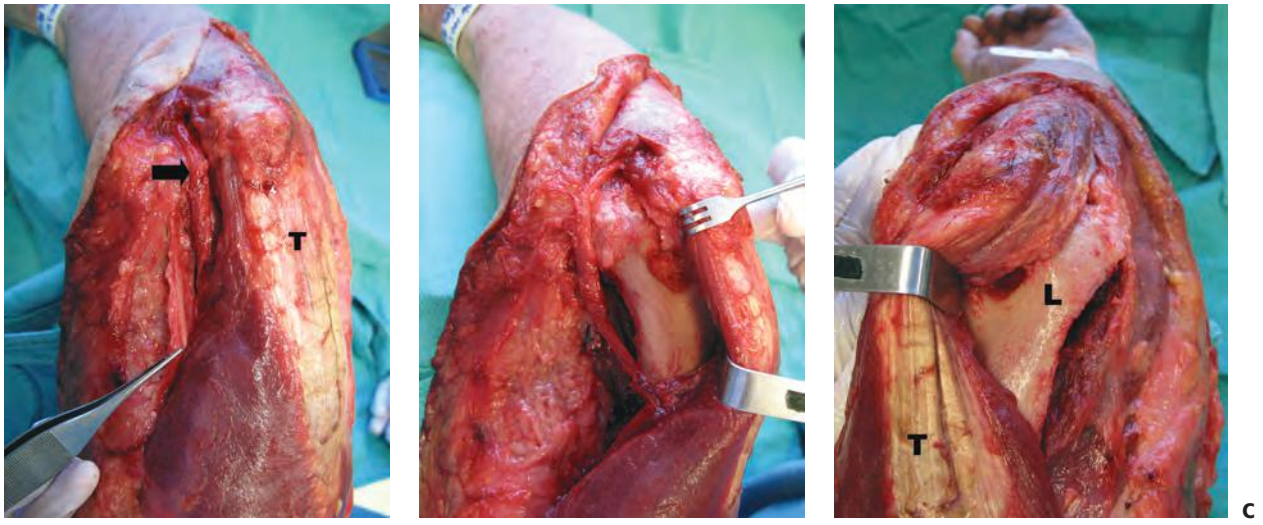
A utilitarian skin approach is used for the majority of surgical approaches associated with T-condylar distal humerus fractures. A long curvilinear posterior skin incision is utilized with the distal extension lateral to the olecranon and then back to the midline onto the proximal ulna. By avoiding the tip of the olecranon, this prevents an irritating posterior scar. Skin and subcutaneous fasciocutaneous flaps are elevated extensively. The ulnar nerve requires careful attention, protection, mobilization, and decompression at this stage and throughout the remainder of the operation. An elastic loop is placed around the nerve, and the nerve is handled gently for the entire surgical procedure.

Triceps Splitting Approach[31] (Fig. 17-7)

- Use long oblique fascial incisions from the medial and lateral epicondyles, to a more proximal connecting point in the midline.
- Reflect the resultant tongue of fascia from proximal to distal down to its insertion on the olecranon while protecting the ulnar nerve on the medial side.
- The triceps muscle is split in the midline and is retracted beyond the medial and lateral columns respectively with broad retractors.
- The radial and ulnar nerves are protected behind retractors during exposure, reduction, and fixation.
- Flexion of the elbow allows for visualization and fixation of the articular fragments.

Triceps Reflecting Approach (Bryan and Morrey)[7,26] (Fig. 17-8)

- The medial aspect of the triceps is elevated from the humerus along the intermuscular septum to the level of the posterior capsule. In children and adolescents, this can be achieved with subperiosteal elevation.
- The superficial fascia of the forearm is incised distally for about 6 cm to the periosteum of the medial aspect of the proximal ulna.



A, B C

FIGURE 17-7 Paratricipital Approach. The paratricipital approach is done through a longitudinal posterior skin incision. Medially **(A)** the ulnar nerve (*black arrow*) is identified. The medial intermuscular septum (forceps) is excised and the triceps muscle is elevated off the posterior aspect of the distal humerus **(B).** Laterally the triceps muscle is elevated off the posterolateral aspect of the distal humerus, allowing exposure of the lateral column, olecranon fossa, and posterior aspect of the trochlea **(C).** (L, lateral column; T, triceps.) (From Bucholz RW, Court-Brown CM, Heckman JD, Tornetta P, *Rockwood and Green's Fractures in Adults.* 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins 2010, with permission)

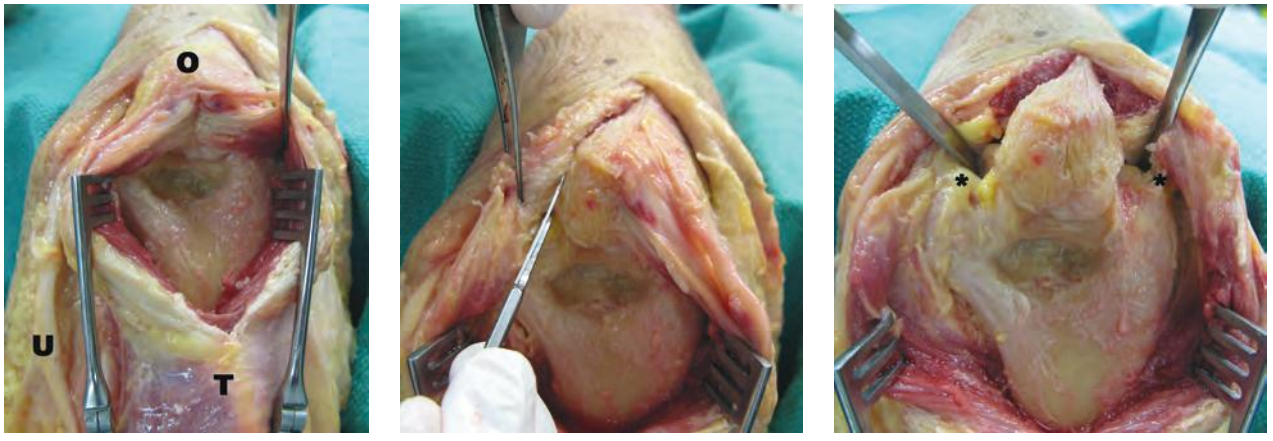


FIGURE 17-8 Triceps Split. A midline approach is made through the center of the triceps tendon and medial head **(A).** The approach can be extended distally by splitting the triceps insertion to the olecranon and raisin medial and lateral full-thickness fasciotendinous flaps **(B, C).** To gain further exposure of the posterior trochlea, the elbow is flexed and the olecranon tip may be excised. (From Bucholz RW, Court-Brown CM, Heckman JD, Tornetta P, *Rockwood and Green's Fractures in Adults.* 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins 2010, with permission).

- The periosteum and fascia are carefully elevated as a single layer from the medial to lateral, distal to proximal. Care must be taken to maintain the continuity of the triceps, periosteum and fascia. The medial aspect of the junction between the triceps insertion and the superficial fascia and periosteum of the ulna is the weakest portion of the reflected tissue. Elevation off the apophysis is also delicate as buttonholing can occur here which will limit the length and strength of the triceps fascial flap and risk destabilizing the triceps insertion into the olecranon.
- At the conclusion of skeletal fixation, the triceps insertion periosteal sleeve is repaired directly to the bone with transosseus sutures or suture anchors.
- This approach is contraindicated in open fractures, where a portion of the triceps may become avascular secondary to the initial trauma from the fracture and further dissection increases this risk.

Olecranon Osteotomy (Fig. 17-9)

- The olecranon osteotomy has been described as a standard approach for adult T-condylar distal humerus fractures.
- In our hands we reserve this approach in children and adolescents for complex T-condylar distal humerus fractures with significant intra-articular comminution (AO C3 T-condylar fractures).

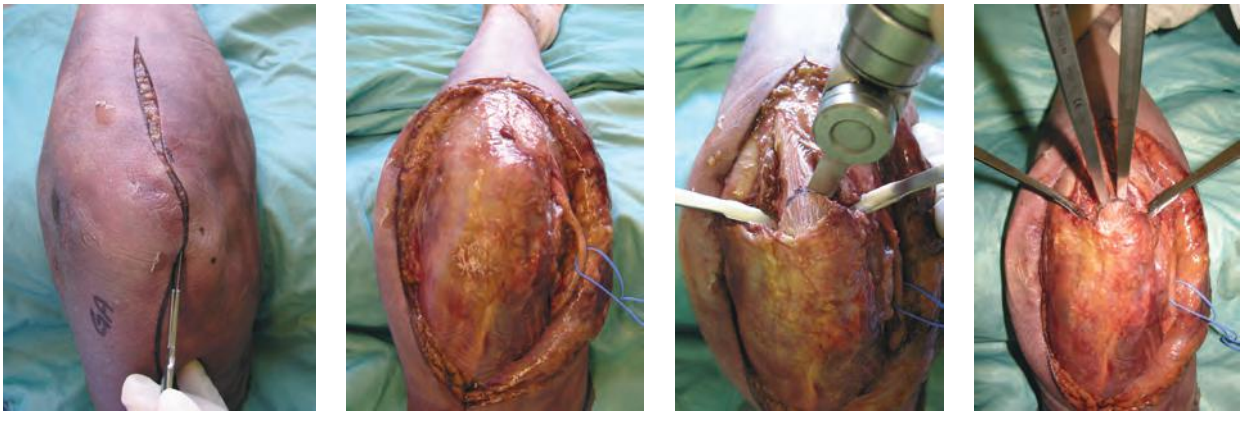

FIGURE 17-9 Olecranon Osteotomy. The olecranon osteotomy is approached via a longitudinal posterior skin incision **(A).** The ulnar nerve is exposed and may be prepared for anterior subcutaneous transposition **(B).** The subcutaneous border of the proximal ulnar is exposed and the nonarticular portion of the greater sigmoid notch between the olecranon articular facet and the coronoid articular facet is clearly defined. Medial and lateral retractors are then placed into the ulnohumeral joint and an apex distal chevron osteotomy entering into the bare area is marked on the subcutaneous border of the ulna. A microsagittal saw is used to complete two-thirds of the osteotomy **(C)** and two osteotomes, placed into each arm of the chevron, apply controlled leverage to fracture the remaining third **(D).** (From Bucholz RW, Court-Brown CM, Heckman JD, Tornetta P, *Rockwood and Green's Fractures in Adults.* 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins 2010, with permission).

- Similar to the paratricipital approach, the triceps is mobilized from the medial and lateral septa and followed distally to the elbow joint.
- A longitudinal cancellous screw is predrilled down the olecranon from the tip or apophysis.
- This screw is removed, and a chevron type osteotomy is performed at the deepest portion of the trochlear notch of the olecranon process and is coincident with an area devoid of articular cartilage (bare area).
- The chevron osteotomy points distally, and is initiated with a fine oscillating saw and completed with a thin osteotome.
- The triceps muscle and the osteotomized proximal half of the olecranon are then reflected superiorly.
- The osteotomy can alternatively be fixed with a precontoured olecranon plate or parallel K-wires and tension band technique.
- At the end of the reduction, the osteotomy is reduced and fixed with compression fixation with cancellous screw and washer fixation.

Technique (Table 17-5)

TABLE 17-5 ORIF of T-Condylar Distal Humerus Fractures

Surgical Steps

- Longitudinal posterior midline skin incision, avoiding the tip of the olecranon
- Elevation of medial and lateral fasciocutaneous flaps as necessary
- Identification of the ulnar nerve, decompression, and mobilization for protection during the remainder of the procedure
- Surgical approach dictated by
  - Fracture type
  - Presence of associated injuries
  - Degree of soft tissue injury
  - Surgeon preference
- Exposure of fracture fragments, removal of intervening soft tissues and fracture hematoma
- Temporarily stabilize the joint anatomically with guide wires from the cannulated screw set (4 or 4.5 depending on the patient)
- Stabilize the anatomic joint fixation to columns temporarily
- Confirm anatomic alignment under direct visualization and fluoroscopically
- Replace temporary cannulated pin fixation with compressive screw fixation across the joint
- Convert the column fixation to orthogonal plates
  - Medial 3.5 pelvic reconstruction or precontoured plate
  - Posterolateral 3.5 reconstruction, dynamic compression, or precontoured plate
- Test stability and flexion and extension arc of motion
- Decide where the ulnar nerve should lie, in its original position or in a transposed position

Author's Preferred Treatment for T-Condylar Distal Humerus Fractures

Because this fracture is rare in children, there are limited standard recommendations for treatment. Our suggestions are based on a combination of our clinical experience and the experience of others in a few series.[10,15,18,23,25,26,31] Our first imperative in these fractures is to re-establish the integrity of the articular surface to maintain the congruity of the joint. Usually, this cannot be achieved adequately by closed methods, so we proceed with an open surgical technique. In the young child, we have divided the simple classification into three types based on the degree of displacement or comminution to be helpful in guiding the aggressiveness of our treatment. In adolescents we guide our treatment according to the AO classification.

Type I (Undisplaced or Minimally Displaced)

In Type I injuries, there is little displacement of the bony supracondylar columns. In children, the periosteum is often intact and can provide some intrinsic stability. In addition, the thicker articular and epiphyseal cartilage in skeletally immature children may still be intact, even if the bony epiphysis appears severed by a vertical fracture line. Because of this condition, we have found two methods to be successful for these types of fractures.

Closed Reduction—Cast Application

Truly nondisplaced fractures can be treated in a cast. Again, it is imperative to judge completely stable fractures from injuries that can displace. Initial 3D imaging and careful radiographic follow-up are necessary to avoid an articular malunion. Because of the rapid healing in these nondisplaced fractures, the cast can be removed in 4 weeks and a hinged elbow brace initiated to permit early protected motion.

Closed Reduction—Percutaneous Pin Fixation or Screw Fixation

The minimally displaced fractures in the young require minimal manipulation under general anesthesia and radiographic control to re-establish the supracondylar columns and articular surface anatomy. If there is minor anterior or posterior rotation in the sagittal plane of the metaphyseal portion of the column, a pin placed into that column can be used as a "joystick" to manipulate the fragment into a satisfactory position. Once a satisfactory reduction is achieved, the pin can then be advanced across the fracture site for fixation. These fractures usually require multiple pins placed percutaneously, such as those used in comminuted supracondylar fractures (Fig. 17-10). Because of the rapid healing, the pins can be removed at 3 to 4 weeks to allow early active motion.

In the setting of mild intra-articular displacement, we employ the use of a large bone reducing forceps to help facilitate with our reduction. Often this can be applied percutaneously or through small stab incisions to ensure that the tines of the clamp are place directly onto the bone (usually medial and lateral epicondyles) of the distal humerus without injury

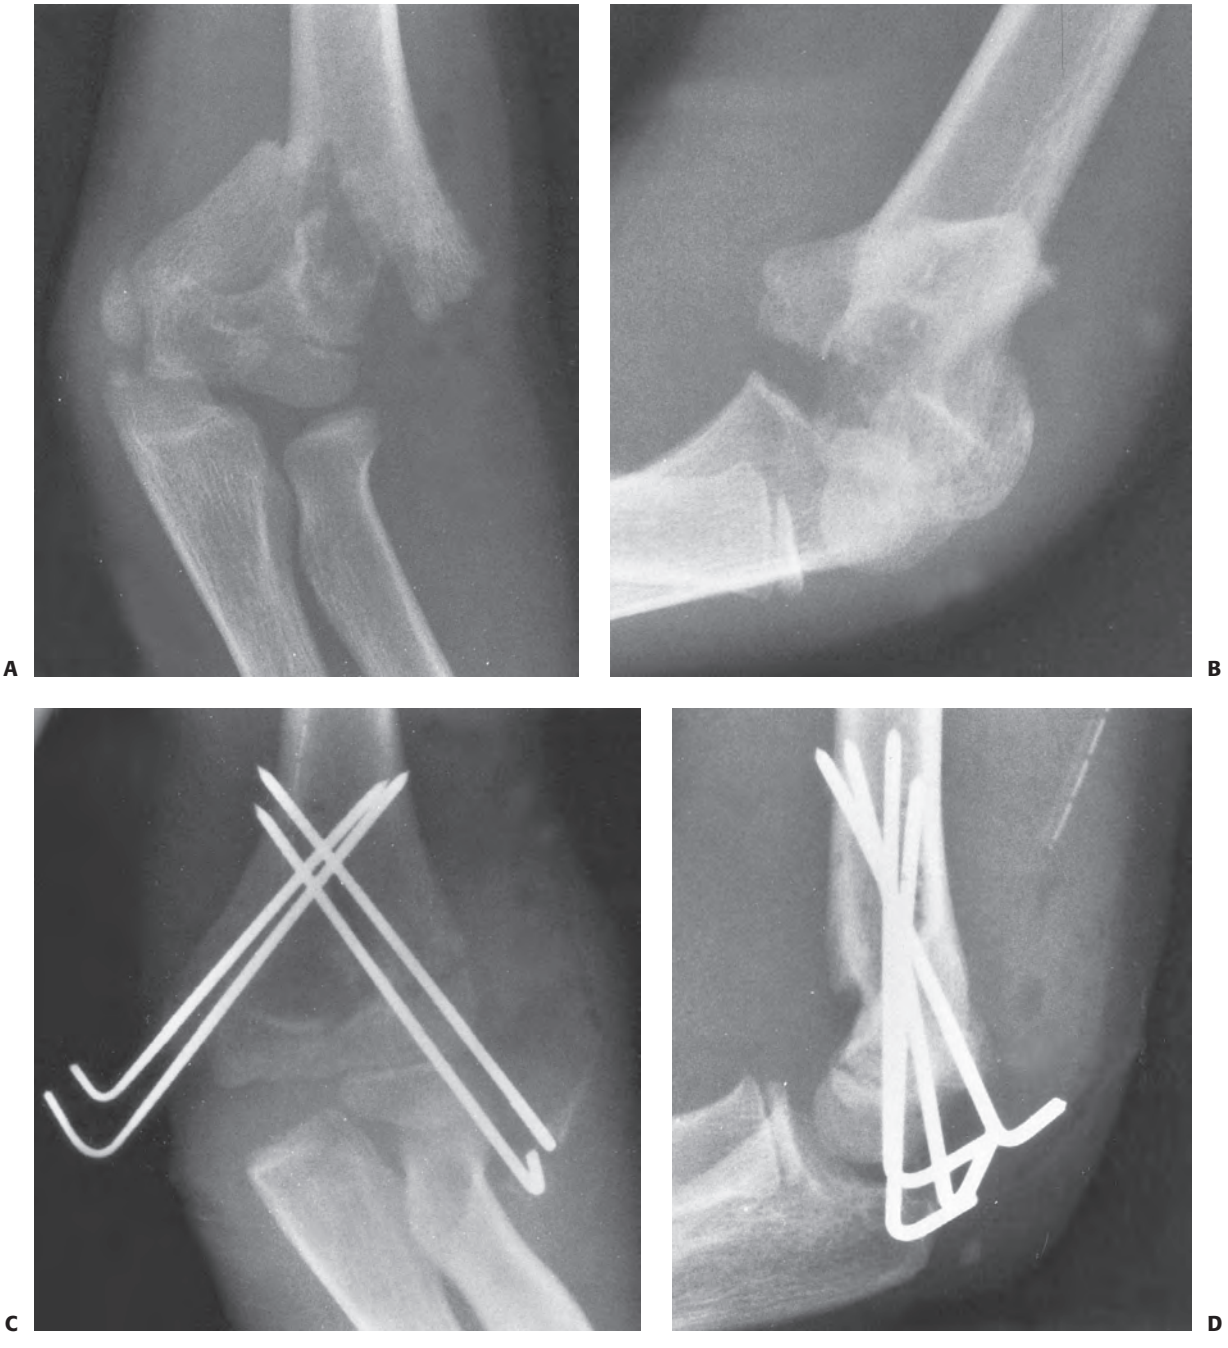

FIGURE 17-10 Closed reduction and pin fixation. **A, B:** Two views of a Type II T-condylar fracture in a 15-year-old. **C, D:** Because an anatomic reduction was achieved by manipulative closed reduction, it was secured with simple multiple pin fixation placed percutaneously. The articular surface was minimally displaced. The pins were removed at 3 weeks. At this age, healing was rapid enough to pull the pins at 3 weeks to allow active motion. Ultimately, the patient was deficient only 10 degrees from achieving full extension.

to the neighboring neurovascular structures. Once the articular diastasis is corrected, guide wires from the cannulated screw set are placed with bicortical fixation perpendicular to the fracture line. Appropriate length screws with washers are placed over the guide wires. Compression is applied sequentially, alternating between screws to ensure optimal and balanced compression.

Type II (Displaced without Comminution)

Open Reduction and Internal Fixation

If there is wide separation of the condylar fragments with marked disruption of the articular surface, stability and articular congruity can be established only with an open surgical procedure.

We prefer a triceps-splitting approach for C1 distal humerus fractures and a triceps sparing Bryan–Morrey approach for C2 distal humerus fractures. Olecranon osteotomy is reserved for severely comminuted C3 articular fractures in adolescents. We place the patient supine in a "sloppy lateral" position to allow for easier lateral fluoroscopic imaging. A sterile tourniquet is used throughout the surgery.

Reconstruction of the Articular Surface

Our first priority is to re-establish the integrity of the articular fragments—in other words, to convert it to a supracondylar fracture (Fig. 17-11). The olecranon and coronoid fossae must be cleared of bony fragments or debris to eliminate the chance of bony impingement against their respective processes with motion. The best way to stabilize the condyles is with a screw passed transversely through the center of the axis of rotation in such a manner as to apply transverse compression. This stabilization method may require a small temporary secondary transverse pin proximal to the screw to prevent rotation of the fragments as the guide hole is drilled or when the compression screw is being applied. This pin can be removed after the fragments are secured.

In most adolescents, this is essentially an adult type of fracture pattern. Direct visualization of the reduction of all fracture fragments is mandatory. It is critical to get the joint surface anatomic and rigidly fixed. A single, short-threaded cancellous screw and washer is most commonly used. A 3.5 mm to 4.5 mm diameter screw is placed from lateral to medial depending on the size of the bone and the available space between the articular surface and the olecranon fossa. Open physes further complicate the delicacy of exact screw placement in this region. The ulnar nerve is protected on the medial side. Once anatomic reduction and fixation of the articular surface is achieved, secure fixation of the columns is performed next. However, do not rush to column fixation unless the joint surface is reduced correctly. In younger teenagers, the joint cartilage can buckle and tear and this can make the anatomic alignment harder to discern than in more skeletally mature patients in which the bony fragments interdigitate nicely (Fig. 17-12A–C).

Stabilization of the Supracondylar Columns

Once the condylar and articular integrity has been re-established, the distal fragments must be secured to the proximal fragment by stabilizing the supracondylar fragment columns. The decision here is how important it is to initiate early motion. In a younger child with rapid bony healing, pin fixation is often satisfactory; the pins can be removed after 3 weeks to start protected motion. In an older adolescent nearer to skeletal maturity, we prefer fixation—usually plates or less commonly, screws—that allows early motion (Figs. 17-11E,F and 17-13). Before applying the plates, the supracondylar columns can be stabilized temporarily with pin fixation (Fig. 17-13).

Principles of Plate Fixation

The plates must be strong; thin semitubular plates are inadequate and may break.[32] However, double stacking semitubular plates can be used in younger or thinner teenagers. Proper rotational bending is harder in these plates. Usually the reinforced malleable reconstructive type of plates used for fixation of pelvic fractures can be anatomically contoured and provide very secure fixation of the distal humerus. It is best to place the plates at 90 degrees to each other, which provides for a more stable construct.[13,19,28,29]

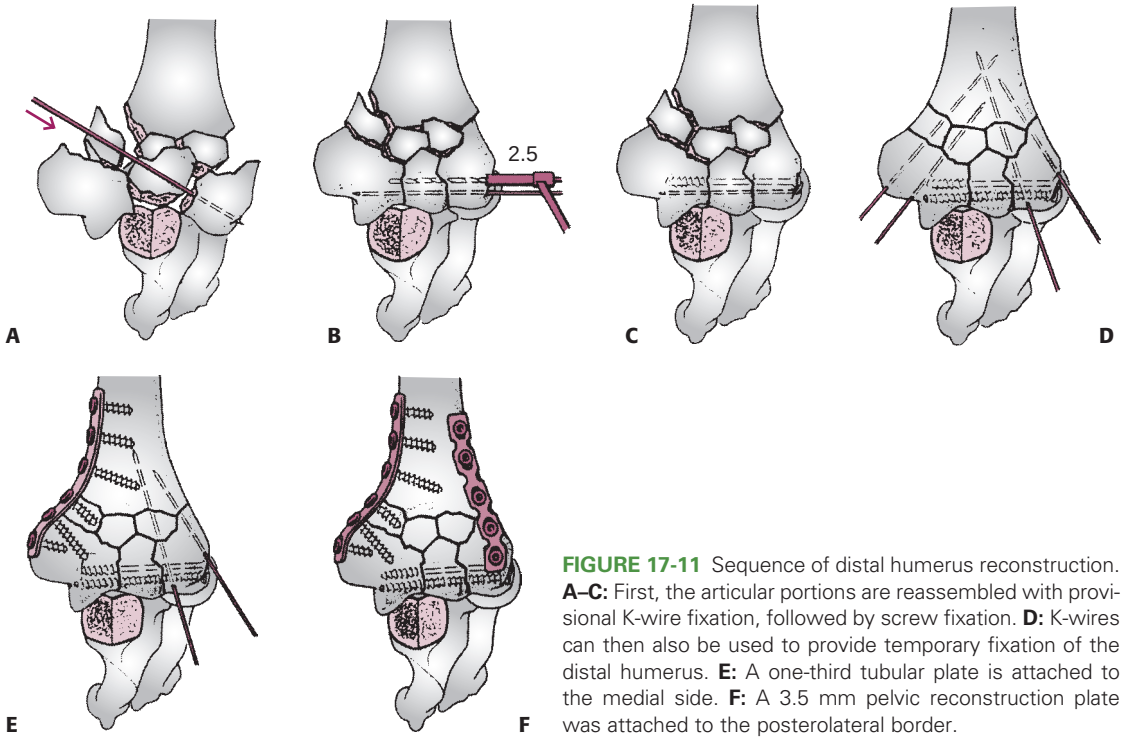

FIGURE 17-11 Sequence of distal humerus reconstruction. **A–C:** First, the articular portions are reassembled with provisional K-wire fixation, followed by screw fixation. **D:** K-wires can then also be used to provide temporary fixation of the distal humerus. **E:** A one-third tubular plate is attached to the medial side. **F:** A 3.5 mm pelvic reconstruction plate was attached to the posterolateral border.

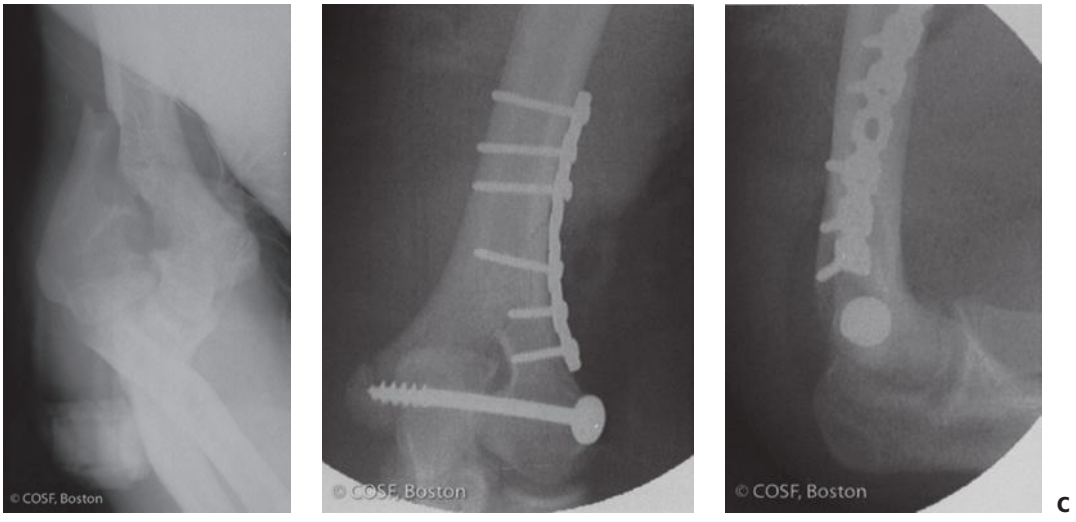

FIGURE 17-12 **A–C:** Type II displaced T-condylar fracture. This fracture was initially treated with distal transarticular compression screw for stability and then followed by single lateral column fixation

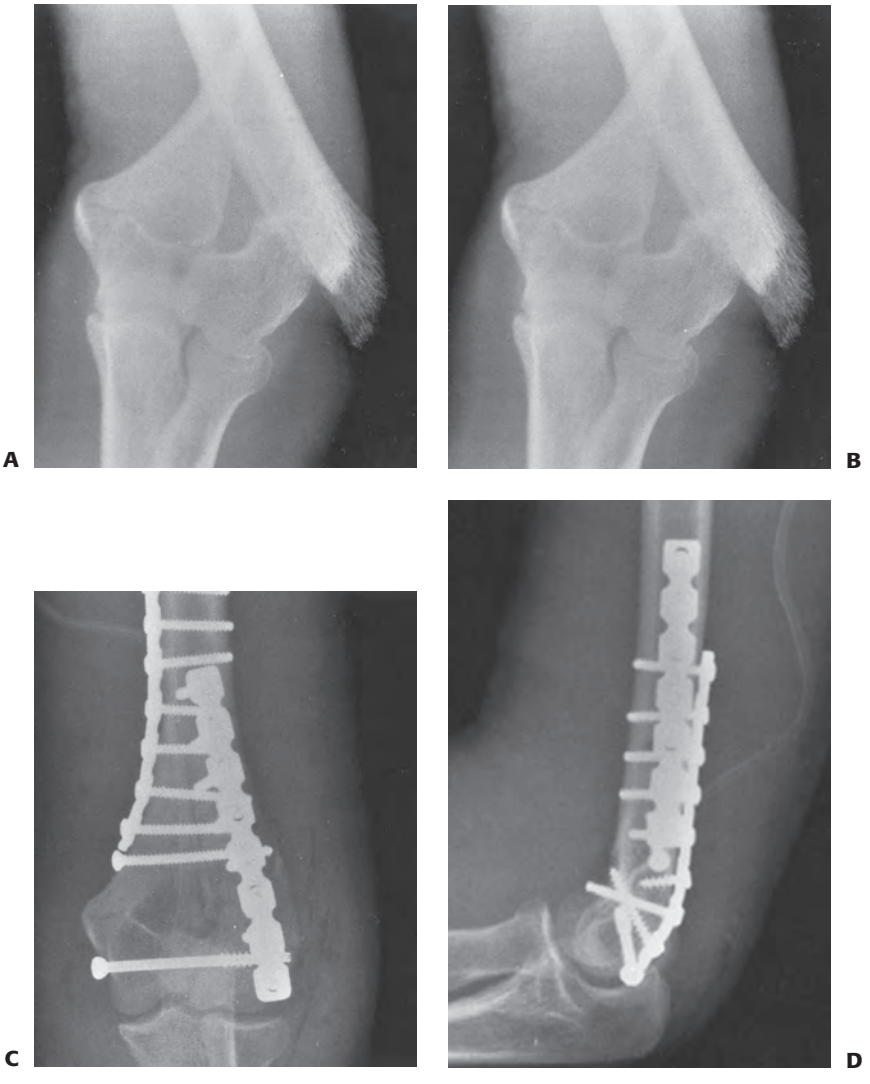

FIGURE 17-13 T-condylar humeral fracture with plate and screw fixation. **A, B:** Injury films of a Type II flexion pattern in a 16-year-old boy. **C, D:** Articular integrity was first restored with a transcondylar compression screw. The condyles were secured to the metaphysis and distal shaft using pelvic reconstruction plates placed at 90 degrees to each other.

Some of the plates specifically designed for distal humerus fracture fixation in the adult either do not fit anatomically or are too prominent for many pediatric patients. In the larger, skeletally mature adolescent, use of these plates is appropriate. Later plate removal may be necessary though.

Type III (Displaced with Comminution)

Limited Open Reduction Followed by Traction

Sometimes, the supracondylar columns are too fragmented or contaminated by an open fracture to allow adequate definitive fixation acutely. In such cases, we have found that the best initial treatment method in children involves re-establishing the articular surface and joint congruity with a limited open reduction. The separated condyles are secured with a transverse screw providing compression through the axis of rotation. This procedure can usually be done with minimal soft tissue dissection. Once this is stabilized, the supracondylar columns are then re-established by placing the extremity in olecranon traction and allowing them to reconstitute with callus formation. The rotational displacement of the condyles created by the origins of the forearm muscles can be neutralized with olecranon traction, in which the elbow is suspended at 90 degrees of flexion. There is usually adequate stability from the callus around the fracture site at 2 to 3 weeks to discontinue the traction. While in traction, motion can be initiated. This technique can also be used in patients seen late with contaminated soft tissue abrasions or severe soft tissue problems. In selected patients, such as an adolescent with severe bone loss, plating followed by bone grafting may be indicated. Following 3 weeks of traction the elbow is then immobilized in a hinged cast brace for an additional 2 to 3 weeks. This immobilization allows the initiation of protected active motion. With the present emphasis on short hospitalization, however, we find that skeletal traction is less acceptable for both social and financial reasons.

Multiple Pin Fixation Treatment

In this time of extreme sports even in the young, there are instances of severely comminuted fractures in which the patient's bone will not allow for screw or plate fixation but the fracture is too displaced and/or comminuted to be successfully treated closed. In these instances, open reduction and pin fixation of each fracture fragment is a treatment option. There are times when even suture repair of fractures is required. The fixation does not allow for immediate motion but is started as soon as feasible (see Fig. 17-5, Fig. 17-14).

Postoperative Care

In situations where closed reduction and pin fixation is performed, a well-padded circumferential cast is applied for a total of 3 to 6 weeks depending on the degree of healing appreciated on the postreduction radiographs. Patients are then transitioned into a hinged-elbow brace and physical therapy is initiated until full range of motion is achieved. Wires are removed when appropriate healing is appreciated.

Children treated with closed reduction and percutaneous screw fixation are transitioned from their circumferential cast at 7 to 10 days and placed into a hinged elbow brace. Increasing motion is permitted over time and healing. Physical therapy is initiated at the first postoperative visit and protected therapy is continued until full range of motion is achieved. Return to sports is dependent on bony healing, restoration of strength and maximum motion, usually at 3 months.

If plate fixation is used, we place the extremity in a well-padded soft dressing and hinged brace. We initiate continuous

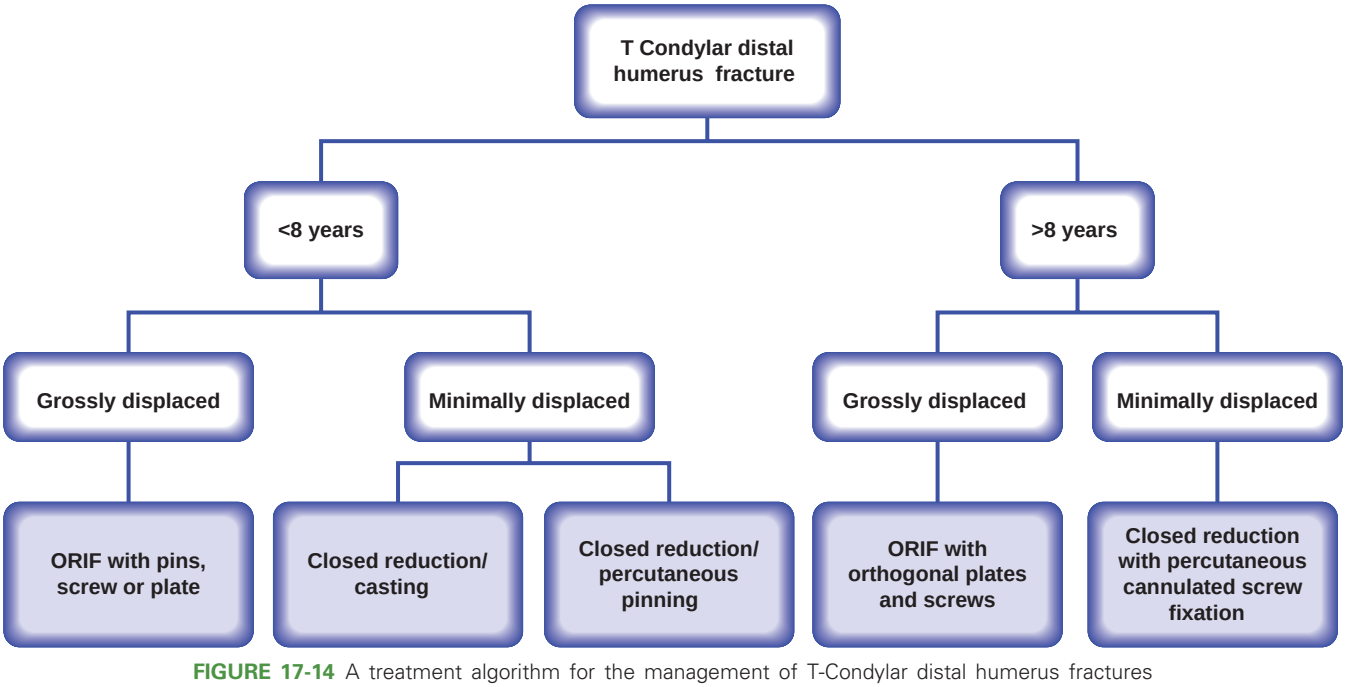

FIGURE 17-14 A treatment algorithm for the management of T-Condylar distal humerus fractures according to age and displacement.

passive motion (CPM) in hospital for all T-condylar fractures treated with ORIF. Patients remain in hospital until full flexion–extension is achieved in usually 5 days. Patients are discharged on home CPM up to 23 hours/day for 3 weeks followed by CPM for part time for another 3 weeks. The active motion of postoperative therapy is performed in a hinged elbow brace with full motion allowed. A mild 10-degree extension contracture in these patients is anticipated in the best results.

Potential Pitfalls and Preventative Measures (Table 17-6)

TABLE 17-6 T-Condylar Distal Humerus Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Articular malreduction	Appropriate skin and soft tissue exposure, with visualization of critical articular components Begin with joint reduction and stabilization, convert from three- or four-part fracture to a two-part supracondylar type fracture
Inadequate stabilization to allow for early range of motion	In most T-condylar fractures, rigid fixation is necessary to allow for early range of motion Use rigid plate fixation for both medial and lateral columns to facilitate early mobilization
Ulnar nerve irritation	At the end of the case examine the ulnar nerve with flexion and extension Consider ulnar nerve transposition if there is evidence of tether or impingement of the nerve during an arc of motion

Treatment Specific Outcomes

The literature reflects good results with surgical management of displaced distal humerus articular fractures. Zimmerman[33] advocated establishing an anatomic reduction with internal fixation so that early motion could facilitate a more rapid rehabilitation. In the two young children described by Beghin et al.[4] operative intervention was necessary to achieve a satisfactory reduction. A review of four series[15,18,23,25] supports surgical management: 44 of the 48 elbows in these combined series were treated operatively. The investigators of these series maintained that open reduction and internal fixation was the best way to restore the integrity of the articular surface and stabilize the fracture sufficiently to allow early mobilization. All but one of the patients in this combined series who were treated surgically had good or very good results at follow-up.

Kanellopoulus and Yiannakopoulos[17] described closed reduction of the intra-articular component, with fixation by partially threaded pins for interfragmentary compression. Two elastic titanium intramedullary nails were used for stabilizing the supracondylar component. The T-condylar fractures in two adolescents healed without complications after using this technique. Both patients returned to sports with full elbow range of motion at 6 weeks after surgery.

The triceps splitting approach, as described by Campbell, was first advocated by Van Gorder.[31] Kasser et al.[18] has demonstrated in children, that the triceps splitting approach did not appear to cause significant muscle dysfunction according to Cybex testing, and concluded that an olecranon osteotomy was unnecessary. The authors concluded that this approach gives adequate exposure of the fracture and the articular surface and does not seem to produce any loss of strength from splitting the triceps. Although one reported patient had radiographic evidence of osteonecrosis of the trochlea,[23] another had a nonunion,[18] and many had some loss of range of motion, none of these surgically treated patients demonstrated any significant loss of elbow function or discomfort.

Alonso-Llames described a paratricipital approach for the treatment of supracondylar and intracondylar fractures in children.[2] Bryan and Morrey[7] described a triceps-sparing approach in which the extensor mechanism is reflected laterally, exposing the whole distal humerus. Re et al.[25] found that both the Bryan–Morrey (Triceps Reflecting) and olecranon osteotomy approaches yielded improved extension compared to the triceps-splitting approach. Recently, Remia et al.[26] evaluated triceps function and elbow motion in nine patients with T-condylar fractures treated with open reduction through a Bryan and Morrey triceps-sparing approach and compared them to those reported after a triceps-splitting approach. No statistically significant differences were found in function or range of motion.

The surgeon must choose the surgical approach that will allow for the best exposure with the least risk. The priority is adequate visualization of all fracture fragments, especially the joint surface, to achieve rigid anatomic fixation. Early motion is desired to lessen the risk of postinjury contractures about the elbow.

Management of Expected Adverse Outcomes and Unexpected Complications in T-Condylar Distal Humerus Fractures

It is important to emphasize to the parents initially that this is a serious fracture. Because of the considerable soft tissue injury and the involvement of the articular surface of the distal humerus, stiffness and loss of motion of the elbow can be expected regardless of the treatment mode.[15,21,23] In adolescents, failure to provide solid internal fixation that facilitates early motion (i.e., using only pin fixation) can result in a satisfactory radiographic appearance but considerable dysfunction because of residual loss of elbow motion.

Although neurovascular complications have not been mentioned in the few cases reported in the literature, the incidence is probably about equal to that of supracondylar fractures. Because these fractures occur late in the growth process, partial or total growth arrest caused by internal fixation is not thought to be a major complication. Likewise, because these are

TABLE 17-7 T-Condylar Distal Humerus Fractures

Common Adverse Outcomes and Complications

Postoperative elbow stiffness
Fracture malunion
Fracture nonunion and hardware failure
Osteonecrosis of trochlea
Hardware impingement and irritation

older children, little remodeling can be expected. Nonunion,[18] osteonecrosis of the trochlea,[23] and failure of internal fixation have also been reported as complications.

Aside from stiffness, the biggest risk is fracture malunion caused by inadequate reduction and/or fixation. Extra-articular malunion can be tolerated especially if mild. Intra-articular malunion is clearly a real risk for pain, loss of motion and function, and eventually arthritis. Intra-articular malreduction should be avoided.

Hardware irritation and/or impingement can occur. Obviously all smooth wires need to be removed after the fracture is healed. Hardware that contributes to impingement pain and/or loss of motion needs to be similarly removed (Table 17-7).

Summary, Controversies, and Future Directions Related to T-Condylar Distal Humerus Fractures

Caring for children and adolescents with T-condylar distal humerus fractures is challenging. The risks of intra-articular incongruity and postoperative stiffness are real concerns. Attention to detail with anatomic stable fixation allows for early range of motion post injury that lessens the risk of postinjury contracture.

18 DISLOCATIONS OF THE ELBOWS, MEDIAL EPICONDYLAR HUMERUS FRACTURES

Anthony A. Stans and J. Todd R. Lawrence

Introduction to Elbow Dislocations and Medial Epicondyle Fractures

Disruptions of the elbow joint represent a spectrum of injuries involving three separate articulations: The radiocapitellar, the ulnohumeral, and the proximal radioulnar joints. Dislocations of the elbow joint in children are not common. Of all elbow injuries in skeletally immature patients, Henrikson[65] found that only about 3% of all were dislocations. The peak incidence of pediatric elbow dislocations typically occurs in the second decade of life, usually between 13 and 14 years of age when the physes begin to close.[65,80] Based on the National Electronic Injury Surveillance System database, the calculated incidence of elbow dislocations in adolescents aged 10 to 19 years old was 6.87 dislocations per 100,000 person-years with an almost 2:1 ratio of injuries in males compared to females (incidence 8.91 vs. 4.72 per 100,000 person-years).[171] The largest proportion of elbow dislocations (44.5%) occur in conjunction with sports activities; football/rugby, wrestling, and basketball being the most common sports for males and gymnastics and skating being the most common sports for females.[171] Almost 60% of medial epicondyle fractures are associated with elbow dislocations in this age group.[89,188] As with all joint dislocations, the principles of treatment include promptly obtaining a concentric reduction of the elbow joint while identifying and treating all associated injuries. The ultimate goal is allowing protected motion and rehabilitation with the goal of restoring full elbow motion without recurrent instability.

Assessment of Elbow Dislocations and Medial Epicondyle Fractures

Because of the location of critical stabilizing factors and surrounding neurovascular structures, elbow dislocations should be considered based on the direction of dislocation and the associated fractures which may be present. As the mechanism of injury, the associated injuries, and imaging differ based on the nature of the injury, these factors should be considered for each dislocation pattern.

Pathoanatomy and Applied Anatomy Relating to Elbow Dislocations and Medial Epicondyle Fractures

Constraints about the elbow preventing dislocation can be considered as either dynamic or static. Dynamic elbow stabilizers consist of the elbow musculature, over which the patient has conscious control, which change depending on the degree of muscular contraction. Unlike the shoulder, dynamic stabilizers play only a modest role in elbow stability.

Static constraints are of greater importance and can be divided into osseous and ligamentous restraints (Figs. 18-1–18-3). The bony geometry of the elbow creates a relatively constrained hinge. The coronoid and olecranon form a semicircle of approximately 180 degrees into which the trochlea of the humerus securely articulates. The concave surface of the radial head matches the convex capitellum and provides stability to the lateral aspect of the elbow joint. The bony configuration of

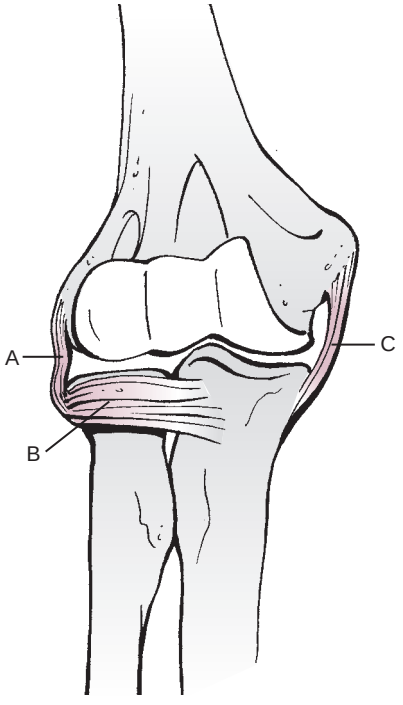

FIGURE 18-1 Anteroposterior view of the elbow illustrates the bone and ligamentous structures which contribute to elbow stability. (**A,** lateral collateral ligament; **B,** annular ligament; **C,** medial collateral ligament.)

the medial and lateral aspects of the elbow complement each other with the ulnohumeral articulation providing stability against medial–lateral or longitudinal translation, whereas the radiocapitellar joint provides resistance to axial compression. The circular nature of the proximal radius allows for nearly 180 degrees of rotation through the full range of flexion and extension allowing for maintenance of these relationships with forearm rotation.

Lateral ligamentous constraints include the annular ligament that is attached to proximal ulna and encircles the radial

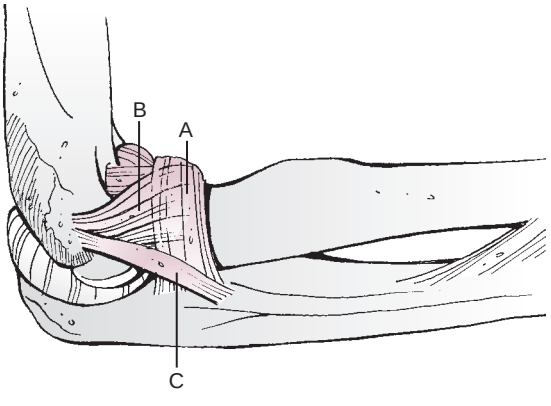

FIGURE 18-2 The annular ligament and lateral collateral ligament complex provides stability to the proximal radioulnar joint and radial capitellar articulation. (**A,** annular ligament; **B,** lateral collateral ligament insertion on annular ligament; **C,** lateral collateral ligament insertion on ulna.)

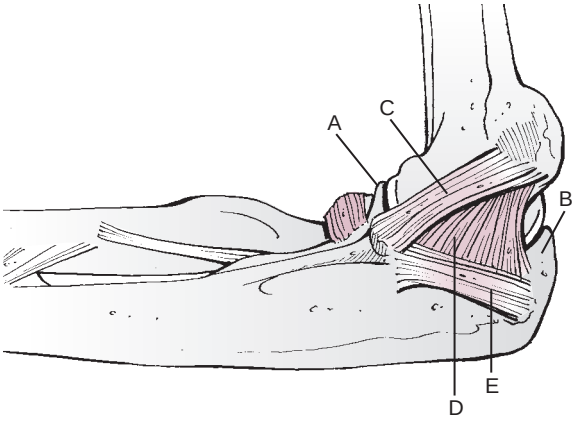

FIGURE 18-3 The medial elbow is stabilized by the hinge articulation between the proximal ulna and the humerus. Three components of the ulnar collateral ligament provide additional elbow stability. (**A,** coronoid process; **B,** olecranon process; **C,** anterior oblique medial collateral ligament; **D,** posterior oblique medial collateral ligament; **E,** transverse medial collateral ligament.)

neck and the lateral collateral ligaments that originate from the lateral epicondyle and insert into the annular ligament and the lateral aspect of the proximal ulna. The primary role of the annular ligament and the lateral collateral ligament complex is to provide stability to the radiocapitellar and proximal radioulnar joints by resisting varus stress.

The medial ulnar collateral ligament is the primary ligamentous restraint to valgus stress, resisting pathologic opening of the medial aspect of the elbow. Having its origin from the inferior aspect of the medial epicondyle, the medial collateral ligament has two primary components that contribute to elbow stability, the anterior and the posterior bands. The band's anterior portion is taut in extension and the posterior fibers are taut in flexion (Fig. 18-4). There is also a fan-shaped posterior oblique ligament that inserts on the olecranon and functions mainly in flexion and a small transverse ligament runs from the olecranon to the coronoid that is thought to have little functional importance. Woods and Tullos[191] pointed out that the major stabilizing ligamentous structure in the elbow is the anterior band of the ulnar collateral ligament.

The medial epicondyle represents a traction apophysis because the forces across its physis are in tension rather than the compressive forces present across the other condylar physes of the distal humerus. The medial epicondylar apophysis actually arises from the posterior surface of the medial distal humeral metaphysis. Ossification begins at about 4 to 6 years of age and fuses at about 15 years of age, making it the last secondary ossification center to fuse with the distal humeral metaphysis. The ossification center starts as a small eccentric oval nucleus (Fig. 18-5A). As it matures, parallel sclerotic margins develop along both sides of the physis (Fig. 18-5B). There may be some irregularity of the ossification process, which gives the ossific nucleus a fragmented appearance. This fragmentation may be falsely interpreted as a fracture.

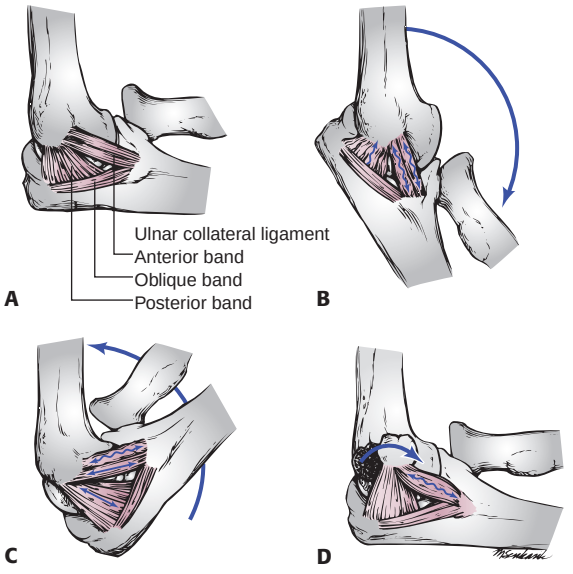

FIGURE 18-4 Ligamentous structures. **A:** The ulnar collateral ligament is divided into anterior, posterior, and oblique bands. **B:** On extension, the anterior fibers of the anterior band are taut. The posterior fibers of the anterior band and the entire posterior band are loose in this position. **C:** In flexion, the posterior fibers of the anterior band and the posterior band become taut. The anterior fibers of the anterior band become loose. **D:** When the epicondyle is rotated anteriorly, the entire anterior band can become loose. (From Woods GW, Tullos HS. Elbow instability and medial epicondyle fractures. *Am J Sports Med.* 1977;5(1):23–30, with permission.)

Superficially the flexor–pronator mass, which includes the origin of the flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis, palmaris longus, and part of the pronator teres, originates from the anterior aspect of the medial epicondylar apophysis (Fig. 18-6).[160] Part of the flexor carpi ulnaris also originates on the posterior aspect of the epicondyle. Deep to these muscular insertions, the medial ulnar collateral ligament originates from the medial epicondyle. In younger children, some of the capsule's origin extends up to the physeal line of the epicondyle. In older children and adolescents, as the epicondyle migrates more proximally, the capsule is attached only to the medial crista of the trochlea.[12] Thus, in older children, if there is a pure muscular avulsion force on the epicondyle, the capsule and part of the medial ligamentous complex may remain attached to the trochlea's outer border and relative elbow stability preserved. However if the medial epicondyle is avulsed via the medial ulnar collateral ligament, given the importance of this ligament in elbow stability, relative elbow instability usually results.

In general, flexion and supination are usually regarded as positions of stability, whereas extension and pronation are positions of relative instability (Fig. 18-7).

Classification of Elbow Dislocations and Medial Epicondyle Fractures

Elbow dislocations are described by the position of the proximal radioulnar joint relative to the distal humerus: Posterior, anterior, medial, or lateral. Posterior dislocations are typically further subdivided into posterolateral and posteromedial injuries. Occasionally, the proximal radioulnar joint is disrupted. When this happens, the radius and ulna can diverge from each other. Rarely, the radius and ulna translocate, with the radius medial and the ulna lateral. Isolated dislocations of the radial head must be differentiated from congenital dislocations. Isolated dislocations of the proximal ulna are exceedingly rare and have not been reported in children. Included in this chapter is a discussion of the commonly occurring subluxation of the radial head, or "nursemaid's elbow." This is not a true subluxation but rather a partial entrapment of the annular ligament in the radiocapitellar joint. Monteggia fracture dislocations are discussed in detail in Chapter 14.

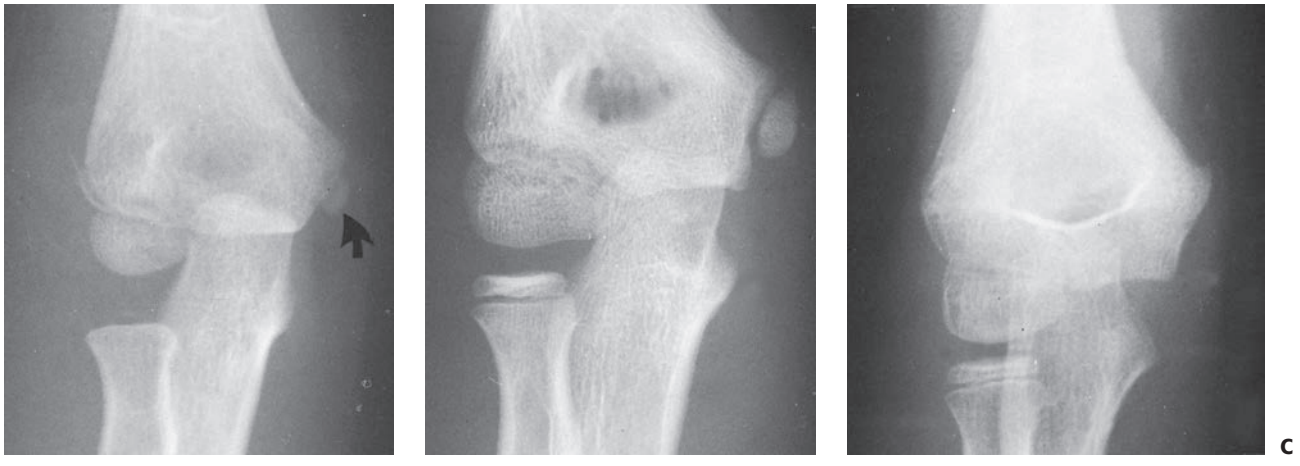

FIGURE 18-5 Ossification of the medial epicondyle. **A:** The concentric oval nucleus of ossification of the medial epicondylar apophysis (*arrow*). **B:** As ossification progresses, parallel smooth sclerotic margins develop in each side of the physis. **C:** Because it is somewhat posterior, on a slightly oblique anteroposterior view the apophysis may be hidden behind the distal metaphysis.

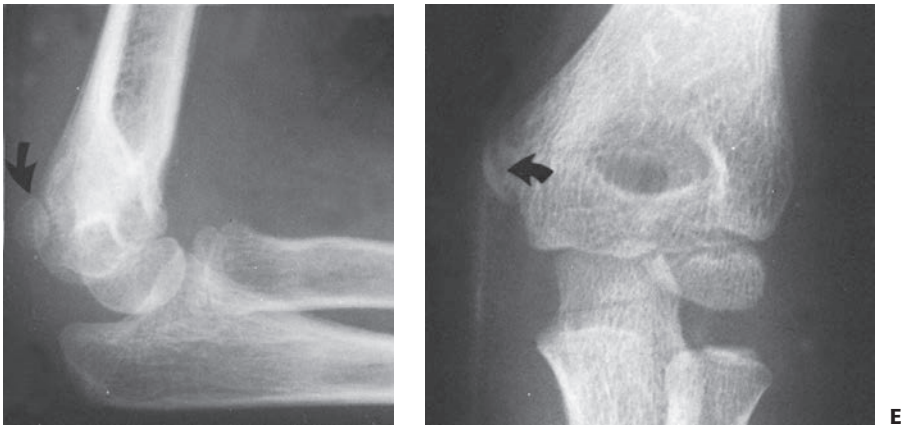

FIGURE 18-5 (*continued*) **D:** The posterior location of the apophysis (*arrow*) is appreciated on this slightly oblique lateral view. **E:** On the anteroposterior view, the line created by the overlapping of the metaphysis (*arrow*) can be misinterpreted as a fracture line (pseudofracture).

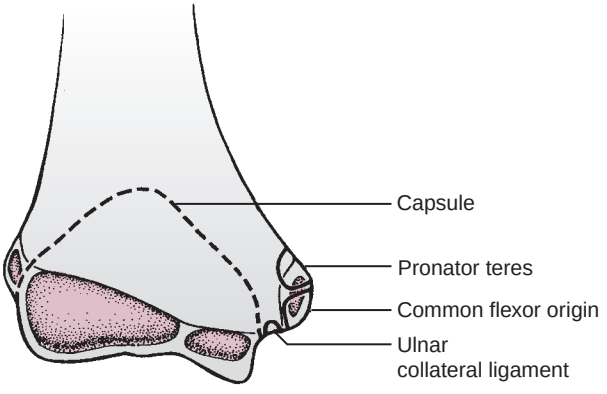

FIGURE 18-6 Soft tissue attachments. The AP view of the distal humerus demonstrates the relationship of the apophysis to the origins of the medial forearm muscles. The origin of the ulnar collateral ligament lies outside the elbow capsule. The margin of the capsule is outlined by the dotted line.

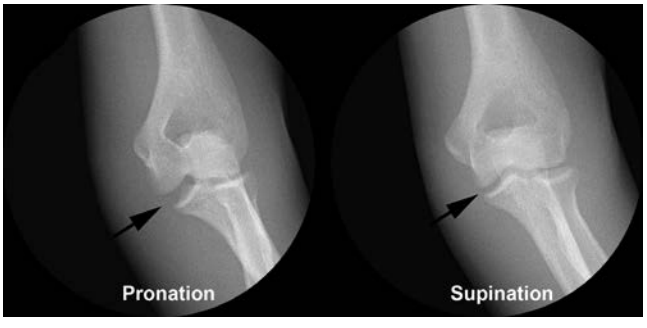

FIGURE 18-7 Assessment of elbow stability based on forearm rotation. Following closed reduction of a posterior elbow dislocation in a 15-year old, stability was assessed. With the forearm in mild pronation, note the significant medial joint space opening (*arrow*) with only mild valgus stress. With the forearm slightly supinated a concentric elbow reduction was maintained through a greater range of motion. Stability should be assessed on an individual case by case basis.

Posterior Elbow Dislocations

Assessment of Posterior Elbow Dislocations

Mechanisms of Injury for Posterior Elbow Dislocations

O'Driscoll et al.[125] have proposed that most posterior elbow dislocations begin with disruption of the lateral ligaments and proceed along the anterior capsular structures to the medial ligaments. Although this is likely the mechanism for the more rarely seen posteromedial elbow dislocation, for the more common posterior and posterolateral elbow dislocations, this notion has been challenged. Clinical and magnetic resonance imaging (MRI)-based studies noting that medial ulnar collateral ligament injuries occur more frequently than lateral ulnar collateral injuries,[76,77,79,144] have led to the competing theory[144] that most posterior elbow dislocations initiate from a valgus force at the elbow leading to failure of the medial ulnar collateral ligament or the medial epicondyle apophysis, to which it is attached, creating a medial epicondyle fracture. As the proximal radius and ulna displace laterally, the coronoid disengages with the intact biceps tendon acting as the center of rotation for the displaced forearm (Fig. 18-8). Application of both an abduction and an extension force leads to forearm external rotation and, with anterior soft tissue disruption, the result is a posterior or posterolateral elbow dislocation.[125,144]

Associated Injuries with Posterior Elbow Dislocations

Fractures Associated with Posterior Elbow Dislocations

Concomitant fractures occur in over one-half of posterior elbow dislocations.[90,121,147,150] The most common fractures involve the medial epicondyle, the coronoid process, and the radial head and the neck. Fractures involving the lateral epicondyle, lateral condyle, olecranon, capitellum, and trochlea occur less frequently.[25] Given the significant association between fractures of the medial epicondyle, the coronoid process and the proximal

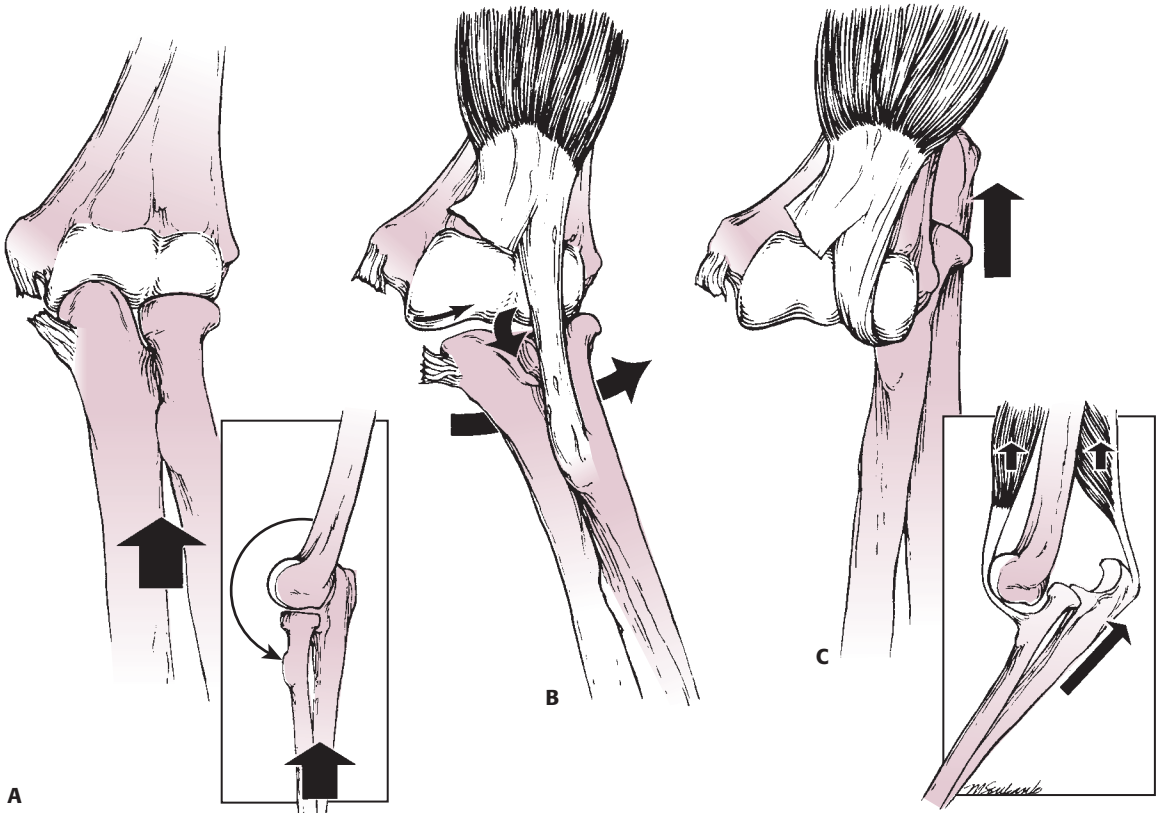

FIGURE 18-8 Mechanism of injury producing a posterior elbow dislocation. **A:** The elbow is forced into extension that ruptures the medial collateral ligaments. The normal valgus alignment of the elbow accentuates the valgus force at the elbow. **B:** The lateral slope of the medial crista of the trochlea forces the proximal ulna posterolaterally (*small arrow*). The biceps tendon serves as a fulcrum for rotation (*medium arrow*) leading to valgus hinging (*large arrow*) of the forearm. **C:** The proximal ulna and radius are then impacted posteriorly and held against the distal articular surface by the contraction of the biceps and triceps (*arrows*).

radius (especially markedly displaced radial neck fractures), and posterior elbow dislocations, evaluating for elbow stability when these fractures are noted is important.

Soft Tissue Injuries Associated with Posterior Elbow Dislocations

Posterior dislocations normally produce moderate soft tissue injury and can be associated with neurovascular injuries in addition to concomitant fractures (Fig. 18-9). The anterior capsule fails in tension, opening the joint cavity. Radial head displacement strips the capsule from the posterolateral aspect of the lateral condyle with the adjacent periosteum. Because of the large amount of cartilage on the posterolateral aspect of the lateral condyle, the posterior capsule may not reattach firmly with healing. This lack of a strong reattachment is believed to be a factor in the rare recurrent elbow dislocation.[126] In a series of 62 adults and adolescents with elbow dislocations requiring surgical treatment, McKee et al.[111] reported that disruption of the lateral collateral ligament complex occurred in all 62 elbows.

Medially, the ulnar collateral ligament complex is disrupted either by an avulsion of the medial epicondyle or a direct tear of the ligament.[157,165] Cromack[30] found that with medial epicondylar fractures, the origins of the ulnar collateral ligaments and the medial forearm flexor muscles remain as a unit, along with most of the pronator teres, which is stripped from its humeral origin proximal to the epicondyle. These structures are then displaced posterior to the medial aspect of the distal humerus. The ulnar collateral ligaments and the muscular origins of the common flexor muscles tear if the epicondyle remains attached to the humerus. With posterolateral displacement of the forearm, the medial aspect of the distal humerus most often passes into the intermuscular space between the pronator teres posteriorly and the brachialis anteriorly. The brachialis, because it has little distal tendon, is easily ruptured. The rent in the anterior capsule usually is in this same area.

The structure most commonly torn on the lateral aspect of the elbow is the annular ligament.[165] On occasion, the lateral collateral ligament either avulses a small osteochondral fragment from the lateral epicondyle or tears completely within its substance.

Neurovascular Injuries Associated with Posterior Elbow Dislocations

When the elbow is dislocated, the medial aspect of the distal humerus typically protrudes between the pronator teres

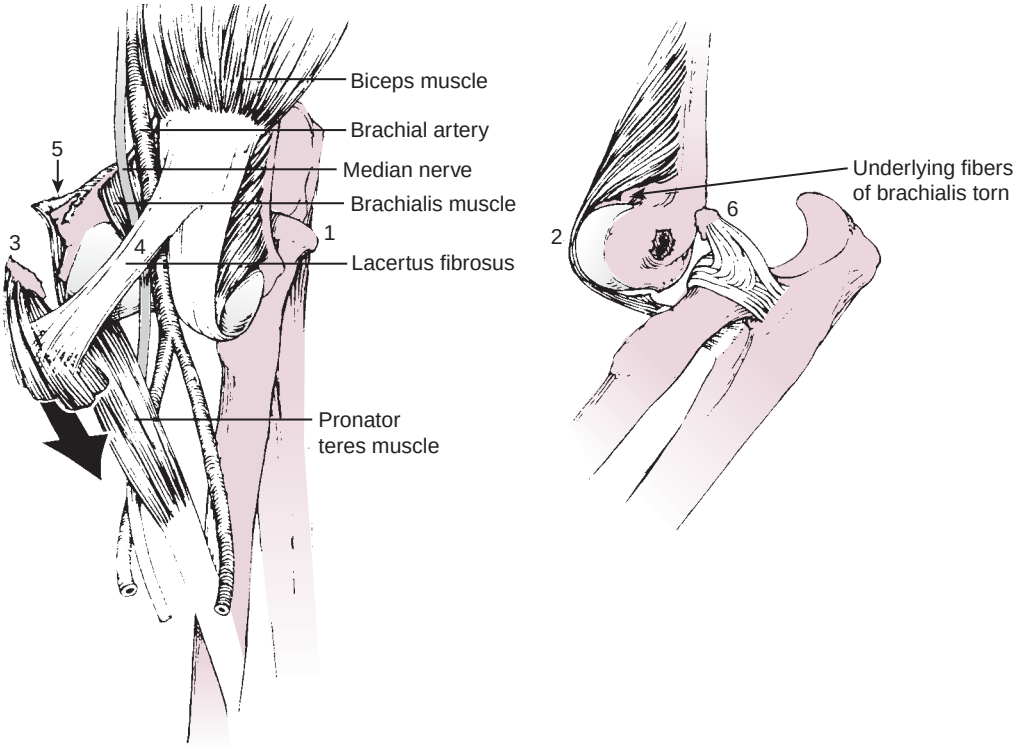

FIGURE 18-9 Injuries associated with elbow dislocation. (*1*) The radial head and olecranon are displaced posterolaterally. (*2*) The brachialis muscle is stretched across the articular surface of the distal humerus. (*3*) The origins of the medial forearm flexion muscles are either torn or avulsed with the medial epicondyle from the medial condyle. (*4*) The median nerve and brachial artery are stretched across the medial condyle and held firmly by the lacertus fibrosus. (*5*) The medial condyle lies in the subcutaneous tissue between the brachialis anteriorly and the pronator teres posteriorly. (*6*) The lateral (radial) collateral ligaments often avulse a piece of cartilage or bone from the lateral condyle.

posteriorly and the brachialis anteriorly. The median nerve and brachial artery lie directly over the distal humerus in the subcutaneous tissues. In a cadaver and clinical study by Louis et al.,[94] there was a consistent pattern of disruption of the anastomosis between the inferior ulnar collateral artery and the anterior ulnar recurrent artery. If the main brachial arterial trunk also is compromised, the loss of this collateral system can result in the loss of circulation to the forearm and hand.

The ulnar nerve is at risk in posterior elbow dislocation because of its position posterior to the medial epicondyle. In clinical cases, the ulnar nerve is the most common neurovascular injury.

Signs and Symptoms of Posterior Elbow Dislocations

Posterior elbow dislocations must be differentiated from extension-type supracondylar fractures of the distal humerus. With both injuries, the elbow is held semiflexed and swelling may be considerable. Swelling initially is usually less with a dislocation than with a type III supracondylar humeral fracture. Crepitus is usually absent in children with a dislocation and the forearm appears shortened. The prominence produced by the distal humeral articular surface is more distal and is palpable as a blunt articular surface. The tip of the olecranon is displaced posteriorly and proximally so that its triangular relationship with the epicondyles is lost. The skin may have a dimpled appearance over the olecranon fossa. If the dislocation is posterolateral, the radial head also may be prominent and easily palpable in the subcutaneous tissues.

Imaging and Other Diagnostic Studies for Posterior Elbow Dislocations

Anteroposterior (AP) and lateral x-rays usually are diagnostic of a posterior elbow dislocation. There is a greater superimposition of the distal humerus on the proximal radius and ulna in the AP view. The radial head may be proximally and laterally displaced, or it may be directly behind the middistal humerus, depending on whether the dislocation is posterolateral, posterior, or posteromedial (Fig. 18-10). The normal valgus angulation between the forearm and the arm usually is increased. On the lateral view, the coronoid process lies posterior to the condyles. Prereduction and postreduction x-rays must be examined closely for associated fractures. The medial epicondyle should be identified on the postreduction films. If it should be present based on the patient's age and elbow ossification pattern and it is not visible, the medial epicondyle is likely fractured and may be entrapped in the joint. Additional radiographs may be necessary to further evaluate an associated medial epicondyle fracture. Postreduction radiographs

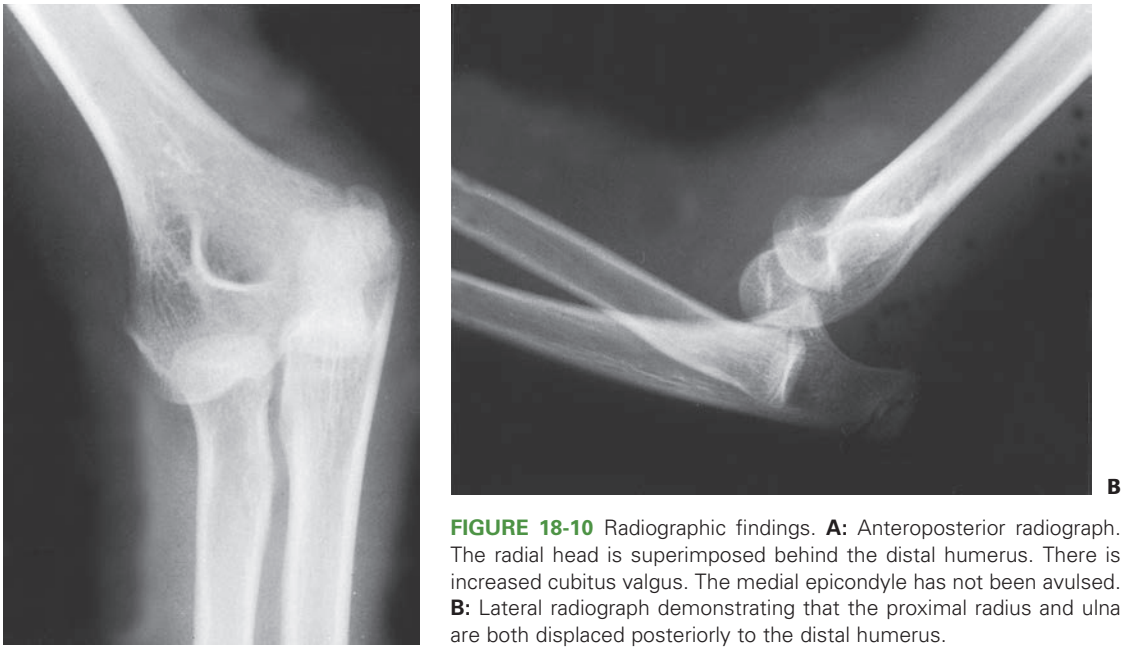

FIGURE 18-10 Radiographic findings. **A:** Anteroposterior radiograph. The radial head is superimposed behind the distal humerus. There is increased cubitus valgus. The medial epicondyle has not been avulsed. **B:** Lateral radiograph demonstrating that the proximal radius and ulna are both displaced posteriorly to the distal humerus.

should be carefully scrutinized for a congruent reduction and for subtle osteochondral fracture fragments that can become entrapped in the joint (Fig. 18-11). If anatomic, congruent reduction is in question or not feasible or if osteochondral fragments are visualized, further evaluation with computerized tomography or MRI is utilized. MRI may be used to further define the extent of soft tissue injury in complex injury patterns.

Treatment Options for Posterior Elbow Dislocations

If untreated, elbow dislocation predictably results in dramatic loss of elbow function characterized by loss of motion and eventually pain (Fig. 18-12). In comparison, reduction of the dislocated elbow usually achieves marked improvement of acute pain as well as restoration of long-term function.

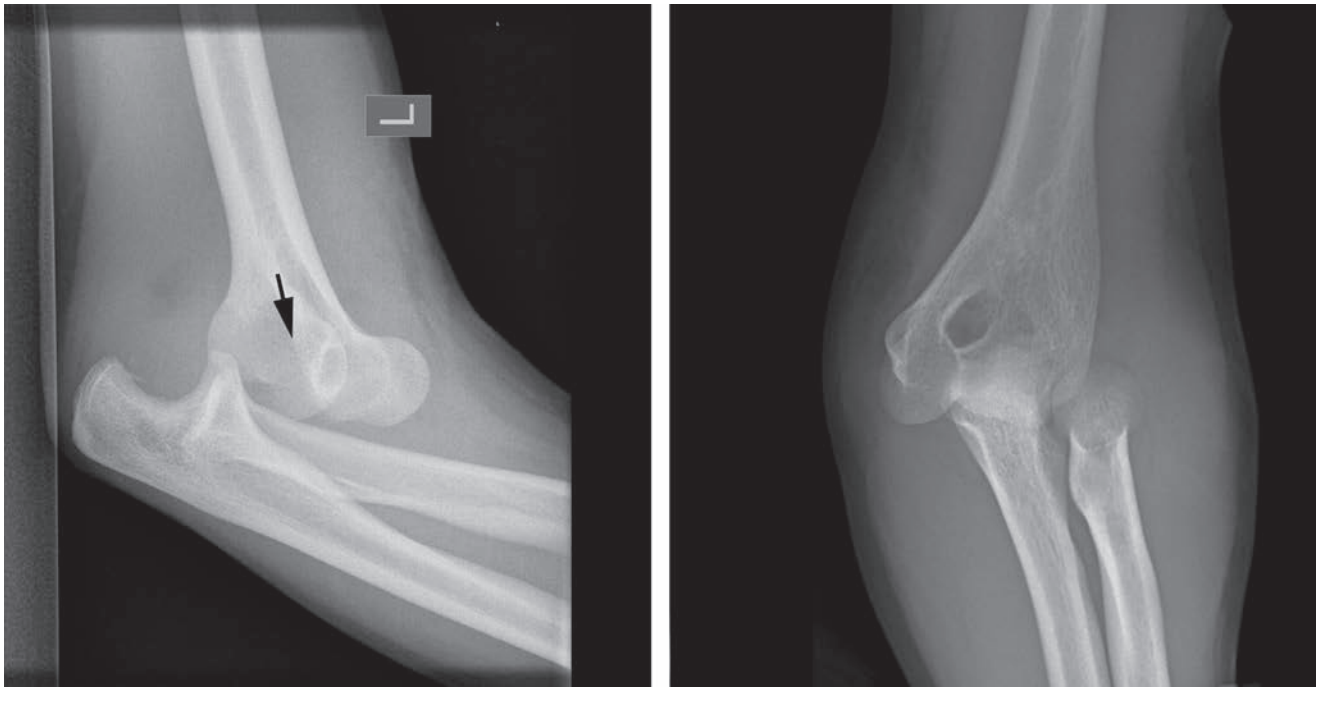

FIGURE 18-11 Intra-articular entrapment of osteochondral fragments following closed reduction of a posterior elbow dislocation. **A:** A 15-year-old female presented with a posterior elbow dislocation.

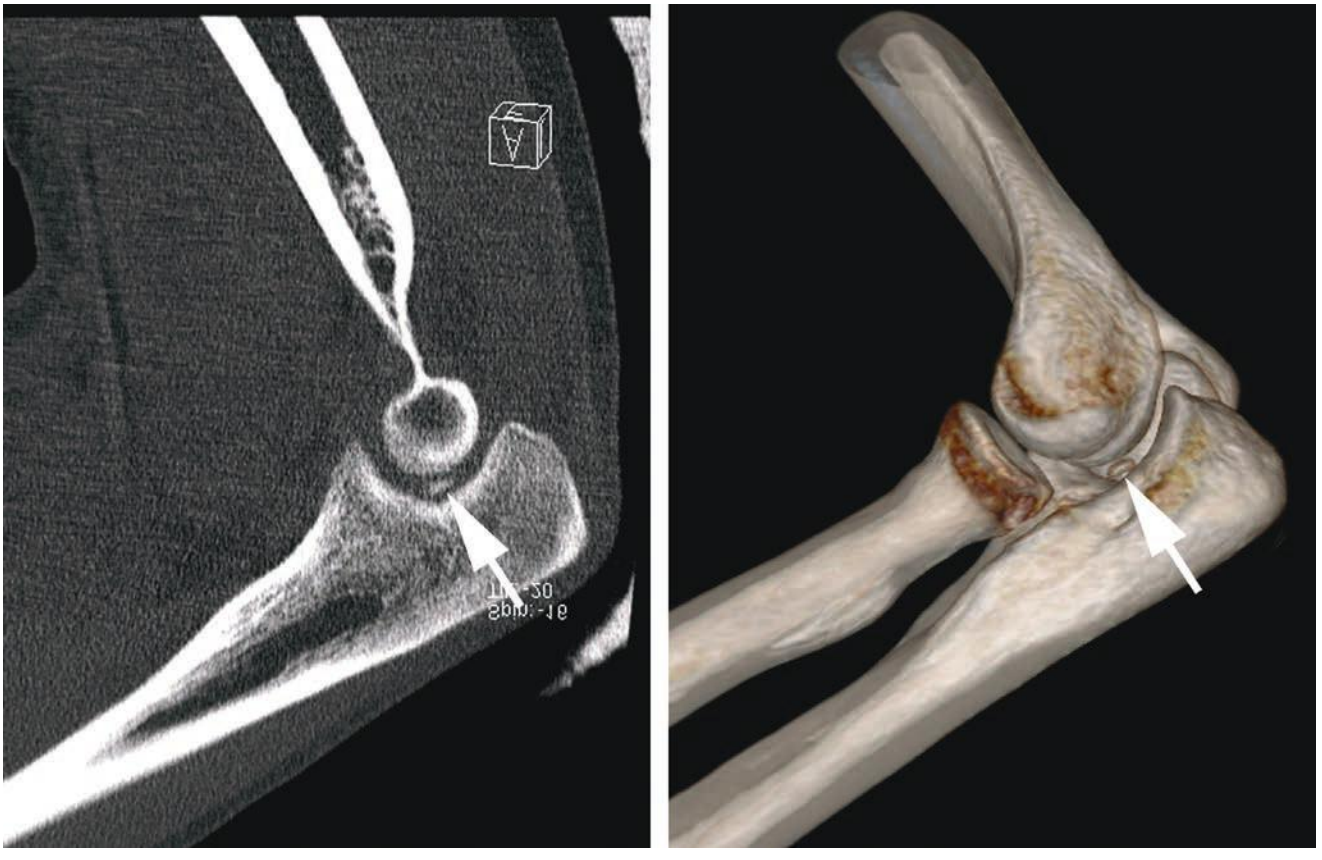
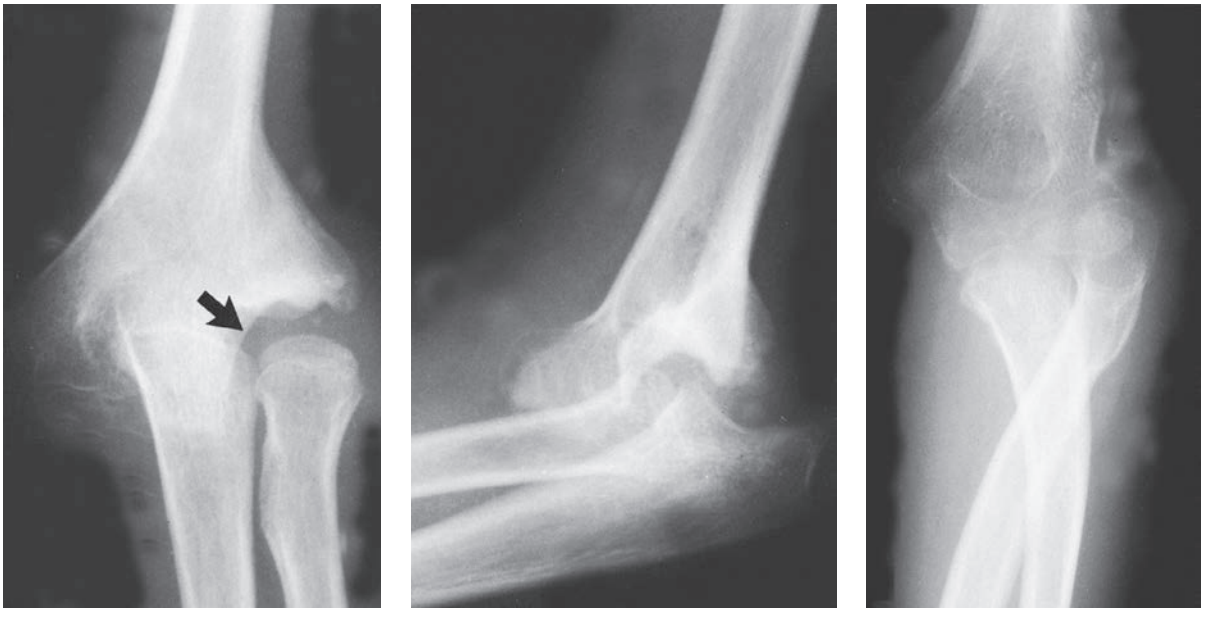


B

FIGURE 18-11 (*continued*) **B:** Following successful closed reduction, fluoroscopic images suggested an entrapped intra-articular osteochondral fragment (*arrow*). This was confirmed with a CT scan. She subsequently underwent early open removal of these fragments via a medial approach. Significant damage was noted to the brachialis musculature.



A, B C

FIGURE 18-12 Unreduced dislocation. **A:** Preoperative anteroposterior radiograph. The elbow sustained an injury 3 years before surgery. Elbow motion was extremely limited and painful. The lateral supracondylar ridge had been eroded by the radial head (*arrow*). **B:** Lateral radiograph. The posterior position of the olecranon is apparent. **C:** Anteroposterior radiograph 3 months postoperatively. Total elbow motion was 30 degrees, but there was less pain and more stability.

Nonoperative Treatment of Posterior Elbow Dislocations

Indications/Contraindications

Progressive elbow swelling secondary to the soft tissue injury associated with an elbow dislocation makes it imperative that all acute elbow dislocations be promptly reduced under adequate sedation or anesthesia. Royle[150] found that dislocations reduced soon after the injury had better outcomes than those in which reduction was delayed. Immediately after reduction, the surgeon should determine and document the stability of the elbow by examination under anesthesia or sedation. Definitive nonoperative treatment following closed reduction can be considered if the elbow is stable through a functional range of motion, a concentric anatomic reduction can be obtained and maintained, and there is no evidence to suggest a vascular injury, nerve entrapment, or significant intra-articular osteochondral fragments (Table 18-1).

TABLE 18-1 Posterior Elbow Dislocation

Nonoperative Treatment Following Successful Closed Reduction

Indications	Relative Contraindications
Stable concentric elbow reduction obtained following closed treatment	Unable to obtain a concentric and stable elbow reduction Intra-articular entrapment of fracture fragments Vascular injury Change in neurologic status following reduction or other indication of nerve entrapment

Techniques for Closed Reduction of Posterior Elbow Dislocations

All methods of closed reduction must overcome the deforming muscle forces so that the coronoid process and the radial head can slip past the distal end of the humerus. Adequate sedation or anesthesia is necessary to permit muscle relaxation. Before the primary reduction forces are applied, the forearm is hypersupinated to dislodge the coronoid process and radial head from their position behind the distal humerus and to reduce tension on the biceps tendon.[126] The reducing forces are applied in two major directions (Fig. 18-13). The first reducing force must be along the long axis of the humerus to overcome the contractions of the biceps and brachialis anteriorly and the triceps posteriorly. Once these forces are neutralized, the proximal ulna and radius must be passed from posterior to anterior. Combined pusher–puller techniques are also possible.[59,183]

Previous authors[90,183] have strongly advised against initial hyperextension before reduction forces are applied to the elbow. Loomis[91] demonstrated that when the coronoid process is locked against the posterior aspect of the humerus and the elbow is extended, the force applied to the anterior muscles is multiplied by as much as five times because of the increased leverage. This places a marked strain on the injured

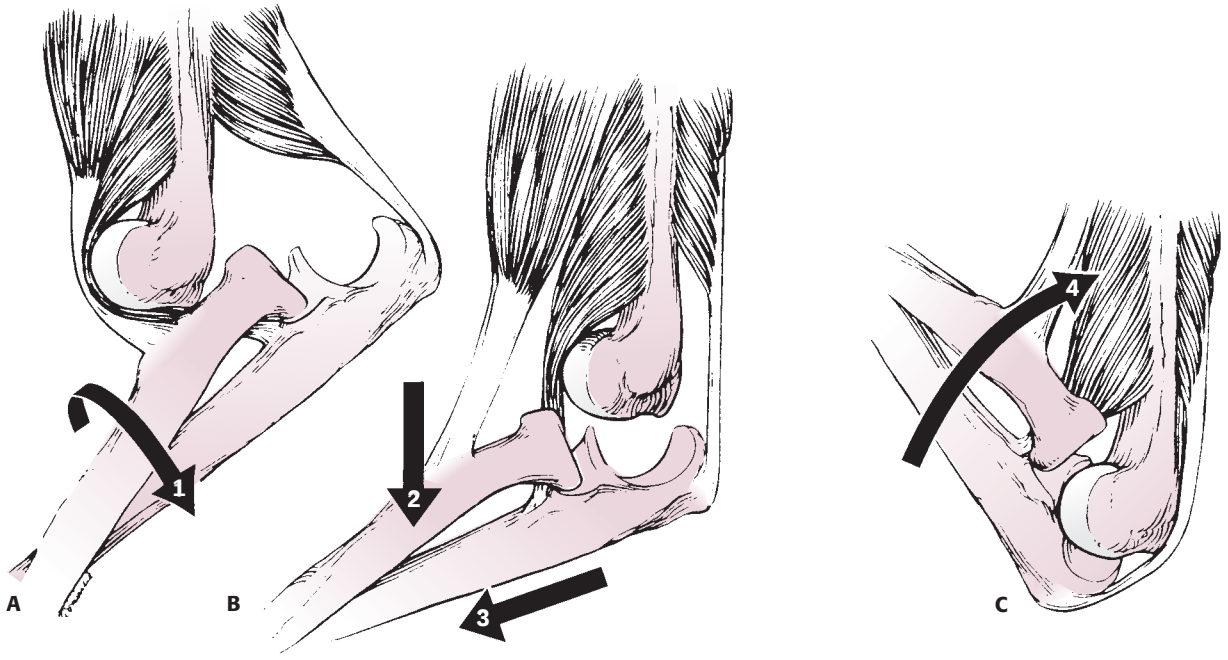


FIGURE 18-13 Forces required to reduce posterior elbow dislocations. **A:** The forearm is hypersupinated (*arrow 1*) to unlock the radial head. **B:** Simultaneous forces are applied to the proximal forearm along the axis of the humerus (*arrow 2*) and distally along the axis of the forearm (*arrow 3*). **C:** The elbow is then flexed (*arrow 4*) to stabilize the reduction once the coronoid is manipulated distal to the humerus.

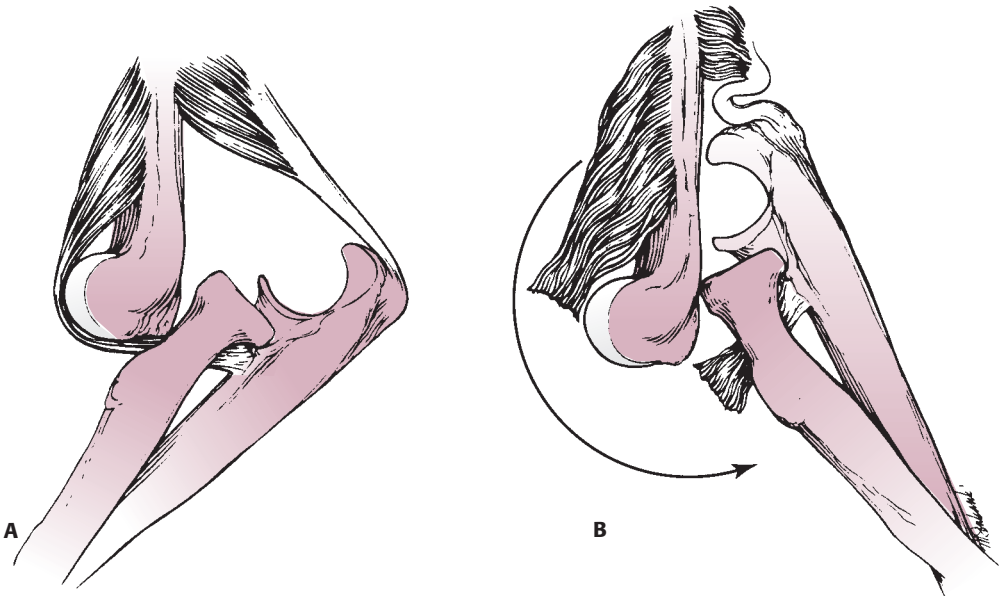

FIGURE 18-14 Hyperextension forces. **A:** The brachialis is stretched across the distal humerus. **B:** Hyperextending the elbow before it is reduced greatly increases the arc of motion and leverage placed across the brachialis. This can result in rupture of large portions of the muscle. (Reprinted from Loomis LK. Reduction and after-treatment of posterior dislocation of the elbow. *Am J Surg.* 1944; 63:56–60, with permission.)

structures in the antecubital fossa including the anterior capsule, the brachialis muscle, and the neurovascular structures (Fig. 18-14). By contrast, when force is applied to the proximal forearm with the elbow flexed, the force exerted against the muscles across the elbow is equal to the distracting force. For patients with posterolateral dislocations, the lateral displacement of the proximal radius and ulna must first be corrected to prevent the median nerve from being entrapped or injured during reduction.[18,22] Hyperextension reduction puts the median nerve more at risk for entrapment.

Closed Reduction of a Posterior Elbow Dislocation by the "Puller" Technique

The puller technique can be performed in various positions including the supine position and the prone position.

Prereduction Planning. If adequate sedation to achieve full muscular relaxation cannot be achieved in the emergency department, the procedure should be performed in the operating room under general anesthesia. An assistant who can provide adequate stabilizing force is required. Use of fluoroscopy is not usually required to assess the reduction. However, if available, it can help assess elbow stability and provide a more dynamic assessment of reduction congruity that postreduction plain radiographs, especially those obtained following placement of immobilization, cannot provide (Table 18-2).

Positioning. The patient is placed on the table either in the supine or the prone position with the shoulder abducted 90 degrees and the elbow off the side of the table. An assistant is positioned on the opposite side of the patient to provide the counterforce. A sheet can be placed around the patient for stabilization purposes if desired. If this is done an additional assistant may be required to stabilize the upper arm during the reduction.

Technique. With the elbow flexed to almost 90 degrees, a traction force is applied to the anterior portion of the forearm along the longitudinal axis of the humerus with one hand while the other hand pulls distally along the forearm. If any medial or lateral displacement is present, this should be corrected before the forearm is translated distally to release soft tissue structures

TABLE 18-2 Closed Reduction of a Posterior Elbow Dislocation by the "Puller" Technique

Preprocedure Planning Checklist

- Location: Emergency room if full muscular relaxation can be obtained. If not, under general anesthesia in the operating room is preferred.
- Table: Any supportive stretcher or operating room table will suffice
- Position/positioning aids: For supine technique the patient is placed supine with the shoulder abducted 90 degrees and the elbow over the edge of the bed. For the prone technique the patient is placed prone with the shoulder abducted 90 degrees and the elbow draped over the side of the table. Proper padding of all peripheral pressure points is critical.
- Fluoroscopy location: The image intensifier is placed alongside the table on the side of elbow dislocation and arranged to assess a lateral x-ray once the elbow is reduced.
- Equipment: Postreduction immobilization supplies (cast or splint)

TABLE 18-3 Closed Reduction of a Posterior Elbow Dislocation by the "Puller" Technique

Technical Steps

- Ensure adequate sedation with near-complete muscular relaxation
- Have assistant to stabilize the body and the humerus
- Flex the elbow to about 90 degrees
- "Milk" the distal humerus out of anterior soft tissues
- Apply force on the anterior forearm in line with the humeral shaft
- Correct any medial or lateral displacement
- Apply a distally directed force in line with the forearm to reduce the elbow joint
- Check the elbow reduction with static and dynamic fluoroscopic evaluation
- Assess elbow stability
- Immobilize elbow in about 90 degrees of flexion

from the distal humerus and prevent entrapment of tissue around the distal humerus. Gently "milking" the anterior soft tissue out from around the distal humerus, by gently pinching and pulling the tissues enveloping the distal humerus forward, as the reduction is performed can also help the reduction. During the procedure, a counterforce is applied by an assistant to offset the manipulating forces and stabilize the humerus. The physician performing the procedure usually appreciates a palpable clunk of the reduction. Using fluoroscopic evaluation, if available, the reduction is assessed in multiple projections. The range of stable motion is assessed, noting stability with the forearm in full supination and in neutral rotation (Table 18-3).

Closed Reduction of a Posterior Elbow Dislocation by the "Pusher" Technique

Like the puller technique, the pusher technique can be performed in various positions.

Prereduction Planning. Again, like the pusher technique, adequate sedation is required and fluoroscopy can be helpful for postreduction evaluation (Table 18-4).

Positioning. The patient is positioned with the distal humerus over a fixed surface, either the back of a chair or the edge of the bed.

Technique. With the elbow flexed to almost 90 degrees, the thumb is used to push the olecranon distally past the humerus. The other arm then pulls distally along the axis of the forearm affecting the reduction. Again, if any medial or lateral displacement is present, this should be corrected before the forearm is translated distally. Fluoroscopic evaluation, if available, can then be performed as with the puller technique. Elbow stability should be assessed and the elbow then immobilized in a position of stability (Table 18-5).

Postreduction Care Following Closed Reduction of a Posterior Elbow Dislocation

Some type of immobilization, usually a posterior splint, is advocated by most investigators. A frequently recommended period

TABLE 18-4 Closed Reduction of a Posterior Elbow Dislocation by the "Pusher" Technique

Preprocedure Planning Checklist

- Location: Emergency room if full muscular relaxation can be obtained. If not, under general anesthesia in the operating room is preferred.
- Table: Any supportive stretcher or operating room table will suffice. The patient can even be supported in the arms of a parent or an assistant.
- Position/positioning aids: For Lavine's method (Fig. 18-18A), the child is held by the parent while the elbow is draped over the edge of the chair. The back of the chair must be well padded. For Meyn's technique (Fig. 18-18B), the patient is placed prone with the shoulder abducted 90 degrees and the elbow draped over the side of the table. Proper padding of all peripheral pressure points is critical.
- Fluoroscopy location: The image intensifier is placed alongside the table on the side of elbow dislocation and arranged to assess a lateral x-ray once the elbow is reduced.
- Equipment: Post reduction immobilization supplies (cast or splint)

of immobilization is 3 weeks,[90,91,130,158] although some have advocated early motion.[149,150,191] In a recent study of 42 adult patients comparing 2 weeks of cast immobilization with the use of a simple arm sling and early motion, Maripuri et al.[106] demonstrated improved early and final functional outcomes in the early mobilization group compared to the group placed in a cast following reduction. O'Driscoll et al.[125] suggested that if the elbow was stable in response to valgus stress with the forearm pronated then the anterior portion of the medial collateral ligament was intact and the patient could begin early motion. Ninety degrees of elbow flexion appears to be the standard position of immobilization. Hinged elbow braces with adjustable blocks to motion are very useful for obtaining progressive, protected motion.

TABLE 18-5 Closed Reduction of a Posterior Elbow Dislocation by the "Pusher" Technique

Technical Steps

- Ensure adequate sedation with near-complete muscular relaxation
- Have assistant to stabilize the body and the humerus over the edge of a fixed surface
- Flex the elbow to about 90 degrees
- "Milk" the distal humerus out of anterior soft tissues
- Using the thumb, apply force on the prominent olecranon translating it distally in line with the humeral shaft
- Correct any medial or lateral displacement
- Apply a distally directed force in line with the forearm with the other hand to reduce the elbow joint
- Check the elbow reduction with static and dynamic fluoroscopic evaluation
- Assess elbow stability
- Immobilize elbow in about 90 degrees of flexion

Posterior Elbow Dislocation Outcomes

Closed reduction of posterior elbow dislocations is successful in most cases. In the combined series of 317 dislocations,[90,121,147,150] only two cases[90] could not be reduced by closed methods. In the Carlioz and Abols[25] series, two dislocations reduced spontaneously and closed reduction was successful in 50 cases, but failed in six cases (10%). Josefsson et al.[78] reported that all 25 dislocations without associated fractures were successfully reduced.

Operative Treatment of Posterior Elbow Dislocations

Indications/Contraindications

Indications for primary open reduction include an inability to obtain or maintain a concentric closed reduction, an open dislocation, a displaced osteochondral fracture with entrapment in the joint, a vascular injury, or a neurologic injury for which there is any indication that there may be entrapment of the nerve.

Primary ligament repair is not routinely indicated. Adults with posterior elbow dislocations without concomitant fracture have no better function or stability following a primary ligamentous repair than those treated nonoperatively.[76,77] All fractures preventing concentric reduction need to be repaired with an open reduction of an elbow dislocation. Beware of elbow dislocations in children less than age 10 as they often have associated osteochondral fractures blocking reduction or preventing stability postreduction (Table 18-6).

Open Posterior Elbow Dislocations. Open dislocations have a high incidence of associated arterial injury.[63,82,90,94] Operative intervention is necessary in open posterior dislocations to irrigate and debride the open wound and elbow and to evaluate the brachial artery. If there is vascular disruption, most advocate vascular repair or reconstruction with a vein graft even in the presence of adequate capillary refill. This may lessen the risk of late cold intolerance, dysesthesias, or dysvascularity.

Fractures Associated with Posterior Elbow Dislocations. Children with an elbow dislocation can have an associated fracture of the coronoid, lateral condyle, olecranon (Fig. 18-15), radial neck, or medial epicondyle (Fig. 18-16). Fractures of the anteromedial facet of the coronoid have been recognized as an important injury associated with elbow dislocations in adolescents and adults.[35,36] The presence of a concomitant displaced fracture is a common indication for surgical intervention.[25,46,185] Surgery for associated fractures produced better results than nonoperative treatment in the series of Carlioz and Abols,[25] and similar results were reported by Wheeler and Linscheid.[185] Repair of an associated medial epicondylar fracture may also improve elbow stability in throwing athletes when the injury is in the dominant arm.[157,191] Entrapment of any fracture fragments within the joint is an absolute indication for surgical treatment. Displaced medial epicondyle fractures can be entrapped within the joint after reduction and are often overlooked on the radiographs (Fig. 18-20). Because of the high association of this fracture with elbow dislocations, the location of the medial epicondyle should be confirmed in every case. Ultimately, the surgical treatment for fractures associated with an elbow dislocation is based on the circumstances surrounding each individual patient. Factors favoring operative treatment include older patient age, instability of the elbow during examination under sedation at the time of reduction, the presence of a displaced intra-articular fracture, injury to multiple elbow stabilizers, injury to the patient's dominant arm, and anticipated high-demand sports, especially overhead sports, or activities on the elbow.

FIGURE 18-15 Lateral radiograph of a 4-year-old child who sustained an elbow dislocation with a concomitant olecranon fracture (*large arrow*) and a coronoid fracture (*small arrow*).

Vascular Injuries Associated with Posterior Elbow Dislocations. With initial evidence of vascular compromise, treatment should consist of urgent reduction of the elbow dislocation which usually returns the displaced brachial vessels to their normal position[64,187] followed by reassessment of the vascular status. With prompt normalization of the vascular status, serial observation is still recommended to evaluate for evolving circulatory compromise. If there is evidence of persistent vascular compromise after reduction, vascular exploration followed by operative repair of those structures that are ruptured or severely damaged should be pursued emergently. Even though

TABLE 18-6 Posterior Elbow Dislocation

Operative Treatment

Indications	Contraindications
Unable to obtain a concentric and stable elbow reduction	Stable concentric elbow reduction obtained following closed treatment
Intra-articular entrapment of fracture fragments	
Vascular injury	
Change in neurologic status following reduction or other indication of nerve entrapment	

FIGURE 18-16 **A:** Anteroposterior and lateral radiograph of a 14-year-old male who sustained an elbow dislocation with an ipsilateral medial epicondyle fracture. **B:** Anteroposterior radiographs after a closed reduction. Note the entrapment of the medial epicondyle in the joint. **C:** This patient was treated with an open reduction to extract the medial epicondyle from the joint and an internal fixation using a cannulated screw that allowed rapid mobilization of his elbow.

collateral vessels may provide adequate vascular flow to give a warm hand with good capillary refill, if there has been a significant vascular injury, failure to repair the injury may predispose the patient to late ischemic changes such as claudication, cold sensitivity, or even late amputation.

Neurologic Injuries Associated with Posterior Elbow Dislocations. As with vascular injuries, initial evidence of neurologic compromise should prompt urgent reduction. A significant negative change in the neurologic status following closed reduction may indicate nerve entrapment and should prompt exploration.

Open Reduction of an Irreducible Posterior Elbow Reduction

Preoperative Planning. The surgical approach will be dictated by the goals of the procedure and based on an estimation of the structures that may be blocking the reduction. The most common structures preventing reduction via closed means include the distal humerus being buttonholed through the brachialis musculature, the radial head being buttonholed through the capsule and lateral collateral ligament, and entrapment of fracture fragments, especially the medial epicondyle, with their attached ligamentous or muscular structures wedging them in place. If the distal humerus or the radial head is easily palpable in the subcutaneous tissues and not able to be milked out of these tissues through closed means, an operative approach to perform this will be necessary. For the distal humerus in the brachialis a medial approach should be performed. For the radial head block, a lateral approach has been described.[55,84] If a fracture fragment, especially the medial epicondyle, can be visualized and is thought to be responsible for the block, the medial approach should be employed to facilitate fracture fixation (Table 18-7). Loose osteochondral fracture fragments can block a congruent reduction and computed tomography (CT) and/or MRI scanning may be required to visualize the fragments and determine operative approach.

Positioning. Supine positioning with a hand table will usually suffice. With an associated medial epicondyle fracture, the lateral position or the prone position may be employed as well. (See the section on medial epicondyle fractures.)

Technique for Open Reduction. For a medial approach, an incision is made just anterior to the predicted mid humeral line and curved distally just anterior the medial epicondyle.

TABLE 18-7 Open Reduction of an Irreducible Posterior Elbow Dislocation

Preprocedure Planning Checklist

- Approach: Lateral approach if radial head noted to be subcutaneous indicating possible block to reduction because of buttonholing through the lateral capsule and around the lateral collateral ligaments. Medial approach if the distal humerus is noted to be subcutaneous indicating a block to reduction because of buttonholing through the brachialis or if an associated medial epicondyle fracture is present and surgical fixation is planned.
- OR Table: Any supportive operating room table will suffice
- Position/positioning aids: Supine positioning with a hand table will usually suffice. However, lateral position or even prone positioning as for fixation of a medial epicondyle fracture may be helpful.
- Fluoroscopy location: The image intensifier is placed alongside the table on the side of elbow dislocation, on the side opposite the anticipated surgical approach.
- Equipment: Loup magnification may facilitate identification of neurovascular structures in the surgical field. Bipolar electrocautery is preferred around neurovascular structures for hemostasis. A headlamp greatly facilitates visualization. Suture anchors may be employed to resecure ligamentous avulsions and should be available.

With gentle spreading of the subcutaneous tissues the significant soft tissue trauma is evident. The buttonholed distal humerus, the median and ulnar nerves, and the brachial artery should be identified. Any intervening tissue or osteochondral fragments are removed from the interval between the joint surfaces. The joint is then reduced through a similar set of distraction and translational forces as described for the closed reduction techniques. Once reduced, joint stability is evaluated and a thorough assessment of the capsular and ligamentous structures is performed. Primary repair or reattachment of the medial collateral ligament complex with small suture anchors or transosseous drill holes may be performed to improve stability. The elbow is stabilized in a posterior splint or hinged elbow brace in a position of stability (Table 18-8).

Postoperative Care

Immobilization after surgery depends on the procedure performed. After open reduction, management is similar to that after satisfactory closed reduction. The length of immobilization for fractures is 5 to 10 days up to 3 to 4 weeks. Protected arc of motion with a hinged brace or intermittent splinting is utilized frequently to lessen the risk of posttraumatic contracture.

Author's Preferred Method of Treatment for Posterior Elbow Dislocations (Fig. 18-17)

The "pusher" technique of reduction of an elbow dislocation is preferred in children 9 years of age or younger. In this age group, the child often can be seated comfortably in the parent's lap (Fig. 18-18). Hanging the arm over the back of a well-padded chair may provide some stabilization.

TABLE 18-8 Open Reduction of an Irreducible Posterior Elbow Dislocation

Technical Steps

- Make a medially based incision just anterior to the humerus curving distally at the elbow (note that the neurovascular structures may be very subcutaneous because of the injury)
- Identify the median and ulnar nerves and the brachial artery. Protect medial antebrachial cutaneous nerves
- Remove any tissue or any other intervening structures
- Visually inspect the joint surfaces and remove any loose osteochondral fragments
- Flex the elbow to about 90 degrees
- Apply force on the forearm in line with the humerus translating it distally in line with the humeral shaft and opening the joint surface
- Correct any medial or lateral displacement
- Apply a distally directed force in line with the forearm, or directly posteriorly translate the distal humerus to reduce the elbow joint
- Check the elbow reduction with visual evaluation as well as dynamic fluoroscopic evaluation
- Assess elbow stability through range of motion
- Assess the extent of capsular and ligamentous damage and repair critical elements such as the medial ulnar collateral ligament and/or the medial epicondyle (see below separate medial epicondyle section)
- Reassess elbow stability through range of motion if repairs are performed
- Immobilize elbow in about 90 degrees of flexion

For a child 9 years of age and older, the puller technique advocated by Parvin[130] is used (Figs. 18-13 and 18-19). The forearm must remain supinated during the process of reduction. Occasionally, it is necessary to hypersupinate the forearm to unlock the coronoid process and the radial head before reduction. Closed reduction is done with either heavy sedation or general anesthesia. The range of stable elbow motion is assessed. Fluoroscopy can be helpful during and after the reduction to assess stability as well. Formal x-rays are obtained after the manipulation to assess the adequacy of the reduction (Fig. 18-20), to be certain the joint is congruently reduced and to assess for the presence of any intra-articular fragments. If the elbow is stable through a functional range of motion, the elbow is immobilized in a posterior splint, hinged brace, or a split cast with the elbow flexed 90 degrees. If there is a question of persistent relative instability, the forearm is held in full supination. If the elbow is absolutely stable following reduction, the forearm can be immobilized in midpronation to allow the patient to be more functional with early progressive motion.

Entrapped intra-articular fragments should be removed before mobilizing the elbow (Fig. 18-16). With the capsule disrupted and the joint full of blood clot, early arthroscopic removal of loose bodies is not recommended. Thus, we prefer to perform loose body removal with an open arthrotomy in the early postreduction period. Given the extensive medial soft tissue disruption, a medial approach with visualization of the joint through the

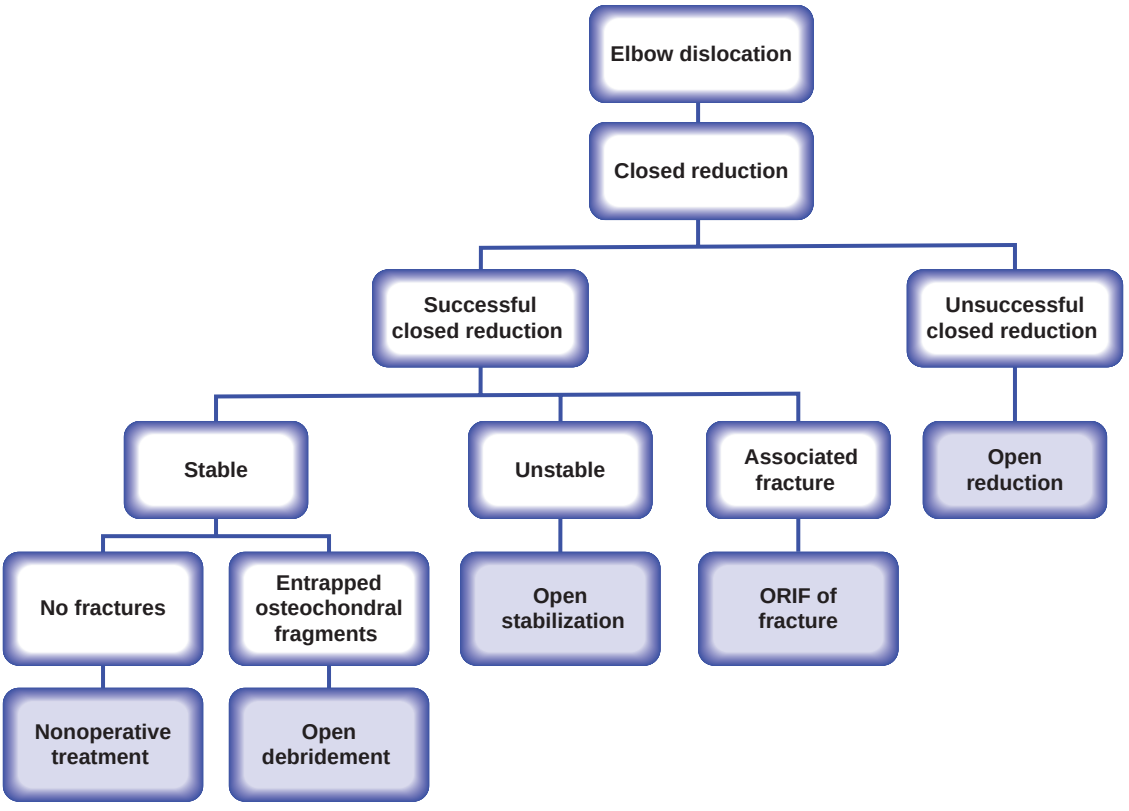

FIGURE 18-17 Algorithm.

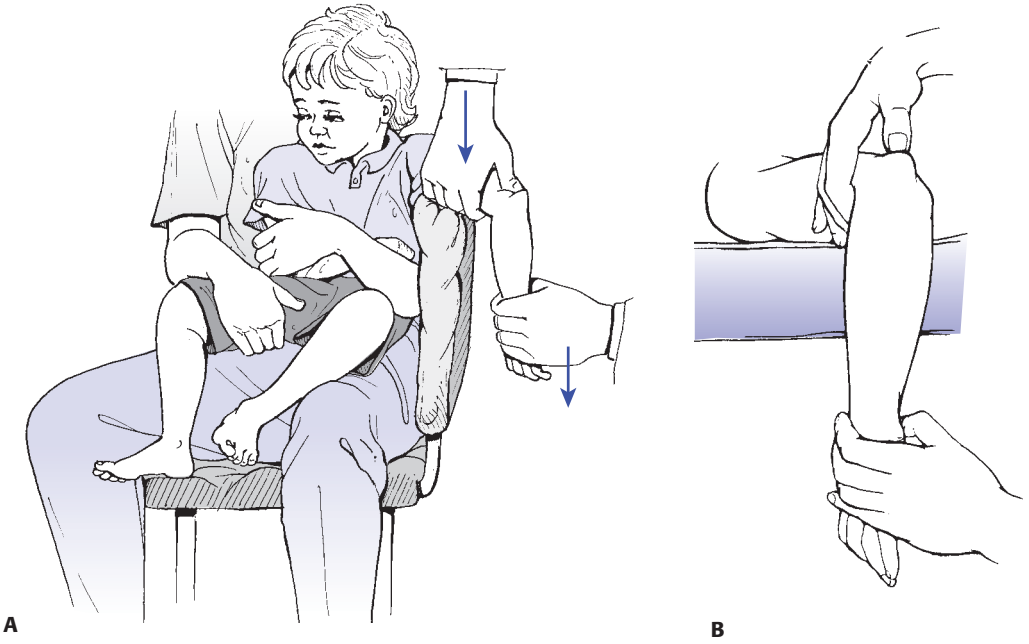

FIGURE 18-18 Reduction by "pusher" techniques. **A:** Lavine's method. The child is held by the parent while the elbow is draped over the edge of the chair. The olecranon is pushed distally past the humerus by the thumb of the physician while the other arm pulls distally along the axis of the forearm. **B:** Meyn's technique with patient lying prone on the table. FIGURE 18-19 Reduction by "puller" techniques in a supine position. **A:** With the elbow flexed to almost 90 degrees, a force is applied to the anterior portion of the forearm with one hand while the other hand pulls distally along the forearm. A counterforce is applied to offset the manipulating forces by direct stabilization of the patient by a second medical person. **B:** The counterforce is applied with a sheet around the chest in the ipsilateral axilla. (Redrawn from Parvin RW. Closed reduction of common shoulder and elbow dislocations without anesthesia. *Arch Surg.* 1957;75(6):972–975, with permission. Copyright 1957, American Medical Association.)

windows created by the injury allows for easy access to all aspects of the joint. Be certain to locate the ulnar nerve and medial antebrachial cutaneous nerves with operative exposure.

Persistent significant elbow instability should prompt a thorough investigation for associated fractures or incongruity of the reduction suggesting incarceration of soft tissue or chondral fragments in the joint. In the postreduction examination an estimation of the direction of instability should be performed: Valgus, varus, or posterolateral rotatory instability. In these circumstances, evaluation with a postreduction MRI to assess the extent of the soft tissue injury may help direct treatment.

Fractures associated with elbow dislocations may necessitate reduction and fixation as dictated by the guiding principles for the individual fracture. Failure to reduce and fix fractures associated with an elbow dislocation may lead to persistent instability. As is discussed at length in the second half of this chapter, we prefer to reduce and fix medial epicondyle fractures associated with elbow dislocations.

D

FIGURE 18-20 (*continued*) **C:** There is a concentric reduction following closed reduction using a puller technique. **D:** Lateral radiograph.

Postreduction Care

Because the major complication of elbow dislocations is stiffness, the initial full-time immobilization is removed after approximately 1 week and the patient transitioned to a removable splint or the hinged brace is unlocked for progressive motion. The patient begins intermittent protected active elbow motion out of the splint multiple times a day as limited by pain. In a reliable patient with minimal risk of additional trauma, the patient can usually dispense with the splint after 10 to 14 days and use a sling. If there are times at high risk for another fall, the splint can be continued up till about 5 to 6 weeks post injury during these times (i.e., during school), but should be removed at other times of the day when there is minimal risk (i.e., meal time) to promote range of motion. The emphasis is on early active motion in a safe environment to prevent stiffness that often occurs after this injury. Before reduction, it is important to emphasize to the parents that there may be some loss of motion, especially extension, regardless of the treatment. This is usually less than 30 degrees and not of functional or aesthetic significance.

Potential Pitfalls and Preventative Measures

Closed reduction of pediatric elbow dislocations should always be done with adequate analgesia, sedation, or anesthesia. In addition to making the experience much less frightening and traumatic for the child, adequate analgesia, sedation, or anesthesia will achieve sufficient muscle relaxation for the reduction to be obtained more effectively with less force, thereby reducing the risk of creating an iatrogenic fracture (such as fracture of the radial neck) during reduction.

A careful neurologic examination must be done before and after the reduction with special attention to the median nerve in terms of entrapment. This same careful examination must be made at all follow-up evaluations. Persistent median nerve motor–sensory loss associated with severe pain and resistance with elbow flexion–extension arc of motion may be indicative of entrapment. Of note, ulnar neuropathy is not uncommon and usually resolves spontaneously (Table 18-9).

Outcomes Following Closed Reduction of Posterior Elbow Dislocations

Outcomes following closed reduction of a posterior elbow dislocation are generally excellent despite some overall loss of range of motion.

TABLE 18-9 Posterior Elbow Dislocation

Potential Pitfalls and Preventions

Pitfall	Preventions
Stiffness	Early mobilization
Inadequate analgesia	Perform the reduction in the OR if adequate analgesia for muscular relaxation is not available in the emergency setting
Median nerve entrapment	Correct lateral displacement before translating anteriorly
Coronoid fracture during reduction	Attempt reduction with the elbow in flexion

Management of Expected Adverse Outcomes and Unexpected Complications Related to Posterior Elbow Dislocations

Complications associated with posterior elbow dislocations can be divided into those occurring early and those occurring later. Early complications include neurologic and vascular injuries. Late complications include loss of motion, myositis ossificans, recurrent dislocations, radioulnar synostosis, and cubitus recurvatum. The special problems of chronic, unreduced dislocations are not considered complications of treatment (Table 18-10).

Associated Neurologic Injuries with Posterior Elbow Dislocations

Ulnar Nerve Lesions

In a combined series of 317 patients,[90,121,147,150] the most commonly injured nerve was the ulnar nerve. Of the 32 patients (10%) who had nerve symptoms after reduction, 21 had isolated ulnar nerve injuries, seven had isolated median nerve injuries, and in four patients both the median and ulnar nerves were involved. Linscheid and Wheeler[90] recommended ulnar nerve transposition if ulnar nerve symptoms were present in a patient undergoing open reduction and internal fixation of a displaced medial epicondylar fracture. Except for the one patient described by Linscheid and Wheeler,[90] the reported ulnar nerve injuries were transient and resolved completely.

Radial Nerve Lesions

Radial nerve injury with posterior elbow dislocation is very rare. Watson-Jones[183] reported two radial nerve injuries associated with elbow dislocation; in both the symptoms rapidly resolved after reduction. Rasool[142] reported a third case.

Median Nerve Lesions

The most serious neurologic injury involves the median nerve, which can be damaged directly by the dislocation or can be entrapped within the joint. Median nerve injuries occur most commonly in children 5 to 12 years of age. These injuries, either isolated median nerve (7 out of 317 total dislocations) or combined median and ulnar nerve injuries (4 out of 317 total dislocations), were present in only 3% of dislocations.[90,121,147,150]

TABLE 18-10 Posterior Elbow Dislocations

Common Adverse Outcomes and Complications
Neurologic injuries: Ulnar and median nerve are injured most commonly
Vascular injuries: Injury to the brachial artery is most common
Loss of elbow range of motion
Heterotopic bone formation
Radioulnar synostosis
Cubitus recurvatum
Recurrent posterior dislocations
Unreduced posterior elbow dislocations

Types of Median Nerve Entrapment. Fourrier et al.,[43] in 1977, delineated three types of medial nerve entrapment (Fig. 18-21).

Type 1. The child has an avulsion fracture of the medial epicondyle or has a rupture of the flexor–pronator muscle origin and the ulnar collateral ligament (Fig. 18-21A). This allows the median nerve, with or without the brachial artery, to displace posteriorly, essentially wrapping posteriorly around the medial aspect of the humerus and then coursing distally around the articular surface of the distal humerus. With the deep groove of the trochlea acting like a hook for the nerve and catching it out of the anterior soft tissues, if the lateral displacement of the proximal radius and ulna is not corrected before reduction, the nerve may become entrapped in the joint, wrapped around the distal humerus alongside or even in the ulnotrochlear articulation during the process of reduction. Hallett[58] demonstrated in cadavers that pronation of the forearm while the elbow is hyperextended forces the median nerve posteriorly during the process of reduction making it vulnerable to entrapment. This type of entrapment also has been reported by other authors.[13,18,22,43,54,138,141,169] If median nerve dysfunction is present prior to reduction, it is often difficult to identify nerve entrapment postreduction. Certainly any significant decrease in median nerve function following a closed reduction or incongruity in the reduction should prompt evaluation for this injury pattern. In some patients with an associated medial epicondyle fracture, the nerve can be so severely damaged after being entrapped that neuroma resection, nerve transposition, and direct repair or grafting is necessary.[18,54] Good recovery of nerve function has been reported after operative decompression and repair.

If the nerve has been entrapped for a considerable period, the Matev sign may be present on the x-rays. This represents a depression on the posterior surface of the medial epicondylar ridge where the nerve has been pressed against the bone.[13,31,54,58,138,141,169] This groove is seen on x-ray as two sclerotic lines parallel to the nerve (Fig. 18-22). This sign disappears when the nerve has been decompressed.

Type 2. The nerve is entrapped between the fracture surfaces of the medial epicondyle and the distal humerus (Fig. 18-21B). The fracture heals and the nerve is surrounded by bone, forming a neuroforamen.[138,145,169] This may or may not be visible on x-ray. The medial epicondyle is osteomized to free the nerve. Again, decompression alone may be an adequate treatment, although neuroma resection and repair or reconstruction with nerve grafts may be necessary.

Type 3. The nerve is kinked and entrapped between the distal humerus and the olecranon (Fig. 18-21C). Only three injuries of this type have been reported.[13,137,140] Decompression, neuroma resection, and repair resulted in return of good function over 6 to 24 months.

Al-Qattan et al.[6] described a fourth type of median nerve entrapment in a 14-year-old boy who had a posterior elbow dislocation with a medial epicondylar fracture. The median nerve was found entrapped in a healed medial epicondylar fracture (type 2) in an anterior to posterior direction 18 months after injury. The nerve then passed through the elbow joint in a posterior to anterior direction (type 1). The nerve was

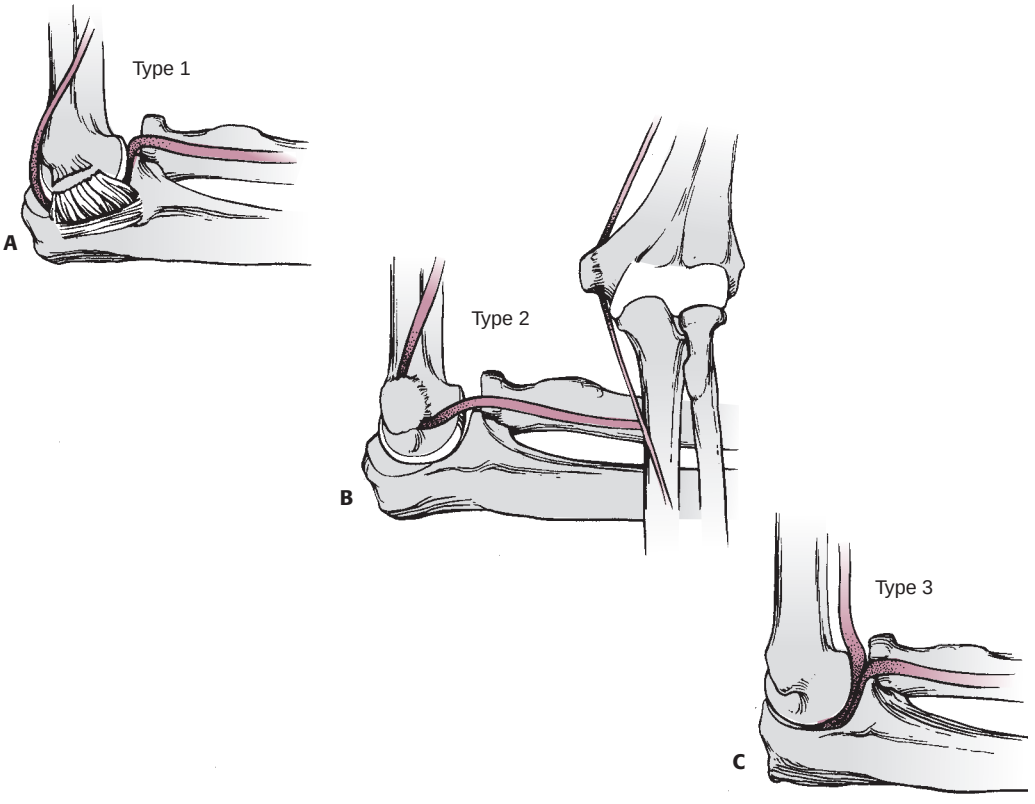

FIGURE 18-21 Median nerve entrapment. **A:** Type 1. Entrapment within the elbow joint with the median nerve coursing posterior to the distal humerus. **B:** Type 2. Entrapment of the nerve between the fracture surfaces of the medial epicondyle and the medial condyle. **C:** Type 3. Simple kinking of the nerve into the anterior portion of the elbow joint. (Redrawn from Hallett J. Entrapment of the median nerve after dislocation of the elbow. *J Bone Joint Surg Br.* 1981;63-B(3):408–412, with permission.)

so severely damaged that it had to be resected and repaired with sural nerve grafts. A second type 4 median nerve entrapment also requiring nerve segment resection and grafting was reported by Ozkoc et al.[127]

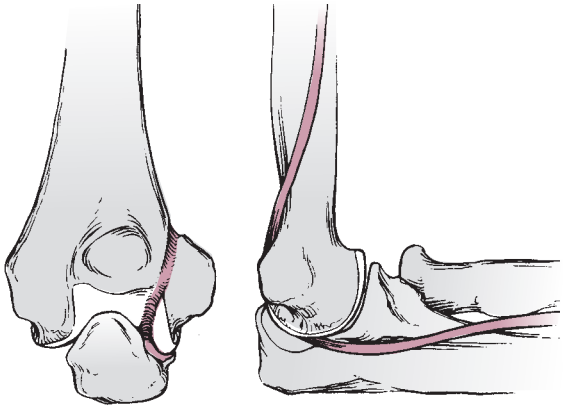

FIGURE 18-22 The Matev sign suggesting entrapment of the median nerve in the elbow joint and impingement of the nerve against the posterior surface of the medial condyle. This produces a depression with sclerotic margins. (Redrawn from Matev I. A radiographic sign of entrapment of the median nerve in the elbow joint after posterior dislocation. *J Bone Joint Surg Br.* 1976;58(3):353–355, with permission.)

The combination of an associated fracture of the medial epicondyle and significant median nerve dysfunction was cited by Rao and Crawford[141] as an absolute indication for surgical exploration of the nerve because of the frequency of median nerve entrapment with fractures of the medial epicondyle. MRI may be helpful in defining the course of the median nerve if entrapment is suspected.[3] Electromyography and nerve conduction studies have been utilized to assist in operative decision making. Painful dysesthesias with arc of motion is usually indicative of entrapment. Once the entrapped nerve is removed from the joint, neurologic function typically improves. Resection and repair or nerve grafting may be necessary.

Associated Arterial Injuries with Posterior Elbow Dislocations

Arterial injuries are uncommon with posterior elbow dislocations in children and adolescents with only eight vascular injuries (3%) reported in the combined series of 317 patients.[90,121,147,150] However, Carlioz and Abols[25] reported four patients with diminished radial pulses that resolved after reduction. Arterial injuries have been associated with open dislocations in which collateral circulation is disrupted.[63,82,94,151] In these situations, usually the brachial artery is ruptured,[57,63,68,82,94,151] but it can also be thrombosed[187] as well as entrapped in the elbow

joint.[64,133,187] Pearce[133] reported an entrapped radial artery in which there was a high bifurcation of the brachial artery. When there is a complete rupture, there usually is evidence of ischemia distally. However, the presence of good capillary circulation to the hand or a Doppler pulse at the wrist does not always mean the artery is intact.[57,68] Arteriograms usually are not necessary because the arterial injury is at the site of the dislocation. If imaging is indicated to evaluate possible arterial injury, its minimal risk and invasiveness make vascular ultrasound an attractive initial imaging choice.

For surgical treatment of vascular injuries about the elbow, simple ligation of the ends has been done in the past with adults, especially if there was good capillary circulation distally.[63,82] However, this may predispose to late ischemic changes such as claudication, cold sensitivity, or even late amputation. Most investigators recommend direct arterial repair or a vein graft.[57,68,94,102,151] Louis et al.[94] recommended arterial repair because their cadaver studies demonstrated that a posterior elbow dislocation usually disrupted the collateral circulation necessary to maintain distal blood flow.

Loss of Motion Associated with Posterior Elbow Dislocations

Almost all patients with elbow dislocations lose some range of elbow motion.[25,46,76–78,] This loss is less in children than in adults[78] and usually is no more than 10 degrees of extension. This rarely is of functional or aesthetic significance. However, the potential for loss of motion must be explained to the parents before reduction and may be an indication for a supervised rehabilitation program. If there is a displaced medial epicondylar fracture, because of the loss of isometry in the medial ligaments, the loss of major range of motion can be severe and limiting. Similarly, an incongruent elbow joint will have marked limitations of motion. In situations where the loss of motion is greater than 45 to 60 degrees, late operative release may be indicated.

Myositis Ossificans Versus Heterotopic Calcification

True myositis ossificans should be differentiated from heterotopic calcification, which is a dystrophic process. Myositis ossificans involves ossification within the muscle sheath that can lead to a significant loss of range of motion of the elbow. Disruption of the brachialis muscle is believed to be a contributory factor.[91] Fortunately, myositis ossificans is rare in children.[78,176] Although heterotopic calcification in the ligaments and capsule of the elbow is common,[78,147] it rarely results in loss of elbow function (Fig. 18-23).

In Neviaser and Wickstrom's[121] series of 115 patients, 10 had x-ray evidence of myositis ossificans; all, however, were asymptomatic. Roberts[147] differentiated true myositis ossificans from heterotopic calcification in his series of 60 elbow dislocations, and noted that only three patients had true myositis ossificans. Linscheid and Wheeler[90] reported that the incidence of some type of heterotopic calcification was 28%, which was most common around the condyles. Only in five patients was it anterior to the capsule (which probably represented true myositis ossificans in the brachialis muscle). Four of these patients had some decrease in elbow function. Josefsson et al.[78] reported that 61% of 28 children with posterior dislocations had periarticular calcification, but this did not appear to be functionally significant.

Radioulnar Synostosis

In dislocations with an associated fracture of the radial neck, the incidence of a secondary proximal radioulnar synostosis is increased (Fig. 18-24). This can occur regardless of whether the radial neck fracture is treated operatively or nonoperatively[22,25,125] and likely occurs because of the extensive periosteal

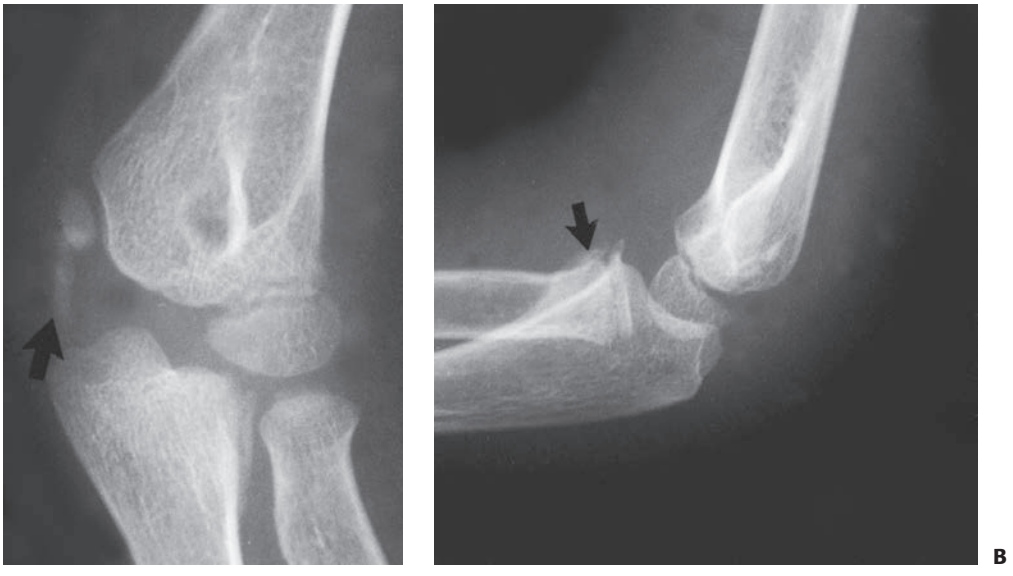

FIGURE 18-23 **A:** Heterotopic calcification of the ulnar collateral ligaments in an elbow that had been dislocated for 2 months (*arrow*). **B:** Lateral view of the same elbow. Some myositis ossification has occurred where the brachialis inserts into the coronoid process (*arrow*).

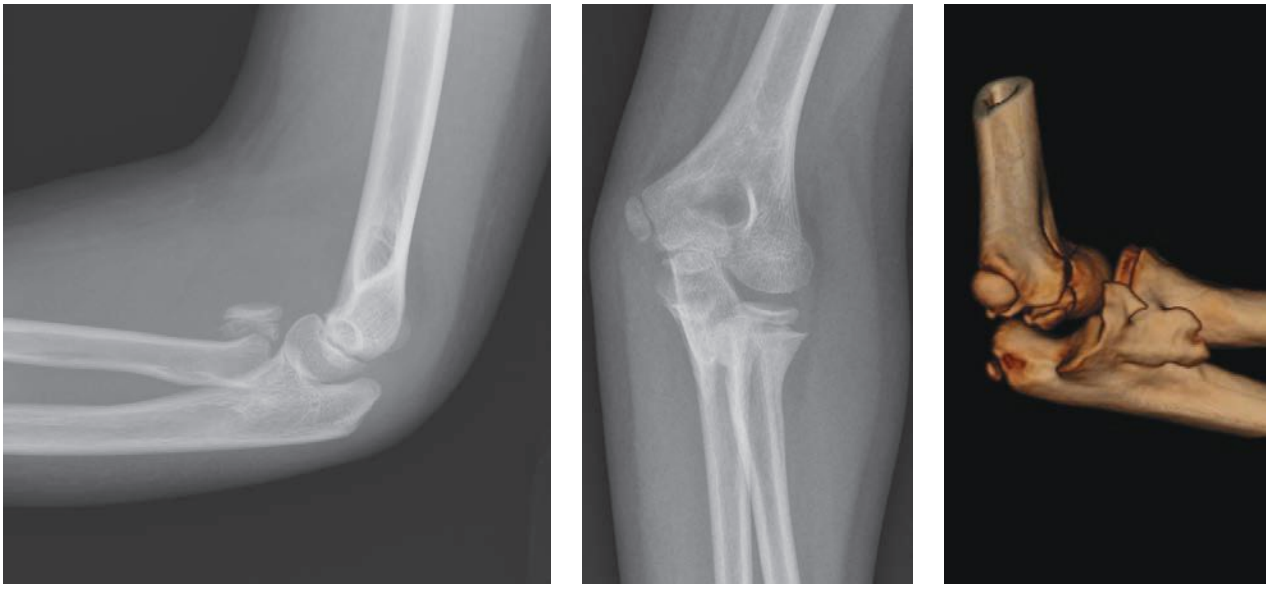

FIGURE 18-24 Radioulnar synostosis. An 11-year-old male fell injuring his nondominant left elbow. An elbow dislocation was reduced by emergency personnel prior to arrival at the hospital. **A:** Initial radiographs demonstrated a significantly displaced radial neck fracture. This was reduced using percutaneous techniques. **B:** Five months later radiographs and (**C**) a CT scan noted a complete radioulnar synostosis.

stripping that occurs along the anterior aspect of the forearm between the proximal radius and ulna. Carlioz and Abols[25] reported a synostosis in one of three patients with posterior elbow dislocations associated with radial neck fractures.

Cubitus Recurvatum

Occasionally, a severe elbow dislocation results in significant tearing of the anterior capsule. As a result, after reduction, when all the stiffness created by the dislocation has subsided, the patient may have some hyperextension (cubitus recurvatum) of the elbow. This is usually minimally symptomatic but if asymmetric, may be aesthetically disturbing to the parents and adolescent.

Recurrent Posterior Dislocations

Recurrent posterior elbow dislocation is rare. In the combined series of dislocations, only 2 of 317 patients (0.6%) experienced recurrent dislocations.[90,121,147,150] Approximately 80% of recurrent dislocations are in males. Three investigators have reported bilateral cases.[81,116,143] The pathology of recurrent dislocation involves any or all of a combination of collateral ligament instability, capsular laxity, and bone and articular cartilage defects.

Pathology Contributing to Recurrent Posterior Dislocations

Osborne and Cotterill[126] suggested that articular changes are secondary and that the primary defect is a failure of the posterolateral ligamentous and capsular structures to become reattached after reduction (Fig. 18-25). Osborne and Cotterill[126] proposed that the extensive articular cartilage covering the surface of the distal humerus leaves little surface area for soft tissue reattachment and the presence of synovial fluid further inhibits soft tissue healing. With recurrent dislocations, the radial head impinges against the posterolateral margin of the capitellum, creating an osteochondral defect (Fig. 18-26). In addition to the defect in the capitellar articular surface, a similar defect develops in the anterior articular margin of the radial head. When these two defects oppose each other, recurrence of the dislocation is more likely. Subsequent studies have confirmed these findings in almost all recurrent dislocations, especially in children.[37,62,124,172,178,190]

O'Driscoll et al.[124] described posterolateral instability in five patients, including two children, in whom laxity of the ulnar part of the radial collateral ligament allowed a transitory rotary subluxation of the ulnohumeral joint and a secondary dislocation of the radiohumeral joint. Patients with posterolateral instability often complain of a feeling of apprehension with certain activities or describe a history of recurrent temporary dislocation of the elbow but, when examined, exhibit no unusual clinical findings. The instability is diagnosed with a posterolateral rotary instability test, which is done by holding the patient's arm over the head while applying proximal axial compression plus a valgus and supination force to the forearm (Fig. 18-27). As the elbow is slowly flexed from an extended position, the radial head, which is initially posteriorly subluxated, reduces producing the appreciation of a "clunk" or "shift." In some cases the only positive finding is that of apprehension with the examination and in others, posterolateral rotary instability can be detected only with the patient completely relaxed under general anesthesia. The prone push-up test (performed with the forearms maximally supinated) or the chair push-up test (also performed with the arms maximally supinated) can often reproduce the patient's symptoms of pain or a feeling of subluxation or apprehension in the office setting, and thus can often help

An osteochondral fragment (*arrow*) is attached to the lateral ligament. **B:** An oblique radiograph shows the defect (*arrow*) in the posterolateral condylar surface. **C:** Radiographs of an 11-year old after his first dislocation. **D:** One year later, after recurrent dislocation and subluxations, blunting of the radial head has developed (*arrow*). (Courtesy of Marvin E. Mumme, MD.)

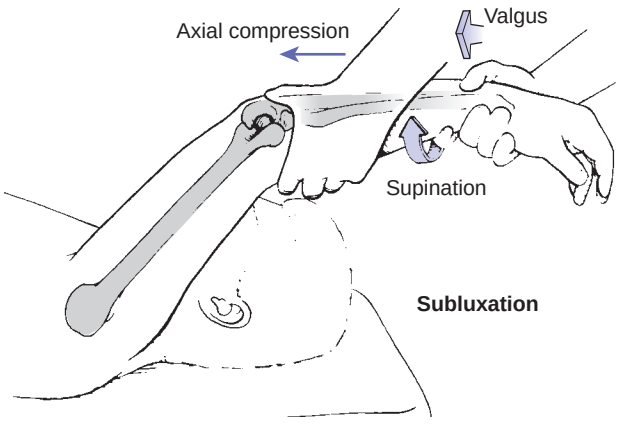

FIGURE 18-27 Posterolateral rotary instability. Posterolateral rotational instability is best demonstrated with the upper extremity over the head with the patient supine. The radial head can be subluxated or dislocated by applying a valgus and supination force to the forearm at the same time proximal axial compression is applied along the forearm. (Reprinted from O'Driscoll SW, Bell DF, Morrey BF. Posterolateral rotary instability of the elbow. *J Bone Joint Surg Am.* 1991;73:441, with permission.)

establish the diagnosis. O'Driscoll et al.[124] reported that surgical repair of the lax ulnar portion of the radial collateral ligament eliminated the posterolateral rotary instability. In children and adolescents, the same instability can occur from cartilage nonunion of the origin of the radial collateral ligament.

In addition to the osteochondral defects in the capitellum and radial head, bone defects may include a shallow semilunar notch resulting from a coronoid fossa process fracture or multiple recurrent dislocations.

Treatment Options for Recurrent Posterior Dislocations

There is only one report of successful nonsurgical management of recurrent elbow dislocations. Herring and Sullivan[66] used an orthosis that blocked the last 15 degrees of extension. After his patient wore this orthosis constantly for 2 years and with vigorous activities for another 6 months, there were no further dislocations, but the follow-up period was only 1 year. Beaty and Donati[14] emphasized that physical therapy and the use of an orthosis should be tried before surgery is considered.

Because nonsurgical management is so often unsuccessful, the treatment of recurrent posterior elbow dislocations is predominately surgical. Various surgical procedures have been described to correct bone and soft tissue abnormalities (Fig. 18-28).

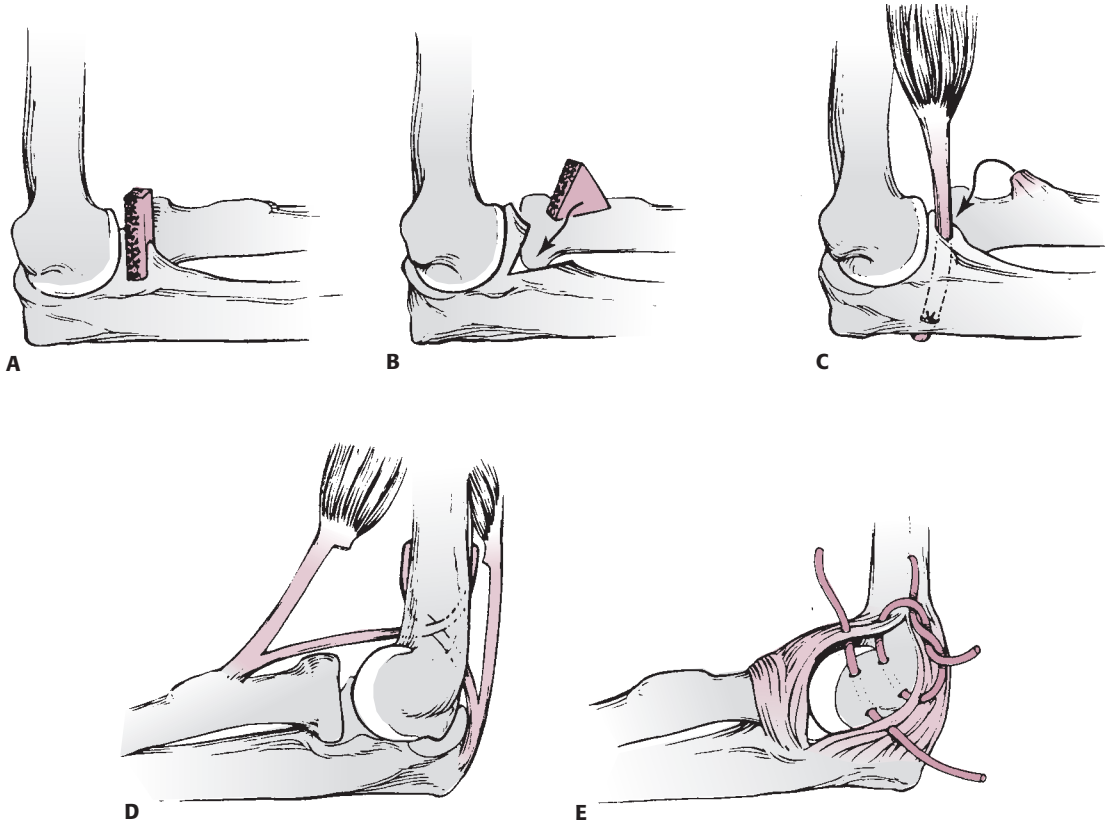

FIGURE 18-28 Surgical procedures for recurrent dislocation. **A:** Simple coronoid bone block. **B:** Open wedge coronoid osteotomy. **C:** Biceps tendon transfer to coronoid process. **D:** Cruciate ligament reconstruction. **E:** Lateral capsular reattachment of Osborne and Cotterill. (Adapted from Osborne G, Cotterill P. Recurrent dislocation of the elbow. *J Bone Joint Surg Br.* 1966;48(2):340–346.)

Bone Procedures. These are directed toward correcting dysplasia of the semilunar notch of the olecranon. Milch[116] inserted a boomerang-shaped bone block. Others[52,112,181] found that a simple bone block was all that was necessary (Fig. 18-28A). Mantle[103] increased the slope of the semilunar notch in two patients with an opening wedge osteotomy of the coronoid process (Fig. 18-28B).

Soft Tissue Procedures. Reichenheim[143] and King[85] transferred the biceps tendon just distal to the coronoid process to reinforce it (Fig. 18-28C). Kapel[81] developed a cruciate ligament-type reconstruction in which distally based strips of the biceps and triceps tendon were passed through the distal humerus (Fig. 18-28D). Beaty and Donati[14] modified this technique by transferring a central slip of the triceps through the humerus posterior to anterior and attaching it to the proximal ulna.

The most widely accepted technique is that described by Osborne and Cotterill,[126] in which the lateral capsule is reattached to the posterolateral aspect of the capitellum with sutures passing through holes drilled in the bone (Fig. 18-28E). The joint should be inspected at surgery because osteocartilaginous loose bodies may be present.[62,101,172] Since Osborne and Cotterill's[126] initial report of eight patients, successful use of this technique has been reported in numerous others.[37,62,101,124,172,178,190] Zeier[194] and O'Driscoll et al.[124] reinforced the lateral repair with strips of fascia lata, triceps fascia, or palmaris longus tendon.

Postoperative Care. Postoperatively, especially after the repair described by Osborne and Cotterill,[126] the arm is immobilized in a long arm cast with the elbow flexed 90 degrees for 4 to 6 weeks. Protected active range-of-motion exercises are performed for an additional 4 to 6 weeks. Strenuous activities are avoided for 12 weeks' postoperative.

Complications. Major complications after correction of recurrent dislocations include loose osteocartilaginous fragments and destruction of the articular surface of the joint (Fig. 18-29), elbow stiffness, or recurrent instability.

Unreduced Posterior Elbow Dislocations

Untreated posterior dislocations of the elbow in children are extremely rare in North America. Most reported series are from other countries.[44]

Diagnosis

Children with untreated dislocations typically have pain and limited midrange of motion (Fig. 18-12). Pathologically, there

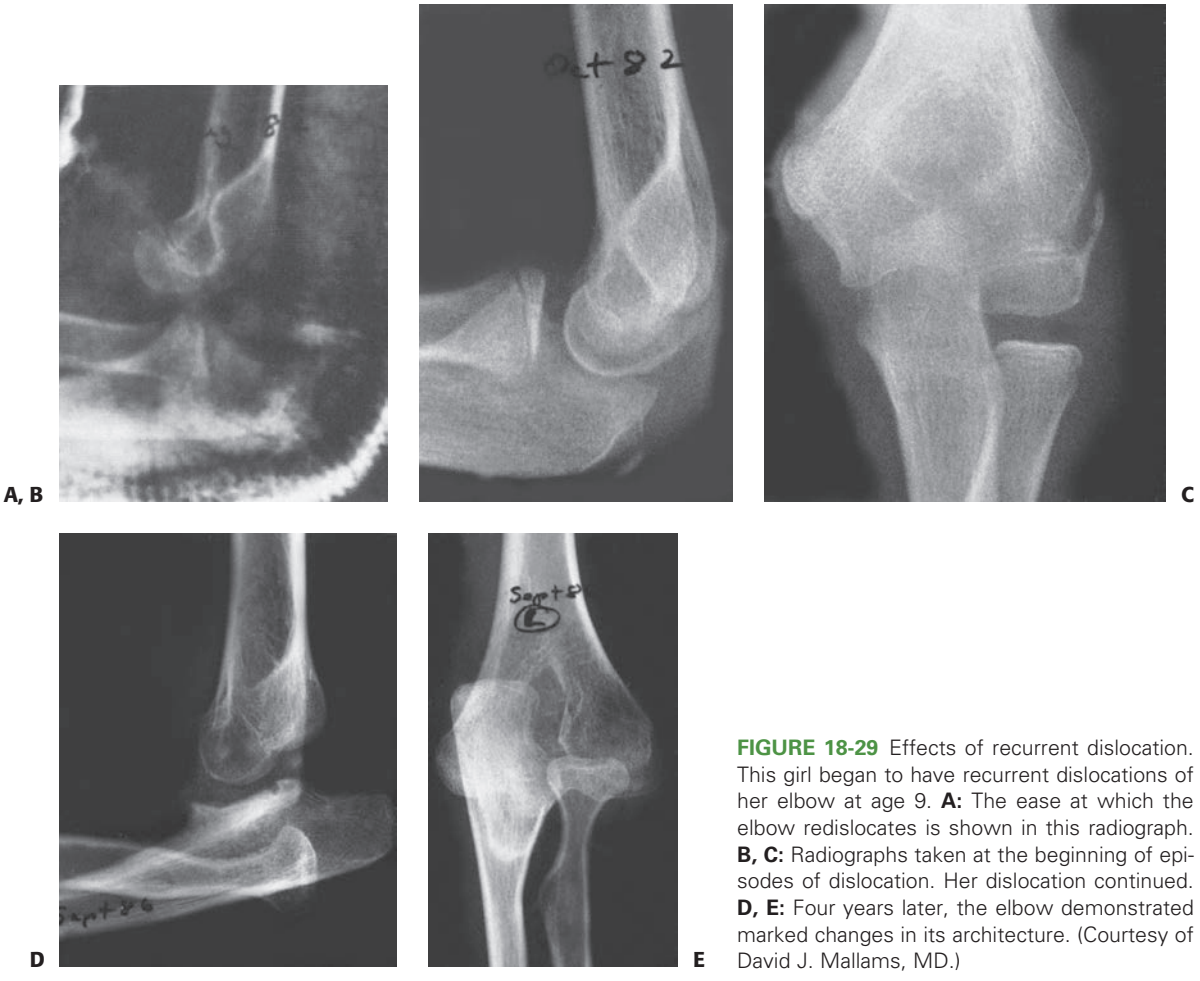

FIGURE 18-29 Effects of recurrent dislocation. This girl began to have recurrent dislocations of her elbow at age 9. **A:** The ease at which the elbow redislocates is shown in this radiograph. **B, C:** Radiographs taken at the beginning of episodes of dislocation. Her dislocation continued. **D, E:** Four years later, the elbow demonstrated marked changes in its architecture. (Courtesy of David J. Mallams, MD.)

is usually subperiosteal new bone formation that produces a radiohumeral horn, myositis ossificans of the brachialis muscle, capsular contractures, shortening of the triceps muscle, contractures of the medial and lateral collateral ligaments, and compression of the ulnar nerve.[43,44] These factors have to be considered when planning treatment.

Treatment Options

Closed Reduction of an Unreduced Posterior Elbow Dislocation. Closed reduction of dislocations recognized within 3 weeks of injury may be possible.[5,44] If this fails or if the dislocation is of longer duration, open reduction is necessary.

Operative Treatment for an Unreduced Posterior Elbow Dislocation. Open reduction through a posterior approach, as described by Speed,[168] involves lengthening of the triceps muscle and release or transposition of the ulnar nerve.[44] Satisfactory results usually can be obtained if a stable concentric reduction is achieved within 3 months of the initial dislocation.[5] Results after surgical reconstruction decline thereafter but still may produce some improvement in function.[33,44,99,115,118] Fixation of the elbow joint to maintain reduction with one or two large smooth pins for 2 to 4 weeks followed by vigorous but protected physical therapy has been recommended.[44,118] Consideration may be given to hinged external fixation instead of transarticular pins.

Mahaisavariya et al.[100] reported improved extension and better functional results 1 to 3 months after injury in 34 patients with chronic elbow dislocation reconstruction in whom the triceps tendon was not lengthened compared with 38 patients who had the triceps lengthened at surgery.

Congenital Elbow Dislocations

Chronic elbow dislocation may be congenital in origin. Altered anatomy and limited motion predispose these patients to injury. The key to differentiating a congenital from an acute traumatic elbow dislocation is examination of the x-ray architecture of the articulating surfaces. In a congenitally dislocated elbow, there is atrophy of the humeral condyles and the semilunar notch of the olecranon. The radial head and neck may be hypoplastic, and the articular surface of the radial head may be dome shaped instead of concave. Unfortunately, these same changes can result from chronic recurrent dislocation after trauma, making the differentiation between congenital and chronic traumatic dislocation difficult. If other congenital anomalies are present or the child has an underlying syndrome, such as Ehlers–Danlos or Larsen syndrome, the dislocation is likely to be nontraumatic. Obtaining comparison x-rays of the asymptomatic, contralateral elbow often reveals identical anatomy, confirming the etiology of the dislocation as congenital or nontraumatic acquired.

Anterior Elbow Dislocations

Anterior elbow dislocations are rare. Of the 317 elbows in the combined series,[90,121,147,150] only 5 were anterior, for an incidence of slightly over 1%. They are associated with an increased incidence of complications, such as brachial artery disruption and associated fractures, compared with posterior dislocations.[73,186]

Assessment of Anterior Elbow Dislocations

Mechanisms of Injury for Anterior Elbow Dislocations

Anterior elbow dislocations usually are caused by a direct blow to the posterior aspect of the flexed elbow.[71] Hyperextension of the elbow also has been implicated in one study.[186]

Associated Injuries with Anterior Elbow Dislocations

Associated fractures are common. In children, the triceps insertion may be avulsed from the olecranon with a small piece of cortical bone.[189] This fragment usually reduces to the olecranon after reduction. Wilkerson[186] reported an anterior dislocation associated with a displaced olecranon fracture in a 7-year-old boy. Inoue and Horii[71] reported an 11-year-old girl with an anterior elbow dislocation with displaced fractures of the trochlea, capitellum, and lateral epicondyle. These were repaired with open reduction and internal fixation using Herbert bone screws.

Signs and Symptoms of Anterior Elbow Dislocations

The elbow is held in extension upon presentation. There is a fullness in the antecubital fossa. Swelling usually is marked because of the soft tissue disruption associated with this type of dislocation. There is severe pain with attempted motion. A careful neurovascular examination is mandatory.

Imaging and Other Diagnostic Studies for Anterior Elbow Dislocations

Routine AP and lateral x-rays are diagnostic. In most cases, the proximal radius and ulna dislocate in an anteromedial direction (Fig. 18-30). As with posterior dislocations, postreduction radiographs should be carefully scrutinized for a congruent reduction and for subtle osteochondral fracture fragments. Evaluation with computerized tomography or MRI may be utilized to further define the extent of soft tissue injury in complex injury patterns.

Treatment Options for Anterior Elbow Dislocations

Nonoperative Treatment of Anterior Elbow Dislocations

Indications/Contraindications

As with posterior elbow dislocations, because of the significant amount of soft tissue swelling and potential for neurovascular compromise, all anterior elbow dislocations should be reduced with adequate analgesia and relaxation as soon as possible. Consideration for nonoperative treatment following closed reduction can only be considered if the elbow is stable

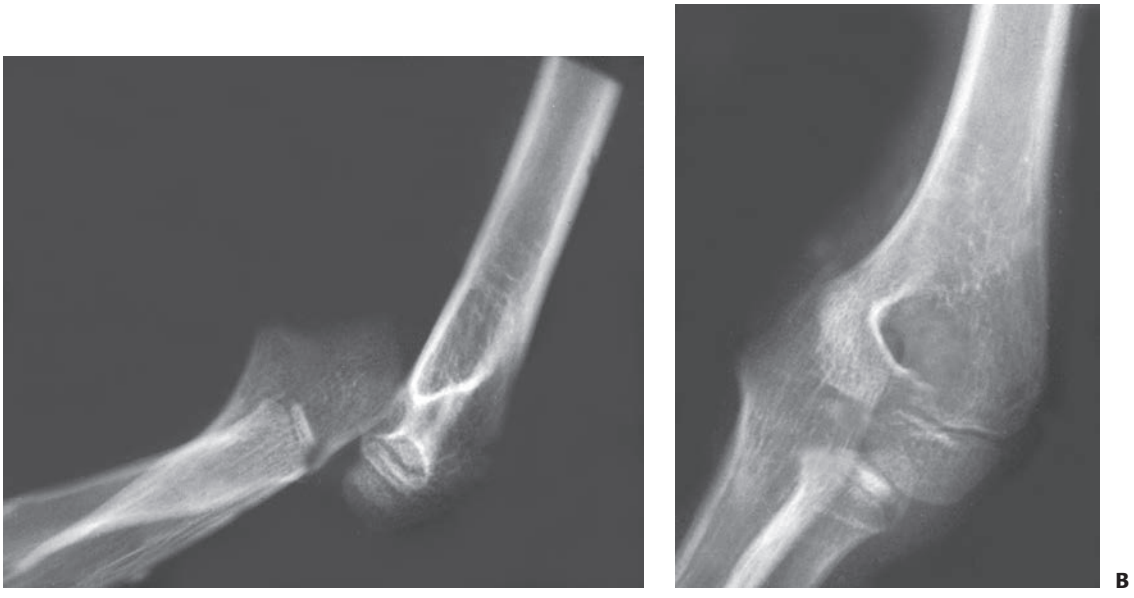

FIGURE 18-30 Anterior dislocation of the elbow. **A:** Initial anteroposterior radiograph. The olecranon lies anterior to the distal humerus. **B:** Initial lateral radiograph. The proximal ulna and radial head lie anteromedial, and the elbow carrying angle is in varus. (Courtesy of Hilario Trevino, MD.)

through close to a functional range of motion, a concentric anatomic reduction can be obtained and maintained, and there is no evidence to suggest a vascular injury, nerve entrapment, or significant intra-articular osteochondral fragments.

Surgery usually is not required unless the dislocation is open, there is a brachial artery injury, or there is an associated fracture that does not realign satisfactorily after closed reduction. Open reduction and internal fixation of the fracture may then be necessary.[71,186]

Techniques for Closed Reduction of Anterior Elbow Dislocations

Reduction usually is accomplished by flexing the elbow and pushing the forearm proximally and downward at the same time.[189] As with posterior dislocations, a force must first be applied longitudinally along the axis of the humerus with the elbow semiflexed to overcome the forces of the biceps and triceps. The longitudinal force along the axis of the forearm is directed toward the elbow (Fig. 18-31). To make reduction easier, the distal humerus can be forced in an anterior direction by pushing on the posterior aspect of the distal arm.

Because most anterior dislocations occur in flexion, the elbow should be immobilized in some extension for 1 to 3 weeks, followed by protected active range-of-motion exercises. Early motion after open reduction and internal fixation of an associated olecranon fracture usually can be allowed.[71,186]

Author's Preferred Method of Treatment for Anterior Elbow Dislocations

Closed reduction (Fig. 18-31) is the initial procedure of choice. A distal force must be applied in line with and parallel to the long axis of the humerus first. Once the length has been reestablished, a posteriorly directed force along the axis of the forearm is applied until the elbow is reduced. The same principles that were discussed for posterior elbow dislocations apply to anterior elbow dislocations as well. There should be a thorough and systematic evaluation of the elbow stability following reduction, postreduction radiographs should be carefully scrutinized for a concentric reduction and associated fractures or entrapped loose bodies, if appropriate a brief period of immobilization followed by an early protected motion program should be employed. Stable fixation of associated fractures is also necessary as dictated by the treatment principles for those fractures.

Management of Expected Adverse Outcomes and Unexpected Complications for Anterior Elbow Dislocations

There appears to be an increased incidence of brachial artery rupture or thrombosis associated with anterior elbow dislocations.[73,167] As discussed with posterior elbow dislocations, early and persistent vigilance for circulatory issues should be exercised. When compromised, as discussed above in more detail with posterior elbow dislocations, a prompt evaluation with consideration for arterial repair or reconstruction with vein grafting may be necessary.

Medial and Lateral Elbow Dislocations

These are rare dislocations. Lateral dislocations, either incomplete or complete, are more common than medial dislocations in adults. There are no recent reports of medial dislocations in children.

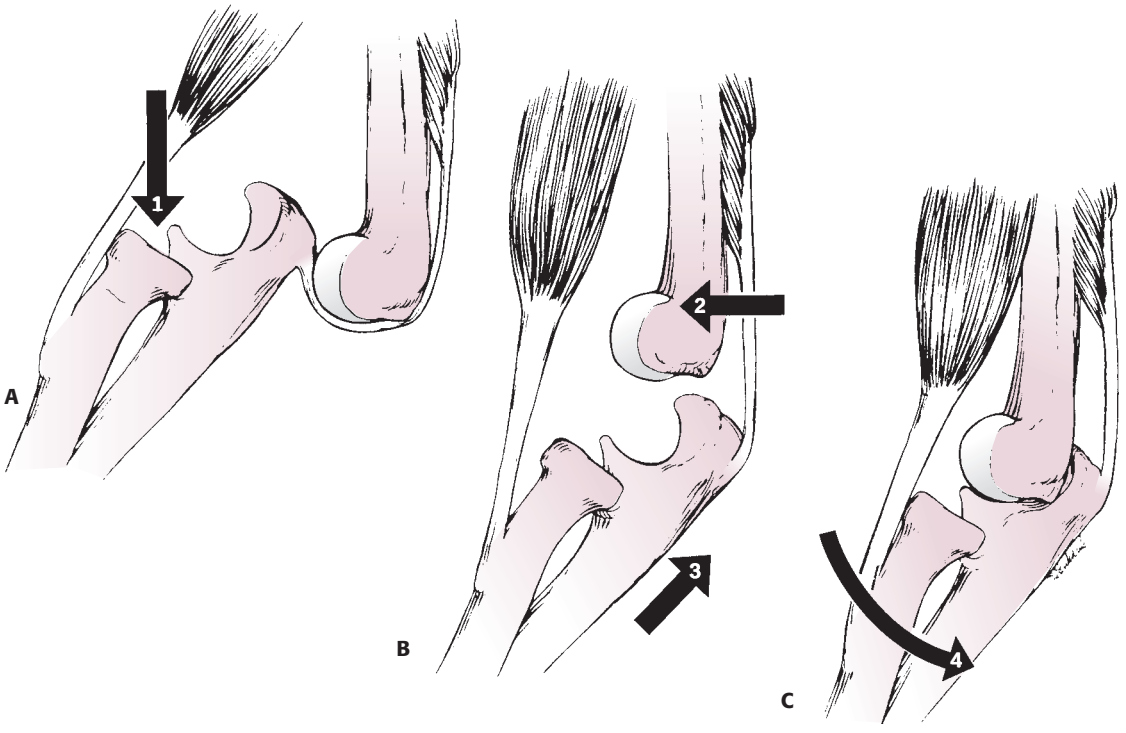

FIGURE 18-31 Reduction of anterior dislocation. **A:** With the elbow semiflexed, a longitudinal force is applied along the long axis of the humerus (*arrow 1*). Pulling distally on the forearm may be necessary to initially dislodge the olecranon. **B:** Once the olecranon is distal to the humerus, the distal humerus is pushed anteriorly (*arrow 2*) whereas a proximally directed force is applied along the long axis of the forearm (*arrow 3*). **C:** Finally, the elbow is immobilized in some extension (*arrow 4*).

Assessment of Medial and Lateral Elbow Dislocations

Signs and Symptoms of Medial and Lateral Elbow Dislocations

In an incomplete lateral dislocation, the semilunar notch articulates with the capitulotrochlear groove, and the radial head appears more prominent laterally. There is often good flexion and extension of the elbow, increasing the likelihood that a lateral dislocation will be overlooked. In a complete lateral dislocation, the olecranon is displaced lateral to the capitellum. This gives the elbow a markedly widened appearance.

X-Ray and Other Imaging Studies for Medial and Lateral Elbow Dislocations

AP x-rays of the elbow usually are diagnostic. On the lateral view, the elbow may appear reduced.

Treatment Options for Medial and Lateral Elbow Dislocations

These rare dislocations can be treated by closed reduction in virtually all patients.[192] A longitudinal force is applied along the axis of the humerus to distract the elbow, and then direct medial or lateral pressure (opposite the direction of the dislocation) is applied over the proximal forearm (Fig. 18-32).

Divergent Elbow Dislocation

Divergent dislocation represents a posterior elbow dislocation with disruption of the interosseous membrane between the proximal radius and ulna with the radial head displaced laterally and the proximal ulna medially (Fig. 18-33). These dislocations are extremely rare.[10,23,32,49,69,70,110,119,158,166,180]

Divergent dislocations are often caused by high-energy trauma. Associated fractures of the radial neck, proximal ulna, and coronoid process are common.[2,23,40,180] It has been speculated that, in addition to the hyperextension of the elbow that produces the dislocation, a strong proximally directed force is applied parallel to the long axis of the forearm, disrupting the annular ligament and interosseous membrane and allowing the divergence of the proximal radius and ulna. In a cadaveric study, Altuntas et al.[7] confirmed that only after release of all the ligamentous stabilizers of the elbow and release of the intraosseous membrane from the elbow to the distal third of the forearm could a divergent dislocation be replicated.

Treatment Options for Divergent Elbow Dislocations

Closed Reduction in Divergent Elbow Dislocations

Divergent dislocations are typically easily reduced using closed reduction under general anesthesia. Reduction is achieved by

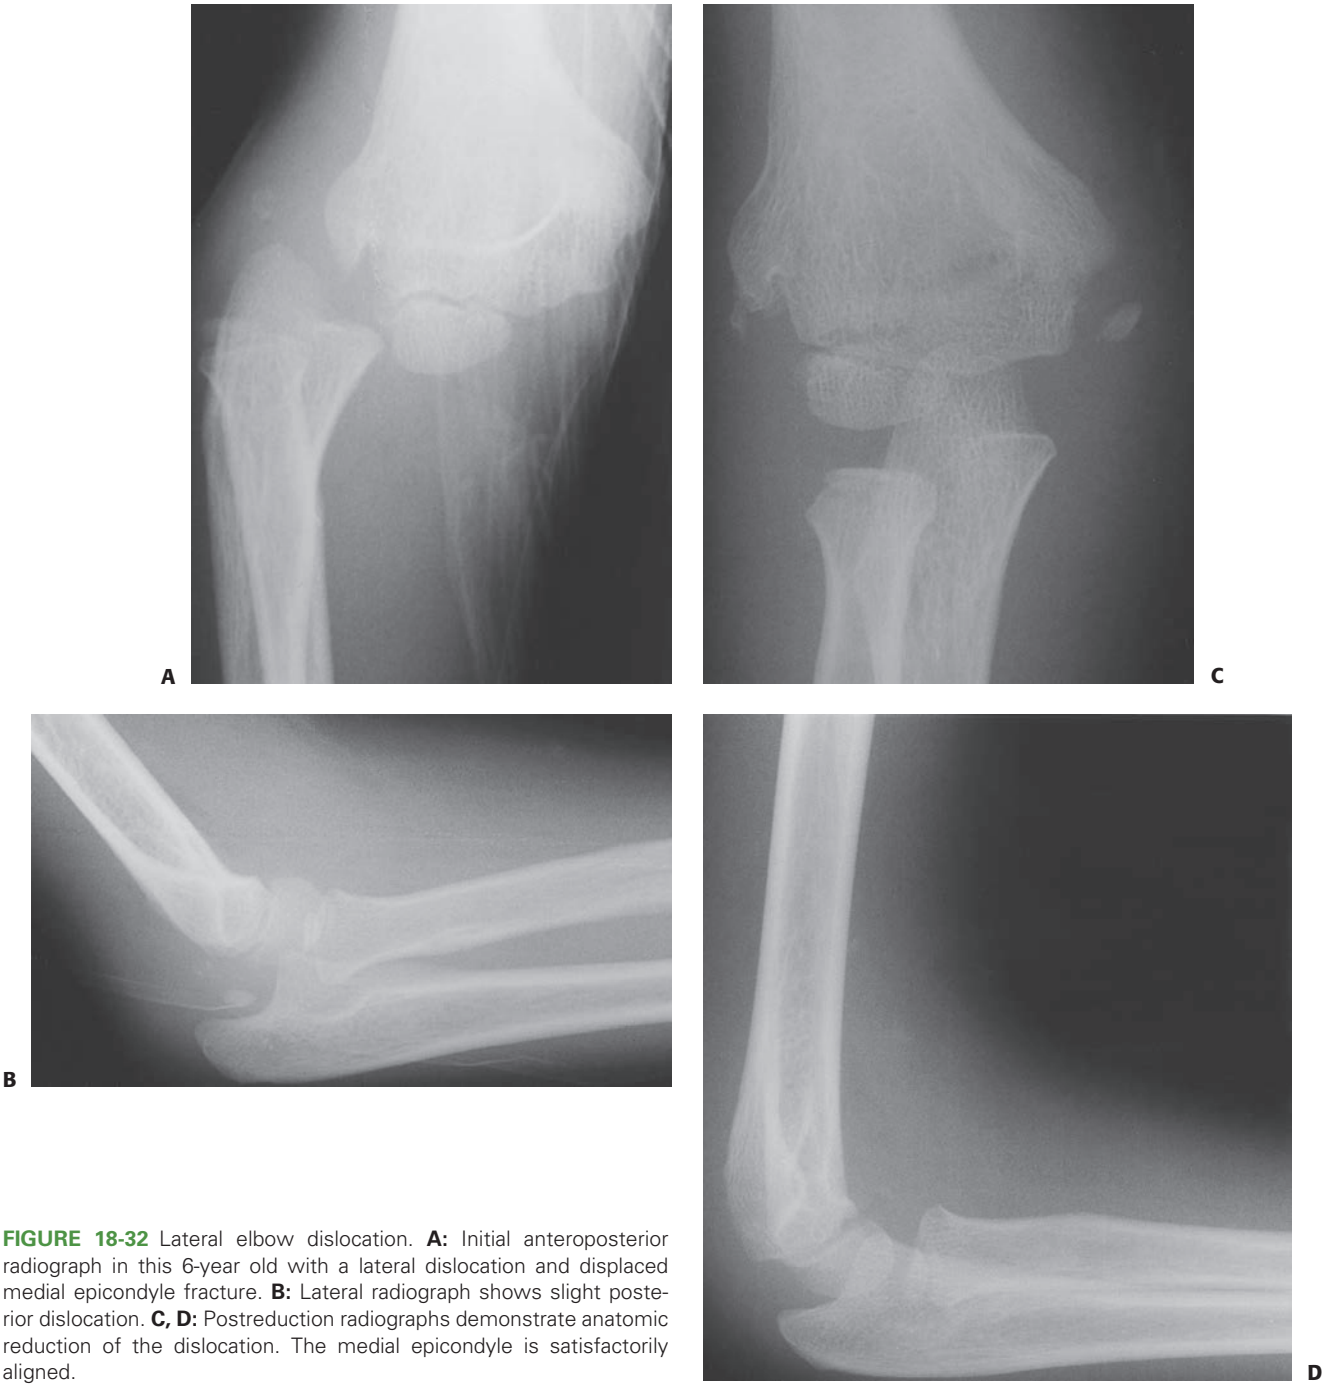

FIGURE 18-32 Lateral elbow dislocation. **A:** Initial anteroposterior radiograph in this 6-year old with a lateral dislocation and displaced medial epicondyle fracture. **B:** Lateral radiograph shows slight posterior dislocation. **C, D:** Postreduction radiographs demonstrate anatomic reduction of the dislocation. The medial epicondyle is satisfactorily aligned.

applying longitudinal traction with the elbow semiextended and at the same time compressing the proximal radius and ulna together.

Open Reduction in Divergent Elbow Dislocations

Very few divergent dislocations reported in the literature have required open reduction.[40,110,120] Failure of closed reduction[110,120] and displaced associated fracture[40] are indications for open reduction. After failed attempted closed reduction was unsuccessful, Nanno et al.[120] performed surgical exploration and identified the avulsed anterior band of the medial collateral ligament complex of the elbow interposed between the medial condyle of the humerus and the olecranon. After removing and repairing the interposed ligament, stable reduction was achieved. van Wagenberg et al.[179] describes a patient with divergent elbow dislocation with associated distal radius and coronoid fractures. After anatomic reduction of the fractures a stable reduction of the divergent elbow dislocation was achieved.

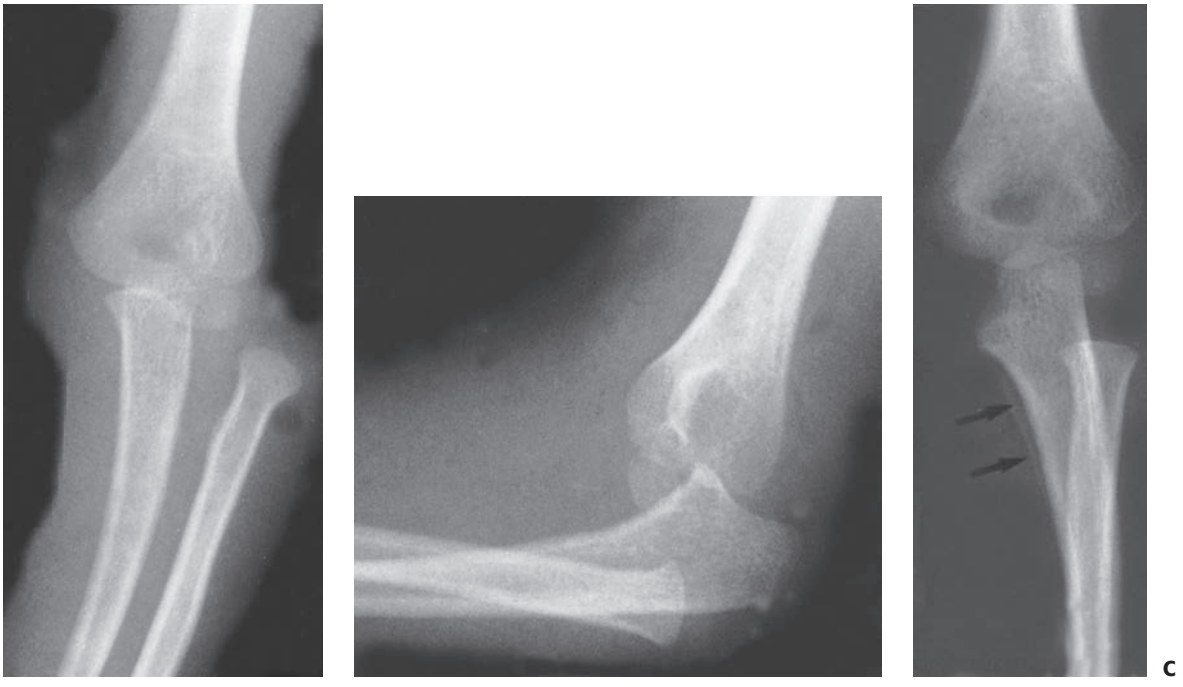

FIGURE 18-33 Medial–lateral divergent dislocation. **A:** Anteroposterior view demonstrating disruption of the proximal radioulnar joint with the radius lateral and the ulna medial. **B:** Lateral radiograph confirms that the radius and ulna are both posterior to the distal humerus. **C:** A radiograph taken 4 weeks after injury shows periosteal new bone formation (*arrows*), indicating where the soft tissues were extensively torn away from the proximal ulna.

Postreduction Care in Divergent Elbow Dislocations

After successful closed reduction, the elbow is immobilized in 90 degrees of flexion and the forearm in neutral for approximately 2 to 3 weeks. Active range-of-motion exercises are then begun. Most patients regain full elbow motion, including forearm pronation and supination.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Divergent Elbow Dislocations

A case of symptomatic radiocapitellar instability 7 years following a transverse, mediolateral divergent dislocation has been reported.[193] No discussion of treatment for this complication was provided, but knowledge of the difficulty treating chronic elbow instability emphasizes the importance of obtaining a stable, congruent reduction during the time of acute injury management.

Proximal Radioulnar Translocations

Translocation of the proximal radius and ulna is an extremely rare injury with very few cases having been reported in the English literature.[11,23,24,28,39,51,61,72,97] Radioulnar translocation is commonly missed on the AP x-ray unless the proximal radius and ulna are noted to be completely reversed in relation to the distal humerus. Translocations are believed to be caused by a fall onto the pronated hand with the elbow in full or nearly full extension, producing an axial force on the proximal radius. The anterior radial head dislocation occurs first, followed by the posterior dislocation of the olecranon. Combourieu et al.[28] suggests that avulsion of the brachialis insertion is necessary for the radial head to translate medially. The radial head, depending on the degree of pronation, can be lodged in the coronoid fossa or dislocated posteriorly. As a consequence, fractures of the radial head, radial neck, or coronoid process may occur.[23,24,39,97] Harvey and Tchelebi[61] reported a case in which the cause of radioulnar translocation may have been iatrogenic: The result of inappropriate technique used to reduce a posterior elbow dislocation.

Assessment of Proximal Radioulnar Translocations

Swelling and pain may obscure the initial examination, and minimal deformity may be apparent. Once pain has been adequately managed with analgesics, the most consistent finding on clinical examination is limited elbow range of motion, especially in supination.

Associated Injuries with Proximal Radioulnar Translocations

Radial neck fracture is the most common fracture associated with proximal radioulnar translocation.[24,39,72,97] Eklof et al.[39] also reported one patient who sustained a fracture of the tip of

the coronoid. Proposed soft tissue injuries include radial collateral ligament, medial collateral ligament, annular ligament, interosseous ligament, and avulsion of the brachialis.[28,39,72] Transient ulnar nerve paresthesia that resolved after reduction of the translocation has been reported in several patients.[28,72] Osteonecrosis of the radial head was noted in one patient after open reduction of a proximal radioulnar translocation and premature closure of the proximal radial physis has been reported.[28,61]

Treatment Options for Proximal Radioulnar Translocations

Closed Reduction in Proximal Radioulnar Translocations

Successful closed reduction of proximal radioulnar translocation has been reported.[28,72,97] The patient must be completely relaxed under general anesthesia, as sedation or regional anesthesia is unlikely to provide sufficient relaxation. With the elbow flexed approximately 90 degrees, longitudinal traction is applied to the elbow while the forearm is supinated (Fig. 18-34). If the radial head can be palpated, gentle anterior-directed pressure may help slide the radial head and neck over the coronoid process, allowing the proximal radius and ulna to resume their normal configuration. As always, just the right amount of force should be used; excessive force risks iatrogenic fracture to the proximal radius. Successful closed reduction should be confirmed on x-ray, and the elbow should be immobilized for approximately 3 to 4 weeks with the forearm supinated and the elbow flexed 90 to 100 degrees.

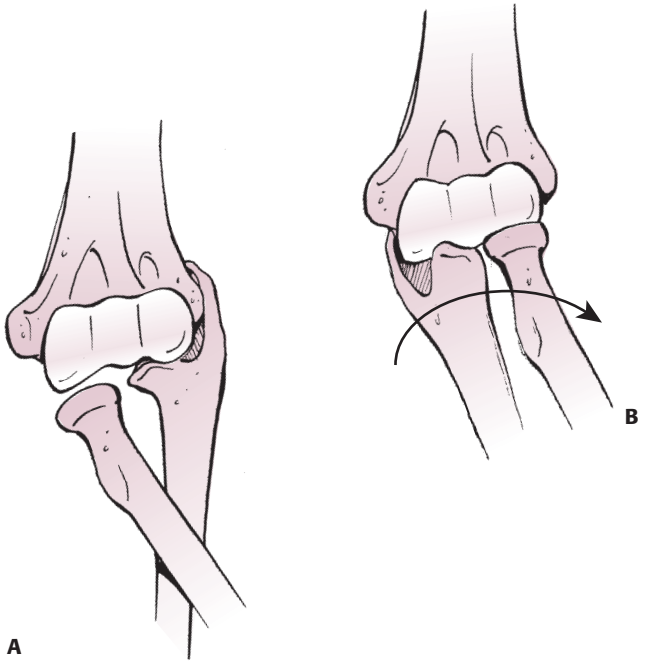

FIGURE 18-34 Proximal radioulnar translocation. **A:** Position of the proximal radius and ulna with a proximal radioulnar translocation. **B:** Closed reduction is rarely successful, but may be attempted under general anesthesia using gentle longitudinal traction while supinating the forearm. (Redrawn from Harvey S, Tchelebi H. Proximal radioulnar translocation. A case report. *J Bone Joint Surg Am.* 1979;61(3):447–449, with permission.)

Open Reduction in Proximal Radioulnar Translocations

Radioulnar translocations may require open reduction.[23,24,39,51,61,72] A lateral approach provides adequate exposure to the translocation and radial neck fracture if present. At surgery, the radial head and neck are typically found trapped beneath the trochlea of the distal humerus. Elbow extension tightens the biceps tendon, making reduction more difficult. With the elbow flexed, a freer or joker elevator can be placed beneath the radial head and neck facilitating delivery over the coronoid process as the forearm is supinated. If present, a radial neck fracture may now be treated in standard fashion. Internal fixation also may be necessary for an unstable displaced fracture.

Harvey and Tchelebi[61] used an osteotomy of the proximal ulna to expose and reduce the radius that was complicated by a postoperative ulnar nerve paralysis that recovered completely over 2 months.

After successful closed or open reduction, the forearm is immobilized for approximately 3 to 4 weeks with the forearm supinated and the elbow flexed 90 to 100 degrees, followed by active elbow range-of-motion exercises.

Medial Epicondyle Apophysis Fractures

In the early 1900s, it was recognized that the medial epicondyle fracture was often associated with elbow dislocation and the apophyseal fragment could become entrapped within the joint.[182] The reported incidence of medial epicondyle fracture associated with dislocation of the elbow in children and adolescents has varied from as low as 30% to as high as 55% in many of the reported series.[15,188] Two bilateral injuries associated with bilateral elbow dislocations have been reported,[17,42] both patients having sustained their injuries while participating in gymnastics (Table 18-11). Fractures involving the medial epicondylar apophysis constitute approximately 14% of fractures involving the distal humerus and 11% of all fractures in the elbow region.[15,17,26] Fractures involving the epicondylar apophysis have a peak age in preadolescence, similar to fractures involving the medial condylar physis. The youngest reported patient with this injury was 3.9 years.[26] In the large series of fractures of the medial epicondylar apophysis, most occurred between ages 9 and 14, and the peak age incidence

TABLE 18-11 Fractures of the Medial Epicondylar Apophysis: Incidence

Overall incidence: Fractures of the elbow region, 11.5%
Age: peak, 11–12 y
Sex: males, 79% (4:1, male:female)
Association with elbow dislocation: Approximately 50% (15–18% of these involve incarceration of the epicondylar apophysis)

was 11 to 12 years.[15,46,67,83,117,128,161,188] Fractures of the epicondylar apophysis preferentially affect males by a ratio of almost 4 to 1 over females. In six large series in the literature, boys constituted 79% of the patients.[46,47,105,148,182,188]

Mechanisms of Injury for Medial Epicondyle Apophysis Fractures

Injuries to the medial epicondylar apophysis most commonly occur as acute injuries in which a distinct event produces a partial or a complete separation of the apophyseal fragment. Three theories have been proposed about the mechanism of acute medial epicondylar apophyseal injuries: A direct blow, avulsion mechanisms, and association with elbow dislocation.

Direct Blow

Stimson[170] speculated that this type of injury could occur as a result of a direct blow on the posterior aspect of the epicondyle. Among more recent investigators, however, only Watson-Jones[183] described this injury as being associated with a direct blow to the posterior medial aspect of the elbow. In rare patients in whom the fragment is produced by a direct blow to the medial aspect of the joint, the medial epicondylar fragment is often fragmented (Fig. 18-35). In these injuries, there may also be more superficial ecchymosis in the skin.

Avulsion Mechanisms

Various investigators have suggested that some of these injuries are due to a pure avulsion of the epicondyle by the flexor–pronator muscles of the forearm.[83,132] This muscle avulsion force can occur in combination with a valgus stress in which the elbow is locked in extension, or as a pure musculature contraction that may occur with the elbow partially flexed.

FIGURE 18-35 Direct fragmentation. The fragmented appearance of the medial epicondyle (*arrows*) in a 13-year old who sustained a direct blow to the medial aspect of the elbow. (From Wilkins KE. Fractures of the medial epicondyle in children. *Instr Course Lect.* 1991;40:1–8, with permission.)

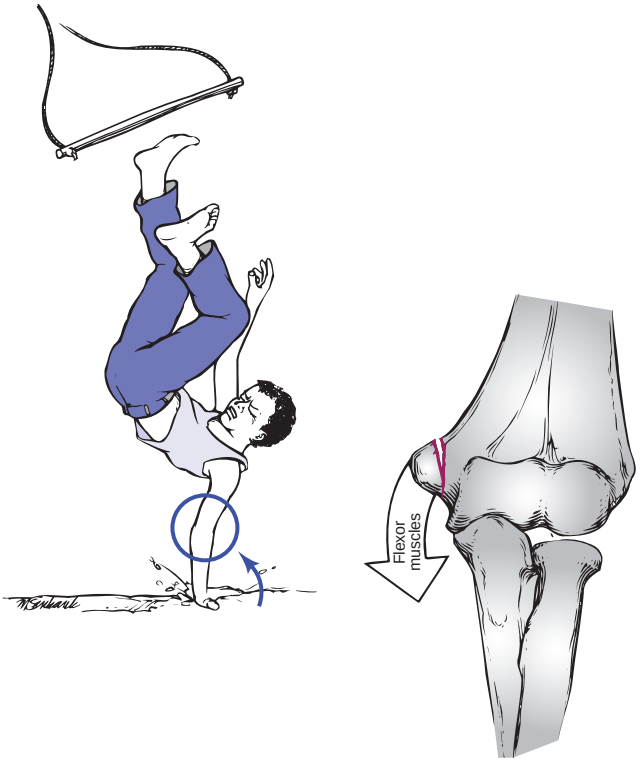

FIGURE 18-36 Hyperextension forces. When a person falls on the outstretched upper extremity, the wrist and fingers are forced into hyperextension (*solid arrow*), which places tension on the forearm flexor muscles. This sudden tension along with the normal valgus carrying angle tends to place a strong avulsion force on the medial epicondyle (*open arrow*).

Smith[161] proposed that when a child falls on his outstretched upper extremity with the elbow in extension, the wrist and fingers are often hyperextended as well, placing an added tension force on the epicondyle by the forearm flexor muscles (Fig. 18-36). The normal valgus carrying angle tends to accentuate these avulsion forces when the elbow is in extension. Many proponents of this theory point to the other associated elbow fractures that have been seen with this injury as evidence to confirm that a valgus force is applied across the elbow at the time of the injury. These associated injuries include radial neck fractures with valgus angulation and greenstick valgus fractures of the olecranon.[83]

Isolated avulsion can also occur in adolescents with the simple act of throwing a baseball. In this instance, the sudden contracture of the forearm flexor muscles may be sufficient to cause the epicondyle to fail (Fig. 18-37). The literature has reflected a high incidence of medial epicondylar apophyseal avulsions occurring with arm wrestling in patients near skeletal maturity.[95,123] The largest series, reported by Nyska et al.[123]

FIGURE 18-37 Muscle avulsion. Isolated avulsion of the medial epicondyle occurred suddenly in this 14-year-old Little League pitcher after throwing a curve ball. (From Wilkins KE. Fracture of the medial epicondyle in children. *Instr Course Lect.* 1991;40:1–8, with permission.)

from Israel, involved eight boys of 13 to 15 years of age, all of whom were treated conservatively with good results.

Associated Injuries with Medial Epicondyle Avulsion Fractures

Avulsion fractures of the medial epicondyle may be associated with elbow dislocation in which the ulnar collateral ligament provides the avulsion force. If the patient presents with the elbow dislocated, there is no doubt that the dislocation is the major factor causing this fracture. If the patient presents with the elbow located, it is less clear as to whether the medial epicondyle fracture may have been caused by an occult or partial elbow dislocation that has reduced spontaneously. Some investigators[15,17,46] have noticed calcification development in the lateral collateral ligaments and adjacent lateral periosteum after fracture. They believed this calcification was evidence that the ligament had been stretched during the process of elbow dislocation. Marion and Faysse[105] found that most elbow dislocations associated with medial epicondyle fractures were posterolateral, but some pure lateral, posterior, and posteromedial dislocations were also observed. A question has also arisen as to whether incarceration of the epicondylar fragment into the joint can occur without a dislocation. Patrick[132] believed that when an extreme valgus stress was applied to the joint, a vacuum was created within the joint that "sucked in" the avulsed epicondylar fragment.

It appears that any of these mechanisms can produce an acute apophyseal injury of the distal humerus. The direct blow mechanism appears to occur only rarely. Many of these injuries may be associated with an elbow dislocation that may or may not have reduced spontaneously.

Assessment of Medial Epicondyle Avulsion Fractures

Clinical Examination of Medial Epicondyle Avulsion Fractures

Medial epicondyle fractures associated with elbow dislocation are associated with gross deformity of the elbow, swelling, and distracting injuries so that the medial epicondyle fracture can be easily overlooked. A careful and focused evaluation looking specifically at the medial epicondyle is necessary to avoid missing this injury. If a fracture of the medial epicondyle has occurred, then tenderness to palpation will be present.

Because the anterior oblique band of the ulnar collateral ligament may be attached to the medial epicondylar apophysis, the elbow may exhibit some instability after injury. To evaluate the medial stability of the elbow, Woods and Tullos[191] and Schwab et al.[157] advocated a simple valgus stress test. This test is performed with the patient supine and the arm abducted 90 degrees. The shoulder and arm are externally rotated 90 degrees. The elbow must be flexed at least 15 degrees to eliminate the stabilizing force of the olecranon. If the elbow is unstable, simple gravity forces will open the medial side. A small additional weight or sedation may be necessary to acquire an accurate assessment of the medial stability with this test.

Ulnar nerve function must be carefully tested before initiating treatment and documented in the medical record.

Imaging Studies of Medial Epicondyle Avulsion Fractures

Good quality AP and lateral radiographs are essential. Oblique radiographs as well as comparison radiographs of the opposite elbow are often helpful when the interpretation of initial images is not conclusive. Widening or irregularity of the apophyseal line may be the only clue in fractures that are slightly displaced or nondisplaced. If the fragment is significantly displaced, the radiographic diagnosis is usually obvious. If the fragment is totally incarcerated in the joint, however, it may be hidden by the overlying ulnar or distal humerus. The clue here is the total absence of the epicondyle from its normal position just medial and posterior to the medial metaphysis. Knowledge of the order and approximate age of appearance of elbow ossification centers is necessary to appreciate the absence of the epicondyle when it should be present. CT scans can be diagnostic in confusing situations.

Potter[136] suggested that properly performed MRI might disclose acute or chronic injury to the medial epicondylar apophysis, recommending pulse sequences for evaluating the apophysis include fat-suppressed gradient-echo imaging. On MRI, increased signal intensity and abnormal widening of the medial epicondylar physis are seen, typically with surrounding soft tissue edema.

Fractures of the medial epicondyle, even if displaced, may not produce positive fat pad signs.[60,160] If the fracture is only minimally displaced and if it is the result of an avulsion injury, there may be no effusion because all the injured tissues remain extra-articular. In fractures associated with elbow dislocation, there is rupture of the capsule, so its ability

to confine the hemarthrosis is lost. In minimally displaced fractures of the medial epicondyle with significant hemarthrosis, the evaluation must be especially thorough to ensure that an unrecognized fracture involving the medial condylar physis is not present.

The ability to accurately measure medial epicondyle fracture displacement has recently been questioned by several authors who have published work regarding this concern. In a study of medial epicondyle fracture radiographs in 38 patients, Pappas et al.[129] reported poor intraobserver and interobserver agreement with regard to fracture displacement measurement, and questioned the value of perceived fracture displacement as a criterion for choosing surgical versus nonsurgical treatment. In a separate publication, a series of 11 patients judged to have nondisplaced or minimally displaced medial epicondyle fractures had their fractures imaged by both standard radiography and CT.[38] Medial and anterior displacement were then measured on standard radiographs and CT images and compared. Edmonds reported statistically significant differences between standard radiographs and CT images in all measurements with marked increased displacement appreciated on CT scan including six fractures with greater than 10 mm of displacement. To improve our ability to accurately measure fracture displacement on standard radiographs, Klatt and Aoki[86] performed a review of 171 normal AP and lateral elbow radiographs describing the relationship between the medial epicondyle center and reproducible local anatomic landmarks. On the AP radiographs the medial epicondyle center was located 0.5 mm inferior to a line based on the inferior olecranon fossa and on the lateral radiograph the medial epicondyle center was located 1.2 mm anterior to the posterior humeral line.

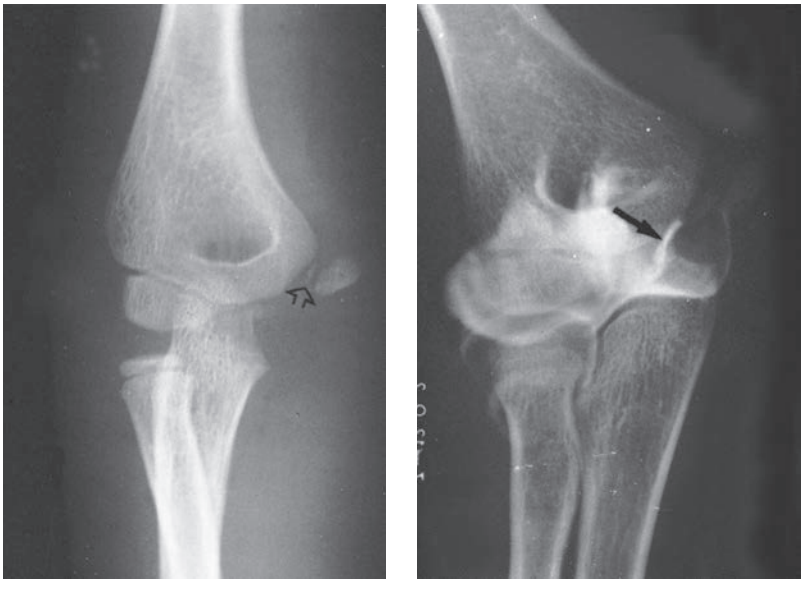
Differential Diagnosis of Medial Epicondyle Avulsion Fractures

The major injuries to differentiate from isolated medial epicondyle fractures are those fractures involving the medial condylar physis. This is especially true if secondary ossification centers are not present (see Chapter 20 "Fractures Involving the Medial Condylar Physis"). If there is a significant hemarthrosis or a significant piece of metaphyseal bone accompanying the medial epicondylar fragment, arthrography or MRI may be indicated to determine if there is an intra-articular component to the fracture (Fig. 18-38). Other elbow fractures that can be associated with this injury include fracture of the radial neck, olecranon, or coronoid process.

Treatment Options for Medial Epicondyle Apophysis Fractures

Better implants, improved surgical technique, greater appreciation of the importance of the ulnar collateral ligament inserting on the medial epicondyle, and increased understanding of the degree of displacement in fractures previously thought to be nondisplaced all contribute to a general trend toward more frequent surgical treatment of medial epicondyle fractures.[53] In a 2012 article titled "Medial Epicondyle Fractures In Children: Clinical Decision Making In The Face Of Uncertainty," Mehlman and Howard[114] acknowledge the dearth of high-level evidence in the published literature on this topic but reports that meta-analysis of clinical research with a particular focus on harm supports surgical treatment for most patients. Independent of whether a nonoperative or operative approach is chosen for the management of a particular medial epicondyle fracture, treatment goals remain to obtain fracture healing and to promote the return of motion, strength, and stability to the elbow.[131]

Even though our ability to measure fracture displacement may be less accurate than we believed in the past, displacement remains an important fracture to consider when making treatment decisions. Additional concerns include intra-articular fragment entrapment, ulnar nerve symptoms, and patient activity level (Fig. 18-39).



A **B**

FIGURE 18-38 Intra-articular extension. **A:** Injury film in a 7-year-old girl who was initially suspected of having only a fracture of the medial epicondyle. In addition to moderate displacement, there was a significant metaphyseal fragment (*arrow*). **B:** An arthrogram revealed intra-articular components (*arrow*), which defined this injury instead as a fracture involving the medial condylar physis. FIGURE 18-39 Algorithm.

Undisplaced or Minimally Displaced Fractures

The apophyseal line remains intact in undisplaced medial epicondyle fractures. The clinical manifestations usually consist only of swelling and local tenderness over the medial epicondyle. Crepitus and motion of the epicondyle are usually not present. On radiographs, the smoothness of the edge of the apophyseal line remains intact. Although there may be some loss of soft tissue planes medially on the radiograph, displacement of the elbow fat pads may not be present because the pathology is extra-articular.[60]

Fractures with displacement usually result from a stronger avulsion force, so there is often more soft tissue swelling. Palpating the fragment may elicit crepitus because the increased displacement allows motion of the fragment. On radiographs, there is a loss of parallelism of the smooth sclerotic margins of the physis (Fig. 18-40).[160] The radiolucency in the area of the apophyseal line is usually increased in width.

Significantly Displaced Fractures

In significantly displaced fractures the fragment may be palpable and freely movable. When displaced a considerable distance from the distal humerus, crepitus between the fragments may not be present. Significantly displaced fractures may be associated with an elbow dislocation that reduced spontaneously and there may be no documentation of the original dislocation. On radiograph, the long axis of the epicondylar apophysis is typically rotated medially (Fig. 18-41). The displacement often exceeds 5 mm, but the fragment remains proximal to the true joint surface.

Entrapment of the Epicondylar Fragment into the Joint

Without Elbow Dislocation

In many instances, the elbow appears reduced. The key clinical finding is a block to motion, especially extension. The epicondylar

FIGURE 18-40 AP radiograph shows loss of normal smooth margins of the physis.

fragment is usually between the joint surfaces of the trochlea and the semilunar notch of the olecranon. On radiograph, any time the fragment appears at the level of the joint, it must be considered to be totally or partially within the elbow joint until proven otherwise.[132] If the radiograph is examined carefully, the elbow is usually found to be incompletely reduced. Because of an impingement of the fragment within the joint, a good AP view may be difficult to obtain because of the inability to extend the elbow fully. If the fracture is old the fragment may be fused to the coronoid process, and widening of the medial joint space may be the only clue that the fragment is lying in the joint. The epicondylar ossification center may become fragmented and mistaken for the fragmented appearance of the medial crista of the trochlea.[26,148] Absence of the apophyseal center on the radiograph may be further confirmatory evidence that the fragment is within the joint. Comparison radiographs of the opposite elbow may be necessary to delineate the true pathology.

FIGURE 18-41 Displaced medial epicondylar fracture. AP view of an elbow in which the epicondyle (*arrow*) is significantly displaced both distally and medially. In addition, the fragment is rotated medially.

With Elbow Dislocation

If the elbow is dislocated, the fragment will occasionally lie within the joint and prevent reduction. Recognition of this fragment as being within the joint before a manipulation should alert the physician to the possible need for open reduction. There should be adequate relaxation during the manipulative process. An initial manipulation to extract the fragment from the elbow joint may need to be accomplished before a satisfactory closed reduction of the elbow joint can be obtained (Fig. 18-42).

Fractures Through the Epicondylar Apophysis

Fractures through the body of the epicondyle can result from either a direct blow or avulsion of only part of the apophysis. In either case, the fragments may or may not be displaced. The normal lucent line formed by the overlying metaphyseal border should not be confused with this injury. Although described by Silberstein et al.,[160] this intrafragment fracture is a rare presentation usually seen with throwing athletes.

Treatment Options for Medial Epicondyle Avulsion Fractures

There appears to be consensus that fractures which are undisplaced or minimally displaced less than 2 mm should be treated nonoperatively. Minimally displaced fractures may be treated using simple immobilization for comfort or cast immobilization for 2 to 3 weeks. Some investigators have recommended initiation of motion early to prevent stiffness, which is the most common complication of this injury.[17,161] Likewise, there is agreement that if the medial epicondyle fragment is irreducible and is incarcerated within the elbow joint, then the accepted treatment is surgical extraction and stable internal fixation.

However, controversy remains as to the optimal treatment method for patients with displacement more than 2 mm.

Nonoperative Treatment of Medial Epicondyle Avulsion Fractures

Josefsson and Danielsson[75] reported 35-year follow-up results in 56 isolated fractures treated nonoperatively. Although

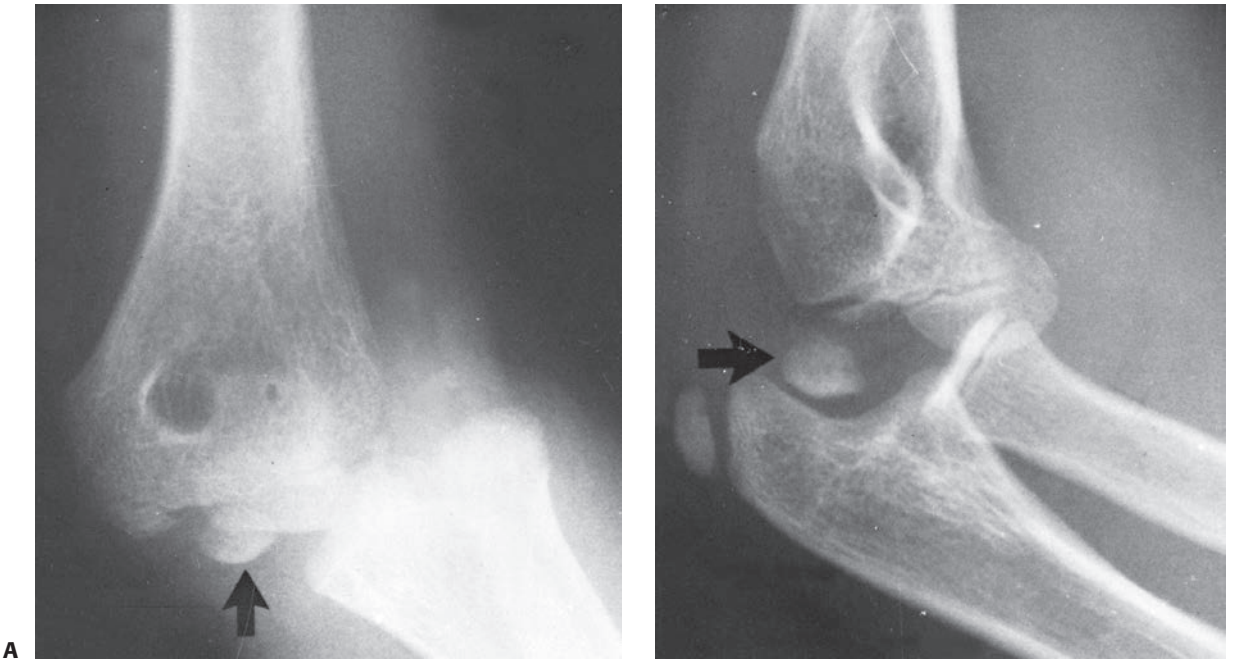

FIGURE 18-42 Dislocation with incarceration. **A:** AP view showing a posterolateral elbow dislocation. The presence of the medial epicondyle within the elbow joint (*arrow*) prevented a closed reduction. **B:** The lateral view of the same elbow demonstrates the fragment (*arrow*) between the humerus and olecranon.

more than 60% of their patients demonstrated nonunion on radiograph, these investigators reported a high percentage of good and excellent results. Other reports in the literature[4,128,188] also demonstrated overall good results with nonoperative management.

Results of fractures associated with a documented elbow dislocation are less favorable[15,46] for patients treated nonoperatively and operatively (Table 18-12).

Operative Treatment of Medial Epicondyle Avulsion Fractures

Early studies comparing nonoperative and operative treatment often reported superior results in the nonsurgical group.[15,17,188] These three studies were published in the 1970s and 1980s reporting patients treated in the decades prior, before the availability of high-quality fluoroscopic imaging and cannulated small-diameter screws. More recent literature describes excellent results obtained with surgical treatment. Louahem et al.[93] from Montpellier, France, report excellent results in 130 and good results in 9 of 139 displaced medial epicondyle fractures treated surgically. Hines et al.,[67] whose practice was to surgically repair all fractures displaced more than 2 mm, found that 96% of their patients had good-to-excellent results. Poor results were attributed mainly to technical errors.

TABLE 18-12 Medial Epicondyle Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Displacement less than 2 mm	Incarcerated fragment within joint
Low-to-moderate activity demands	Displacement greater than 10 mm
	Displaced fracture involving the dominant arm in a throwing athlete; either arm in gymnast or wrestler

Indications for Operative Intervention in Medial Epicondyle Avulsion Fractures

Indications for operative intervention in acute injuries are divided into two categories: Absolute and relative. The single absolute indication is incarceration of the epicondylar fragment within the joint. The relative indications include ulnar nerve dysfunction, a need for elbow stability, and a desire to avoid symptomatic nonunion.

Incarceration in the Joint—Absolute

If the fragment is found in the joint acutely, it must be removed. There are proponents of nonsurgical and surgical techniques for extraction.

Nonoperative Extraction. Various methods of extracting the fragment by nonoperative methods have been proposed. The success rate of extracting the fragment successfully from the joint by manipulation alone at best has been reported at approximately 40%.[132] All the nonoperative

methods require either heavy sedation or light general anesthesia.

Roberts Manipulative Technique. The manipulative technique most commonly used is the method popularized by Roberts.[41,146] It involves placing a valgus stress on the elbow while supinating the forearm and simultaneously dorsiflexing the wrist and fingers to place the forearm muscles on stretch; theoretically, this maneuver should extract the fragment from the joint. To be effective, this procedure should be carried out within the first 24 hours after injury.

Operative Extraction. Failure to extract the fragment by manipulative techniques is an indication to proceed with open surgical extraction. Once open extraction and reduction have been performed, many methods have been advocated to stabilize the fragment, including screw fixation or suture fixation in comminuted fractures. Excision has also been advocated, especially if the fragment is comminuted.

Ulnar Nerve Dysfunction—Relative

Ulnar nerve dysfunction is a relative indication for operative intervention. If there are mild-to-moderate ulnar nerve symptoms at the time of the injury, there is usually no need to explore the nerve, because most of these mild symptoms resolve spontaneously.[17,34] If the dysfunction is complete, then the ulnar nerve may be directly impinged upon by the fracture or entrapped within the fracture site and should be explored surgically. One of the original fears was that the raw surface of the fracture fragment would create scar tissue around or adjacent to the nerve and cause continued dysfunction. Thus, it was originally recommended that the ulnar nerve should be transposed at the time of open reduction.[184] Subsequent reports have not found this step to be necessary.[174]

There has been some question as to whether delayed ulnar nerve symptoms can occur after fractures of the epicondyle that are not associated with elbow dislocation. However, in a review of more than 100 patients with uncomplicated fractures involving the medial epicondylar apophysis, Patrick[132] could not find any instance in which a delayed ulnar neuritis developed.

Joint Stability—Relative

Woods and Tullos[191] suggested that even minor forms of valgus instability after elbow injuries involving the medial epicondylar apophysis can cause significant disability in athletes. This condition is especially true in athletes who must have a stable upper extremity, such as baseball pitchers, gymnasts, or wrestlers. In younger adolescents (younger than 14 years of age), the anterior band of the ulnar collateral ligament often displaces with the apophyseal fragment. In older individuals (15 years or older), large fragments may be avulsed without a ligamentous injury. Rather than depending on arbitrary measurements of fracture displacement, Woods and Tullos[191] recommended using the gravity valgus stress test to determine the presence or absence of valgus instability. They believed that demonstration of a significant valgus instability, using this simple gravity test, was an indication for surgical intervention in patients who require a stable elbow for their athletic activities (Table 18-13).

TABLE 18-13 ORIF of Medial Epicondyle Fractures

Preoperative Planning Checklist

- OR Table: Spine table or flat radiolucent table
- Position: Prone, "sloppy lateral," or supine position
- Fluoroscopy location: C-arm and monitor are positioned on the side of the table opposite the surgeon
- Equipment: 4- or 4.5-mm diameter cannulated or solid screws
- Tourniquet: Nonsterile tourniquet high on the affected arm

Author's Preferred Treatment for Medial Epicondyle Fractures

Determining the appropriate treatment for each patient involves a process of shared decision making in which the benefits and risks of each treatment alternative are discussed with the family. We use the general treatment guidelines outlined in Table 18-14 as a starting point for discussion with the patient and family. We strongly consider the expected activity of the patient and extremity in deciding with the patient and family on nonoperative or operative treatment.

For uncomplicated fractures of less than 2 mm of displacement we recommend nonoperative treatment. The parents are warned that no matter which type of treatment is provided, some loss of elbow extension may occur. They should be reassured, however, that this loss of motion, if it does occur, is not usually of any functional or cosmetic significance. The elbow is immobilized initially with a posterior splint or hinged elbow brace, used mainly for comfort and some support.

Because stiffness is the most common complication of this injury, we promote early active motion. Five to 10 days following the injury, the initial splint is exchanged for a removable splint and the patient is instructed on range-of-motion exercises. The patient uses the splint at school and outside the home, but within the home the splint is exchanged for a sling as soon as the patient feels he or she no longer needs the splint for support. Redislocation or instability is rare but elbow stiffness is common, so it is more important to initiate motion early.

TABLE 18-14 Author's Preferred Treatment for Medial Epicondyle Fractures

Nonoperative Treatment Indications
Nondisplaced or minimally displaced
Displaced in patients with low-demand upper-extremity function
Operative Treatment Indications
Absolute: Irreducible incarcerated fragment in the elbow joint
Relative: Ulnar nerve dysfunction
Relative: Patient with high-demand upper-extremity function

FIGURE 18-43 A 13-year-old boy is referred for treatment following posterolateral elbow dislocation. **A, B:** Notice on the AP and lateral radiographs that a medial epicondyle fracture cannot be easily seen but the medial epicondyle ossification center is absent from its normal anatomic position at the distal medial posterior humerus. **C, D:** A prereduction CT scan was obtained at the outside facility clearly demonstrating the medial epicondyle fragment within the elbow joint. **E, F:** Four months following surgical removal of the incarcerated medial epicondyle fragment and internal fixation of the fracture, a follow-up CT scan demonstrates anatomic reduction and excellent position of the single screw (with washer) within the medial column of bone, engaging subcortical bone for maximum fixation. The fracture is completely healed and the patient has returned to virtually all activities.

Physical therapy should be used only if voluntary active motion is difficult to obtain. The therapist should emphasize modalities designed to decrease swelling and pain and reestablish strength. Range of motion should be achieved only by active means, not by passive stretching.

Operative Indications

Our indications for operative intervention are twofold. First and foremost are fractures in which the fragments cannot be extracted by manipulative means from within the elbow joint. Second, we stabilize the epicondyles operatively in patients whose expected physical activity level requires a stable elbow. We realize that it is difficult to predict the athletic potential of a young child but most parents do see great possibilities for their offspring.

Acute Incarceration in the Joint

If the elbow is reduced and if the ulnar nerve is intact, we use Roberts' manipulative technique[146] to attempt to extract the fragment. If this technique fails to remove the fragment or if there is any ulnar nerve dysfunction, we proceed directly with an open procedure, extracting the fragment under direct vision.

We usually stabilize these fractures with a single cannulated screw and washer, which allows almost immediate motion, rather than wires or pins (Fig. 18-43). Follow-up care is essentially the same as after closed treatment. Active motion is initiated 5 to 10 days postoperatively.

Prevention of Valgus Instability

Currently, our most common indication for operative intervention is to ensure a stable elbow in patients participating in activities which may require stability to valgus stress (Fig. 18-44). This usually involves the dominant extremity of baseball pitchers, tennis players, or football quarterbacks. In wrestlers and gymnasts, the stability of the nondominant extremity also must be considered, which is best achieved with operative fixation.

We have not found the valgus stress test to be helpful in deciding on the need for operative stabilization of an athlete's medial epicondyle. Almost all of these patients with any significant displacement have a positive valgus stress test. Our decision is based primarily on the patient's need to have a very stable elbow for his or her athletic or work activity.

Fixation must be stable enough to allow early motion. Pins provide stability but do not allow early motion. Fortunately,

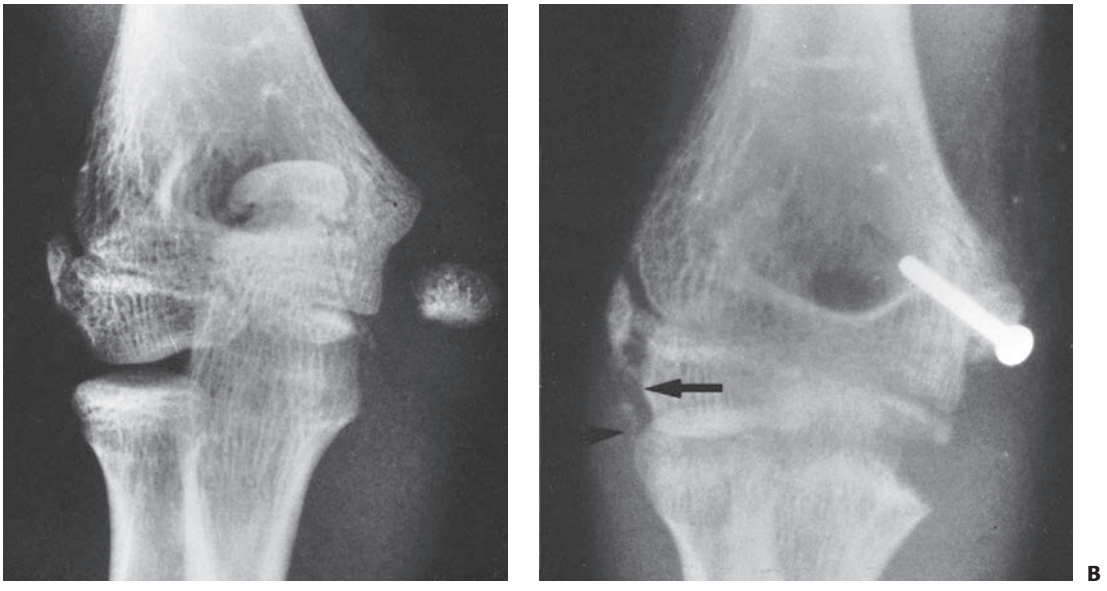

FIGURE 18-44 Operative stabilization. **A:** Injury film in a 12-year-old gymnast. Although this was a nondominant extremity, it was thought that both elbows needed stability. **B:** Radiographs taken 4 weeks postoperatively show stabilization of the fragment with a single screw. There was also calcification of the lateral ligaments (*arrows*), confirming that the elbow was probably originally dislocated as well. (From Wilkins KE. Fractures of the medial epicondyle in children. *Instr Course Lect.* 1991;40:1–8, with permission.)

most patients are mature enough so that the fragment can be secured with a solid or cannulated screw (Table 18-15).

Operative Technique

Our preferred operative technique involves positioning the patient prone or in a "sloppy lateral" position on a radiolucent table (Table 18-13) (Fig. 18-45). The arm is placed in a "figure 4" position with the forearm resting across the patient's back. This position places a varus stress on the elbow which facilitates fracture reduction while allowing a direct medial approach to the fracture site. The fragment is usually displaced distally and anteriorly. Interposed periosteum and soft tissue are removed from the fracture site, and the clot is extracted by irrigation. It is important to identify and protect the ulnar nerve along with medial antebrachial cutaneous nerves. If not already disrupted by the fracture, we typically release the cubital tunnel retinaculum, but a complete dissection of the nerve is usually unnecessary. A small towel clip or clamp is used to grasp the fascia and tendinous origin of the flexor–pronator group, avoiding fragmentation of the medial epicondyle, and the fracture is reduced while the elbow is flexed and the forearm is pronated. The medial epicondyle is reduced under direct vision to its anatomic position on the posterior aspect of the distal medial humerus. Temporarily stabilization with one or two small K-wires, or the guide pin for a cannulated screw, is performed. Final fixation is achieved using a partially threaded screw to compress the medial epicondyle fragment against the humeral metaphysic. In large male patients a 4.5-mm diameter screw is used, and a 4-mm diameter screw is appropriate for smaller elbows. Because cannulation increases the core diameter of the screw shaft, small-diameter cannulated screws have less coarse threads and potentially less fixation. For this reason we will often use a noncannulated 4-mm diameter screw. All fixations depend on a single screw which must be strong enough to allow early motion. Therefore every effort should be made to optimize its strength. Bicortical fixation has been used but injury to the radial nerve when penetrating the opposite cortex with a cannulated screw has been reported.[104] Dense cancellous bone of the medial condyle provides excellent fixation but care should be taken to avoid using a longer screw with threads solely within the hollow central intramedullary canal proximal to the olecranon fossa where fixation is less secure (Figs. 18-43 and 18-44).

A washer may be added to increase fixation surface area and reduce the risk of fragmenting the medial epicondyle with compression but this does make the implant slightly more prominent. After removal of the guide pin or K-wires, the elbow is assessed to ensure valgus stability and reestablishment of a full range of motion. After the surgical incision is closed, the extremity is placed in a well-padded posterior splint which is removed 5 to 10 days postoperatively and replaced with a removable splint or hinged brace, allowing initiation of early active range-of-motion exercise.

If the epicondyle is fragmented and if there is a need to achieve elbow stability, an American Society for Internal Fixation spiked washer can be used to secure the multiple pieces to the metaphysis. If the washer is used, a second procedure may be necessary to remove the spike washer once the epicondyle is securely united to the metaphysis. If internal fixation is impossible, we simply excise the fragments and reattach the ligament to the bone and periosteum at the base of the epicondylar defect (Table 18-16).

TABLE 18-15 ORIF of Medial Epicondyle Fractures

Surgical Steps

- Position patient prone or "sloppy lateral" allowing the arm to be positioned in a "figure 4" configuration with the forearm resting behind the patient's back (Fig. 18-45). This applies a varus force to the elbow and facilitates fracture reduction.
- A longitudinal 5-cm incision is made just posterior to the anatomic location of the medial epicondyle.
- Expose the ulnar nerve and ensure that it is not trapped within the fracture. Transposition of the nerve is not necessary. If not already torn by the injury, release the fascia overlying the ulnar nerve as the nerve travels in its groove behind the medial epicondyle. This allows mobilization of the nerve and gentle retraction.
- Exposure of the ulnar nerve will also expose the fracture site. The medial epicondyle fragment will typically be displaced distally and rotated anteriorly.
- Preserve soft tissue attachments to the medial epicondyle and elevate just enough soft tissue at the fracture site to allow adequate visualization to achieve an anatomic reduction.
- Using a penetrating towel clamp, grasp the flexor–pronator group *fascia* where it attaches to the medial epicondyle. This will prevent fragmentation of the medial epicondyle.
- Using the towel clamp to manipulate the fragment, anatomically reduce the medial epicondyle to the distal humeral metaphysis. Consider provisionally fixing the fragment in place with a small-diameter K-wire.
- Under fluoroscopic guidance place a cannulated guide pin or solid drill through the center of the medial epicondyle fragment into the center of the medial column of bone in the distal humerus and confirm anatomic reduction of the fracture.
- Drill and tap into the medial column of the distal humeral metaphysis.
- Place a single screw within the dense cancellous bone of the medial column. Do not use a screw so long that it ends within the central intramedullary canal where screw purchase is poor (Figs. 18-43 and 18-44).
- Confirm anatomic reduction of the fracture and position of the implant with fluoroscopy before wound closure.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Medial Epicondyle Fractures

Although much has been written about fractures involving the medial epicondylar apophysis, few complications are attributed to the fracture itself. The major complications that result in loss of function are failure to recognize incarceration in the joint and ulnar or medial nerve dysfunction. Most of the other complications are minor and result in only minimal functional or cosmetic sequelae (Table 18-17).

Major Complications in Medial Epicondyle Fractures

Failure to Recognize Fragment Incarceration

Failure to recognize incarceration of the epicondylar fragment into the joint can result in significant loss of elbow motion, especially if it remains incarcerated for any length of time. Fowles et al.[45] challenged the opinion that surgery is detrimental in patients with late incarceration, and the idea remains controversial. In their patients in whom the fragment was surgically extracted an average of 14 weeks after injury, 80% more elbow motion was regained. In addition, the patients' preoperative pain was relieved, and the ulnar nerve dysfunction resolved. Lopez et al.[92] described a case report of an incarcerated fragment treated 12 weeks following injury by excision of the fragment. Twelve months following surgery the ulnar neuropathy had resolved, the patient had minimal symptoms and excellent motion.

The long-term outcome following intra-articular retention of the medial epicondyle fragment is unpredictable. Rosendahl[148] reported an 8-year follow-up of a fragment retained within the joint. The epicondyle had fused to the semilunar surface of the ulna, producing a large bony prominence clinically. There was only minor loss of elbow motion, with little functional disability. Potenza et al.[135] described a case report of a neglected intra-articular medial epicondyle fracture with

FIGURE 18-45 **A:** The patient is positioned prone on a radiolucent table with the shoulder internally rotated and the arm resting on the patient's back. **B:** The medial aspect of the elbow is immediately accessible to the surgeon. The prone position results in application of a gentle varus stress to the elbow which facilitates maintenance of reduction while stable internal fixation is achieved.

TABLE 18-16 Medial Epicondyle Fractures

Potential Pitfalls and Preventions

Pitfalls	Preventions
Pitfall #1 Failure to recognize a medial epicondyle fragment entrapped within the joint following elbow dislocation	*Prevention 1:* All children older than age 5 years should have a medial epicondyle ossification center which must be visualized in its normal anatomic location following elbow dislocation reduction.
Pitfall #2 Fragmentation of the medial epicondyle during ORIF	*Prevention 2a:* Instead of grasping the medial epicondyle bone with a clamp, grasp the flexor–pronator fascia where it attaches to the medial epicondyle. *Prevention 2b:* Avoid overtightening the screw which is fixing the medial epicondyle in place. *Prevention 2c:* Consider using a washer to distribute pressure over greater surface area
Pitfall #3 Injury to the radial nerve	*Prevention 3a:* Do not obtain bicortical fixation in the lateral cortex of the distal humerus with the medial epicondyle screw

48-year follow-up resulting in minimal symptoms. Similar to the case reported by Rosendahl, the fragment had fused to the olecranon where it caused minimal problems.

Ulnar Nerve Dysfunction

The other major complication associated with this injury is the development of ulnar nerve dysfunction. The incidence of ulnar nerve dysfunction varies from 10% to 16%.[15,105] If the fragment is entrapped in the joint, the incidence of ulnar nerve dysfunction may be as high as 50%.[15,42] More profound ulnar nerve injury has been reported after manipulative procedures.[132] Thus, in patients with fragments incarcerated in the joint, manipulation may not be the procedure of choice if a primary ulnar nerve dysfunction is present. Patients in whom the fragment was left incarcerated in the joint for a significant time have experienced poor recovery of the primary ulnar nerve injury.[105] A consistent finding noted by surgeons when exploring the ulnar nerve and removing the incarcerated fragment from the joint has been a thick fascial band binding the ulnar nerve to the underlying muscle.[12,132] Constriction by this band has been noted to cause immediate or late dysfunction of the ulnar nerve.

Delayed ulnar nerve palsy has also been reported following surgical treatment. Anakwe et al.[9] described two cases in which open reduction of a medial epicondyle was performed. Patients presented at 1- and 2-week follow-up with complete ulnar nerve palsy despite normal neurologic examination immediately postoperatively. In both patients, on re-exploration the ulnar nerve was found to be compressed by scar tissue between two heads of the flexor carpi ulnaris just distal to the medial epicondyle. Both patients experienced a complete recovery following ulnar nerve decompression.

Nonunion in the high-performance athlete

Symptomatic Nonunion

Nonunion of the medial epicondyle fragment with the distal metaphysis occurs in up to 50% of fractures with significant displacement.[15] Although the majority of the nonunions cause minimal problems, symptomatic nonunions do occur (Fig. 18-46). Smith et al.[162] from Boston Children's Hospital reviewed 137 patients treated for medial epicondyle fracture at their institution. Of the 42 fractures which were treated nonoperatively, nonunion occurred in 19 fractures and 8 of those fracture nonunion patients experienced symptoms significant

FIGURE 18-46 Nonunion in an athlete. This 15-year-old baseball pitcher had an untreated medial epicondyle fracture 1 year before this radiograph. He developed a fibrous union, but the epicondyle was shifted distally (*arrow*). His elbow was unstable enough to prevent him from pitching.

enough to warrant surgical treatment at a mean of 12 months following their initial injury. All patients were treated with open reduction and internal fixation of the ununited fragment, three of whom underwent grafting of the nonunion site. Successful fracture union was achieved in seven of the eight fractures and all patients experienced significant symptomatic improvement. Shukla and Cohen[159] described the treatment results of five patients with chronic medial epicondyle nonunion using a tension band construct At a mean follow-up of 31 months all fractures were healed, patients reported being satisfied with their surgery and measurable outcome measures were significantly improved.

Valgus Instability

Valgus instability following displaced medial epicondyle fracture nonunion is a very challenging problem and has been used as an argument for surgical treatment. Gilcrist and McKee[50] reported good and excellent treatment results following excision of the ununited fragment and advancement of the medial collateral ligament complex with fixation to the distal humerus with suture anchors in five patients with symptomatic valgus elbow instability. Mayo Elbow Performance Score improved from 66 preoperatively to 91 postoperatively, and all patients were satisfied with the result.

Radial Nerve Injury

When fixing a medial epicondyle fragment the operating surgeon must decide whether to accept fixation within the cancellous bone of the medial column or achieve bicortical fixation by gaining purchase in the lateral cortex of the proximal humeral metaphysis. Unfortunately the radial nerve travels on the surface of the humerus at the location where a bicortical screw penetrates the cortex. Marcu et al.[104] have reported two cases of radial nerve injury with cannulated screw fixation.

Minor Complications in Medial Epicondyle Fractures

The most common minor complication is loss of the final degrees of elbow extension. A loss of 5% to 10% can be expected to develop in about 20% of these fractures. Little functional deficit is attributed to this loss of elbow motion. Prolonged immobilization seems to be the key factor in loss of elbow extension. Again, it is important to emphasize before treatment is begun that loss of motion is common after this injury, regardless of the treatment method used. Sufficient fracture stability to allow for early motion is paramount to lessening the risk of functional loss of motion.

Myositis ossificans is a rare occurrence following vigorous and repeated manipulation to extract the fragment from the joint. As with many other elbow injuries, myositis may be a result of the treatment rather than the injury itself. Myositis ossificans must be differentiated from ectopic calcification of the collateral ligaments, which involves only the ligamentous structures. This condition may occur after repeated injuries to the epicondyle and ligamentous structures (Fig. 18-47). Often, this calcified ligament is asymptomatic and does not seem to create functional disability. The cosmetic effects are minimal. In some patients, an accentuation of the medial prominence of the epicondyle creates a false appearance of an increased carrying angle of the elbow. In his extensive review, Smith[161] recognized a slight decrease in the carrying angle in only two patients (Table 18-18).

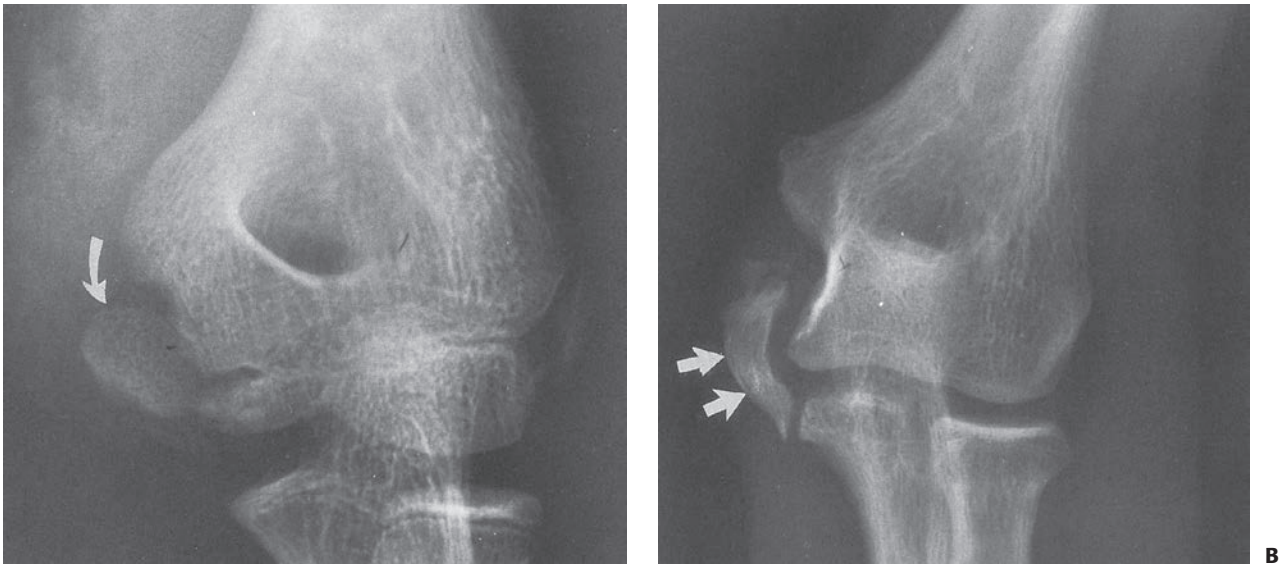

FIGURE 18-47 Heterotopic calcification. **A:** Injury to an 11-year old who had moderate displacement of the medial epicondyle (*arrow*). **B:** One year later, she had considerable calcification of the ulnar collateral ligament (*arrows*). Other than mild instability with valgus stress, the patient had full range of motion and was asymptomatic. (Courtesy of Mark R. Christofersen, MD.)

Chronic Tension Stress Injuries (Little League Elbow) in Medial Epicondyle Fractures

This chronic injury is related to overuse in skeletally immature baseball pitchers. Brogdon and Crow[21] described the original radiographic findings in 1960. Later, Adams[1] demonstrated that the radiographic changes were due to excessive throwing and emphasized the need for preventive programs. This injury is thought to be due to excessive tension on the medial epicondyle with secondary tendinitis. There can also be a repeated compression on the lateral condyle, producing an osteochondritis.

Studies have shown that as long as the rules outlined by the Little League are followed (i.e., pitch counts of 50 to 75 pitches per game depending on age), the incidence of these chronic tension stress injuries is fairly low.[47] Most of the problems arise when overzealous parents and coaches require excessive pitching preseason, at home between practices and/or participation on multiple teams. Albright et al.[4] found a greater incidence in pitchers who had improper pitching techniques. The spectrum of these chronic injuries is outlined in Table 18-19.

In chronic tension stress injuries (Little League Elbow Syndrome), the history is usually quite characteristic. It is found in young baseball pitchers who are throwing an excessive number of pitches or who are just starting to throw curve pitches.[47] Clinically, this syndrome is manifested by a decrease in elbow extension. Medial epicondylar pain is accentuated by a valgus stress to the elbow in extension. There is usually significant local tenderness and swelling over the medial epicondyle.

On radiographs, the density of the bone of the distal humerus is increased because of the chronicity of the stress. The physeal line is irregular and widened. If the stress has been going on for a prolonged period, there may be hypertrophy of the distal humerus with accelerated bone growth.

TABLE 18-19 Spectrum of Chronic Tension Stress Injuries of Medial Elbow Epicondylar Apophysis

Stress fracture of the epicondylar physis
Calcification of the ulnar collateral ligaments
Hypertrophy of the medial epicondyle
Acceleration of growth maturity with generalized synovitis and stiffness
Osteochondritis of the lateral condyle

We use a multifaceted approach that involves educating the parents, coaches, and player. Once symptoms develop, all pitching activities must cease until the epicondyle and adjacent flexor muscle origins become nontender. In addition, local and systemic measures to decrease the inflammatory response are used. Once the initial pain and inflammation have decreased, a program of forearm and arm muscle strengthening is initiated. The pitching technique is also examined to see if any corrections need to be made. Once strength has been reestablished in the muscles in the upper extremity and motion has been fully reestablished, the patient is gradually returned to pitching with careful monitoring of the number of innings and pitches within a specified time period.

In cases of chronic nonunion due to a chronic medial epicondylar stress fracture in older pitchers, open reduction with a compression screw and washer may be necessary to achieve union, stop pain, and allow return to full function.

Pulled Elbow Syndrome (Nursemaid's Elbow)

Subluxation of the annular ligament, or pulled elbow syndrome, is a common elbow injury in young children.[8,27,70,74,163] The term "nursemaid's elbow" and other synonyms have been used to describe this condition. The demographics associated with subluxation of the radial head have been well described.[8,27,70,74,163] The mean age at injury is 2 to 3 years, with the youngest reported patient 2 months of age. It rarely occurs after 7 years of age; 60% to 65% of the children affected are girls, and the left elbow is involved in approximately 70%. It is difficult to determine the actual incidence because many subluxations are treated in primary care physician's offices, by parents, or resolve spontaneously before being seen by a physician.

Mechanisms of Injury for Pulled Elbow Syndrome

Longitudinal traction on the extended elbow is the usual mechanism of injury (Fig. 18-48). Cadaver studies have shown that longitudinal traction on the extended elbow can produce a partial slippage of the annular ligament over the head of the radius and into the radiocapitellar joint, sometimes tearing the subannular membrane.[108,115,154] Displacement of the annular ligament occurs most easily with the forearm in pronation. In this position, the lateral edge of the radial head, which opposes the main portion of the annular ligament, is narrow and round at its margin.[98,108] In supination, the lateral edge of the radial head is wider and more square at its margin, thereby restricting slippage of the annular ligament. McRae and Freeman[113] demonstrated that forearm pronation maintained the displacement of the annular ligament.

After 5 years of age, the distal attachments of the subannular membrane and annular ligament to the neck of the radius have strengthened sufficiently to prevent its tearing and subsequent displacement.[154] Previously, the theory was proposed that the

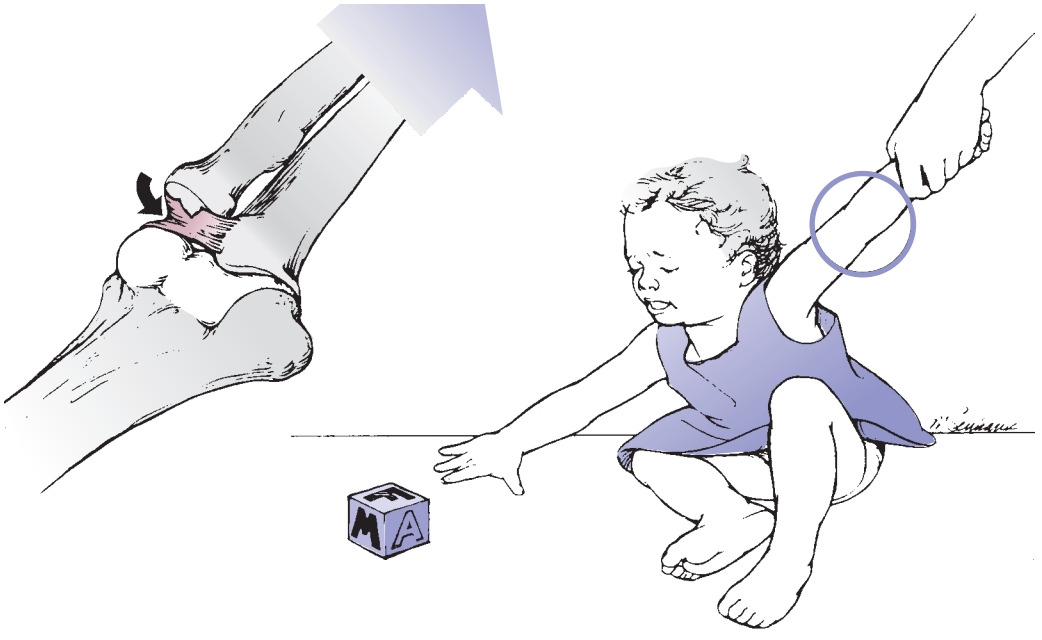

FIGURE 18-48 The injury most commonly occurs when a longitudinal pull is applied to the upper extremity. Usually the forearm is pronated. There may be a partial tear in the subannular membrane, allowing the annular ligament to subluxate into the radiocapitellar joint.

radial head diameter was less in children than in adults and this contributed to subluxation of the annular ligament. However, cadaver studies of infants, children, and adults have shown that the ratio of the head and neck diameters is essentially the same.[152,154] Griffin[56] suggested that the lack of ossification of the proximal radial epiphysis in children less than 5 years of age made it more pliable, thereby facilitating slippage of the annular ligament.

Amir et al.[8] performed a controlled study comparing 30 normal children with 100 who had pulled elbow syndrome. They found an increased frequency of hypermobility or ligamentous laxity among children with pulled elbows. Also, there was an increased frequency of hypermobility in one or both parents of the involved children compared with noninvolved children, suggesting that hypermobility could be a factor predisposing children to this condition.

Thus, the most widely accepted mechanism is that the injury occurs when the forearm is pronated, the elbow extended, and longitudinal traction is applied to the patient's wrist or hand (Fig. 18-48).[109,113,156] Such an injury typically occurs when a young child is lifted or swung by the forearm or when the child suddenly steps down from a step or off a curb while one of the parents is holding the hand or wrist.

Unusual Mechanisms

Newman[122] reported that five of six infants under 6 months of age with a pulled elbow sustained the injury when rolling over in bed with the extended elbow trapped under the body. It was believed that this maneuver, especially if the infant was given a quick push to turn over by an older sibling or a parent, provided enough longitudinal traction to displace the annular ligament proximally.

Associated Injuries with Pulled Elbow Syndrome

No other associated injuries have consistently been linked with pulled elbow syndrome.

Assessment of Patients with Pulled Elbow Syndrome

History and Physical Examination

The history is usually that of an episode of a longitudinal pull on the elbow of the young child. The initial pain usually subsides rapidly, and the child does not appear to be in distress except that he or she is reluctant to use the involved extremity. The upper extremity is typically held at the side with the forearm pronated. A limited painless arc of flexion and extension may be present; however, any attempt to supinate the forearm produces pain and is met with resistance. Although there is no evidence of an elbow effusion, local tenderness may be present over the radial head and annular ligament. In some patients, the pain may be referred proximally to the shoulder but most complain of pain distally toward the wrist.[8,70]

Unfortunately, the classic history is not always present.[27,134,139,153,156] In some studies 33% to 49% of patients had no clear history of longitudinal traction to the elbow.[153,156] In patients without a witnessed longitudinal traction injury, other causes, such as occult fracture or early septic arthritis, must be carefully ruled out.

Imaging Studies for Pulled Elbow Syndrome

Standard Radiographs

Should x-rays be taken of every child before manipulation is attempted? If there is a reliable history of traction to the elbow, the child is 5 years of age or younger, and the clinical findings strongly support the diagnosis, x-rays are not necessary.[8,27,139,154,177] If, however, there is an atypical history or clinical examination, x-rays should be obtained to be certain that there is not a fracture before manipulation is attempted.

AP and lateral x-rays usually are normal,[20,27,56,139,154,156,164] but subtle abnormalities may be present. Normally, the line down the center of the proximal radial shaft should pass through the center of the ossification center of the capitellum (radiocapitellar line).[48,164] Careful review of x-rays may demonstrate the radial capitellar line to be lateral to the center of the capitellum in up to 25% of patients.[48,164] Determination of this subtle change requires a direct measurement on the x-ray. Interestingly, the pulled elbow can be reduced by the radiology technician because the elbow x-rays are usually taken with the forearm supinated. The subluxation is reduced inadvertently when the technician places the forearm into supination to position it for the x-ray. Bretland[19] suggested that if the best x-ray that can be obtained is an oblique view with the forearm in pronation, pulled elbow syndrome is the likely diagnosis.

Ultrasonography

When the diagnosis is not evident, ultrasonography may be helpful,[88,98] although not always reliable.[155] The diagnosis is made by demonstrating an increase in the echo-negative area between the articular surfaces of the capitellum and the radial head and increased radial capitellar distance. Kosuwon et al.[88] found that this distance is normally about 3.8 mm with forearm pronated. With a subluxated radial head, this measured 7.2 mm. A difference of 3 mm between the normal and affected sides, therefore, suggests radial head subluxation.

Treatment Options for Pulled Elbow Syndrome

Nonoperative Treatment: Closed Reduction

Virtually all annular ligament subluxations are successfully treated by closed reduction. The traditional reduction maneuver has been to supinate the forearm.[27,56,70,139,156,163] Some authors have recommended that supination be done with the elbow flexed, and others have found that supination alone with the elbow extended can affect a reduction. In many patients, a snapping sensation can be both heard and palpated when the annular ligament reduces (Fig. 18-49). More recently there has been significant interest in forearm hyperpronation as a reduction maneuver. More than one prospective randomized study has reported that hyperpronation is more successful than supination.[16,96] Macias reported that reduction was successful in 40 of 41 patients (98%) in the hyperpronation group compared with 38 of 44 patients (86%) in the supination group. They concluded that the hyperpronation technique was more successful, required fewer attempts, and was often successful when supination failed. Generally, a full arc of supination to pronation of the forearm, with elbow flexion and extension, will reduce all pulled elbows.

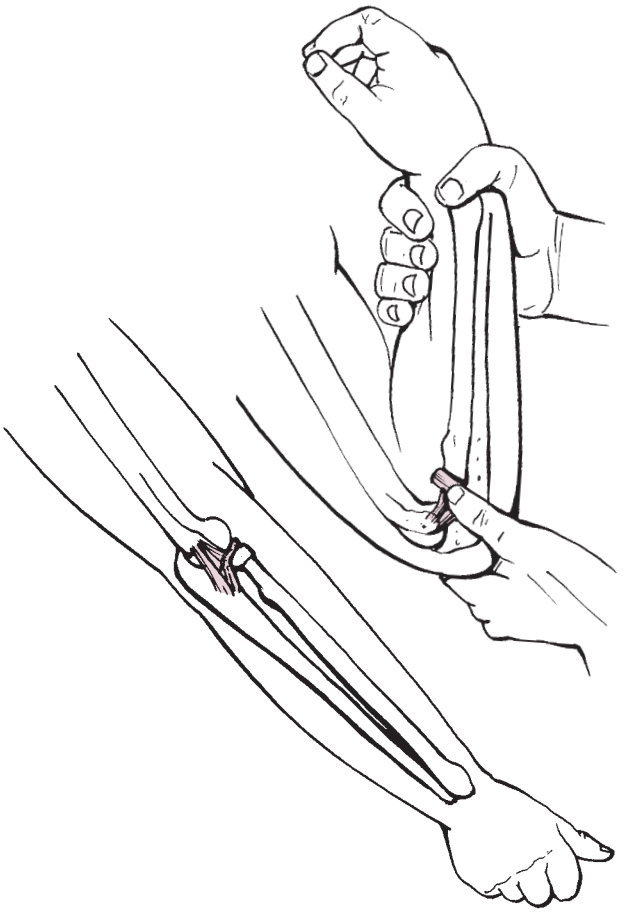

FIGURE 18-49 Reduction technique for nursemaid's elbow. **Left:** The forearm is first supinated. **Right:** The elbow is then hyperflexed. The surgeon's thumb is placed laterally over the radial head to feel the characteristic snapping as the ligament is reduced.

The value of immobilizing the elbow following reduction has been debated. Taha[173] reported a decreased rate of recurrence during the 10 days following reduction if the elbow was splinted in a flexed supinated position for 2 days following reduction. Salter and Zaltz[154] recommended the use of a sling, mainly to prevent the elbow from being pulled a second time. Kohlhaas and Roeder[87] recommended a T-shirt technique for flexed elbow stabilization in very young children. This provided adequate immobilization without the use of a sling by pinning the sleeve of the long sleeve T-shirt to the opposite chest. In general, after a successful closed reduction of a first-time annular ligament subluxation, immobilization of the extremity is not necessary if the child is comfortable and using the arm normally. After the reduction, it is important to explain to the parents the mechanism of injury and to emphasize the need to prevent longitudinal pulling on the upper extremities. Picking the child up under the axillae and avoiding games such as "ring around the roses" and involve longitudinal traction to the arm are stressed. However, recurrence rate is high even

with the most diligent parents. Therefore, instruction in home reduction of the pulled elbow is very useful and lessens visits to the emergency room and primary care physician.

Surgical Treatment

Even if untreated, most annular ligament subluxations reduce spontaneously. There are no reported cases of negative long-term sequelae following untreated annular ligament subluxation. Therefore, open reduction is rarely, if ever, indicated for annular ligament subluxation. An indication for surgery might be the chronic, symptomatic, irreducible subluxation.[29,177] In such a circumstance, the annular ligament may need to be partially transected to achieve reduction.

Author's Preferred Treatment: Pulled Elbow Syndrome—Closed Reduction

It is important to elicit a reliable history as to whether or not the child had a traction force applied across the extended elbow. The entire extremity is then carefully examined. Focal tenderness should be present directly over the radiocapitellar joint. If the history or physical examination is not entirely consistent with annular ligament subluxation, then x-rays of the upper extremity are obtained to assess for other injuries before manipulating the elbow.

Once the diagnosis of annular ligament subluxation is clearly established, manipulation is performed. It is first explained to the parents that there will be a brief episode of pain followed by relief of the symptoms. The patient usually is seated on the parent's lap. The patient's forearm is grasped with the elbow semiflexed while the thumb of the surgeon's opposite hand is placed over the lateral aspect of the elbow. The forearm is first supinated. If this fails to produce the characteristic snap of reduction, then the elbow is gently flexed maximally until the snap occurs (Fig. 18-31). Just before reaching maximal flexion, there often is an increase in the resistance to flexion. At this point, a little extra pressure toward flexion is applied, which usually produces the characteristic snap as the annular ligament suddenly returns to its normal position. If this fails, then the hyperpronation technique of Macias et al.[96] is used. Full flexion–extension elbow motion and forearm pronation–supination motion is performed to the extremes, and this usually resolves the "outliers" which do not reduce with the usual mechanisms.

What should be done if a definite snap or pop is not felt or if the patient fails to use the extremity after manipulation? In a subgroup of patients, discomfort may persist despite successful annular ligament reduction. If the subluxation has occurred more than 12 to 24 hours before the child is seen, there often is a mild secondary synovitis, and recovery may not be immediate and dramatic. One must confirm that the initial diagnosis was correct. If not taken before the manipulation, x-rays should be obtained and the entire extremity carefully reexamined. If the x-ray results are normal and the elbow can be fully flexed with free supination and pronation, the physician can be assured that the subluxated annular ligament has been reduced. In this circumstance, the patient's arm may be placed in a splint or sling for a few days to 1 week and reexamined clinically and by x-ray if needed (Table 18-20).

TABLE 18-20 Pulled Elbow Syndrome

Potential Pitfalls and Preventions

Pitfalls	Preventions
Never assume that an unwitnessed fall has resulted in annular ligament subluxation	Obtain radiographs on all patients whose elbow injury was unwitnessed or occurred with a mechanism other than longitudinal traction
Persistent pain following apparent successful reduction maneuver	Place the child in an elbow sling, allow the child to use the elbow and reevaluate in 2–7 days with radiographs if necessary

Management of Expected Adverse Outcomes and Unexpected Complications Related to Pulled Elbow Syndrome

There are no reports of long-term sequelae from unrecognized and unreduced subluxations. Almost all subluxations reduce spontaneously. The only problem seems to be discomfort to the patient until the annular ligament reduces.

Recurrent Subluxations in Pulled Elbow Syndrome

The reported incidence of recurrent subluxation has varied from 5% to 39%.[27,56,70,139,156,163,175] Children 2 years of age or younger appear to be at greatest risk for recurrence.[156,177] Recurrent subluxations usually respond to the same manipulative procedure as the initial injury. They eventually cease after 4 to 5 years when the annular ligament strengthens and ligament laxity lessens. Recurrences do not lead to any long-term sequelae. If recurrent annular ligament subluxation significantly impacts a patient's quality of life because of pain or limited activity, immobilization in an above-elbow cast with the forearm in supination or neutral position for 2 to 3 weeks is usually effective at preventing recurrence.

Summary, Controversies, and Future Directions Related to Elbow Dislocations and Medial Epicondyle Fractures

The vast majority of dislocation about the elbow in children and adolescents can be successfully managed nonoperatively. Recurrent dislocation and instability appear to be very rare complications with stiffness being a much more common potential occurrence. Following elbow dislocation reduction patients may be successfully managed in a well-padded posterior splint for 5 to 10 days at which time a removable splint may be applied

and early elbow range of motion initiated. Medial epicondyle fractures commonly occur in association with elbow dislocation and the treating physician must have a high index of suspicion for this injury. Careful physical examination and thoughtful use of imaging studies will allow the treating physician to detect medial epicondyle fractures in all patients. The most common cause of a missed medial epicondyle fracture is that the treating physician did not think to specifically look for this injury. There is general agreement that medial epicondyle fractures displaced less than 2 mm can be effectively treated with immediate splint immobilization and initiation of active elbow range of motion 5 to 10 days following the injury. Medial epicondyle fractures entrapped within the elbow joint must be extracted, with open reduction and stable internal fixation allowing early elbow range of motion indicated in most patients. Controversy remains regarding treatment of medial epicondyle fractures displaced more than 2 mm. Shared decision making with patient and family, considering activity demands, dominant extremity, and displacement allow formulation of an optimal treatment strategy for each patient. Better implants, improved surgical technique, greater appreciation of the importance of the ulnar collateral ligament function, and increased understanding of the degree of displacement in fractures previously thought to be nondisplaced all contribute to a general trend toward more frequent surgical treatment of medial epicondyle fractures.

ACKNOWLEDGMENTS

We thank James H. Beaty, James R Kasser, Stephen D. Heinrich, Kaye Wilkins, and George Thompson for their contributions to this chapter. The information presented in this chapter is based on their efforts in previous editions.

19 LATERAL CONDYLAR AND CAPITELLAR FRACTURES OF THE DISTAL HUMERUS

Jeffrey R. Sawyer and James H. Beaty

Introduction to Lateral Condylar Fractures of the Distal Humerus

All the physes of the distal humerus are vulnerable to injury, each with a distinct fracture pattern. Next to those of the distal radius, injuries to the distal humeral physes are the most common physeal injuries. The vulnerability of the various physes to injury is altered by age and injury mechanism.[1,3] Fractures involving the total distal humeral physis may occur in neonates or within the first 2 to 3 years of life.[13,49] Fractures involving the lateral condylar physis occur early, with the average age around 6 years.[25,29,32,37] Fractures concerning the medial condylar physis are rare and occur most often in children 8 to 12 years of age (see Chapter 20 for medial condylar fractures).[25,32,37]

The specific fracture patterns, incidence, and mechanism of injury are discussed in detail in the following sections dealing with these specific fractures.

Fractures Involving the Lateral Condylar Physis

Assessment of the Fractures Involving Lateral Condylar Physis

Fractures involving the lateral condyle in the immature skeleton can either cross the physis or follow it for a short distance into the trochlear cartilage. Fractures of the lateral condylar physis, which are less common than supracondylar fractures, constitute 17% of distal humeral fractures.

Fractures of the lateral condylar physis rarely are associated with injuries outside the elbow region[27,30,45] and unlike supracondylar humeral fractures, fractures of the lateral condyle rarely are associated with neurovascular injuries. Within the elbow region, the associated injuries that uncommonly occur with this fracture include dislocation of the elbow (which may be a result of the injury to the lateral condylar physis rather than

a separate injury), radial head fractures, and fractures of the olecranon, which are often greenstick fractures. Acute fractures involving only the articular capitellum are rare in skeletally immature patients but are serious injuries that need to be recognized and treated appropriately.

The diagnosis of lateral condylar physeal injuries may be less obvious both clinically and on radiographs than that of supracondylar fractures (Fig. 19-1), especially if the fracture is minimally displaced. Oblique views of the distal humerus are very helpful in making accurate diagnosis and defining the extent of fracture displacement for treatment decisions.

Mechanism of Injury

Two mechanisms have been suggested: "push-off" and "pull-off." The pull-off or avulsion theory has more advocates than the push-off mechanism.[33,72] In early studies,[72] this injury was consistently produced in young cadavers by adducting the forearm with the elbow extended and the forearm supinated. The push-off mechanism has also been reproduced in cadavers by applying a sharp blow to the palm with the elbow flexed, causing the radial head to push off the lateral condyle. This push-off injury also can result from a direct blow to the olecranon.

It is likely that both mechanisms can produce this injury. The more common type of fracture, which extends to the apex of the trochlea, probably is a result of avulsion forces on the condyle, with the olecranon's sharp articular surface serving to direct the force along the physeal line into the trochlea. When a child falls forward on his or her palm with the elbow flexed, the radial head is forced against the capitellum and may cause the less common physeal fracture that courses through the ossific nucleus of the capitellum.

Signs and Symptoms

Compared with the marked distortion of the elbow that occurs with displaced supracondylar fractures, little distortion of the elbow, other than that produced by the fracture hematoma, may be present with lateral condylar fractures. The key to the clinical evaluation of this fracture is the location of soft-tissue swelling and pain concentrated over the lateral aspect of the distal humerus.[41] Stage I displacement may produce only local tenderness at the condylar fracture site, which may be increased by flexing the wrist, placing the wrist extensors, which are attached to the fracture fragment, on stretch. The benign appearance of the elbow with some stage I displacements may account for the delay of parents seeking treatment for a child with a minimally displaced fracture. With stage II or III displacement, there often is a hematoma present laterally, and attempted manipulation may result in some local crepitus with motion of the lateral condylar fragment. This obviously would be associated with pain and should be avoided if there is a clear radiographic evidence of a fracture.

Radiographic Findings

The radiographic appearance varies according to the fracture line's anatomic location and the displacement stage. In the AP view, the metaphyseal fragment or "flake" may be small and seemingly minimally displaced. The degree of displacement may be seen on the true lateral view. In determining whether the articular hinge is intact (i.e., stage I vs. stage II), the relationship of the proximal ulna to the distal humerus is evaluated for the presence of lateral translocation. Oblique views are especially helpful in patients in whom a stage I displacement is suspected but not evident on AP and lateral views.

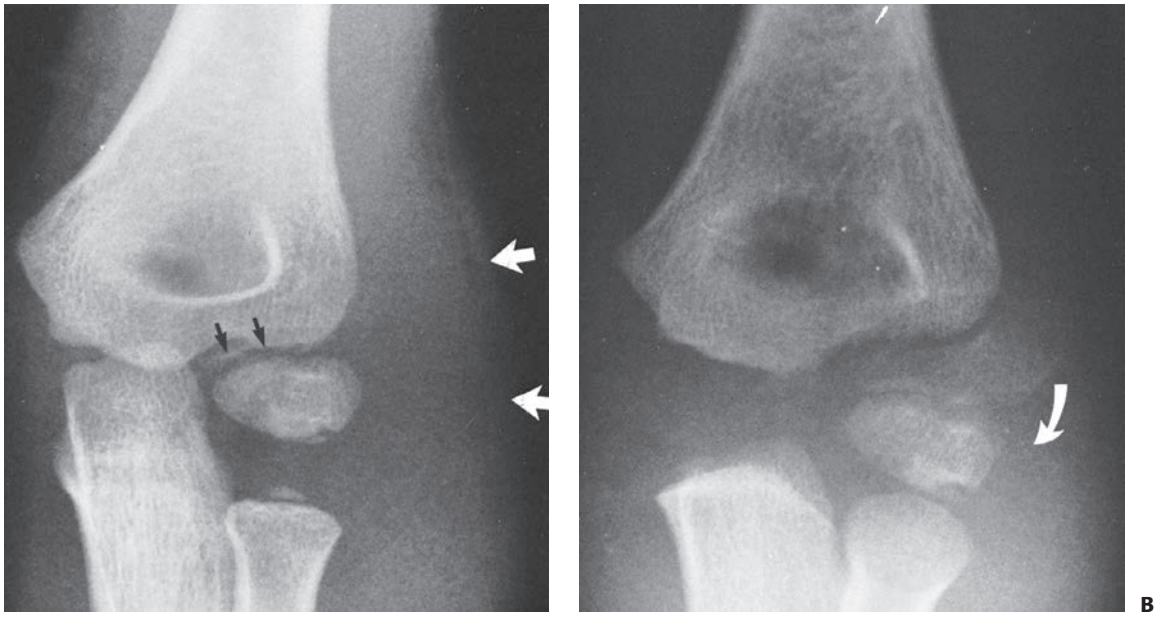

FIGURE 19-1 **A:** Injury film of a 7-year old with a nondisplaced fracture of the lateral condyle (*small arrows*). Attention was drawn to the location of the fracture because of extensive soft-tissue swelling on the lateral aspect (*white arrows*). **B:** Because of the extensive soft-tissue injury, there was little intrinsic stability, allowing the fracture to become displaced at 7 days (*arrow*).

TABLE 19-1 Risk of Subsequent Displacement of Lateral Humeral Condylar Fractures Immobilized in a Cast

Fracture Type	Description	Risk Ratio	95% Confidence Interval
Group A (stable)	No gap or small gap in radial or radiodorsal aspect of metaphyseal fracture; fracture could not be followed all the way to epiphyseal cartilage	0	0–5.52
Group B (undefinable risk)	Same as Group A, but fracture could be clearly observed all the way to epiphyseal cartilage	0.17	6.56–33.65
Group C (high risk)	Gap in fracture as wide, or almost as wide, medially as laterally	0.42	15.17–72.33

Modified from: Finnbogason T, Karlsson G, Lindberg L, et al. Nondisplaced and minimally displaced fractures of the lateral humeral condyle in children: A prospective radiographic investigation of fracture stability. *J Pediatr Orthop.* 1995;15:442–425.

To determine the importance of the internal oblique view in the radiographic evaluation of nondisplaced or minimally displaced lateral condylar fractures, Song et al.[66] compared the oblique view to standard AP views and found that the amount of displacement differed between the two views in 75% of children. They recommended routine use of an internal oblique view to evaluate the amount of fracture displacement and to assess stability if a lateral condylar fracture is suspected.

Three groups of nondisplaced and minimally displaced fractures of the lateral condyle have been described and correlated with the risk of late displacement: stable fractures, fractures with an undefinable risk, and fractures with a high risk of later displacement (Table 19-1).[19] Arthrography or MRI evaluation has been suggested to identify unstable fractures in the acute setting and to aid in preoperative planning for those with late displacement, delayed union, or malunion. Although not used with all fractures, MRI can be a very useful diagnostic aid to guiding treatment, especially with delayed unions.

A major diagnostic difficulty lies in differentiating a lateral condylar fracture from a fracture of the entire distal humeral physis. In a young child in whom the condyle is unossified, an arthrogram or MRI may be helpful (Figs. 19-2, 19-3, and 19-4).[11,27] Ultrasonography, which often can avoid MRI sedation issues, can be used to identify transphyseal separations in young patients.

In fractures of the entire distal humeral physis, the proximal radius and ulna usually are displaced posteromedially (Fig. 19-5A). The relationship of the lateral condylar ossification center to the proximal radius remains intact. In true fractures involving only the lateral condylar physis, the relationship of the condylar ossification center to the proximal radius is disrupted (Fig. 19-5B). In addition, displacement of the proximal

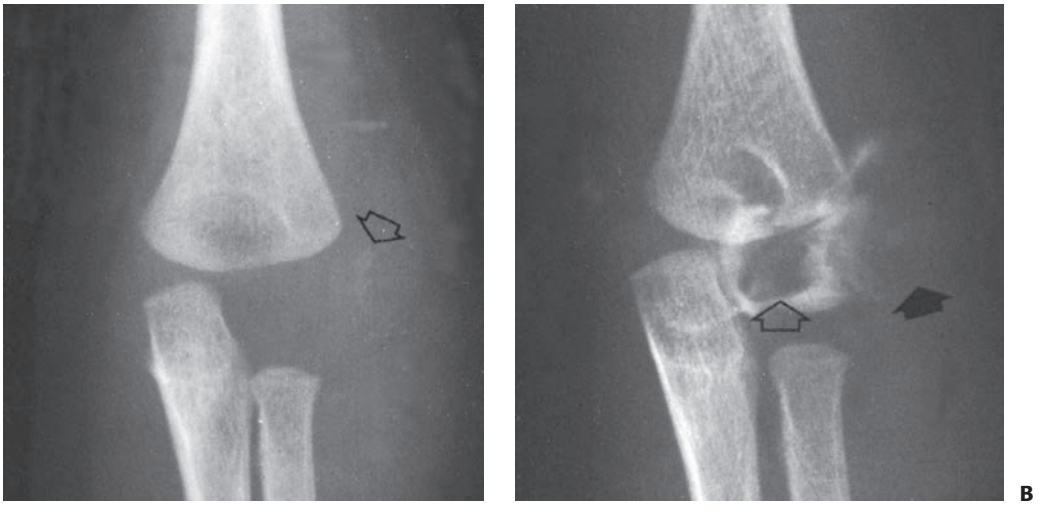

FIGURE 19-2 Unossified lateral condyle. **A:** AP view. A small ossific nucleus can barely be seen (*arrow*) in the swollen lateral soft tissues. **B:** An arthrogram shows the defect left by the displaced lateral condyle (*closed arrow*). The displaced condyle is outlined in the soft tissues (*solid arrow*). Note the large cartilaginous fragment that is not visible on radiograph.

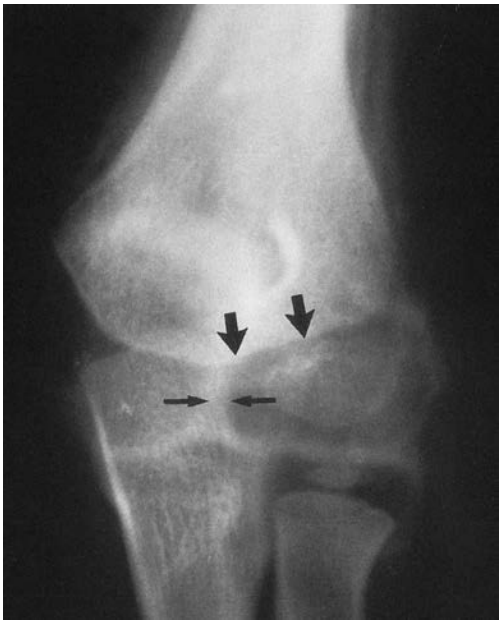

FIGURE 19-3 Arthrogram of stage I fracture of the lateral condyle (*large arrows*). Articular surface is intact with no displacement (*small arrows*).

radius and ulna is more likely to be lateral because of the loss of stability provided by the lateral crista of the distal humerus.

Classification

Lateral condylar physeal fractures can be classified by either the fracture line's anatomic location or by the amount of displacement.

Anatomic Location. The Milch classification, based on whether or not the fracture extends through (type I) or around (type II) the capitellar ossific nucleus, is used infrequently because of its poor reliability and poor predictive value[79] and is primarily of historic interest. Salter and Harris[59] classified lateral condylar physeal injuries as a form of type IV injuries in their classification of physeal fractures. Because the fracture line starts in the metaphysis and then courses along the physeal cartilage, a lateral condylar humeral fracture has some of the characteristics of both type II and IV injuries. A true Salter–Harris type IV injury through the ossific nucleus of the lateral condyle is rare. Although lateral condylar fractures are similar to Salter–Harris type II and IV fractures, treatment guidelines follow those of a type IV injury: open reduction and internal fixation of displaced intra-articular fractures. The Salter–Harris classification is of little clinical use and is debatable as to the accuracy of terminology, because the fracture exits the joint in the not-yet-ossified cartilage of the trochlea.

Stages of Displacement. The amount of fracture displacement has been described by Jakob et al.[33] in three stages (Fig. 19-6).[75] In the first stage, the fracture is relatively nondisplaced, and the articular surface is intact (Fig. 19-6A, B). Because the trochlea is intact, there is no lateral shift of the olecranon. In the second stage, the fracture extends completely through the articular surface (Fig. 19-6C, D). This allows the proximal fragment to become more displaced and can allow lateral displacement of the olecranon. In the third stage, the condylar fragment is rotated and totally displaced laterally and proximally, which allows translocation of both the olecranon and the radial head (Fig. 19-6E, F).

Weiss et al.[79] modified this classification based on fracture displacement and disruption of the cartilaginous hinge (Fig. 19-7). Type I fractures are displaced less than 2 mm; type II fractures are displaced more than 2 mm but have an intact cartilaginous hinge; and type III fractures are displaced more than 2 mm and do not have an intact cartilaginous hinge. In their series of 158 types II and III fractures, they found that all type II fractures had less than 4 mm of displacement on initial radiographs and all type III fractures had more than 4 mm of displacement. This classification was found to be predictive of complications, with both the major and minor complication rates correlating with fracture type.

A

B

FIGURE 19-4 **A:** Radiograph of what appears to be a stable type II fracture of the lateral condyle in a 10-year-old child. **B:** Gradient-echo MRI clearly shows that this is a fracture of the entire distal humeral physis.

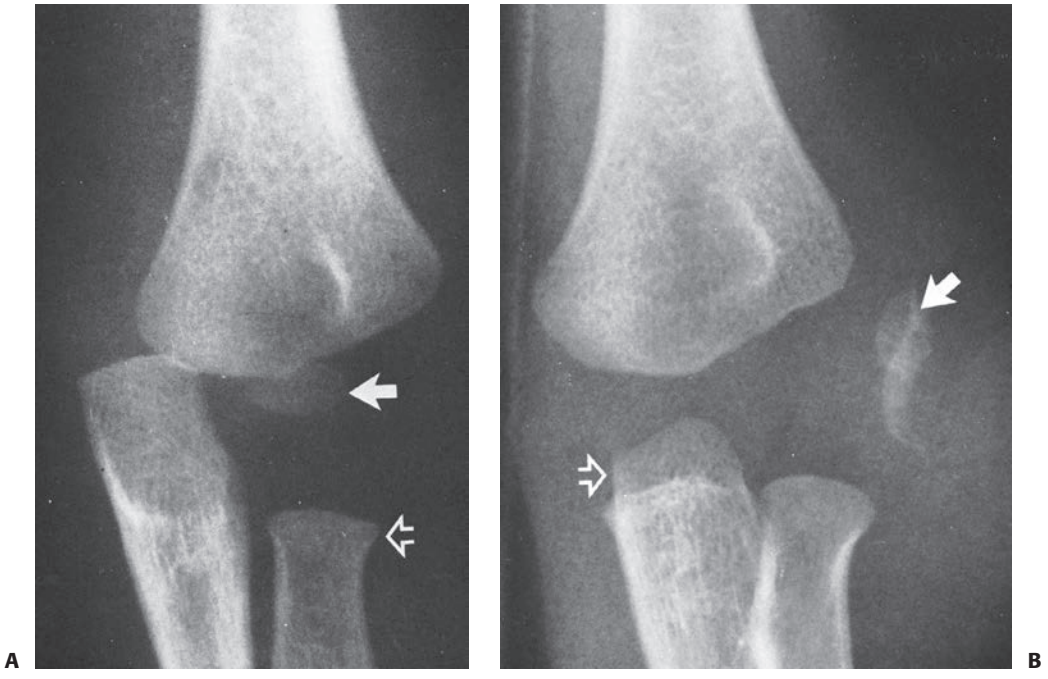

FIGURE 19-5 **A:** Total distal humeral physeal fracture in a 2-year old. The lateral condyle (*closed arrow*) has remained in line with the proximal radius. The proximal radius, ulna, and lateral condyle have all shifted medially (*open arrow*). **B:** Displaced fracture of the lateral condyle in a 2-year old. The relationship of the lateral condyle (*closed arrow*) to the proximal radius is lost. Both the proximal radius and ulna (*open arrow*) have shifted slightly laterally.

Soft-Tissue Injuries. The fracture line usually begins in the posterolateral metaphysis, with a soft-tissue tear in the area between the origins of the extensor carpi radialis longus and the brachioradialis muscle. The extensor carpi radialis longus and brevis muscles remain attached to the distal fragment, along with the lateral collateral ligaments of the elbow. If there is much displacement, both the anterior and posterior aspects of the elbow capsule are usually torn. This soft-tissue injury, however, usually is localized to the lateral side and may help identify a minimally displaced fracture. More extensive soft-tissue swelling at the fracture site may indicate more severe soft-tissue injury,[41,54] which may indicate that the fracture is unstable and prone to late displacement.

Displacement of the Fracture and Elbow Joint. The degree of displacement varies according to the magnitude of the force applied and whether the cartilaginous hinge of the articular surface remains intact.[31] If the articular surface is intact, the resultant displacement of the condylar fragment is simply a lateral tilt hinging on the intact medial articular surface. If the fracture is complete, the fragment can be rotated

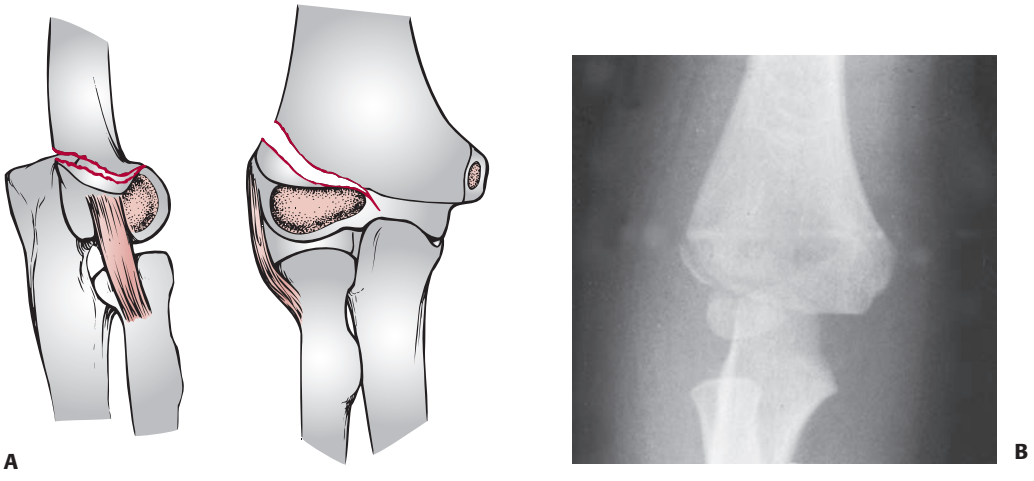

FIGURE 19-6 Stages of displacement. **A, B:** Stage I displacement—articular surface intact.
(*continues*)

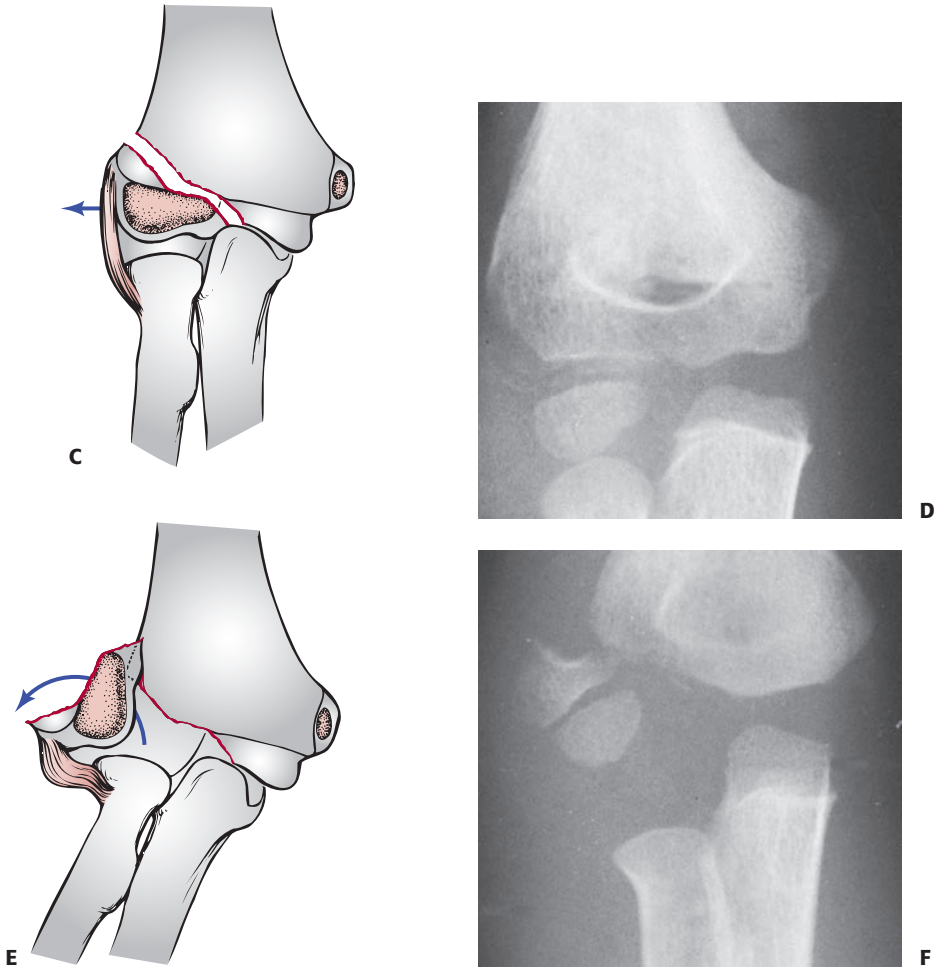

FIGURE 19-6 (*continued*) **C, D:** Stage II displacement—articular surface disrupted. **E, F:** Stage III displacement—fragment rotated. (**A, C, E:** Adapted from: Jakob R, Fowles JV, Rang M, et al. Observations concerning fractures of the lateral humeral condyle in children. *J Bone Joint Surg Br.* 1975; 57(4):430–436.)

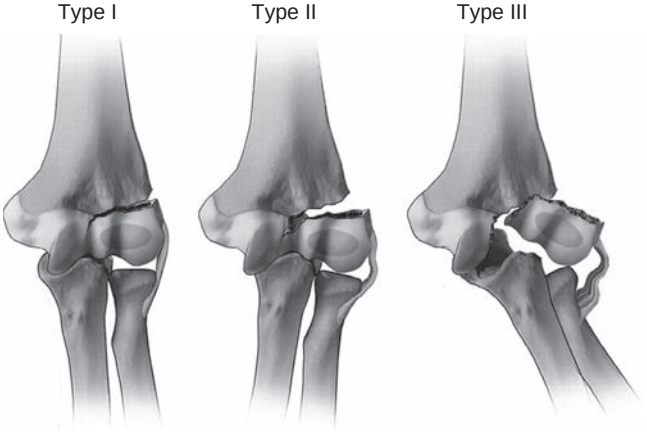

FIGURE 19-7 Classification of lateral humeral condylar fractures. Type I, less than 2 mm of displacement; type II, 2 mm or more of displacement and congruity of the articular surface; type III, more than 2 mm of displacement and lack of articular congruity. (Reprinted with permission from: Weiss JM, Graves S, Yang S, et al. A new classification system predictive of complications in surgically treated pediatric humeral lateral condyle fractures. *J Pediatr Orthop.* 2009;29:602–605.)

and displaced in varying degrees; in the most severe fractures, rotation is almost full 180 degrees, so that the lateral condylar articular surface opposes the denuded metaphyseal fracture surface. In addition to this coronal rotation of the distal fragment, rotation can also occur in the horizontal plane.[81] The lateral margin is carried posteriorly, and the medial portion of the distal fragment rotates anteriorly.

Because the usual fracture line disrupts the lateral crista of the trochlea, the elbow joint may be unstable, creating the possibility of posterolateral subluxation of the proximal radius and ulna. Thus, the forearm rotates along the coronal plane into valgus, and there may also be lateral translocation of the lateral condyle with the radius and ulna (Fig. 19-8). This concept of lateral translocation is important in the late reconstruction of untreated fractures.

In physeal fractures, where the fracture line traverses the lateral condylar epiphysis, the elbow remains reasonably stable because the trochlea remains intact. Total coronal rotation of the condylar fragment can occur with this injury. The axial deformity that results is pure valgus without translocation (Fig. 19-8).

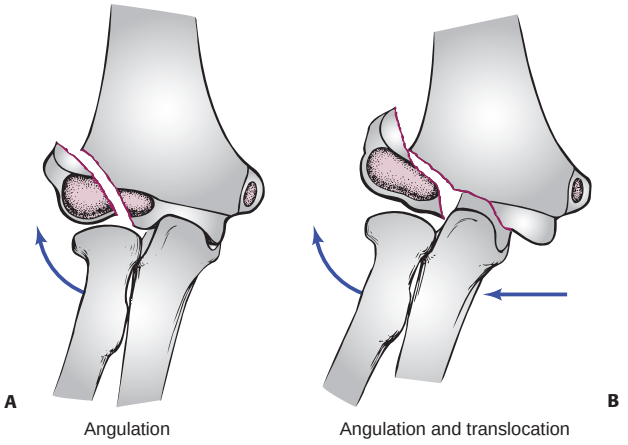

FIGURE 19-8 Angular deformities. **A:** Capitellar fracture. **B:** Fracture extending into the trochlea.

This posterolateral elbow instability with the lateral condylar physeal injury has led to a mistaken concept that this injury is associated with a primary dislocation of the elbow,[12] which is rarely the case. The posterolateral instability of the elbow is usually a result of the injury, not a cause of it. The displacement of the joint is through the fracture.[57]

Treatment Options for Lateral Condylar Fractures

Fractures involving the lateral condylar physis can be treated with immobilization alone, closed reduction and percutaneous pinning, or open surgical reduction depending on the degree of displacement and amount of instability.

Nonoperative Treatment of Lateral Condylar Fractures

Immobilization

Minimally displaced fractures (<2 mm) are stable and have intact soft-tissue attachments that prevent displacement of the distal fragment. About 40% of lateral condylar physeal fractures are nondisplaced, are not at risk for late displacement, and can be treated with immobilization alone.[33] If the fracture line is barely perceptible on the original radiographs, including internal oblique views (stage I displacement), the chance for subsequent displacement is low. Immobilization of nondisplaced or minimally displaced (less than 2 mm) fractures in a posterior splint or cast is adequate.[4,5,7,10,69] Radiographs are obtained during the first 3 weeks after injury to ensure that rare late displacement does not occur (Table 19-2).

Operative Treatment of Lateral Condylar Fractures

Closed Reduction and Percutaneous Pinning

When a lateral condylar fracture is displaced more than 2 mm, closed or open reduction is required to restore anatomic alignment of the joint and physis. Several techniques have been described for initial closed reduction, with the recommended elbow position ranging from hyperflexion to full extension. However, clinical experience and experimental studies indicate that closed reduction is best achieved with the forearm supinated and the elbow extended. Placing a varus stress on the extended elbow allows easier manipulation of the fragment. Unfortunately, it is difficult to maintain reduction of a displaced lateral condylar fracture with closed techniques, and thus, closed reduction alone is not generally recommended for treating displaced lateral condylar fractures.

TABLE 19-2 Lateral Condylar Fractures

Nonoperative Treatment Following Successful Closed Reduction

Indications	Relative Contraindications
Stable articular reduction <2 mm of displacement	Inability to obtain acceptable reduction

Mintzer et al.[46] advocated percutaneous reduction and fixation for unstable, moderately displaced lateral condylar fractures (Jakob type II). Standard closed reduction with thumb pressure on the fracture fragment, elbow flexion, forearm supination, and wrist dorsiflexion usually results in an aligned fracture. An alternative method that is quite reliable is to add percutaneous pin reduction from the lateral column. The smooth pins are then advanced across the fracture site to the opposite cortex to obtain stability.[44,46] Anatomic alignment of the joint and fracture stability are confirmed by stress testing and arthrography. If a satisfactory reduction cannot be obtained, then reduction can be achieved and maintained by open reduction and internal fixation.

Expected Outcomes of Percutaneous Reduction and Pinning. Song et al.[66] reported good results in 46 (73%) of 63 unstable lateral condylar fractures, 53 of which were treated with closed reduction and percutaneous pinning. They formulated a treatment algorithm based on a five-stage classification system that considered degree of displacement and fracture pattern (Figs. 19-9 and 19-10). Closed reduction was attempted in all fractures, regardless of the amount of displacement. If closed reduction was successful (n = 53), then percutaneous fixation was used. If closed reduction failed to achieve less than 2 mm of displacement, open reduction and internal fixation was performed (n = 10). These authors suggested that open reduction is not necessary for all lateral condylar fractures. They listed three elements as essential to obtaining good results with percutaneous reduction and pinning treatment: (1) accurate interpretation of the direction of fracture displacement (mainly posterolaterally, not purely laterally) and the amount of displacement of the fracture fragment, (2) routine intraoperative confirmation of the reduction on both AP and internal oblique radiographs, and (3) maintenance of the reduction with two parallel percutaneous, smooth Kirschner wires (K-wires).

More recently, Song and Waters[67] described closed percutaneous manipulation of 24 completely displaced and rotated fractures (Jakob type III) followed by percutaneous pinning. In this series, closed reduction was successful in 18 (75%).

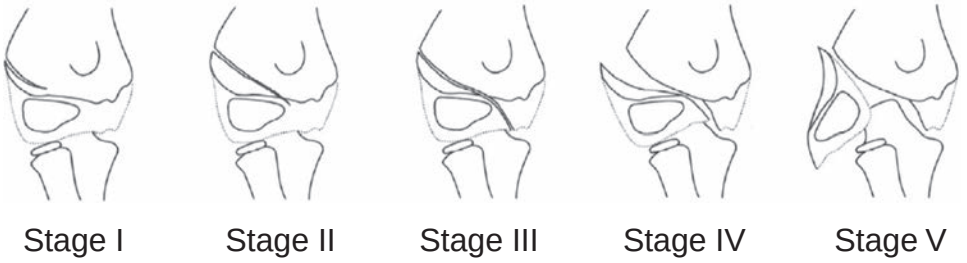

FIGURE 19-9 Stages of displacement of fractures of the lateral humeral condyle in children. Stage I, stable fracture with 2 mm or less of displacement and fracture line limited to within the metaphysis. Stage II, indefinable fracture with 2 mm or less of displacement and fracture line extending to the epiphyseal articular cartilage; there is a lateral gap. Stage III, unstable fracture with 2 mm or less of displacement and a gap that is wide laterally as medially. Stage IV, unstable fracture with displacement of more than 2 mm. Stage V, unstable fracture with displacement of more than 2 mm with rotation. (Reproduced with permission from: Song KS, Kang CH, Min BW, et al. Closed reduction and internal fixation of displaced unstable lateral condylar fractures of the humerus in children. *J Bone Joint Surg Am.* 2008;90:2673–2681.)

Excellent results were obtained in 17 of the 18 patients; one patient had a good result. It should be noted that this technique is technically difficult, and the authors admit that it has a difficult learning curve; these results have not yet been reproduced at any other institution (Table 19-3).

Open Reduction and Internal Fixation

Because of the risk of poor functional and aesthetic results with closed reduction methods in unstable fractures, open reduction has traditionally been the advocated treatment method for unstable and irreducible fractures with stage II and stage III displacement.[9,10,12,29,33,34,44,47,58,63,68,75,80,84] About 60% of all fractures involving the lateral condylar physis are types II and III fractures.[33,79]

Open reduction is performed through a lateral incision, usually under tourniquet control. There usually is a large hematoma just beneath the skin that requires superficial subcutaneous exposure for evacuation. The joint is exposed anteriorly through the fracture site, with care taken to preserve the soft-tissue attachments of the posterior extensor–supinator muscle origins. Extensive posterolateral soft-tissue dissection risks osteonecrosis of the condyle and so dissection is performed anteriorly with minimal soft-tissue stripping. Adequate visualization of the trochlea is required for an anatomic reduction of the joint.

Most investigators recommend fixation with smooth K-wires in children or screws and/or plates in adolescents nearing skeletal maturity. A report from Germany showed better maintenance of reduction with the use of compressive (threaded) K-wires ("screw-wires") than with standard K-wires.[82] Use of compressive K-wires is not widespread, and further study is necessary to determine their efficacy and safety (Table 19-4).

Expected Outcomes of Pin or Screw Internal Fixation. Smooth pins are the most frequently used method of fragment fixation.[7,22,33,69,75,80,84] The passage of a smooth wire through the physis does not result in any growth disturbance,[18,40] which may be due to the fact that the cross-sectional area of

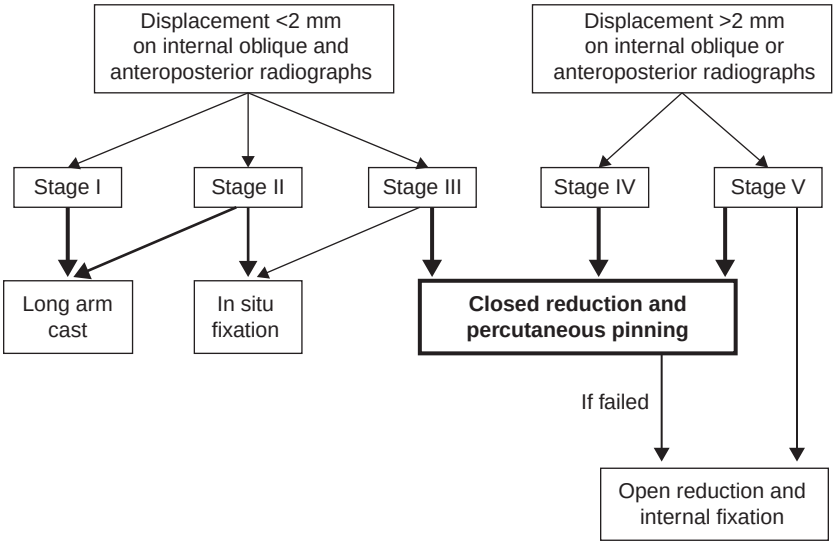

FIGURE 19-10 Treatment algorithm based on stage of fracture displacement described in Fig. 19-9. (Reproduced with permission from Song KS, Kang CH, Min BW, et al. Closed reduction and internal fixation of displaced unstable lateral condylar fractures of the humerus in children. *J Bone Joint Surg Am.* 2008;90:2673–2681.)

TABLE 19-3 Lateral Condylar Fractures

Closed Reduction Percutaneous Pinning

Indications	Contraindications
Anatomic reduction with closed reduction	Inability to obtain adequate reduction
Arthrographic confirmation of articular congruity	Unstable fracture that cannot be maintained with percutaneous pins

the pins is small relative to the surface area of the physis and because only 20% of humeral growth occurs through the distal humeral physis.

The pins should start in the metaphysis if the metaphyseal fragment is large enough and diverge as much as possible to enhance the stability of fixation. When there is only a small metaphyseal fragment, the pins can be safely placed across the physis.

When adequate reduction and internal fixation are carried out within the first few days after the injury, the results are uniformly good. The key, however, is to be sure that the reduction of the joint is anatomic. Surgery alone does not ensure a good result unless an anatomic reduction is obtained and the fixation is secure enough to maintain the reduction.

Early surgical intervention is essential, because organization of the clot with early fibrin development makes it difficult to achieve a reduction without extensive soft-tissue dissection in fractures that are treated late. The pins can be buried or left protruding through the skin with a low incidence of infection. Leaving pins buried requires a second operative procedure, even though it usually can be accomplished with a local anesthetic or outpatient sedation. A recent comparison of pins left outside or below the skin found that, while exposed pins had a slightly higher infection rate, buried pins had higher rates of pin migration, symptomatic implants, and protrusion through the skin and increased treatment cost.[39]

Screw fixation has been used less frequently in children because of concerns about growth arrest. Sharma et al.[60] reported painless, full range of elbow motion in 36 of 37 children who had displaced lateral condylar fractures fixed with partially threaded 4-mm AO cancellous screws. In a series of 62 patients, Li and Xu[39] found lower rates of infection (0% vs. 17%), lateral prominence (13% vs. 37%), and loss of motion (6% vs. 30%) in patients treated with open reduction and fixation with cannulated screws compared to those treated with K-wires. Although the two groups were similar, the type of fixation was not randomized.

Open Reduction Internal Fixation

Indications	Contraindications
Type III fracture with articular malangulation and malrotation	Able to obtain an adequate reduction and stabilize it with percutaneous reduction and pinning

Author's Preferred Treatment for Lateral Condylar Fractures

Immobilization

If the fracture is minimally displaced on all three radiographic views (i.e., the metaphyseal fragment is less than 2 mm from the proximal fragment on AP, lateral, and internal oblique views) and the clinical signs also indicate there is reasonable soft-tissue integrity, we immobilize the elbow in a long arm cast with the forearm in neutral rotation and the elbow flexed 60 to 90 degrees. Radiographs are taken within the first week after the fracture with the cast removed and the elbow extended. If there is no displacement, the radiographs are repeated once again during the next 1 to 2 weeks. Immobilization is continued until fracture union is apparent, usually between 4 and 6 weeks after injury.

In some fractures with more than the allowable 2 mm of displacement (type II injury), the fracture pattern is such that the articular cartilage appears intact. If there is any question about the stability at the time of the fracture, MRI can be obtained or the extremity can be examined with the patient under general anesthesia. If examination is performed in the operating room, gentle varus stress views with the forearm supinated and the elbow extended should be taken to determine if the fracture displaces significantly. Intraoperative arthrography can also be used to determine the stability of the nonossified articular cartilage. Usually in these circumstances, percutaneous pins are placed to maintain articular alignment until healed.

Percutaneous Pins

For fractures with stage II displacement (2 to 4 mm), reduction and percutaneous pin fixation are done because open reduction often is not necessary in these circumstances and closed reduction alone is too risky for redisplacement (Fig. 19-11). If there are concerns about reduction or stability after percutaneous pinning, varus stress radiography and elbow arthrography are performed.

Open Reduction

If the fracture is completely displaced, malrotated, and/or grossly unstable (stage III), open reduction and internal fixation are indicated. We prefer open reduction and internal fixation of all fractures with stage III displacement. It is important that open reduction is performed within a few days after the injury. The standard lateral Kocher approach provides sufficient exposure of the fragment. Often, a tear in the aponeurosis of the brachioradialis muscle laterally leads directly to the fracture site. Extreme care must be taken to avoid dissection near the posterior portion of the fragment because this is the entrance of the blood supply of the lateral condylar epiphysis.

A posterolateral approach has been recommended because of proposed advantages of excellent exposure with minimal dissection and improved cosmetic results because of more posterior placement of the surgical scar. This approach requires

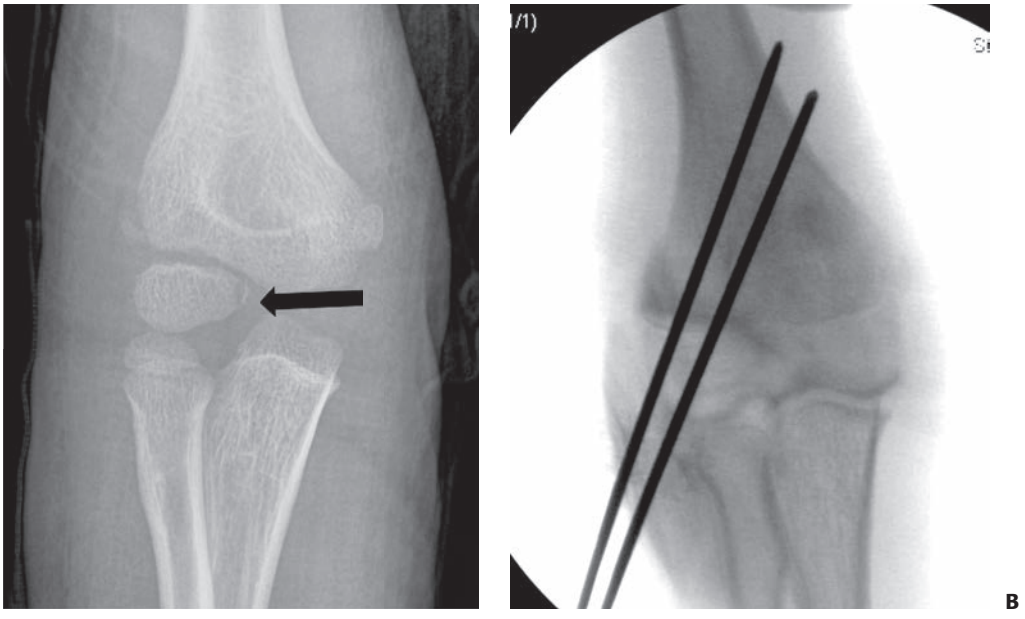

FIGURE 19-11 Stage II fracture of the lateral condyle. **A:** AP radiograph shows 4 mm of displacement with fracture line extending to nonossified trochlea (*arrow*). **B:** Intraoperative fluoroscopic image after pinning shows intact articular surface.

special care to avoid excessive dissection of the posterior soft-tissue attachments.

The quality of the reduction is determined by evaluating the fracture line along the anterior aspect of the articular surfaces. This usually can be determined by direct observation. Often there is plastic deformation of the metaphyseal bone on the displaced fragment, and reduction based on this can result in joint incongruity. We prefer to use smooth parallel to slightly divergent K-wires just medial to the condylar fragment to maintain the reduction (Fig. 19-12). The wires penetrate the skin through a separate stab incision posterior to the main incision. A long arm cast is applied with the elbow flexed 90 degrees and the forearm in neutral or slight pronation. The cast and pins are removed in 4 weeks if there is adequate healing on radiographs. Early active motion is started at that time. If necessary, pin removal can be delayed 1 to 2 weeks to allow further healing in older children.

Technique of Open Reduction and Internal Fixation of Lateral Humeral Condylar Fractures

The elbow is exposed through a 5- to 6-cm lateral approach, placing two-thirds of the incision above the joint and one-third distal (Fig. 19-13). In the interval between the brachioradialis and the triceps, the dissection is carried down to the lateral humeral condyle. The joint's anterior surfaces are exposed by separating the fibers of the common extensor muscle mass. Soft-tissue detachment is limited to only that necessary to expose the fragment, the fracture, and the joint; the posterior soft tissues are left intact. With widely displaced fractures, these soft tissues often are already stripped and the surgeon can follow the fracture hematoma directly into the joint. Care must be taken to prevent injury to the distal humeral articular surface, which often is rotated into the wound. Retracting the antecubital structures exposes the anterior joint surface. A small metacarpal retractor can be passed across the joint to the opposite side, taking care to protect the ulnar nerve medially. The trochlea and fracture site are inspected. The displacement and the size of the fragment are always greater than is apparent on the radiographs because much of the fragment is cartilaginous. The fragment usually is rotated as well as displaced. The joint is irrigated to remove blood clots and debris, the articular surface and the metaphyseal fragment are reduced accurately, and the reduction is confirmed by observing the articular surface, particularly at the trochlea. The position is held with a small tenaculum, bone holder, towel clip, or percutaneous pins as "joysticks." Two smooth K-wires are inserted in a parallel or slightly divergent configuration, across the physis, and into the humeral metaphysis, penetrating the medial cortex of the humerus. Occasionally a third lateral pin, more parallel to the joint surface, is used if greater stability is required. The reduction and the position of the internal fixation are checked by direct observation as well as by AP, lateral, and oblique radiographs before wound closure. The ends of the wires are cut off to allow easy removal. The arm is placed in a posterior splint or bivalved long arm cast with the elbow flexed 90 degrees.

The cast is worn for 4 to 6 weeks after surgery until the fracture is healed. The pins can be removed at 4 to 6 weeks if union is progressing. Gentle active motion of the elbow usually is then resumed and continued until full range of motion returns.

Complications

If an adequate reduction is obtained promptly and maintained with solid fixation, results are uniformly good. In supracondylar fractures, an incomplete reduction may result in an aesthetic

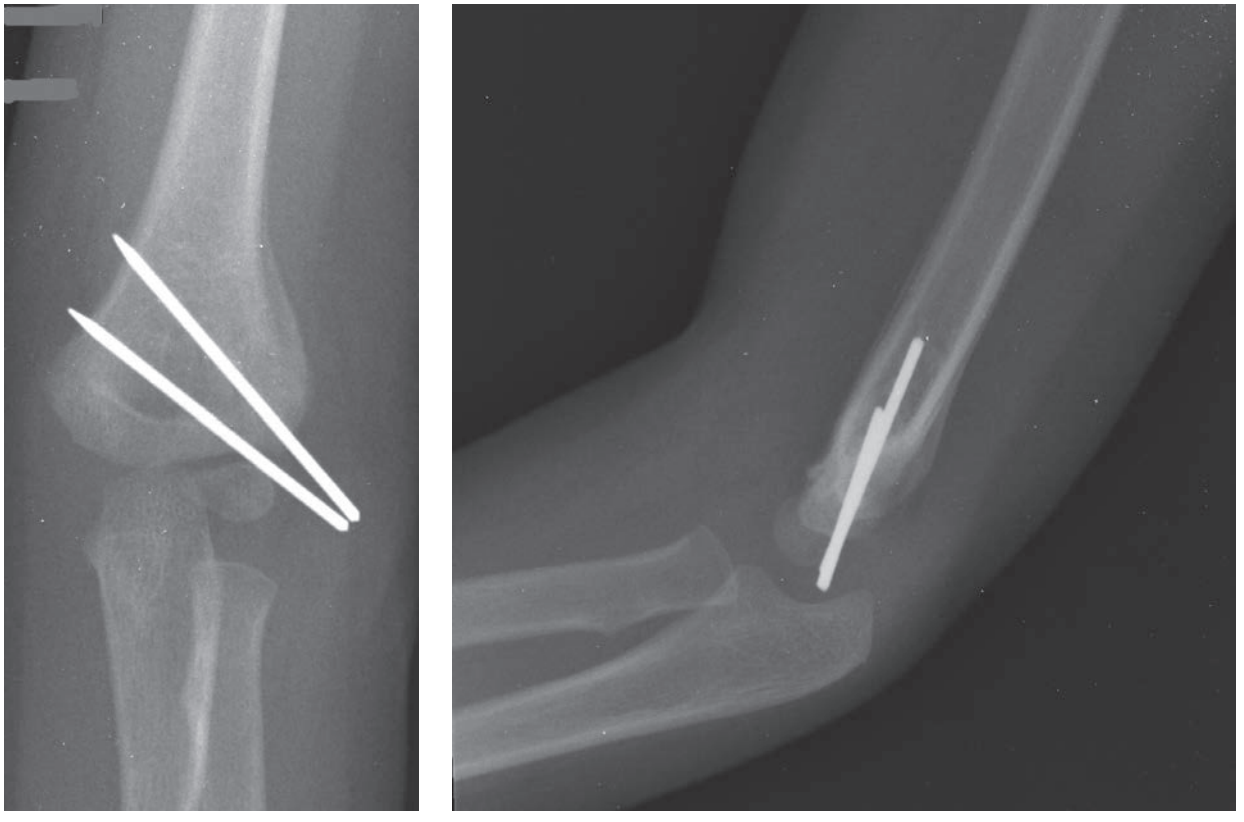

FIGURE 19-12 Fixation of lateral condylar fracture with two smooth K-wires placed in divergent configuration.

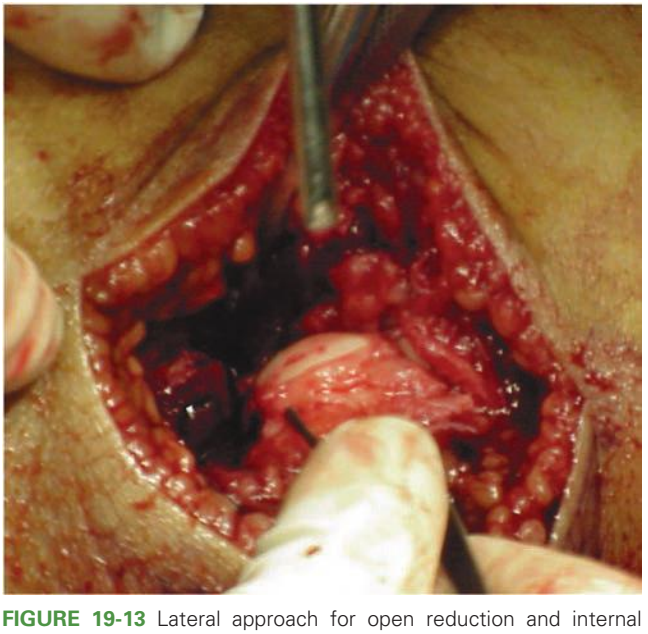

FIGURE 19-13 Lateral approach for open reduction and internal fixation of a lateral humeral condylar fracture of the left elbow. The approach is made through the brachioradialis–triceps interval; an anterior retractor is used to expose the joint surface. Note the large unossified articular fragment.

deformity, but functional results are generally good. In contrast, with displaced fractures of the lateral condylar physis and joint surface, a marginal reduction can result in both aesthetic deformities and functional loss of motion.[70] The complications that affect the outcome can be classified as either biologic or technical. Biologic problems occur as a result of the healing process, even if a perfect reduction is obtained. These problems include spur formation with pseudocubitus varus or a true cubitus varus. The technical aspects include failure to recognize a displaced fracture, immobilization treatment of an unstable fracture that displaces in a cast, internal fixation of a malreduced articular fracture fragment, and osteonecrosis due to extensive posterior soft-tissue dissection.

Lateral Spur Formation

Lateral condylar spur formation is one of the most common sequelae after a fracture involving the lateral condylar physis.[36,79] The spur occurs after both nonoperative and operative treatment. In a review of 175 patients, Koh et al.[36] found overall rates of lateral spur formation of 77% radiographically and 22% clinically; the spurs persisted at a mean of 20 months after fracture. Spur formation was more frequent after displaced fractures (Jakob types II and III) and those treated with percutaneous pinning or open reduction and internal fixation than in those treated with cast immobilization. Pribaz et al.[56] found a similar frequency of 73% development of lateral spurs in

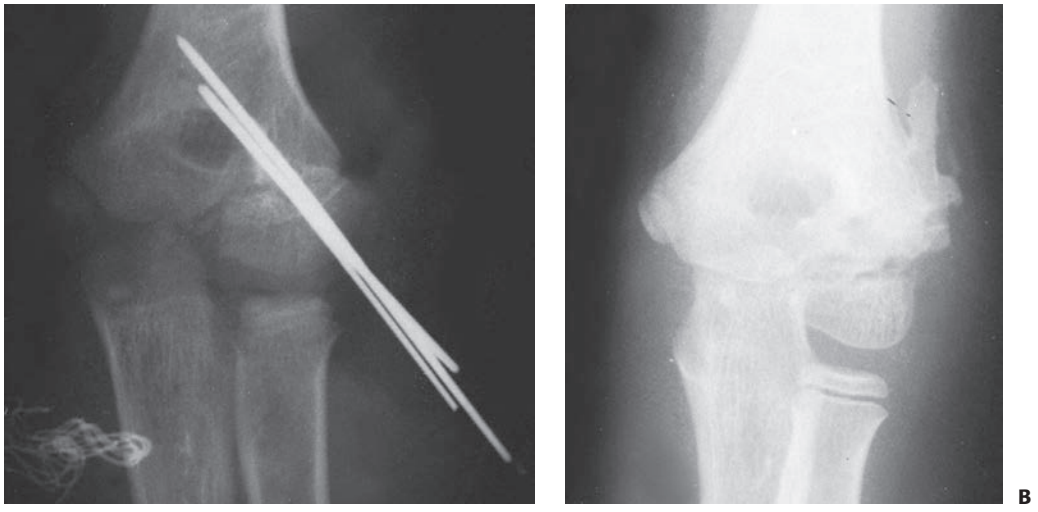

FIGURE 19-14 **A:** Considerable soft tissue dissection was performed in the process of open reduction of this lateral condylar fracture. **B:** At 2 months after surgery, there is a large irregular spur formation secondary to periosteal new bone formation from the extensive dissection. (From: Wilkins KE. Residuals of elbow fractures. *Orthop Clin N Am.* 1990;21:289–312, with permission.)

212 consecutive lateral condylar fractures and also correlated spur development with the amount of initial displacement and with surgical treatment.

After nonoperative treatment, lateral spurs result from the minimal displacement of the metaphyseal fragment and usually have a smooth outline. In patients with no real change in carrying angle, the lateral prominence of the spur may produce an appearance of mild cubitus varus (pseudovarus). In patients in whom a true cubitus varus develops, the presence of the lateral spur accentuates the varus alignment. The spur that occurs after operative treatment has a more irregular outline and is hypothesized to be the result of hypertrophic bone formation from open reduction and internal fixation (Fig. 19-14). During open reduction, care should be taken to limit the amount of dissection and to carefully replace the lateral periosteal flap of the metaphyseal fragment to lessen the amount of lateral spur.

Before treatment of lateral condylar fractures, the parents should be told that either lateral overgrowth with mild cubitus varus or lateral spur with pseudovarus is very likely to develop, regardless of the treatment method. They should be told that this mild deformity usually is not of functional significance and often resolves over the next 1 to 2 years.

Elbow Stiffness

Elbow stiffness can occur following lateral condylar fractures, but most patients regain full elbow range of motion within 4 to 6 months after cast removal.[8,76] Bernthal et al.,[8] in a study of 141 patients with lateral condylar fractures, found that at a mean of 29 weeks there was no difference in range of motion between surgically and nonsurgically treated patients; however, surgically treated patients took longer (up to 18 weeks) to regain their motion arc. They also found that increased patient age, length of immobilization, and need for surgical treatment were independently correlated with greater loss of motion at final follow-up.

Cubitus Varus

Reviews of lateral condylar fractures show that a surprising number heal with some residual cubitus varus angulation (Fig. 19-15).[23,30,44,48,58,62,64,74] In some series, the incidence of cubitus varus is as high as 40%,[23,64] and the deformity seems to be as frequent after operative treatment as after nonoperative treatment.[58,64] The exact cause is not completely understood. It can be due to an inadequate reduction, growth stimulation of the lateral condylar physis from the fracture insult, or a combination of both (Fig. 19-16).[64]

The cubitus varus deformity rarely is severe enough to cause concern or require further treatment. This is probably because it is a pure coronal varus angulation rather than the horizontal anterior rotation along with the sagittal extension of the distal humerus that make the cubitus varus after supracondylar fractures a less acceptable deformity. Some investigators have noted that children with cubitus varus deformities can have pain, decreased range of motion, epicondylitis, and problems with sports such as sidearm pitching, swimming, judo, and push-ups.

Cubitus Valgus

Cubitus valgus is much less common after united lateral condylar fractures than cubitus varus. It has rarely been reported to result from premature epiphysiodesis of the lateral condylar physis.[75] As with cubitus varus, it usually is minimal and rarely of clinical or functional significance. If cubitus valgus is symptomatic, it can be treated with a medial closing wedge osteotomy or dome osteotomy and internal fixation or with osteotomy and gradual distraction through an external fixator.[55]

The more difficult type of cubitus valgus associated with nonunions is discussed in the next section on nonunions.

Delayed Union and Nonunion

Some of these fractures may go unrecognized or untreated for a prolonged period. Even in modern medical settings, elbow

FIGURE 19-15 Cubitus varus. **A:** Follow-up radiograph of a boy whose lateral condylar fracture was treated nonoperatively and healed with a mild varus angulation. **B:** Clinical appearance of deformity (*arrow*).

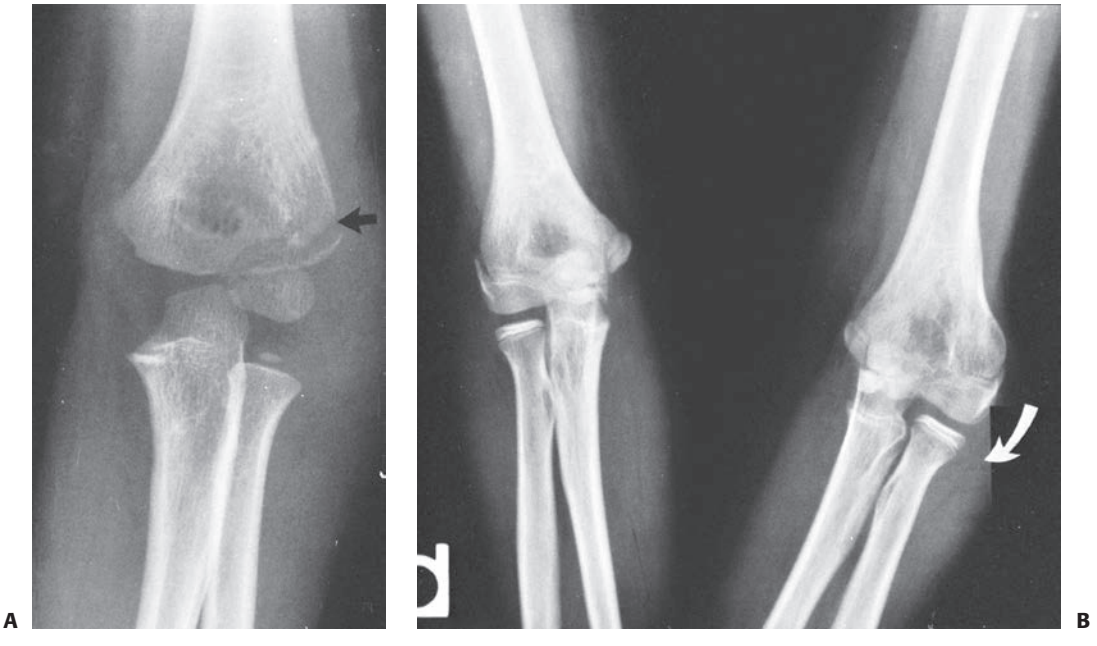

FIGURE 19-16 True varus. **A:** The injury film with a minimally displaced fracture (*arrow*). This 5-year-old child was treated with immobilization until the fracture was healed. **B:** Five years later, the patient had a persistent cubitus varus (*arrow*) that remained clinically apparent. The carrying angle of the uninjured right elbow measured 5 degrees of valgus; the injured elbow had 10 degrees of varus. (From: Wilkins KE. Residuals of elbow trauma in children. *Orthop Clin N Am.* 1990;21:289–312, with permission.)

injuries may be treated as "sprains," and the diagnosis of a displaced lateral condylar fracture is not made, especially in young children. Thus, patients can present weeks later with a delayed union or months or even years later with a nonunited or malunited fracture fragment.

Delayed Union

Delayed union, in contrast to nonunion or malunion, occurs in a fracture in which the fracture fragments are in satisfactory position but union of the lateral condylar fragment to the metaphysis is delayed. Various reasons have been suggested for delayed union of lateral condylar fractures, including poor circulation to the metaphyseal fragment[21] and bathing of the fracture site by articular fluid, which inhibits fibrin formation and subsequent callus formation.[29] It is most likely that a combination of these two factors, in addition to the constant tension forces exerted by the extensor musculature arising from the condylar fragment, are responsible for delayed union.

This complication is most common in patients treated nonoperatively. The symptoms and clinical examination determine the appropriate treatment. If on clinical examination the fragment is stable, the elbow is nontender, the range of elbow motion increases progressively, and the position of the fragment remains unchanged on radiographs, the fracture usually heals (Fig. 19-17). Lateral spur formation or cubitus varus is relatively common with these late healing fractures. The need for further treatment depends on the presence of significant symptoms, limited motion, or risk of further displacement that may disrupt the joint surface and cause functional impairment. If there is any question as to the integrity of the joint surface, an MRI or arthrogram may help determine any loss of continuity and the need for surgical treatment.

Most minimally displaced fractures with no significant displacement of the condylar fragment will ultimately unite with long-term immobilization.[20,29] Percutaneous pinning can expedite the healing. Screw fixation with bone grafting can be done if union appears unlikely by immobilization or pin fixation alone.[34]

Controversy exists as to whether elbow function can be improved by a late open reduction and internal fixation of the nonunited, malaligned fracture fragment. Delayed open reduction (more than 3 weeks after injury) has a risk of osteonecrosis and further loss of elbow motion.[14,33,69,85] Osteonecrosis of the fragment is believed to be due to the extensive soft-tissue dissection necessary to replace the fragment anatomically (Fig. 19-18), and a transarticular approach with olecranon osteotomy has been recommended to avoid this.[10,83] The key to preventing osteonecrosis is to recognize the course of the blood supply to the lateral condyle. Only a small portion of the condyle is extra-articular, and the vessels that supply the lateral condylar epiphysis penetrate the condyle in a small posterior nonarticular area[28] (Fig. 19-19). Careful late open reduction through a lateral approach generally is recommended to prevent the complications of nonunion and/or malunion.

Nonunion

True nonunion occurs in patients with progressive displacement of the fragment or late of initial treatment of a displaced fracture. The mobile fragment can be palpated, or the patient has weakness or pain in the elbow. If the fracture is displaced and is not united by 12 weeks, it is considered a nonunion.[20]

Nonunion can occur with or without angular deformity. Many patients with nonunions and minimal fragment displacement have no angulation and remain relatively asymptomatic for many activities of daily living (Fig. 19-19). Weakness or symptoms can occur when the arm is used for high-performance activities. Because they are not significantly displaced, these fractures often can be stabilized with minimal extra-articular

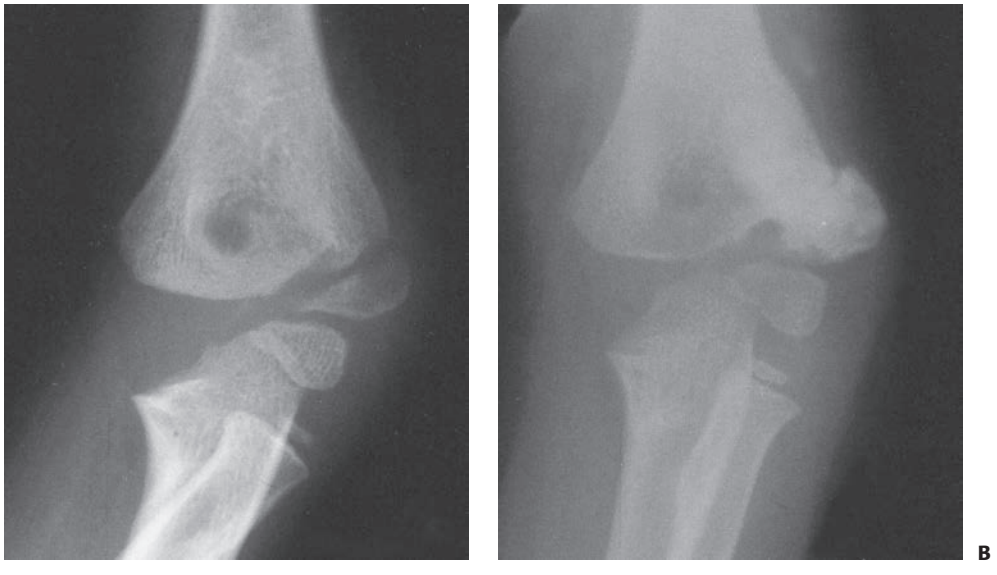

FIGURE 19-17 Delayed union and cubitus varus. **A:** Stage III lateral condylar fracture in a 7-year-old boy was treated in a cast. **B:** Seven months later, delayed union with malunion of the fracture and cubitus varus deformity was present.

dissection using a combination of screw fixation and a laterally placed bone graft.

Nonunion with subsequent fragment displacement is more common after nonfixation treatment of unstable fractures with stage II and III displacement. If the fragment is mobile, it tends to migrate proximally with a subsequent valgus elbow deformity. Nonunion can lead to a cubitus valgus deformity, which in turn, is associated with the development of a tardy ulnar nerve palsy. All of these nonunions have articular incongruity.

Nonunion seems to occur when the distal fragment is displaced enough to allow the condylar fragment's cartilaginous articular surface to oppose the bony surface of the humeral metaphysis. In such a situation, union is impossible. Stable internal fixation with percutaneously placed pins or cannulated screws has been recommended for impending, minimally displaced nonunions.[20,52] For late displaced nonunions, staged procedures have been described[52]: (1) ulnar nerve transposition and bone grafting and fixation in situ of the lateral condyle followed by (2) distal humeral osteotomy to correct angulation once the nonunion is healed and elbow range of motion is regained.

The most common sequela of nonunion with displacement is the development of a progressive cubitus valgus deformity. The fragment migrates both proximally and laterally, giving not only an angular deformity but also lateral translocation of the proximal radius and ulna (Fig. 19-20). Lateral translocation is not as likely to develop in the more lateral type of these fractures because the lateral crista of the trochlea is intact (Fig. 19-21).

FIGURE 19-20 **A:** A 10-year-old boy with cubitus valgus resulting from a fracture of the lateral condylar physis with nonunion. **B:** Nonunion with cubitus valgus. Radiograph showing both angulation and translocation secondary to nonunion of the condylar fragment.

Surgical treatment of the nonunion deformity of the lateral condylar fragment is difficult and requires correcting two problems. First, articular cartilage may be opposing the distal humeral metaphysis, and union seldom can be obtained without mobilizing the fragments and applying an internal compressive device. The second problem is correcting the angular deformity (Fig. 19-22).

To prevent progression of cubitus valgus deformity and subsequent ulnar nerve dysfunction, Shimada et al.[61] recommended osteosynthesis for nonunion of lateral humeral condylar fractures in children because union is easily achieved, the range of motion is maintained, ulnar nerve function remains intact, and remodeling of the articular surfaces can be expected. They noted that

FIGURE 19-21 Nonunion without translocation. Despite nonunion, elbow stability was maintained because the lateral crista of the trochlea had remained intact (*arrow*). Valgus angulation also developed.

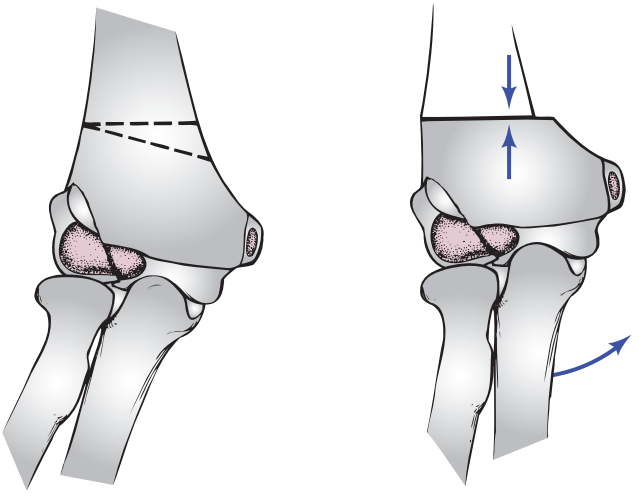

FIGURE 19-22 With fracture through the capitellum sparing the trochlea, an angular deformity can be corrected with a closing wedge osteotomy. (Adapted and reprinted with permission from: Milch HE. Fractures and fracture-dislocations of the humeral condyles. *J Trauma.* 1964;4:592–607.)

bone grafting is essential to bridge the defect, to obtain congruity of the joint and to promote union; damage to the blood supply should be avoided to prevent osteonecrosis. To avoid the development of osteonecrosis after delayed (1 to 3 weeks) open reduction and internal fixation of acute fractures, Wattenbarger et al.[78] accepted malreduction rather than stripping the soft tissue off the lateral condylar fragment to achieve a more anatomic reduction. For fractures with more than 1 cm of displacement, the position of the fragment often was improved very little by surgery, but all fractures were united, alignment of the arm was good, and no child had developed osteonecrosis at an average 6-year follow-up.

Tien et al.[73] described a technique that includes in situ compression fixation of the lateral condylar nonunion and a dome-shaped supracondylar osteotomy of the distal humerus through a single posterior incision. They recommended this procedure for minimally displaced, established lateral condylar nonunions with a cubitus valgus deformity of 20 degrees or more, especially when the deformity is progressing, is complicated by a concurrent ulnar neuropathy, or is in patients with elbow instability or elbow pain during sports activities. They listed as a contraindication to the procedure a lateral condylar nonunion associated with radiographic evidence of prominent displacement and rotation. In situ fixation of the nonunion is recommended because the extensive soft-tissue stripping required for mobilization and reduction of the fracture fragments results in devascularization of the fragment, which can cause osteonecrosis, loss of motion, and persistent nonunion.

Author's Preferred Treatment of Lateral Condylar Nonunions

We distinguish between fractures seen late (more than 7 to 14 days after injury) and established nonunions (usually from 3 months to several years after injury). In all late presenting fractures, we strive to obtain fracture union without loss of elbow motion and perhaps avoiding osteonecrosis of the lateral condyle through a careful open reduction and internal fixation.

Treating an established nonunion of a lateral humeral condylar fracture poses a more difficult dilemma. If no treatment is rendered, a progressive cubitus valgus deformity may occur with growth. Patients usually are asymptomatic initially, except for those with high-demand athletic or labor activities. A mild flexion contracture of the elbow is present, but the cubitus valgus deformity initially can be more aesthetic than functional. The danger in this approach is failure to recognize that late deformity and tardy ulnar nerve palsy can occur. If surgery is performed for an established nonunion, the potential risks of osteonecrosis and loss of elbow motion must be carefully considered.

We believe the criteria outlined by Flynn et al.[20,21] are helpful in determining if surgical treatment is appropriate for an established nonunion:

- A large metaphyseal fragment
- Displacement of less than 1 cm from the joint surface
- An open, viable lateral condylar physis

It is also helpful to distinguish between three distinct clinical situations. First, for an established nonunion with a large metaphyseal fragment, minimal migration, and an open lateral condylar physis, we recommend modified open reduction, screw fixation, and a lateral extra-articular bone graft. This technique is markedly different from the surgical treatment of an acute lateral condylar fracture. The metaphyseal fragment of the lateral condyle and the distal humeral metaphysis are exposed, but no attempt is made to anatomically realign the articular surface. Intra-articular dissection and posterior dissection should be avoided to help prevent osteonecrosis and any further loss of elbow motion. The metaphyseal fragments are débrided by gently removing any interposed fibrous tissue. The lateral condylar fragment usually can be moved distally a small distance for improved apposition and alignment. The metaphyseal fragments are firmly apposed, and a screw is used to fix the fragments with interfragmentary compression. Bone graft can be placed between the metaphyseal fragments before compression and then laterally after fixation. The elbow is immobilized in 80 to 90 degrees of flexion until motion is no longer a risk for displacement (Fig. 19-23).

Second, in patients with a nonunion who have aesthetic concerns because of their malalignment but no functional complaints, treatment is similar to that for cubitus varus deformity after a supracondylar humeral fracture. If the patient and family desire, a supracondylar osteotomy can be performed.[43] Rigid internal fixation should be used if possible to allow early motion.

Third, patients with asymptomatic nonunion, cubitus valgus deformity, and symptomatic tardy ulnar nerve palsy can be treated with anterior transposition of the ulnar nerve. However, isolated ulnar nerve transposition rarely is done alone and usually is done in conjunction with corrective osteotomy.

Growth Disturbance: Fishtail Deformity

Two types of "fishtail deformity" of the distal humerus may occur. The first is more common and is a sharp-angled wedge (Fig. 19-24). It is believed that this type of malformation is caused by persistence of a gap between the lateral condylar physis ossification center and the medial ossification of the trochlea.[75,80] Because of this gap, the lateral crista of the trochlea may be underdeveloped, which may represent a small "bony bar" in the distal humeral physis.[30] Thus, this may be both an articular malunion and minor growth disturbance problem. Despite some reports of loss of elbow motion and functional pain with this type of fishtail deformity,[50,75] most investigators[4,7,14,23] have not found this type of radiographic deformity to cause major functional deficiencies. Arthroscopic debridement of the articular flap has been used in symptomatic individuals.[77]

The second type of fishtail deformity is a gentler, smooth curve. It is believed to be associated with osteonecrosis or larger growth arrest of the lateral part of the medial crista of the trochlea.[48] The mechanisms of the development of this type of deformity are discussed in the section on osteonecrosis of the trochlea (Chapters 17-20).

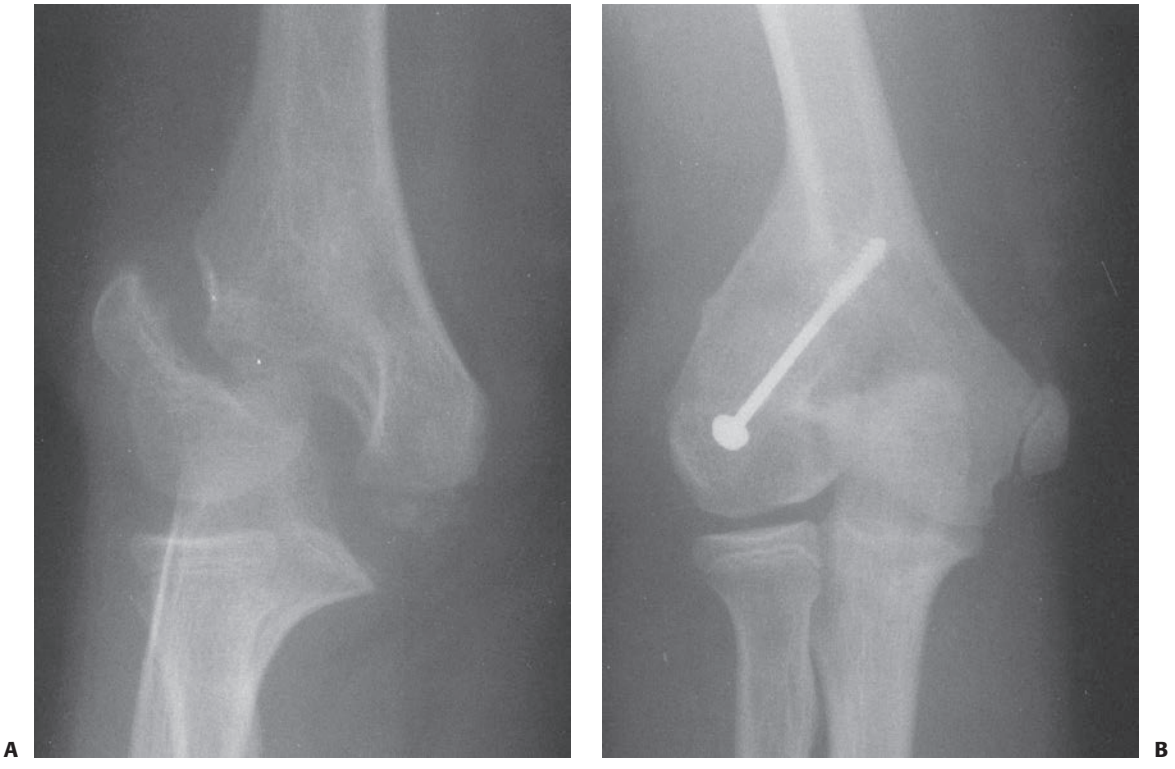

FIGURE 19-23 **A:** Established nonunion with a large metaphyseal fragment. **B:** After fixation with a cancellous screw and bone grafting of the metaphyseal fragment.

FIGURE 19-24 An angular "fishtail" deformity that persisted in this 14-year-old boy after operative treatment of a lateral condylar fracture, which occurred 6 years previously.

Neurologic Complications

Neurologic complications can be divided into two categories: acute nerve problems at the time of the injury and/or treatment and delayed neuropathy involving the ulnar nerve (the so-called tardy ulnar nerve palsy).

Acute Nerve Injuries

Reports of acute nerve injuries associated with this injury are rare. McDonnell and Wilson[44] reported a case of transient radial nerve paralysis after an acute injury. Smith and Joyce,[63] reported two patients with posterior interosseous nerve injury after open reductions of the lateral condylar fragment, both of whom recovered spontaneously.

Tardy Ulnar Nerve Palsy

Tardy ulnar nerve palsy as a late complication of fractures of the lateral condylar physis is well known, especially after the development of cubitus valgus from malunion or nonunion of fractures of the lateral condylar physis.[26] The symptoms usually are gradual in onset. Motor loss occurs first, with sensory changes developing somewhat later.[26] In Gay and Love's[26] series of 100 patients, the average interval of onset was 22 years.

Various treatment methods have been advocated, ranging from anterior transposition of the ulnar nerve (originally the most commonly used procedure) to simple in situ decompression of the cubital tunnel. We prefer subcutaneous anterior transposition of the nerve. As noted in the nonunion section, there are times when the nerve surgery is part of a more extensive reconstruction.

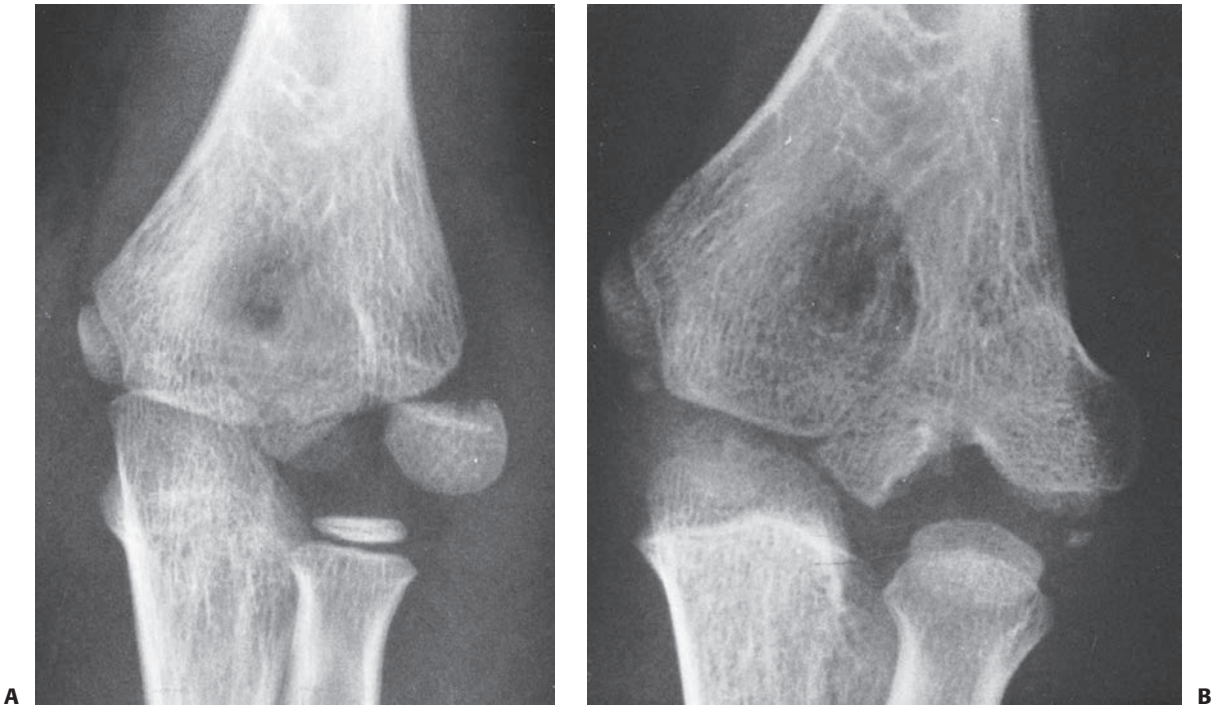

FIGURE 19-25 **A:** Injury film of a 7-year old who sustained a fracture of the capitellum that spared the trochlea and was treated with cast immobilization alone. **B:** Radiograph taken 2 years later showed complete fusion of the condylar epiphysis to the metaphysis, with the development of a "bifid" condyle.

Physeal Arrest

Physeal arrest may merely be premature fusion of the various secondary ossification centers with little or no deformity. Because only 20% of humeral growth occurs in the distal physis, physeal arrest seldom causes any clinically significant angular or length deformities.

Malunion

If not properly reduced and stabilized, the fragment can unite in an undesirable position. Cubitus valgus has been reported to occur as a result of malunion of the fracture fragments.[75] Malunion can result in the development of a bifid lateral condyle that may not be symptomatic if the malalignment is minor (Fig. 19-25). Late osteotomy is complicated but can improve the situation if there is marked articular malalignment, loss of motion, and pain.[6]

Osteonecrosis

Osteonecrosis of the condylar fragment may be iatrogenic and is most commonly associated with the extensive dissection necessary to effect a late reduction or from loss of the blood supply at the time of injury.[29,33,44] Partial osteonecrosis has been described in an essentially nondisplaced fracture of the lateral condylar physis that had a radiographic appearance and clinical course similar to those of osteochondritis dissecans.[80] Osteonecrosis is rare in fractures of the lateral condylar physis that receive little or no initial treatment and result in nonunion.[33,81]

Overly vigorous dissection of fresh fractures can result in osteonecrosis of either the lateral condylar ossification center[23,53] or, rarely, the metaphyseal portion of the fragment, leading to nonunion (Fig. 19-26). If the fracture unites, osteonecrosis of the lateral condyle reossifies over many years, much like Legg–Calvé–Perthes disease in the hip. Residual deformity can result in loss of motion, deformity, and/or pain.

Ipsilateral Injuries

Fractures of the lateral condyle have been associated with elbow dislocations,[10] ulnar shaft fractures,[45] and fractures of the medial epicondyle. A lateral condylar fracture may be misdiagnosed as an elbow dislocation. Loss of the lateral crista can make the elbow unstable and allow the proximal radius or ulna to translocate laterally. This is a part of a normal pathologic condition associated with completely displaced lateral condylar fractures. In a true elbow dislocation, the proximal radius and ulna are displaced not only medially or laterally but also proximally (Fig. 19-27).

Fractures of the Capitellum

Fractures of the capitellum involve only the true articular surface of the lateral condyle. This includes, in some instances, the articular surface of the lateral crista of the trochlea. Generally, this fragment comes from the anterior portion of the distal articular surface. These fractures are rare in children. In their review of 2,000 elbow fractures in children, Marion and Faysse[42] found only one fracture of the capitellum. Since then, this fracture has been frequently reported in older adolescents.[24,35,40,42,51] Although verified fractures of the capitellum

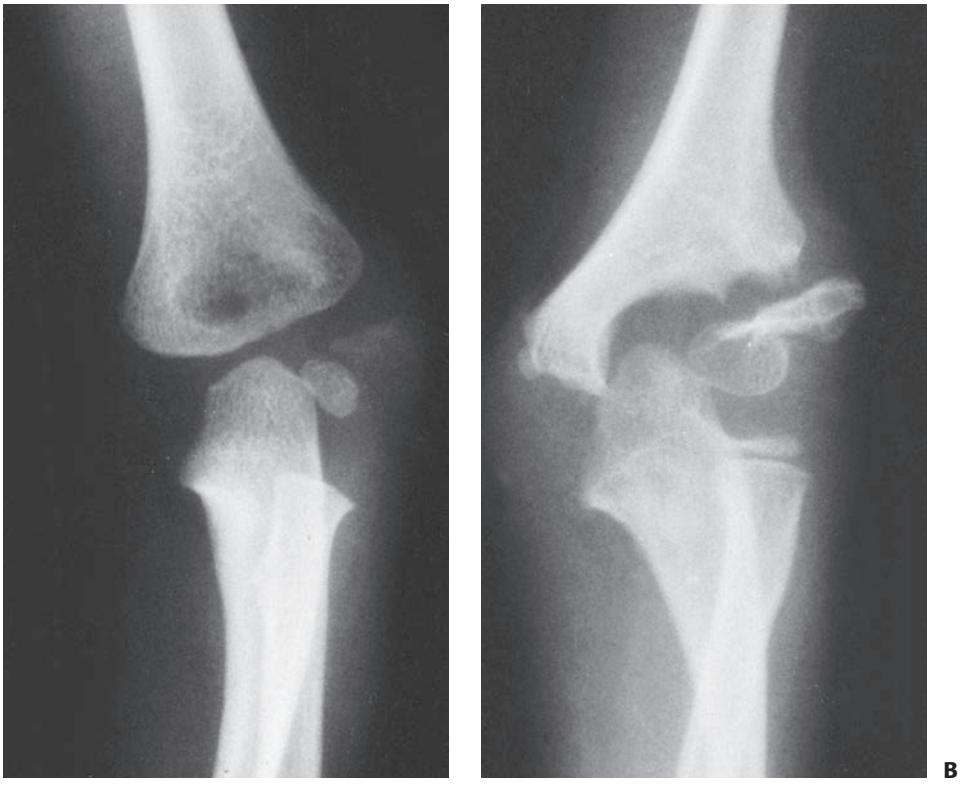

FIGURE 19-26 Osteonecrosis and nonunion developed in this child after extensive dissection and difficulty in obtaining a primary open reduction. **A:** Injury film. **B:** Two years later, there was extensive bone loss in the metaphysis and a nonunion of the condyle.

(From: Drvaric DM, Rooks MD. Case report. Anterior sleeve fracture of the capitellum. *J Orthop Trauma.* 1990;4:188–192, with permission.)

have not been described in children under 12 years of age, there have been two reports[2,15] of so-called anterior sleeve fractures of the lateral condyles, both in 8-year olds (Fig. 19-28). These fractures involved a good portion of the anterior articular surface, although technically they could not be classified as pure capitellar fractures because they contained nonarticular epicondylar and metaphyseal portions in the fragment.

This fracture often is difficult to diagnose because there is little ossified tissue. It is composed mainly of pure articular surface from the capitellum and essentially nonossified cartilage from the secondary ossification center of the lateral condyle.

Classification of Capitellar Fractures

Two fracture patterns have been described. The first is the more common Hahn–Steinthal type,[71] which usually contains a rather large portion of cancellous bone of the lateral condyle. The lateral crista of the trochlea is also often included (Fig. 19-29). The second, or Kocher–Lorenz, type is more of a pure articular fracture with little if any subchondral bone attached and may represent a piece of articular cartilage from an underlying osteochondritis dissecans. This type of fracture is rare in children.[2,65]

Assessment of Capitellar Fractures

The most commonly accepted mechanism is shearing of the anterior articular surface of the lateral condyle by the radial head.[24] The presence of cubitus hyperextension or cubitus valgus seems to predispose the elbow to this fracture pattern.

Often swelling is minimal, and the presence of the fragment restricts flexion. If the fragment is large, it may be readily apparent on a lateral radiograph (Fig. 19-30). On an AP radiograph, however, the fragment may be obliterated by the overlying distal metaphysis (Fig. 19-29). If the fragment is small, it is often hard to see on plain radiographs. Oblique views may be necessary to show the fragment. In younger children, arthrography or MRI may be required to diagnose this rare fracture. Often CT or MRI scans are used to confirm the diagnosis and plan operative fixation.

Because the mechanism is postulated to be a pushing off of the capitellum by the radial head, it stands to reason that there may be an associated radial head or neck fracture;[35] associated injuries of the proximal radius were reported in 31% of adults and children with capitellar fractures.[51]

Treatment Options for Capitellar Fractures

Excising the fragment and open reduction and reattachment are the two most common forms of treatment. Closed reduction is not likely to be successful.

Excision of the Fragment

Through an open arthrotomy, the fragment can be either excised or reattached. Excision can be successful in very young patients, late presenting small fractures, and osteochondritis dissecans lesions that no longer fit back in place.[24,42] In these circumstances, motion and rehabilitation can be initiated early. Even when large fragments are excised, joint instability does not appear to be a problem.[24] In patients in whom treatment is delayed, although the results are not as good as when treatment is provided immediately after injury, improvement in function can be expected, even with late excision.

Reattachment of the Fragment

A large fragment in an older child or adolescent is indicative of an intra-articular fracture, for which reduction is recommended.

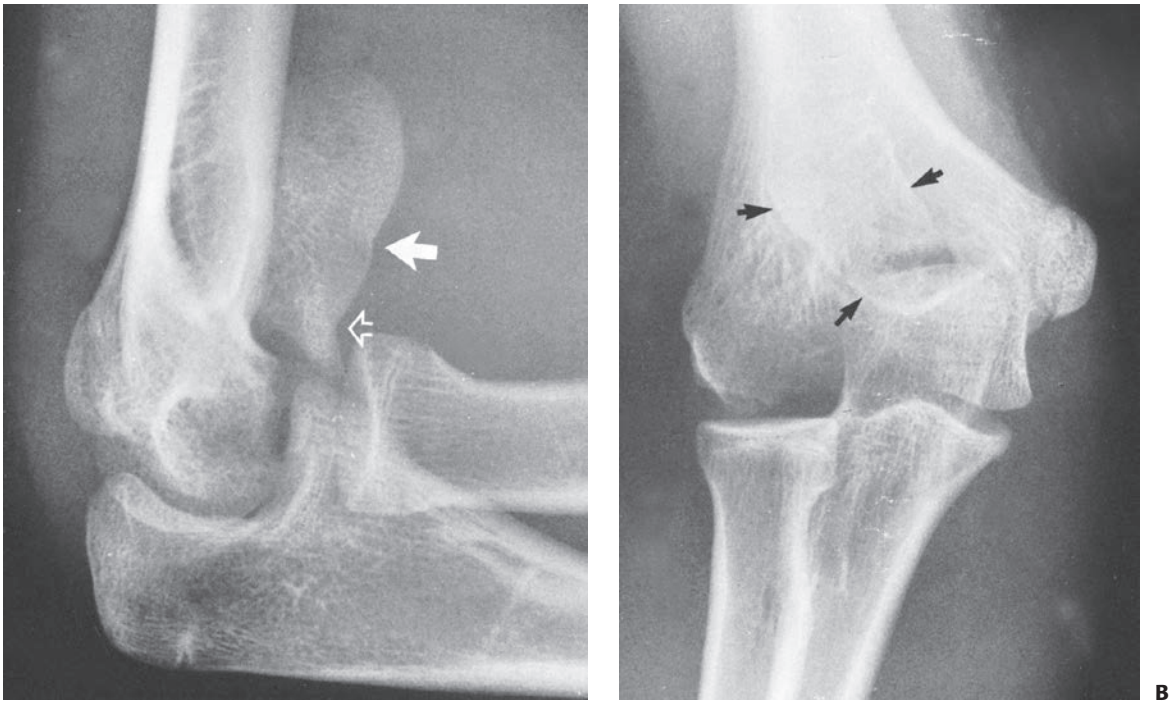

FIGURE 19-29 Fracture of the capitellum in a 13-year-old girl. **A:** Injury film, lateral view, shows the large capitellar fragment lying anterior and proximal to the distal humerus. Both the radiocapitellar (*solid arrow*) and trochlear grooves (*open arrow*) are seen in the fragment. **B:** In the AP view, only a faint outline of the fragment is seen (*arrows*).

The stability of the fracture is provided by wires or screws inserted through the posterior surface of the lateral condyle. The major risk of open reduction and internal fixation is osteonecrosis of the reattached fragment. Satisfactory results have been reported with fixation with K-wires, Herbert screws, cannulated screws,[38] compression screws,[16,17] and even sutures.[65] An advantage of compression screw fixation is that it may not require later removal and allows for earlier motion. Advantages cited for suture fixation include a low risk of growth arrest, sufficient stability to allow immediate postoperative motion, avoidance of implant removal, and facilitation of the acquisition of high-quality postoperative MR images to evaluate healing.

Author's Preferred Treatment for Capitellar Fractures

If the fragment is large, if the fracture is acute, and if an anatomic reduction can be achieved with a minimum of open manipulation or dissection, then we prefer to reattach it with two small cannulated screws inserted from posterior to anterior through a lateral approach. Enough bone must be present in the capitellar fragment to engage the screw threads, and if possible, countersink the heads of the screws (Fig. 19-30). If the fracture is old, if there is any comminution of the fragment, or

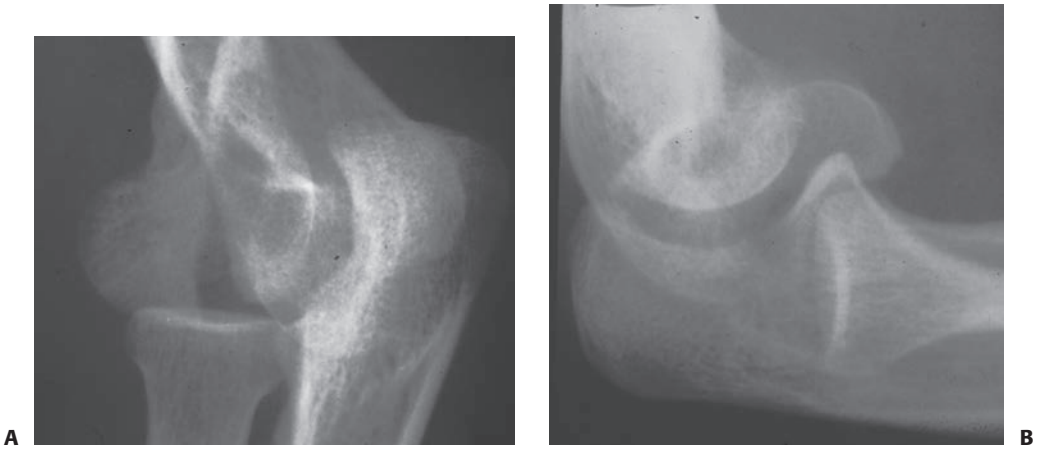

FIGURE 19-30 **A, B:** Fracture of the capitellum in a 14-year-old boy.

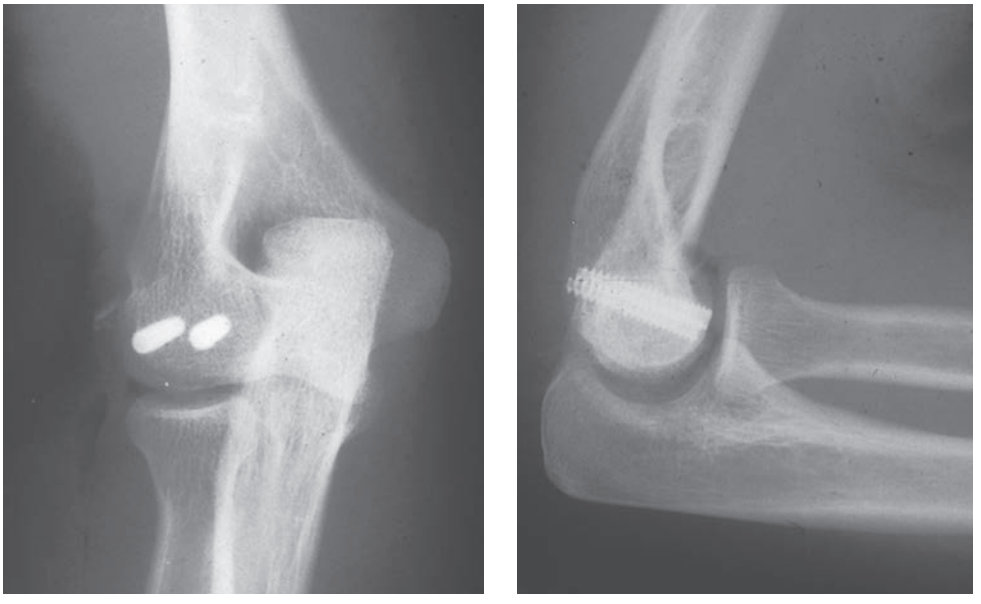

C D

FIGURE 19-30 (*continued*) **C, D:** After open reduction and fixation with two small cannulated screws through a lateral approach.

if there is little bone in which to engage the screw threads, we excise the fragment, perform microfracture of the bony surface, and start early motion.

Complications in Capitellar Fractures

The major complication is osteonecrosis of the fragment. This occurs only in fractures in which the capitellar fragment is retained. Posttraumatic degenerative arthritis can occur whether the fragments are excised or retained. Many patients who are treated operatively or nonoperatively can expect to lose some range of motion, but this loss is not always of functional or aesthetic significance. It is important to emphasize to the parents before the onset of treatment that some motion may be lost regardless of the treatment method.

20 DISTAL HUMERAL PHYSEAL, MEDIAL CONDYLE, LATERAL EPICONDYLAR, AND OTHER UNCOMMON ELBOW FRACTURES

Michael P. Glotzbecker and James R. Kasser

There are rare injuries about the elbow that can be underappreciated or missed acutely that have serious long-term implications for patients. We have labeled these as TRASH (The Radiographic Appearance Seemed Harmless) lesions about the elbow. Most commonly these occur in the very young before secondary centers of ossification would make the acute diagnosis and treatment easier. Examples of TRASH lesion are: (1) Distal humeral physeal fractures before the capitellum ossifies; (2) medial condylar fractures before the trochlea ossifies; and (3) osteochondral fractures in the children less than age 10 years that leads to joint incongruity and instability. Often additional radiographic evaluation with ultrasound, arthrography, and/or MRI scans is necessary to make the diagnosis acutely and intervene appropriately for the best long-term outcome. This chapter will cover many of the rare, potentially problematic injuries about the elbow.

Introduction to Fractures Involving the Entire Distal Humerus

From 1960 to 1978, many individual patients who suffered a distal humeral physeal separation were reported.[38,66,69,73] Once the presence of this injury became recognized, larger series appeared. Subsequently, seven separate series reported a total of 45 fractures,[2,16,17,34,46,53,62] and Abe et al.[1] reported a series of 21 fractures. Originally thought to be a rare injury, it appears that fractures involving the entire distal humeral physis occur frequently in children as they now have become more commonly reported. The major problem is the initial recognition of this injury.

Most fractures involving the entire distal humeral physis occur before the age of 6 or 7 and are most common under the age of 2. The younger the child is, the greater the volume of the distal humerus epiphysis. As the humerus matures, the physeal line progresses more distally, with a central V forming between the medial and lateral condylar physes (Fig. 20-1). Ashurst[3] believed that this V-shaped configuration of the physeal line helps protect the more mature distal humerus from physeal fractures.

Assessment of Fractures Involving the Entire Distal Humerus

Mechanisms of Injury for Fractures Involving the Entire Distal Humerus

The exact mechanism of this injury is unknown and probably varies with the age group involved. A few consistent factors are evident. First, many fractures of the entire distal humeral physis have occurred as birth injuries associated with difficult deliveries.[2,4,6,19,69] Siffert[69] noted that the clinical appearance of these injured elbows at the time of delivery was not especially impressive. There was only moderate swelling and some crepitus.

Second, DeLee et al.[17] noted a high incidence of confirmed or suspected child abuse in their very young patients. Other reports[2,16,49,56,79] have confirmed the frequency of child abuse

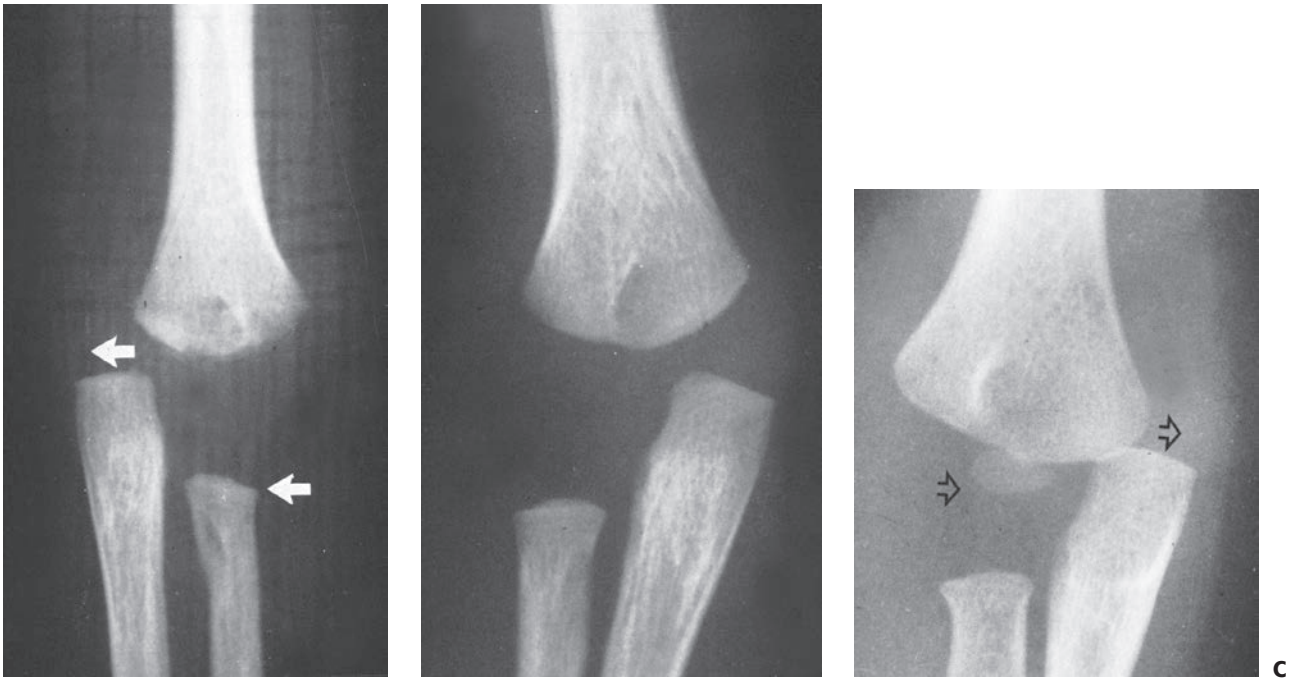

FIGURE 20-1 **A:** Group A—AP view of a small infant who had a swollen left elbow after a difficult delivery. The displacement medially of the proximal radius and ulna (*arrows*) helps to make the diagnosis of a displaced total distal humeral physis. **B:** Normal elbow for comparison. **C:** Group B—AP view showing the posteromedial displacement of the distal fragment (*arrows*). The relationship between the ossification center of the lateral condyle and the proximal radius has been maintained.

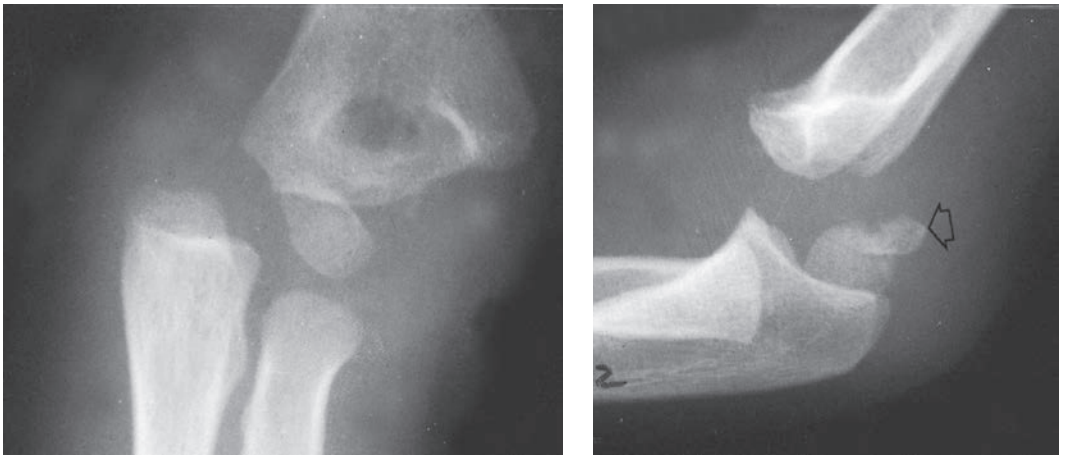

D E

FIGURE 20-1 (*continued*) **D:** Group C—AP view with marked medial displacement of the distal fragment. **E:** Group C—lateral view of the same patient showing posterior displacement of the distal fragment. There is also a large metaphyseal fragment associated with the distal fragment (*arrow*).

in infants and young children with these fractures, and up to 50% of these fractures in children under the age of 2 may be the result of abuse.

Bright[9] showed that a physis is more likely to fail with rotary shear forces than with pure bending or tension forces. Young infants have some residual flexion contractures of the elbow from intrauterine positioning; this prevents the hyperextension injury that results in supracondylar elbow fractures in older children. Rotary or shear forces on the elbow, which can be caused by child abuse or birth trauma in young infants, are probably more responsible for this injury in young children. In older children, a hyperextension force on an outstretched arm may cause the injury. Abe et al.[1] reported 21 children, ranging in age from 1 to 11 years (average: 5 years), with fracture separations of the distal humeral epiphysis, all of which were sustained in falls.

Associated Injuries with Fractures Involving the Entire Distal Humerus

Child abuse should always be considered in children with this injury, especially a type A fracture pattern (see classification below), unless it occurs at birth. A young infant is unlikely to incur this type of injury spontaneously from the usual falls that occur during the first year of life. Of the 16 fractures reported by DeLee et al.,[17] six resulted from documented or highly suspected child abuse, all in children younger than 2 years of age. Therefore, other injuries commonly found in cases of child abuse should be considered. If child abuse is suspected, a bone scan and a skeletal survey are warranted, to look for metaphyseal corner fractures, rib fractures, or fractures at various stages of healing, and the possibility of head trauma should not be ignored.

Signs and Symptoms of Fractures Involving the Entire Distal Humerus

In an infant less than 18 months of age, whose elbow is swollen secondary to trauma or suspected trauma, a fracture involving the entire distal humeral physis should be considered. In a young infant or newborn, swelling may be minimal with little crepitus. Poland[64] described the crepitus as "muffled" crepitus because the fracture ends are covered with softer cartilage than the firm osseous tissue in other fractures about the elbow. Because of the large, wide fracture surfaces, there are fewer tendencies for tilting with distal fragment rotation, and the angular deformity is less severe than that with supracondylar fractures. In older children, the elbow is often so swollen that a clinical assessment of the bony landmarks is impossible, and only radiographic evaluation can provide confirmation of the diagnosis.

Imaging and Other Diagnostic Studies for Fractures Involving the Entire Distal Humerus

Confirming radiographic evidence of a distal humeral physeal separation can be difficult, especially if the ossification center of the lateral condyle is not visible in an infant. The only relationship that can be determined is that of the primary ossification centers of the distal humerus to the proximal radius and ulna. The proximal radius and ulna maintain an anatomic relationship to each other but are displaced posteriorly and medially in relation to the distal humerus. This posteromedial relationship is diagnostic. Although theoretically, the distal fragment can be displaced in any direction, with rare exceptions,[6] most fractures reported have been displaced posteromedially. Comparison views of the opposite uninjured elbow may be helpful to determine the presence of posteromedial displacement (Fig. 20-1A, B).

Distinguishing the injury from an elbow dislocation may be challenging. It should be remembered that elbow dislocations are rare in the peak age group for fractures of the entire distal humeral physis. With elbow dislocations, the displacement of the proximal radius and ulna is almost always posterolateral, and the relationship between the proximal radius and lateral condylar epiphysis is disrupted. Unfortunately, this can be especially difficult to assess in young children when the capitellum is not ossified. In contrast, the anatomic relationship of the lateral condylar epiphysis with the radial head is maintained with a transphyseal separation, even though the distal humeral

FIGURE 20-2 Displaced fracture of the lateral condyle in a 2-year old. The relationship of the lateral condyle (*closed arrow*) to the proximal radius is lost. Both the proximal radius and ulna (*open arrow*) have shifted slightly laterally.

epiphysis is displaced posterior and medial in relation to the metaphysis of the humerus. Once the lateral condylar epiphysis becomes ossified, displacement of the entire distal epiphysis is much more obvious.

Because they have a large metaphyseal fragment, type C fractures may be confused with either a low supracondylar fracture or a fracture of the lateral condylar physis. The key diagnostic point is the smooth outline of the distal metaphysis in fractures involving the total distal physis. With supracondylar fractures, the distal portion of the distal fragment has a more irregular border.

Differentiation from a fracture of the lateral condylar physis in an infant can be made on radiograph. With a displaced fracture of the lateral condylar physis, the relationship between the lateral condylar epiphysis and the proximal radius can be disrupted but may remain normal (Fig. 20-2). If the lateral crista of the trochlea is involved, the proximal radius and ulna may be displaced posterolaterally. Oblique radiographs or other advanced imaging may be needed to distinguish these injuries.

If differentiation of this injury from an intra-articular fracture is uncertain, arthrography or MRI may be helpful (Fig. 20-3).[56] In neonates and infants in whom ossification has not begun, ultrasonography can be used to identify the displaced epiphysis of the humerus (Fig. 20-4).[18]

If the diagnosis is delayed, new periosteal bone forms around the distal humerus, and the whole epiphysis may remain displaced posteriorly and medially (Fig. 20-5).

Classification of Fractures Involving the Entire Distal Humerus

DeLee et al.[17] classified fractures of the entire distal humeral physis into three groups based on the degree of ossification of the lateral condylar epiphysis (Fig. 20-1). Group A fractures occur in infants up to 12 months of age, before the secondary ossification center of the lateral condylar epiphysis appears (Fig. 20-1A). They are usually Salter–Harris type I physeal injuries. This injury may be missed because of the lack of an ossification center in the lateral condylar epiphysis. Group B fractures occur most often in children of 12 months to 3 years of age in whom there is definite ossification of the lateral condylar epiphysis (Fig. 20-1C). Although there may be a small flake of metaphyseal bone, this is also essentially a type I Salter–Harris physeal injury. Group C fractures occur in older children, from 3 to 7 years of age and result in a large metaphyseal fragment that is most commonly lateral but can be medial or posterior (Fig. 20-1 D, E).

These fractures are almost always extension-type injuries with the distal epiphyseal fragment displacing posterior to the metaphysis. A rare flexion type of injury can occur in which the epiphyseal fragment is displaced anteriorly.[6] Stricker et al.[72] reported a coronal plane transcondylar (Salter–Harris type IV) fracture in a 3-year-old child that was initially diagnosed as a fracture of the lateral humeral condyle. No growth disturbance was evident 3 years after open reduction and pin fixation.

Pathoanatomy and Applied Anatomy Relating to Fractures Involving the Entire Distal Humerus

Distal humeral physeal injuries have similar anatomic considerations as supracondylar humerus fractures. However, because the patients who suffer this injury are often very young, diagnosis and treatment can be more challenging.

Because fractures coursing along the distal humeral physis traverse the anatomic centers of the condyles, they are the pediatric counterparts of the adult bicondylar fracture. Because

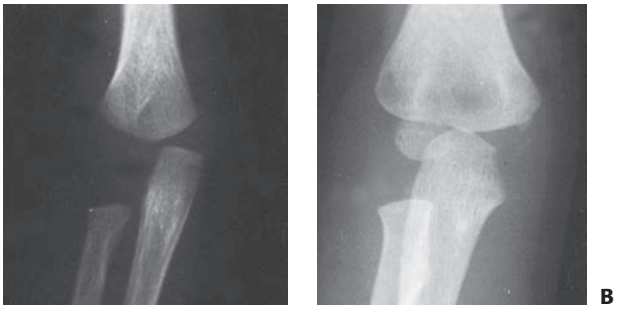

FIGURE 20-6 **A:** At 5 months of age, the metaphysis has advanced only to the supracondylar ridges. **B:** By 4 years of age, the edge of the metaphysis has advanced well into the area of the epicondyles.

the fracture is distal, the fracture surfaces are broader than those proximally through the supracondylar fractures. This broader surface area of the fracture line may help prevent tilting of the distal fragment. Because the fracture lines do not involve the articular surface, development of joint incongruity with resultant loss of elbow motion is unlikely if malunion occurs.

The distal humeral epiphysis extends across to include the secondary ossification of the medial epicondyle until about 6 to 7 years of age in girls and 8 to 9 years in boys. Thus, fractures involving the entire physeal line include the medial epicondyle up to this age. In older children, only the lateral and medial condylar physeal lines are included.

Finally, part of the blood supply to the medial crista of the trochlea courses directly through the physis. The blood supply to this area is vulnerable to injury, which may cause osteonecrosis in this part of the trochlea.

Because the physeal line is more proximal in young infants, it is nearer the center of the olecranon fossa (Fig. 20-6). A hyperextension injury in this age group is more likely to result in a physeal separation than a bony supracondylar fracture.[14]

Treatment Options for Fractures Involving the Entire Distal Humerus

Treatment is first directed toward prompt injury recognition. Because this damage may be associated with child abuse, the parents may delay seeking treatment. The goal of treatment is to obtain acceptable alignment until the fracture heals over 2 to 3 weeks.

Simple splint or cast immobilization has been suggested by several authors.[4,17,46,59] In some small children, this may be the only treatment option that is reasonable. However, some investigators have shown cubitus varus after nonoperative treatment of these fractures.[1,16,17,34] The rate of varus was noted in 3/12,[17] 15/21,[1] and 5/7[34] in these series. De Jager and Hoffman[16] reported 12 fracture separations of the distal humeral epiphysis, three of which were initially diagnosed as fractures of the lateral condyle and one as an elbow dislocation. Because of the frequency of cubitus varus after this injury in young children, they recommended closed reduction and percutaneous pinning in children younger than 2 years of age so that the carrying angle can be evaluated immediately after reduction and corrected if necessary. Arthrography may be helpful for diagnostic reasons and to assess reduction after fixation.

Several investigators have reported open reduction, usually performed owing to misdiagnosis as a displaced fracture of the lateral humeral condyle.[2,34,66,79] Mizuno et al.,[53] however, recommended primary open reduction because of their poor results with closed reduction. They approached the fracture posteriorly by removing the triceps insertion from the olecranon with a small piece of cartilage. If the fracture is old (more than 5 to 6 days) and the epiphysis is no longer mobile, manipulation should not be attempted, and the elbow should be splinted for comfort. Many essentially untreated fractures remodel completely without any residual deformity if the distal fragment is only medially translocated and not tilted (Fig. 20-7). In the more displaced malunions, a later osteotomy may be indicated.

Nonoperative Treatment of Fractures Involving the Entire Distal Humerus

Indications/Contraindications

In neonates and very small infants in whom general anesthesia or percutaneous pin fixation may be difficult, splint or cast immobilization can be used to treat these fractures (Table 20-1).

Techniques

The arm is simply immobilized in up to 90 degrees of flexion with the forearm pronated. The extremity is then externally stabilized with a swathe or figure-of-eight splint.

Outcomes

Outcome and function is usually good, however some investigators have shown cubitus varus after nonoperative treatment of these fractures.[1,16,17,34] The rate of varus was noted in 3/12,[17] 15/21,[1] and 5/7[34] in these series.

Operative Treatment of Fractures Involving the Entire Distal Humerus

Indications/Contraindications

In most infants and young children with a displaced fracture, external immobilization is usually not dependable in maintaining the reduction, and therefore operative intervention is indicated.

Surgical Procedure

Closed reduction and percutaneous pin fixation.

TABLE 20-1 Nonoperative Treatment of Fractures Involving the Entire Distal Humerus

Indications	Relative Contraindications
Neonate/small infants where anesthesia or pin fixation difficult	Markedly displaced fractures with prompt diagnosis
Minimal displacement	

FIGURE 20-7 Remodeling of untreated fractures. **A:** AP view of a 2-year old who had an unrecognized and untreated fracture of the distal humeral physis. The medial translocation is apparent. There was no varus or valgus tilting. **B:** Four years later, there had been almost complete remodeling of the distal humerus. A small supracondylar prominence (*arrow*) remains as a scar from the original injury. **C:** Clinical appearance 4 years after injury shows no difference in elbow alignment.

Preoperative Planning. Planning is similar to that of treating a supracondylar humerus fracture. In cases where the elbow is largely unossified, one must prepare for possible arthrography to help with diagnosis and to assess reduction (Table 20-2).

Positioning. You can choose to position the patient in one of the two ways. You can position the patient on the edge of the table with the affected extremity free over the side of the table and use the base of the C-arm as the operative surface. Alternatively you can position the patient on a radiolucent table on the edge opposite of the affected extremity. The C-arm can be brought underneath the table so that you can use the radiolucent table as the operative surface rather than the C arm. In the very young, the head and body may also need to be on the radiolucent table.

Technique. Under general anesthesia, the elbow is initially manipulated while extension to correct the medial displacement, and then the fragment is stabilized by flexing the elbow and pronating the forearm. When the forearm is supinated with the elbow flexed, the distal fragment tends to displace medially. This displacement is usually a pure medial horizontal translocation without mediolateral coronal tilting. The fragment

Preoperative Planning Checklist

- OR Table: Regular OR table with C arm used as table vs. radiolucent table
- Position/positioning aids: Position on edge of bed with arm free over side if using C arm, position to opposite edge of table if using radiolucent table. In small infants, may need to position head and body on radiolucent table.
- Fluoroscopy location: Parallel to table from head or from below
- Equipment: K-wires or C wires

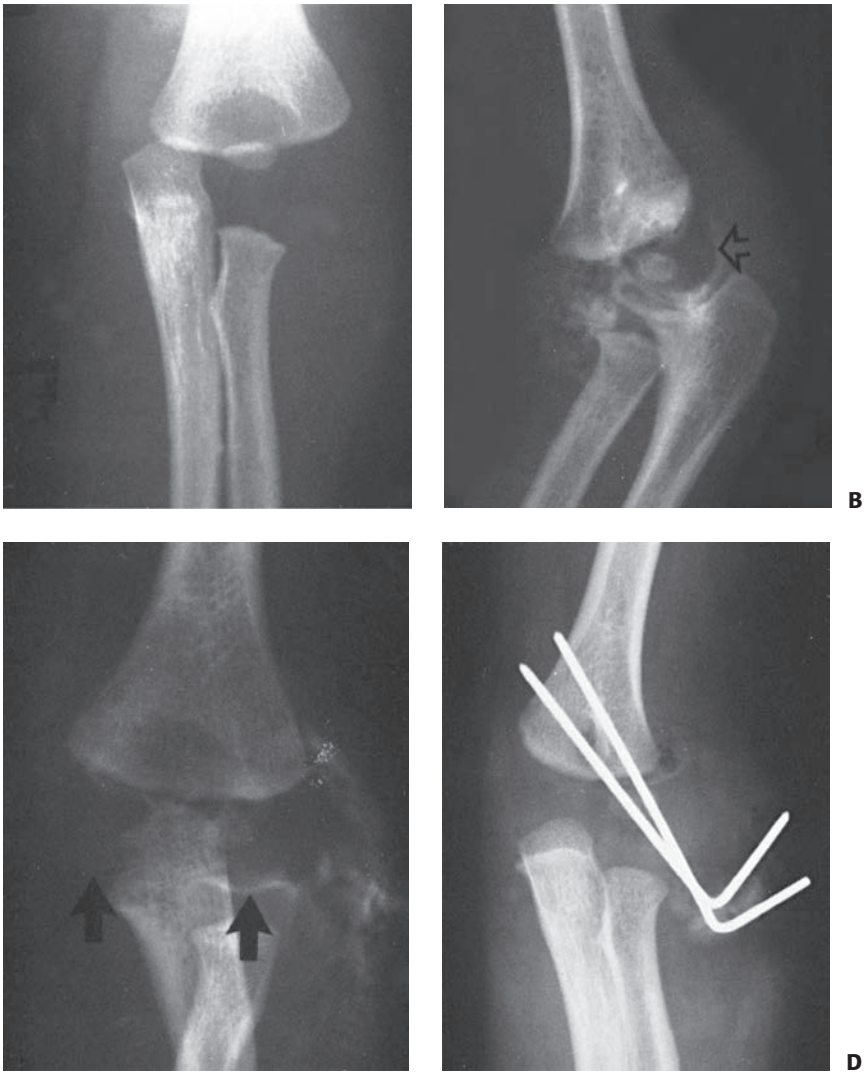

FIGURE 20-8 **A:** Injury film of a 20-month old showing medial displacement of the distal fragment. **B, C:** The medial and posterior displacement of the condylar fragment (*arrows*) is better defined after an arthrogram. **D:** Fixation is achieved by two lateral pins placed percutaneously.

is secured with two lateral pins (Fig. 20-8). Because of the swelling and immaturity of the distal humerus, the medial epicondyle is difficult to define as a distinct landmark, making it risky to attempt the percutaneous placement of a medial pin. If a medial pin is necessary for stable fracture fixation, a small medial incision can be made to allow direct observation of the medial epicondyle and the ulnar nerve. Usually two or lateral small, smooth lateral pins are used. In small infants and young children with minimal ossification of the epiphyseal fragment, an intraoperative arthrogram may be obtained to help determine the quality of the reduction (Table 20-3).

Author's Preferred Treatment for Fractures Involving the Entire Distal Humerus

In neonates and very small infants in whom general anesthesia or percutaneous pin fixation may be difficult, we typically simply immobilize the extremity in 90 degrees of flexion with

TABLE 20-3 Closed Reduction and Pinning of Fractures Involving the Entire Distal Humerus

Surgical Steps

- Assess arm under fluoroscopy
- In extension, correct medial or lateral displacement
- Flex elbow up while pronating arm
- Secure fracture with two divergent lateral pins
- If medial pin is needed for stability, make small incision over medial epicondyle and visualize directly, and pull back ulnar nerve to avoid injury
- If difficult to assess reduction, perform arthrogram to assess alignment. Arthrogram can be performed by injecting posteriorly into olecranon fossa or laterally into soft spot of elbow
- Bend and cut pins, and place xeroform and drain sponge under underneath pins
- Place well-padded bivalved long arm cast in comfortable amount of flexion (approximately 60–80 degrees)

the forearm pronated. The extremity is then externally stabilized with a figure-of-eight splint.

In most older infants and young children, external immobilization is usually not dependable in maintaining the reduction. As a rule, in these patients, we perform the manipulation with the patient under general anesthesia and the fragment is secured with two lateral pins (Fig. 20-8). If a medial pin is necessary for stable fracture fixation, a small medial incision should be made. An intraoperative arthrogram may be obtained to help determine the quality of the reduction in patients with limited ossification. We have done similar surgery in neonates and very young children who can tolerate anesthesia safely.

If treatment is delayed more than 3 to 5 days and if the epiphysis is not freely movable, the elbow is simply immobilized in a splint or cast. It is probably better to treat any resulting deformity later with a supracondylar osteotomy rather than to risk the complication of physeal injury or osteonecrosis of the epiphysis by performing a delayed manipulation or open reduction. Only occasionally does an untreated patient have a deformity severe enough to require surgical correction at a later date. Because the articular surface is intact, complete functional recovery can usually be expected.

Postoperative Care

A cast or splint is maintained for 3 weeks. At 3 weeks, the patient's cast is removed, imaging is obtained, and the pins are removed in the office. The patient is discharged without immobilization and active elbow motion is resumed. The patient is then followed until full motion is regained and until there is radiographic evidence of normal physeal and epiphyseal growth.

Potential Pitfalls and Preventative Measures

Because of the swelling and immaturity of the distal humerus, the ulnar nerve is at risk with placement of a medial pin. Making a small incision and by pulling ulnar nerve out of the way helps prevent iatrogenic injury. Quality of reduction is difficult to assess in small infants and young children and an intraoperative arthrogram can ensure adequate reduction (Table 20-4).

TABLE 20-4 Fractures Involving the Entire Distal Humerus

Potential Pitfalls and Preventions

Pitfalls	Preventions
Use medial pin, inaccurate placement or iatrogenic ulnar nerve palsy	Lateral entry pin placement If medial pin absolutely needed, make small incision over medial epicondyle and visualize directly, pull ulnar nerve posteriorly with your finger
Difficulty gauging reduction because of elbow being largely unossified	Perform arthrogram to assess reduction

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures Involving the Entire Distal Humerus

Malunion

Significant cubitus varus deformity can occur after this injury (Fig. 20-7**C**).[46,50] Because the fracture surfaces are wider with this injury than with supracondylar fractures, the distal fragment tends to tilt less, which seems to account for the lower incidence of cubitus varus after this injury than after untreated supracondylar fractures; however, reduction and percutaneous pinning are recommended for acute fractures with displacement to prevent this complication. Late supracondylar humerus osteotomy may be indicated when there is insufficient remodeling. (See Chapter 16 for details of surgical techniques for osteotomies.)

Neurovascular Injuries

Neurovascular injuries, either transient or permanent, are rare with this fracture. This is probably because the fracture fragments are covered with physeal cartilage and do not have sharp edges. In addition, the fracture fragments are usually not as markedly displaced as supracondylar humerus. Finally, the fracture displacement is usually posteromedial rather than posterolateral.

Nonunion

Only one nonunion after this fracture has been reported; it occurred in a patient seen 3 months after the initial injury.[53] Because of the extreme vascularity and propensity for osteogenesis in this area, union is rapid even in patients who receive essentially no treatment.

Osteonecrosis

Osteonecrosis of the epiphysis of the lateral condyle or the trochlear epiphysis has rarely been reported after fractures of the entire distal humeral physis. Yoo et al.[81] reported eight patients with osteonecrosis of the trochlea after fracture separations of the distal end of the humerus. Six of the eight fractures were diagnosed initially as medial condylar fractures, lateral condylar fractures, or traumatic elbow dislocation. All eight patients had rapid dissolution of the trochlea within 3 to 6 weeks after injury, followed by the development of a medial or central condylar fishtail defect. Further discussion regarding the etiology of this complication is discussed in the section on osteonecrosis of the trochlea (Table 20-5).

Osteonecrosis of lateral condyle or trochlear epiphysis (rare)

Summary, Controversies, and Future Directions for Fractures Involving the Entire Distal Humerus

Transphyseal injuries of the distal humerus are rare. In young children, child abuse should be suspected and the patient should be evaluated for associated injuries. The injury should be distinguished from an elbow dislocation, which may be difficult in the unossified elbow. In neonates or children in which anesthesia is difficult, simple immobilization can be used, but patients may heal in varus. In children who can tolerate anesthesia, closed reduction and pin fixation can improve alignment and minimize complications of cubitus varus. An arthrogram may be needed to assess reduction.

Introduction to Fractures Involving the Medial Condyle

Fractures of the medial condyle can be thought of as the mirror image of lateral condyle fractures, which are more commonly encountered (see Chapter 19). Fractures involving the medial condyle have two components. The intra-articular component involves, in some manner, the trochlear articular surface. The extra-articular portion includes the medial metaphysis and medial epicondyle. Because the fracture line extends into the articular surface of the trochlea, these often are called *trochlear fractures.* For purposes of description in this chapter, fractures of the trochlea are those that include only the articular surface.

Fractures involving the medial condyle are rare in skeletally immature children, accounting for less than 1% of fractures involving the distal humerus.[35] Many of the large series of elbow fractures in the literature and early fracture texts do not mention these fractures as a separate entity. Blount[8] described only one such fracture in his classic text. In Faysse and Marion's[21] review of more than 2,000 fractures of the distal humerus in children, only 10 fractures involved the medial condyle. Although it has been reported in a child as young as 2 years of age,[3] this fracture pattern is generally considered to occur during later childhood. These rare injuries are very problematic as they can occur before the trochlear secondary center of ossification appears. A high index of suspicion is necessary to avoid missing a displaced, intra-articular fracture in the young (Fig. 20-9A, B) .

Most series[21,60] show medial condylar fractures occurring somewhat later than lateral condylar fractures. A review of 38 patients in nine series[3,12,13,20,21,24,28,60,65,78] in which the specific ages were given showed that 37 patients were in the age range of 8 to 14 years. Thus, this fracture seems to occur most often after the ossification centers of the medial condylar epiphysis begin to appear. As mentioned, a medial condylar fracture can occur as early as 6 months of age, however, before any ossification of the distal humerus has appeared,[5,15] making the diagnosis extremely difficult and outcome poor if missed and not treated acutely.

Assessment of Fractures Involving the Medial Condylar Physis

Mechanisms of Injury for Fractures Involving the Medial Condylar Physis

Two separate mechanisms can produce physeal fractures of the medial condyle. Ashurst's[3] patients described falling directly on the point of the flexed elbow. This mechanism was also implicated in other reports.[5,12,31,65] In this mechanism, it is speculated that the semilunar notch's sharp edge of the olecranon splits the trochlea directly (Fig. 20-10A). This mechanism is also supported by a recent case report of a medial condyle fracture in the setting of a pre-existing fishtail deformity.[55]

In three more recent series,[11,23,24] many patients sustained this injury when they fell on their outstretched arms. The theory is that this is an avulsion injury caused by a valgus strain at the elbow (Fig. 20-10B). Fowles and Kassab[23] reported a patient with a concomitant valgus greenstick fracture of the olecranon associated with a fracture of the medial condyle. They believed

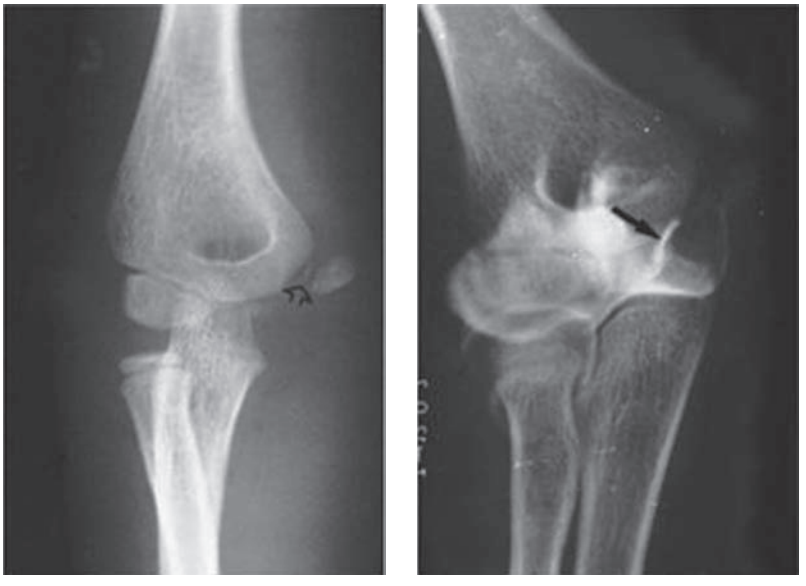

FIGURE 20-9 Intra-articular extension. **A:** Injury film in a 7-year-old girl who was initially suspected of having only a fracture of the medial epicondyle. In addition to moderate displacement, there was a significant metaphyseal fragment (*arrow*). **B:** An arthrogram revealed intra-articular components (*arrow*), which defined this injury instead as a fracture involving the medial condylar physis. (Courtesy of Carl McGarey, MD.)

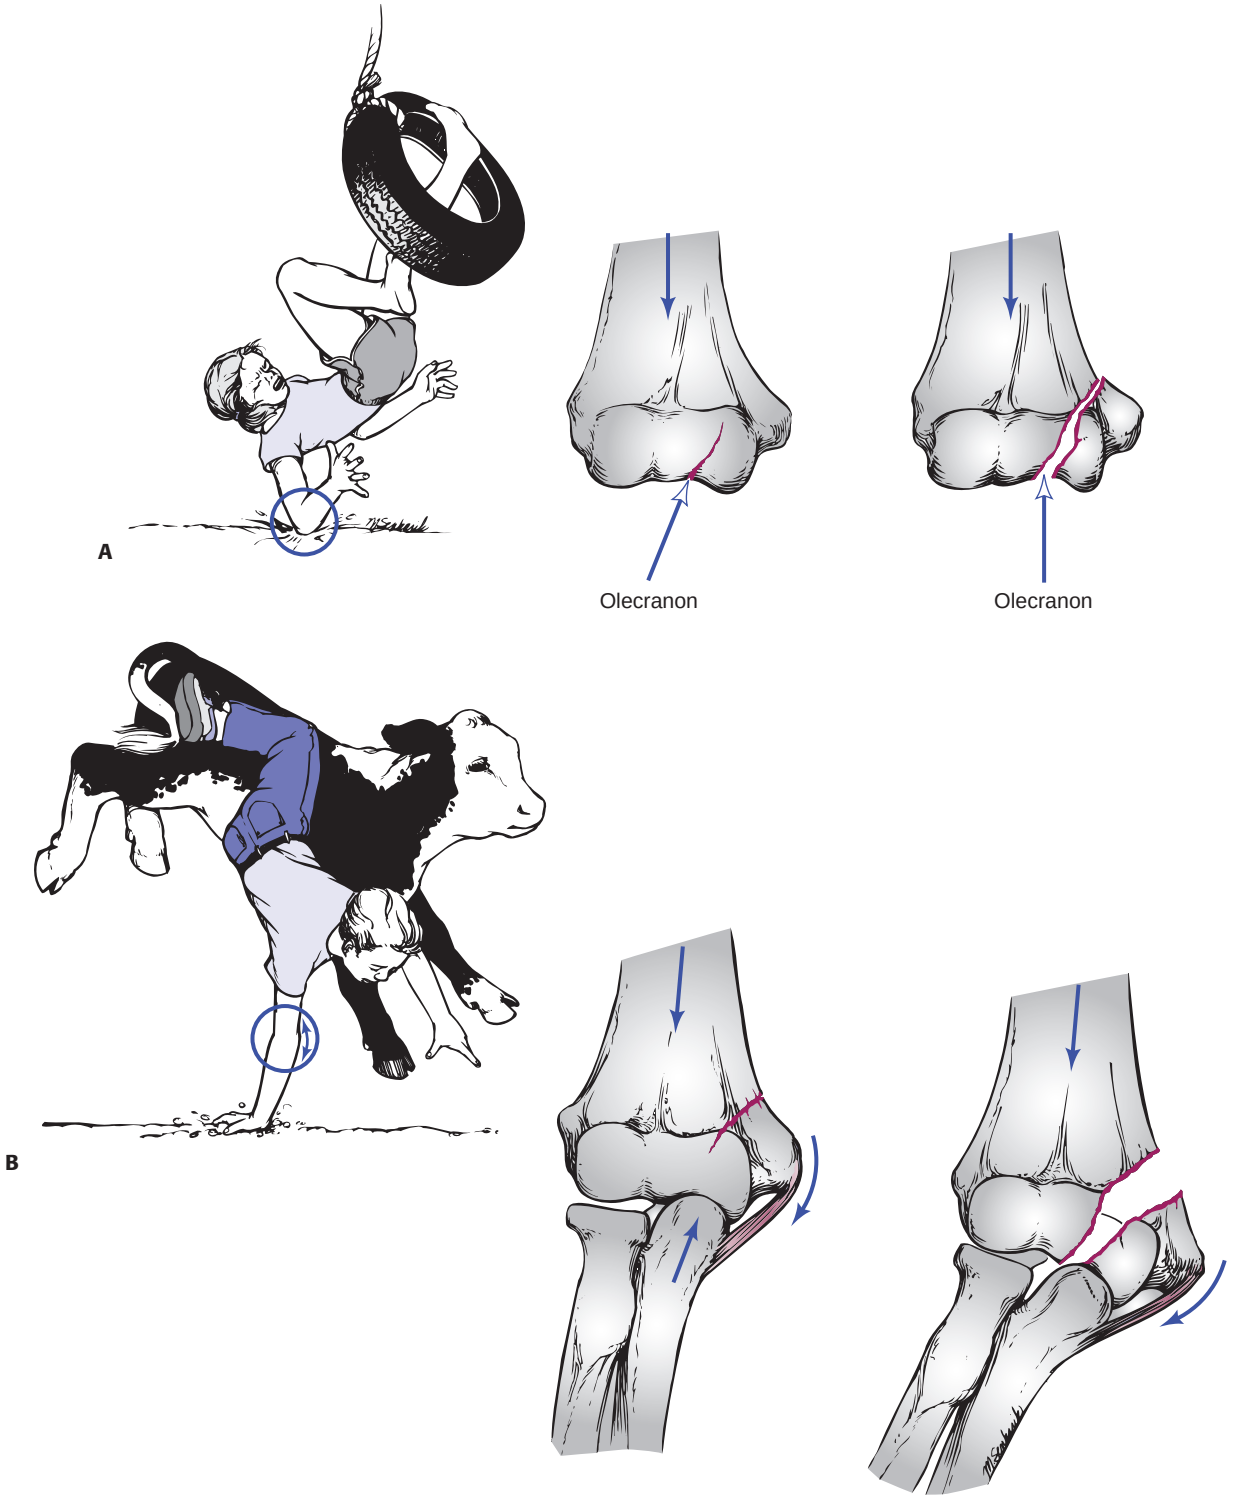

FIGURE 20-10 Medial condylar fracture mechanisms of injury. **A:** A direct force applied to the posterior aspect of the elbow causes the sharp articular margin of the olecranon to wedge the medial condyle from the distal humerus. **B:** Falling on the outstretched arm with the elbow extended and the wrist dorsiflexed causes the medial condyle to be avulsed by both ligamentous and muscular forces.

this fracture provided further evidence that this was a valgus avulsion type of injury. Once the fragment becomes disassociated from the distal humerus, the forearm flexor muscles produce a sagittal anterior rotation of the fragment.

Associated Injuries with Fractures Involving the Medial Condylar Physis

As this fracture is rare, studies describing associated injuries are rare. Medial condylar physeal fractures have been reported in association with greenstick fractures of the olecranon and with true posterolateral elbow dislocations (Fig. 20-11).[5,15,23] Some investigators[5,15] found that child abuse was more common in their younger patients with these fractures than with other elbow fractures. Regardless, the extremity should be evaluated for concomitant injuries of forearm, wrist, or hand, and the radiographs should be inspected for additional fractures about the elbow.

Signs and Symptoms of Fractures Involving the Medial Condylar Physis

Clinically and on radiographs, a fracture of the medial condylar physis is most often confused with a fracture of the medial epicondyle.[41] In both types of intra- and extra-articular fractures, swelling is concentrated medially, and there may be valgus instability of the elbow joint. In a true intra-articular fracture, however, there is varus instability as well. Such is usually not the case with an isolated extra-articular fracture of the medial epicondyle. Ulnar nerve paresthesia may be present with both types of fractures.

Imaging and Other Diagnostic Studies for Fractures Involving the Medial Condylar Physis

In older children with a large metaphyseal fragment, involvement of the entire condyle is usually obvious on radiographs (Fig. 20-12A); in younger children, in whom only the epicondyle is ossified, fracture of the medial condylar physis may be erroneously diagnosed as an isolated fracture of the medial epicondyle (Fig. 20-12B, C).[13,20,23]

In differentiating these two fractures, it is helpful to remember that medial epicondylar fractures are often associated with elbow dislocations, usually posterolateral, and that elbow dislocations are rare before ossification of the medial condylar epiphysis begins. With medial condylar physeal fractures, the elbow tends to subluxate posteromedially[13] because of the loss of trochlear stability.

Any metaphyseal ossification with the epicondylar fragment suggests the presence of an intra-articular fracture of the medial condyle and is an indication for further evaluation. Often, the medial condyle and the medial epicondyle are markedly displaced as a unit. A positive fat pad sign indicates that the injury has entered the elbow joint and a fracture of the medial condyle is likely.[31,71] Isolated fractures of the medial epicondyle are extra-articular and usually do not have positive fat pad signs.

If the true location of the fracture line is questionable in a child younger than 8 to 10 years of age with significant medial elbow ecchymosis, arthrography or MRI of the elbow should be performed.

FIGURE 20-11 **A:** (lateral) and **(B)** (AP) injury films of a 10-year-old girl who sustained a type III displaced fracture of the medial condyle associated with a posterolateral elbow dislocation. (Part A Courtesy of Elizabeth A. Szalay, MD.)

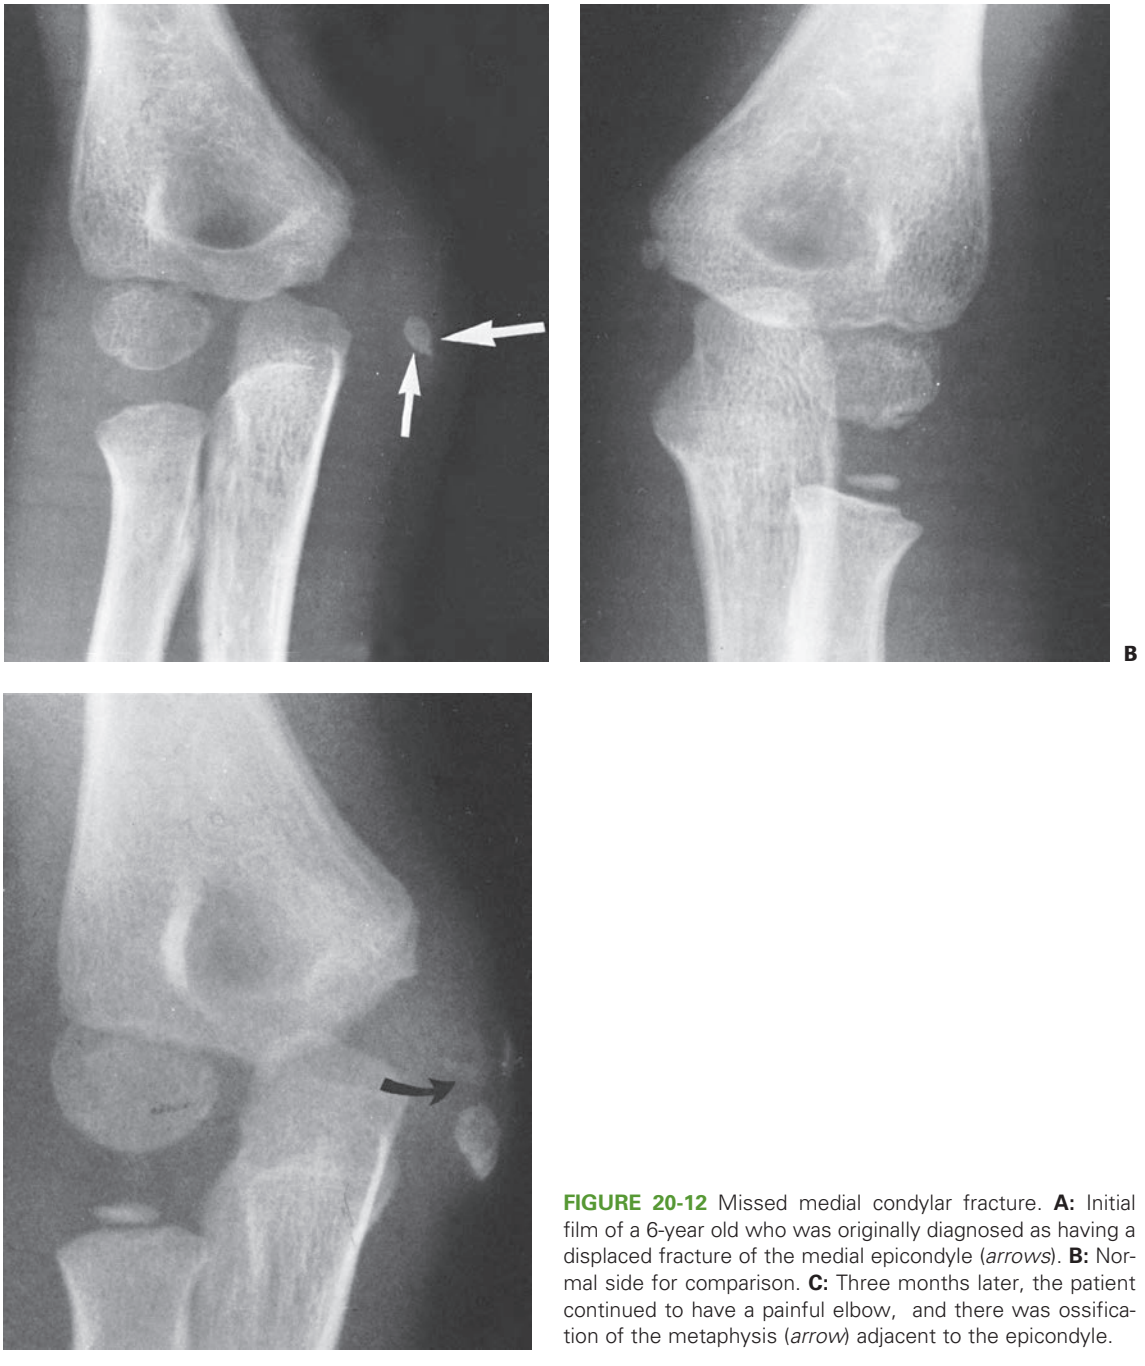

FIGURE 20-12 Missed medial condylar fracture. **A:** Initial film of a 6-year old who was originally diagnosed as having a displaced fracture of the medial epicondyle (*arrows*). **B:** Normal side for comparison. **C:** Three months later, the patient continued to have a painful elbow, and there was ossification of the metaphysis (*arrow*) adjacent to the epicondyle.

Classification of Fractures Involving the Medial Condylar Physis

Classification, as with fractures of the lateral condylar physis, is based on the fracture line's location and the degree of the fracture's displacement.

Location of the Fracture Line

Milch[51] classified fractures of the medial condylar physis in adults into two types. In type I fractures, the fracture line traverses the apex of the trochlea. In type II fractures, it traverses more laterally through the capitulotrochlear groove. He believed that the origin of the fracture line depended on whether the radial head, as in type II, or the semilunar notch of the olecranon, as in type I, served as the impinging force for the abduction injury. Both fracture patterns occur in children (Fig. 20-13A), but type I fractures seem to be more common because the common physeal line, which serves as a point of weakness, ends in the apex of the trochlea.

Displacement of the Fracture

Kilfoyle[39] described three fracture displacement patterns that can be helpful in determining appropriate treatment (Fig. 20-13B).

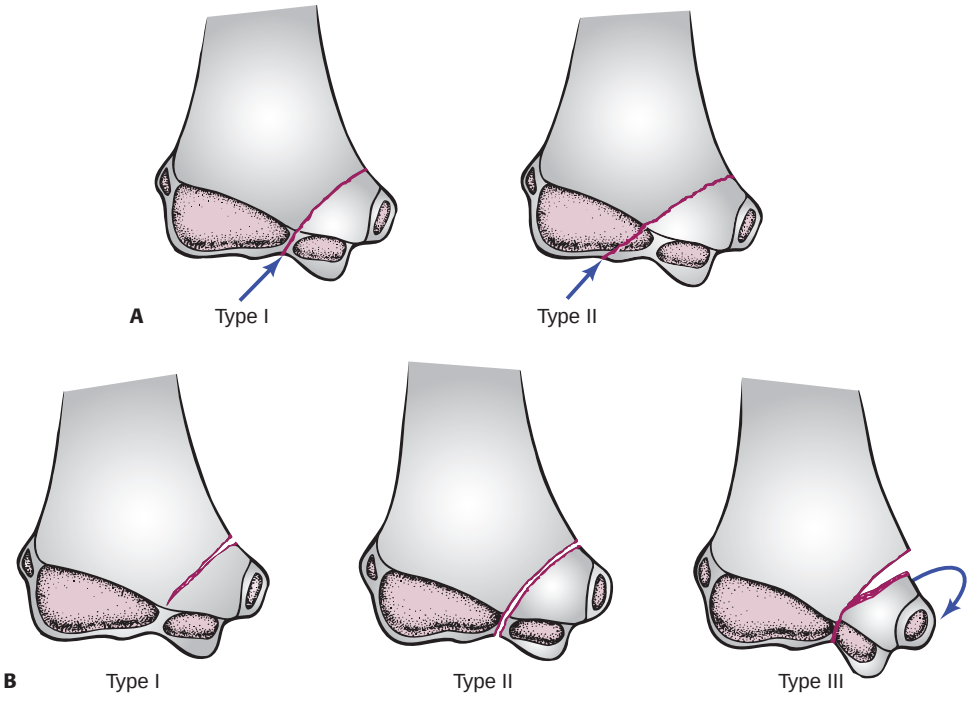

FIGURE 20-13 **A:** Medial condylar fracture patterns. In the Milch type I injury, the fracture line terminates in the trochlear notch (**left,** *arrow*). In the Milch type II injury, the fracture line terminates more laterally in the capitulotrochlear groove (**right,** *arrow*). (Adapted and reprinted with permission from Milch H. Fractures and fracture–dislocations of the humeral condyles. *J Trauma.* 1964;4:592–607.) **B:** Kilfoyle classification of displacement patterns. Degrees of displacement for fracture type I is an incomplete fracture that does not violate the joint but may hinge open; type II is a fracture that enters the joint but has less than 2 mm displacement; type III enters the joint and results in malangulation, malrotation, and articular displacement. (Adapted and reprinted with permission from Kilfoyle RM. Fractures of the medial condyle and epicondyle of the elbow in children. *Clin Orthop.* 1965;41:43–50.)

In type I, the fracture line in the medial condylar metaphysis extends down to the physis. He noted that some of these might represent incomplete supracondylar fractures. Unless there is a greenstick crushing of the medial supracondylar column, these fractures are usually of no clinical significance. In type II, the fracture line extends into the medial condylar physis. The intra-articular portion, as it is in preosseous cartilage, is often not recognized. In this second type, the medial condylar fragment usually remains undisplaced. In type III, the condylar fragment is both rotated and displaced. Some authors use a modification of Kilfoyle's classification based on amount of displacement and describe it as nondisplaced (<2 mm), minimally displaced (2 to 4 mm), and displaced (>4 mm).[77] Bensahel et al.[5] and Papavasiliou et al.[60] found that type III displacement fractures, which accounted for only 25%, were more likely to occur in older adolescents, and type I fractures were more common in younger children. These studies also confirmed the correlation between the type of displacement and the treatment method.

Pathoanatomy and Applied Anatomy Relating to Fractures Involving the Medial Condylar Physis

Fractures of the medial condylar physis involve both intra- and extra-articular components. They behave as Salter–Harris type IV physeal injuries, but not enough fractures have been described to show whether the fracture line courses through the secondary ossification center of the medial condylar epiphysis or whether it enters the common physeal line separating the lateral condylar ossification center from the medial condylar ossification center. This common physeal line terminates in the notch of the trochlea. The trochlea's lateral crista is ossified from the lateral condylar epiphysis. Only the medial crista is ossified by the secondary ossification centers of the medial condylar epiphysis. We believe that this fracture is a "mirror image" of the lateral condylar physeal injury and thus has characteristics of Salter–Harris type IV physeal injuries (Fig. 20-14). The deformity that develops if the fracture is untreated is nonunion, similar to that after lateral condylar physeal fracture, rather than physeal fusion, as occurs after a typical Salter–Harris type IV injury. The resultant deformity of a medial condylar nonunion is cubitus varus instead of the cubitus valgus deformity that occurs with nonunion of the lateral condyle.

Characteristically, the metaphyseal fragment includes the intact medial epicondyle along with the common flexor origin of the muscles of the forearm. These flexor muscles cause the loosened fragment to rotate so that the fracture surface is facing anteriorly and medially and the articular surface is facing posteriorly and laterally (Fig. 20-15).[3,12] Rotation of the fragment is especially accentuated when the elbow is extended. Chacha[12]

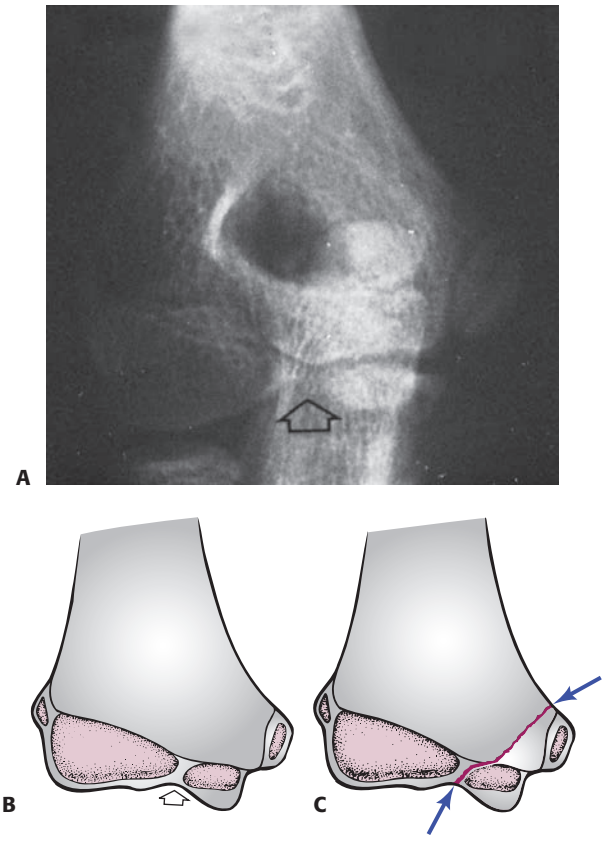

FIGURE 20-14 **A:** The AP radiograph of a 9-year-old boy demonstrates the location of the ossification centers. A common physeal line (*arrow*) separates the medial and lateral condylar physes. **B:** Relationship of the ossification centers to the articular surface. The common physis terminates in the trochlear notch (*arrow*). **C:** Location of the usual fracture line involving the medial condylar physis (*arrows*).

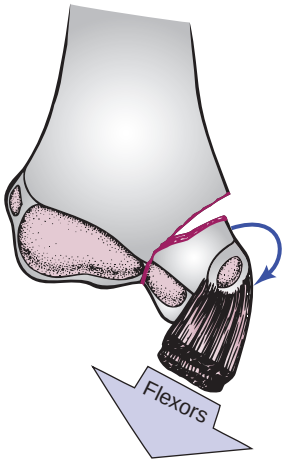

FIGURE 20-15 Displacement of the medial condyle. The pull of the forearm flexor muscles rotates the fragment so that the fracture surface is facing anteromedially and the articular surface is posterolateral. (Adapted and reprinted with permission from Chacha PB. Fractures of the medial condyle of the humerus with rotational displacement. *J Bone Joint Surg Am*. 1970;52:1453–1458.)

also noted that often the lateral aspect of the common flexor origin and the anterior capsule of the joint were torn and the fracture surface could usually be reached through this anterior opening into the joint.

The blood supply to the medial epicondyle and medial metaphysis courses extra-articularly along with the medial flexor muscle groups. The blood supply to the lateral ossification center of the medial crista of the trochlea, however, must traverse the surface of the medial condylar physis. If the fracture line disrupts these small intra-articular vessels, disruption and subsequent circulation loss to the lateral portion of the medial crista can result, leading to the development of a fishtail deformity.

Treatment Options for Fractures Involving the Medial Condylar Physis

In Kilfoyle's displacement types I and II fracture patterns, enough residual internal stability is usually present to allow the fracture to be simply immobilized in a cast or posterior splint.[5,21,25,39,60] As with fractures of the lateral condylar physis, union may be slow. In fractures treated promptly, results have been satisfactory.[12,20,23] Because there is usually more displacement in older children, the results in this age group are not as satisfactory as those in younger children, who tend to have relatively nondisplaced fractures.[5]

For displaced fractures, open reduction with internal fixation is the most often used treatment method.[5,11,23,24,39,60,63,65] The fracture fragment can be approached by a posteromedial incision that allows good exposure of both the fracture site and the ulnar nerve. Fixation is easily achieved with smooth K-wires or with screws in older adolescents (Fig. 20-16A, B). Two wires are necessary because of the sagittal rotation forces exerted on the fracture fragment by the common flexor muscles. El Ghawabi[24] reported frequent delayed union and nonunion in fractures that were not rigidly stabilized.

Nonoperative Treatment of Fractures Involving the Medial Condylar Physis

Indications/Contraindications

Nondisplaced or minimally displaced fractures (Kilfoyle types I and II) can be treated nonoperatively with either splint or cast immobilization (Table 20-6).

Operative Treatment of Fractures Involving the Medial Condylar Physis

Indications/Contraindications

For displaced fractures (Kilfoyle type III) operative fixation is recommended, as well as minimally displaced fractures (Kilfoyle type II) that demonstrate instability and/or progressive displacement.

Surgical Procedure

Open reduction internal fixation of medial condyle fracture.

Preoperative Planning. Adequate radiographs including oblique radiographs should be obtained to assess fracture morphology (Table 20-7).

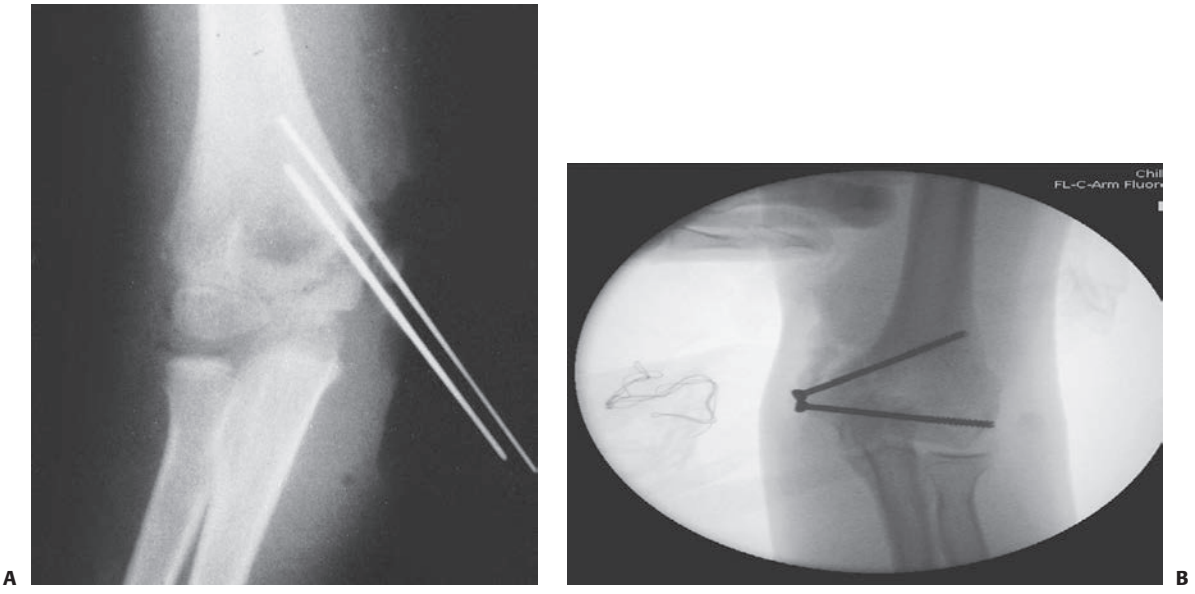

FIGURE 20-16 **A:** Medial condyle fracture in an adolescent fixed with wires. **B:** Medial condyle fracture fixed with cannulated screws to allow early range of motion.

Positioning. Although medial epicondyle fractures may be approached supine or prone,[26] typically the patient is positioned supine to approach a medial condyle fracture. You attach a hand table on the affected side. The arm can be externally rotated through the shoulder to access the medial condyle, and the elbow is flexed to relax the flexor mass.

Surgical Approach. A posteromedial approach to the elbow is used that allows good exposure of both the fracture site and the ulnar nerve.

Technique. An incision is centered over the medial condyle/epicondyle. Often there is significant soft tissue swelling and displacement. Dissection is carefully carried out to the level of the bony condyle and usually the fracture hematoma is quickly encountered. The medial brachial and antebrachial cutaneous nerves that transverse the field are protected. Care in the dissection avoids injury to the ulnar nerve, which sits posterior to the fragment but may be displaced by the fracture. The ulnar nerve is identified and protected to ensure that it is not entrapped in the reduced fracture and it is not iatrogenically injured by a fixation pin or screw. The fracture is cleared out of hematoma. The entire fracture line and joint surface should be identified to ensure accurate reduction of the joint surface. The fracture is reduced. In the supine position this requires flexion of the elbow and wrist with pronation of the forearm, which takes tension off of the condyle. The condyle is held in place, and K-wires are passed in a divergent manner to hold the fracture in place. Alternatively cannulated screws or a plate can be used in older patients near skeletal maturity to allow more rigid fixation and early motion (Table 20-8).

Author's Preferred Treatment for Fractures Involving the Medial Condylar Physis

We generally treat Kilfoyle type I nondisplaced fractures with simple observation and a posterior splint or long arm cast. Follow-up radiographs at weekly intervals are taken to ensure there is no late displacement. When there is good callus at the metaphyseal portion of the fracture line by 3 to 4 weeks, the splint is removed and early active motion is initiated. We continue to follow the patient until there is a full range of motion and obliteration of the fracture line. Some type II fractures that maintain alignment can also be treated nonoperatively; however, careful follow-up on weekly intervals are required to document that the fragment has not moved.

TABLE 20-6 Medial Condyle Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Nondisplaced fractures (Kilfoyle type I)	Displaced fractures (Kilfoyle type III)
Minimally displaced fractures (some) (Kilfoyle type II)	

TABLE 20-7 ORIF of Fractures Involving the Medial Condylar Physis

Preoperative Planning Checklist

- OR Table:
  - Position/positioning aids: Supine
  - Fluoroscopy location: From head of bed under hand table
  - Equipment: K-wires, cannulated screws (for patients near skeletal maturity)

TABLE 20-8 ORIF of Fractures Involving the Medial Condyle

Surgical Steps

- Posteromedial incision over medial condyle
- Identify and protect ulnar nerve
- Clean fracture hematoma and identify fracture and joint surface
- Reduce fracture by taking tension of flexor mass by flexing elbow and wrist and pronating forearm
- Reduce joint and fracture
- Stabilize fracture with divergent K-wires (cannulated screws in older patients/adolescents)
- Apply bivalved long arm cast

Unstable Kilfoyle type II and type III displaced fractures must be reduced and stabilized. This is usually difficult to do by closed methods because the swelling associated with this injury makes it hard to accurately identify the landmarks for pin placement. We proceed with an open reduction through a medial approach with identification and protection of the ulnar nerve. The posterior surface of the condylar fragment and the medial aspect of the medial crista of the trochlea should be avoided in the dissection because these are the blood supply sources to the ossific nuclei of the trochlea. Fixation with two parallel pins should be in the metaphyseal segment if possible. We prefer cannulated screw fixation in adolescents near skeletal maturity to allow early protected range of motion.

Postoperative Care

Patients will be immobilized largely dependent upon age, fracture pattern, and type of fixation. Nonoperatively treated fractures may be casted for 4 to 6 weeks, in a similar fashion to the treatment of lateral condyle fractures based on age, displacement, and amount of healing. Those treated with pin fixation similarly will be casted for 4 to 6 weeks depending on healing, and the pins are often removed at 4 weeks if exposed, and can be removed any time after 6 weeks if buried. In patients treated with more rigid fixation, early (10 to 14 days) transition to a hinged elbow brace with protected range of motion is recommended.

Potential Pitfalls and Preventative Measures

Nondisplaced or minimally displaced fractures should be monitored closely to ensure that progressive displacement does not occur, which could lead to delayed union or nonunion. When treating patients operatively, the posterior surface of the condylar fragment and the medial aspect of the medial crista of the trochlea should be avoided in the dissection because these are the blood supply sources to the ossific nuclei of the trochlea. The ulnar nerve should be identified to avoid iatrogenic injury (Table 20-9).

TABLE 20-9 Fractures Involving the Medial Condylar Physis

Potential Pitfalls and Preventions

Pitfalls	Preventions
Progressive displacement of minimally displaced fracture leading to delayed union	Monitor fractures treated nonoperatively with careful radiographic follow-up
Disruption of blood supply leading to osteonecrosis	Avoid dissection posteriorly on the fragment on the medial aspect of the medial crista of the trochlea
Iatrogenic ulnar nerve injury	Perform adequate exposure to identify and protect ulnar nerve during reduction and pin fixation

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures Involving the Medial Condylar Physis

The major complication is failure to make the proper diagnosis. This is especially true in younger children, in whom a medial condylar fracture can be confused with a displaced fracture of the medial epicondyle (Fig. 20-12). When the diagnosis is a real possibility, especially in a child with no ossification of the trochlea, examination with anesthesia, arthrography, and/or MRI is required (Fig. 20-9). Leet et al.[42] reported complications after 33% of 21 medial condylar fractures, including osteonecrosis of the trochlea, nonunion, and loss of reduction. Untreated displaced fractures usually result in nonunion with cubitus varus deformity (Fig. 20-17).[23,78] These patients are at high risk for loss of motion, function, pain, and eventual arthrosis. Ryu et al.[68] described a painful nonunion of the medial condyle in an adolescent that apparently resulted from a fracture when he was 3 years old. An osteotomy was made to remove the nonunited section of bone, and an iliac bone graft was inserted and fixed with two malleolar screws. Union was obtained, and the patient was able to participate in sports without pain. Delayed union has been reported in patients treated with insecure fixation or simply placed in a cast.[24,39]

Some disturbance of the vascular supply to the medial condylar fragment may occur during open reduction and internal fixation or at the time of initial injury. Several investigators have reported subsequent avascular changes in the medial crista of the trochlea.[23,24,39,60] Hanspal[28] reviewed Cothay's original patient[13] 18 years after delayed open reduction and found that despite some minimal loss of motion, the patient was asymptomatic. Radiographs, however, showed changes compatible with osteonecrosis of the medial condyle.

Both cubitus varus and valgus deformities have been reported in patients whose fractures united uneventfully. The valgus deformity appears to be caused by secondary stimulation or overgrowth of the medial condylar fragment. Some simple stimulation of the medial epicondyle's prominence may also produce the false appearance of a cubitus valgus deformity. Cubitus varus appears to result from decreased growth of the trochlea, possibly caused by a vascular insult. Principles for treating nonunion of lateral condylar fractures are generally applicable to nonunions of the medial condyle (Fig. 20-18).

El Ghawabi[24] described one partial ulnar neuropathy occurring after this type of injury. The neuropathy almost completely recovered after anterior transposition of the ulnar nerve (Table 20-10).

Summary, Controversies, and Future Directions in Fractures Involving the Medial Condylar Physis

Medial condyle fractures are rare. The key is identifying them and making the proper diagnosis. The classification, radiographic assessment, and treatment goals are similar to lateral condyle fractures which are encountered much more commonly. Although nondisplaced or minimally displaced fractures can be treated nonoperatively in a cast, careful monitoring is required to identify further displacement and delayed union. When displaced, open treatment with identification of the ulnar nerve and direct visualization of the joint surface is needed. The rate of complications is relatively high and may include osteonecrosis, elbow stiffness, malunion, or delayed union.

Introduction to Fractures Involving the Lateral Epicondylar Apophysis

Fracture of the lateral epicondylar apophysis is a rare injury, with only a few isolated injuries described, mostly in textbooks.[32,47,70,75] In a review of 5,228 fractures of the distal humerus, Chambers and Wilkins identified one fracture of the lateral epicondyle.[70]

The origins of the forearm and wrist extensor muscles, radial collateral ligament, and outline of the capsule are shown in relation to the lateral epicondylar apophysis. (From Hasner E, Husby J. Fracture of the epicondyle and condyle of humerus. *Acta Chir Scand.* 1951;101:195–202, with permission.)

Assessment of Fractures Involving the Lateral Epicondylar Apophysis

Mechanisms of Injury for Fractures Involving the Lateral Epicondylar Apophysis

In adults, the most common etiology is that of a direct blow to the lateral side of the elbow. In children, because the forearm extensor muscles originate from this area, it is believed that avulsion forces from these muscles can be responsible for some of these injuries. Hasner and Husby[32] suggested that the location of the fracture line in relation to the origins of the various extensor muscles determines the degree of displacement that can occur (Fig. 20-19). If the proximal part of the fracture line lies between the origin of the common extensors and the extensor carpi radialis longus, there is usually little displacement. If the fracture lines enter the area of origin of the extensor carpi radialis longus, then considerable displacement can occur.

Associated Injuries with Fractures Involving the Lateral Epicondylar Apophysis

As this fracture is so rare, associated injuries are not well described.

Signs and Symptoms of Fractures Involving the Lateral Epicondylar Apophysis

Patients will present similar to other elbow fractures, with pain and swelling in the elbow, with pain often localized to the lateral aspect of the distal humerus.

Imaging and Other Diagnostic Studies for Fractures Involving the Lateral Epicondylar Apophysis

Fractures can often be confused with normal anatomy of the lateral epicondyle.[70] The distal part of the epiphysis fuses with the capitellum before the proximal part unites with the adjacent humerus. This frequently results in the physis appearing like a fracture. Also, ossification of the epiphysis begins at the level of the capitellar physis and proceeds first to a typical sliver shape and then to a triangular shape. This natural separation can be confused with an avulsion fracture.[70] The key to determining true separation is looking beyond the osseous tissues for the presence of associated soft tissue swelling (Fig. 20-20). If the ossification center lies distal to the osteochondral border of the lateral condylar epiphysis, it should be considered displaced (Fig. 20-21). Comparing radiographs of the contralateral elbow can be used to aid in diagnosis.

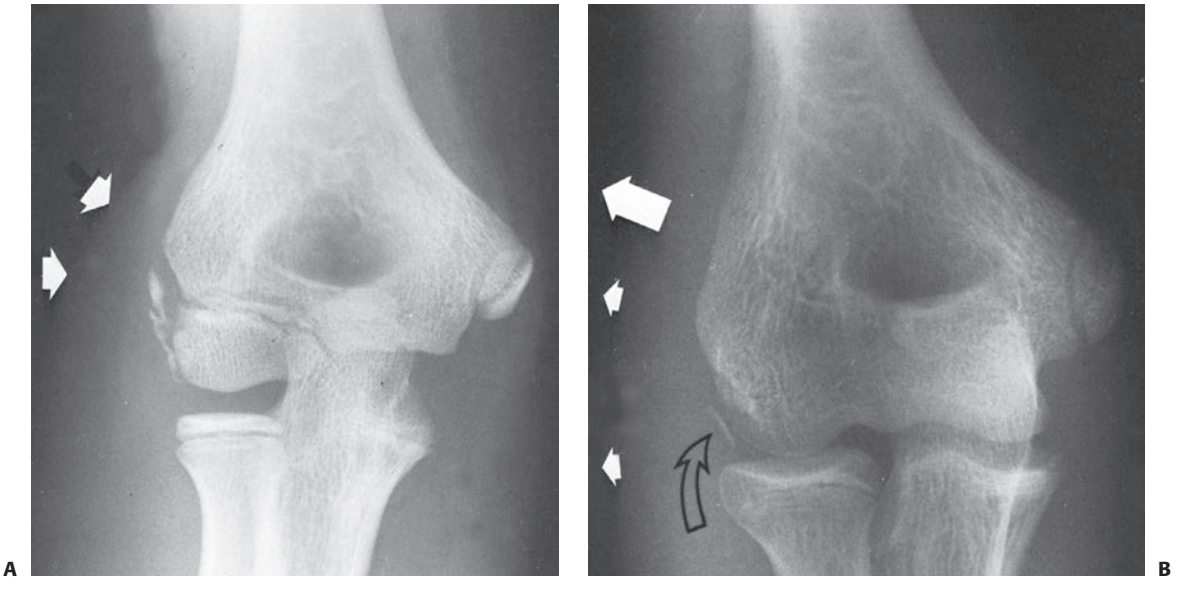

FIGURE 20-20 Lateral swelling. **A:** Soft tissue swelling in the area of the lateral epicondylar apophysis (*arrows*) suggests an undisplaced fracture involving the apophysis. The fragmentation of the apophysis is caused by irregular ossification. **B:** A small avulsion of the lateral epicondyle (*open arrow*) in an adolescent who is almost skeletally mature. There was considerable soft tissue swelling in this area (*solid arrows*).

Most of the epicondyle has fused to the condyle. **B:** The appearance 9 months later shows fragmentation and partial union of the fragment. (Courtesy of R. Chandrasekharan, MD.)

Pathoanatomy and Applied Anatomy Relating to Fractures Involving the Lateral Epicondylar Apophysis

Because the presence of the lateral epicondylar apophysis is often misinterpreted as a small chip fracture, a thorough understanding of the anatomy and ossification process is essential for evaluating injuries in this area and distinguishing normal from pathoanatomy.

Late Ossification. The lateral epicondylar apophysis is present for a considerable period but does not become ossified until the second decade. The best discussion of the anatomy of the ossification process is in a report by Silberstein et al.,[70] and much of the following discussion is paraphrased from their work. Just before ossification of the apophysis, the ossification margin of the lateral supracondylar ridge of the distal metaphysis curves abruptly medially toward the lateral condylar physis (Fig. 20-22). This process causes the osseous borders on the lateral aspect of the distal humerus to take the shape of the number 3. The central wedge of this defect contains the cartilaginous lateral epicondylar apophysis, which begins to ossify around 10 to 11 years of age. Ossification begins at the level of the lateral condylar physeal line and proceeds proximally and distally to form a triangle, with the apex directed toward the physeal line. The shape of the epicondylar apophyseal ossification center may also be in the form of a long sliver of bone with an irregular ossification pattern. Silberstein et al.[70] noted that the fracture line involving the lateral condylar physis often involves the proximal physeal line of the lateral epicondylar apophysis. Thus, this apophysis is almost always included with the lateral condylar fragment.

Treatment Options for Fractures Involving the Lateral Epicondylar Apophysis

Unless the fragment is incarcerated within the joint,[47] treatment usually consists of simple immobilization for comfort. Although nonunion of the fragment can occur, this radiographic finding

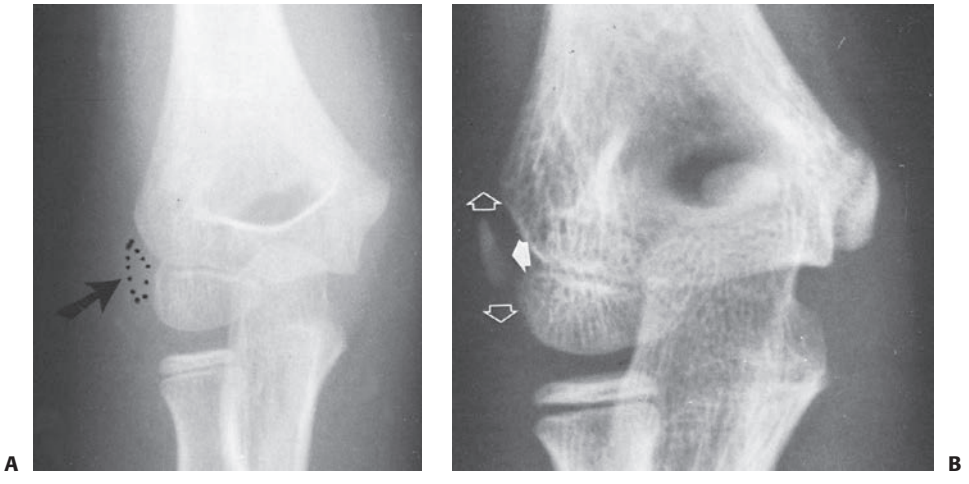

FIGURE 20-22 Lateral epicondylar apophysis. **A:** The cartilaginous apophysis occupies the wedge-shaped defect at the margin of the lateral condyle and metaphysis (*arrow*). The *dotted line* shows the margin of the cartilaginous apophysis. **B:** Ossification of the apophysis begins at the central portion of the wedge defect (*solid arrow*) and progresses both proximally and distally (*open arrows*) to form a triangular center.

usually does not affect elbow function. There are lateral column osteochondral nonunions that represent chronic lateral ligament instability. Those patients are symptomatic, have functional limitations, and benefit from open repair.

Management of Expected Adverse Outcomes and Unexpected Complications in Fractures Involving the Lateral Epicondylar Apophysis

Only one rare major complication has been described with fractures involving the lateral epicondylar apophysis: Entrapment of the fragment, either within the elbow joint[47] or between the capitellum and the radial head.[22]

Summary, Controversies, and Future Directions Related to Fractures Involving the Lateral Epicondylar Apophysis

Fractures of the lateral epicondyle are extremely rare. The radiographic appearance of the lateral epicondyle during growth can be confused with what appears to be a fracture. Unless there is entrapment in the joint, treatment is nonoperative.

Fractures Involving the Trochlea

Osteochondral fractures involving only the articular portion of the trochlea are extremely rare in skeletally immature children. Grant and Miller[27] reported a 13-year-old boy who had a posterolateral dislocation of the elbow with marked valgus instability and fractures of the medial epicondyle and radial neck. When the elbow was explored to secure the epicondyle, a large osteochondral fragment from the medial crista of the trochlea was found lying between the two articular surfaces. The fragment was replaced and fixed, and a satisfactory result was obtained, although the presence of the fragment was not detected preoperatively.

Patel and Weiner[61] described osteochondritis dissecans (OCD) in two patients (three elbows) aged 12 and 14 years. In one patient, open biopsy was done because the osteochondral lesion was thought to be a neoplastic lesion. The other patient with bilateral lesions was treated conservatively with good results. Matsuura et al.[44] evaluated 1,802 young baseball players, 717 (40%) of whom had elbow pain. Of the 150 who had bilateral elbow radiographic examination, osteochondral lesions of the elbow were identified in 121 (81%); trochlear lesions accounted for 0.5% of these. More recently, Marshall et al.[43] reported osteochondral lesions of the trochlea in 18 young athletes ranging in age from 6 to 17 years; 10 of the 18 were throwing athletes and two were gymnasts. Based on MRI and MR arthrogram findings, injuries were classified as chondral/osteochondral injury/OCD lesions (13 patients) or trochlear osteonecrosis (five patients). Ten of the 13 osteochondral lesions involved the lateral trochlea and were described as classic OCD; the three medial trochlear lesions were small (<6 mm) and were located on the posterior articular surface of the medial trochlea. Trochlear osteonecrosis in five patients was characterized by growth disturbance involving the ossification centers of the trochlea. The affected trochleas were misshapen and underdeveloped, and radiographs showed the secondary ossification centers to be fragmented, small, and sclerotic, or absent entirely. All five of the patients with osteonecrosis had histories of distal humeral fractures treated with K-wire fixation earlier in childhood (two lateral condylar fractures and one each supracondylar, medial epicondylar, and medial condylar fracture). The authors suggested that the athletic demands placed on the adolescent elbow revealed osteonecrosis from these earlier fractures.[43] The OCD lesions consistently occurred in the posteroinferior aspect of the lateral trochlea corresponding to a watershed zone of diminished vascularity, and the authors hypothesized that the lesions were caused by repeated forced elbow extension/hyperextension that led to impingement of the normal blood supply.[43] Small osteochondral lesions on the posteromedial trochlea were suggested to result from olecranon abutment occurring in an elbow with collateral ligament laxity or insufficiency.

In an older child who sustains an elbow dislocation and in whom there is some widening of the joint after reduction, an intra-articular osteochondral or chondral fracture of the trochlea, capitellum, or radial head should be suspected. Arthrography, MRI, or computed tomography–arthrography, should be used for confirmation.

Osteonecrosis of the Trochlea

Incidence

Toniolo and Wilkins[76] reported a series of 30 cases collected over the past 20 years from various sources and suggested that osteonecrosis of the trochlea is probably one of the most unrecognized sequela of injuries to the distal humerus. Because avascular necrosis of the trochlea is rare, or often unrecognized, the true incidence is unknown. Bronfen reported six cases in 288 displaced supracondylar humerus fractures.[10] McDonnell and Wilson reported four cases in a series of 53 supracondylar humerus fractures.[45] We recently examined 15 cases of osteonecrosis of the trochlea, and during the same time period, greater than 3,500 patients were treated operatively for a supracondylar or humeral condylar fracture at our institution.[25] This gives an incidence of less than 0.5% and does not include fractures treated nonoperatively, although some mild osteonecrosis cases may have been missed.

Etiology

Three theories have been proposed to account for the posttraumatic changes that occur in the distal humerus after fractures in the vicinity of the trochlea: Malunion, partial growth arrest, and vascular injury. The most common form follows some type of elbow trauma. In some cases, the trauma is occult or poorly defined.[7,37,45,48,54,81] It can occur after displaced or minimally displaced supracondylar humerus fractures, lateral condylar fractures, physeal separations, or medial condylar fractures, or may occur iatrogenically from excessive soft tissue stripping during operative exposure.[57,76] Posttraumatic trochlear osteonecrosis results in a spectrum from simply a small defect of the trochlea (fishtail deformity) to complete destruction of the medial aspect of

the distal humerus with a progressive varus deformity, decreased range of motion, and associated instability of the elbow.

Vascular Anatomy

In Haraldsson's classic studies[29,30] of the blood supply of the distal humerus, it was demonstrated that the medial crista of the trochlea had two separate blood supply sources (Fig. 20-23). Neither has anastomoses with each other or with the other metaphyseal vessels. In the young infant, the vessels are small and lie on the surface of the perichondrium.

The lateral vessels supply the apex of the trochlea and the lateral aspect of the medial crista. These vessels cross the physis to enter the posterior aspect of the lateral trochlear ossification center. Their terminal branches lie just under the articular surface. Thus, they are particularly vulnerable to injury when the fracture line occurs through this area, as is typical in fractures of the medial condylar physis, lateral condyle, or a T-condylar fracture. By the same token, a fracture in the supracondylar area in which the fracture line is very distal or a total distal humeral physeal displacement can also disrupt the lateral trochlear epiphyseal vessels as they course along the surface of the metaphysis or at their entrance into the physeal plate.

Another set of vessels enters medially through the nonarticulating surface of the trochlea. This set of vessels supplies the most medial aspect of the medial crista or the medial portion of the trochlear epiphysis. As shown in Haraldsson's studies,[29,30] there appear to be no anastomoses between the two sets of vessels supplying the trochlear epiphysis.

Ossification centers need blood supply for their appearance and development. Before these centers appear, the vessels are more superficial and less well defined. It is speculated that a lesion in these immature vessels in children leads only to a delay in the appearance of the centers. In older children, where there is already a well-defined ossification center, disruption produces a true bony osteonecrosis of one or both of the trochlea's ossification centers. This can result in a partial or total absence of further epiphyseal ossification, leading to either hypoplasia of the central or whole medial aspect of the trochlea respectively.

Patterns of Osteonecrosis

Osteonecrosis of the trochlea can appear as either a central defect (type A) or total hypoplasia manifest by complete absence of the trochlea (type B), depending on the extent of the vascular injury.

Type A—Fishtail Deformity

In the type A deformity, only the lateral portion of the medial crista or apex of the trochlea becomes involved in the necrotic process, which produces the typical fishtail deformity (Fig. 20-24). This more common pattern of necrosis seems to occur with very distal supracondylar fractures or with fractures involving the lateral condylar physis.

Type B—Malignant Varus Deformity

The type B deformity involves osteonecrosis of the entire trochlea and sometimes part of the metaphysis (Fig. 20-25). This type of necrosis has occurred as a sequela of fractures involving the entire distal humeral physis or fractures of the medial condylar physis[78] and can lead to a cubitus varus deformity in which the angulation progresses as the child matures.

Clinical Presentation

Early there are often minimal, if any symptoms. When symptoms are present, they can include pain and loss of motion secondary to joint incongruity and locking, which is related to loose body formation and joint instability.[10,40,54,57,58,76]

The clinical signs and symptoms differ considerably between the two patterns of necrosis. Patients who have the type A or fishtail deformity usually do not develop any angular deformities. The severity of the fishtail deformity is related to the degree of necrosis and seems to dictate the severity of the symptoms. In children who have a pattern of total osteonecrosis of the trochlea, including part of the nonarticular surface, a progressive varus deformity usually develops. Because the total medial trochlear surface is disrupted, significant loss of range of motion also develops. These deformities usually worsen aesthetically and functionally as the child matures. Early degenerative joint disease with a loss of range of motion is the most common sequela in severe cases.

Some children with osteonecrosis of the trochlea develop late-onset ulnar neuropathy,[52,67,74,80] thought to be due to a multiplicity of factors, including joint malalignment, abnormal position of the ulnar nerve and triceps tendon, loss of protection by a deep ulnar groove, and the acute angle of entrance of the two heads of the flexor carpi ulnaris. Rarely, a patient may present with fracture (Fig. 20-26).

Radiographic Evaluation

Radiographically, in our series, loss of motion is associated with subluxation of the radial head.[25] With proximal migration of the ulna, the coronoid impinges anteriorly and olecranon impinges posteriorly, leading to progressive loss of motion.[33] Proximal migration of the ulna, radial head escape, or the combination of both may all lead to loss of motion. Plain radiographs can be used, but advanced imaging including the use of MRI or CT can better characterize the deformity and identify arthrosis and loose bodies.[33,36,40]

Treatment

Descriptions of treatment options in the literature are extremely limited. In addition to observation and nonoperative care, proposed treatment options include debridement, capsulotomy,[45,54] interposition arthroplasty, surgical arrest of the remaining medial or lateral physis,[57] and osteotomy for persistent deformity.[57]

Because the osteonecrosis of the trochlea is a direct consequence of trauma to the vessels at the time of injury, there is no effective prevention or treatment of the primary necrosis. Treatment is aimed at only the sequelae of the osteonecrosis of the trochlea. If a loss of range of motion is due to a significant disruption of the articular surface itself, there does not appear to be any good operative or nonoperative method that significantly improves elbow function. If the osteonecrosis of the trochlea has

FIGURE 20-23 Blood supply of the trochlea. **A:** Intraosseus vasculature in a 3-year-old boy. Only two small vessels supply the medial crista of the trochlea (*arrows*). The central portion of the crista appears avascular. **B:** In the lateral view through the medial crista of the trochlea, note that the vessels penetrate the physis posteriorly (*arrow*) to enter the epiphyseal cartilage. **C:** Close-up view showing the extent of the vascular supply of the trochlea. Note that no anastomoses are seen between these medial and lateral vessels. **D:** Lateral view through the medial crista of the trochlea. Note that the vessels penetrate the physis posteriorly (*arrow*) to enter the epiphyseal cartilage. (A–D: Reprinted from Haraldsson S. On osteochondritis deformans juvenilis capituli humeri including investigation of intraosseous vasculature in distal humerus. *Acta Orthop Scand Suppl.* 1959;38:1–232, with permission.) **E:** Radiograph of a 12-year-old boy. The persistence of the two separate ossification centers (*arrows*) of the media crista is seen. The area supplied by the lateral vessel.

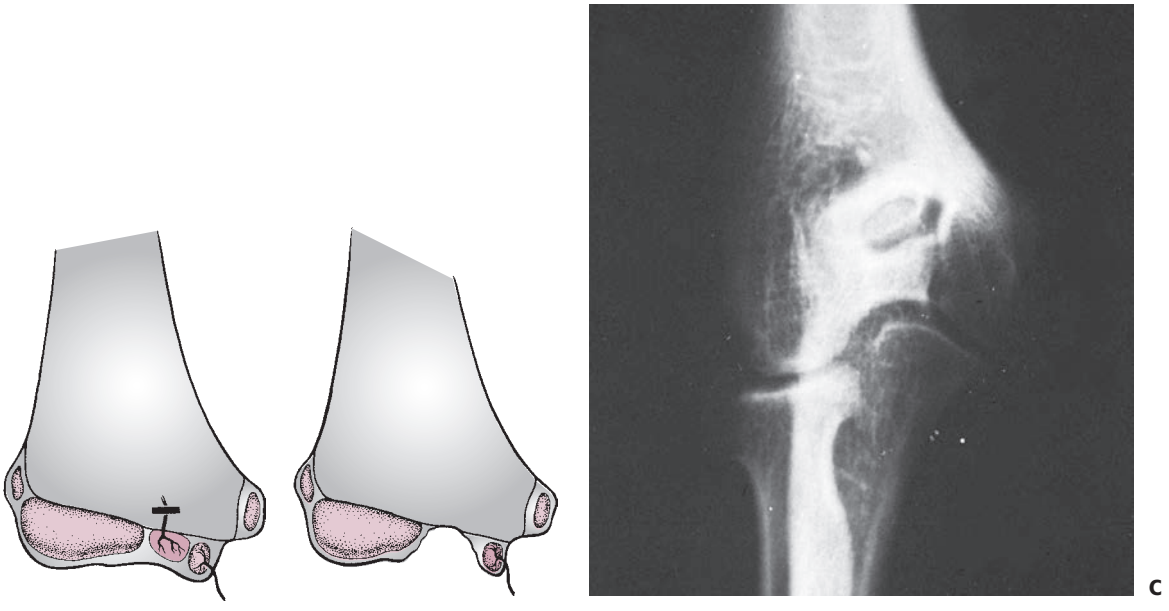

FIGURE 20-24 Fishtail deformity. **A, B:** Type A deformity. Osteonecrosis of only the lateral ossification center creates a defect in the apex of the trochlear groove. **C:** The typical fishtail deformity is seen in a radiograph of a 14-year-old boy who sustained an undisplaced distal supracondylar fracture 5 years previously.

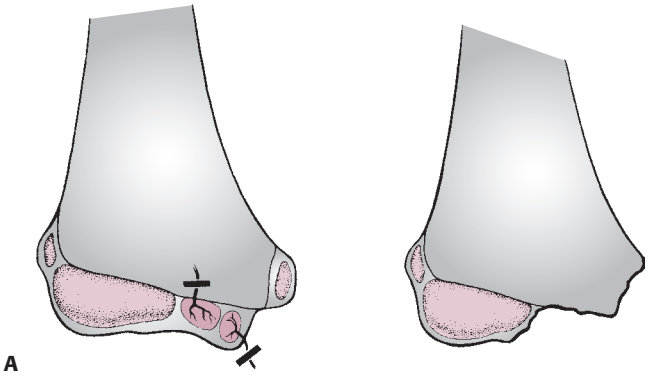

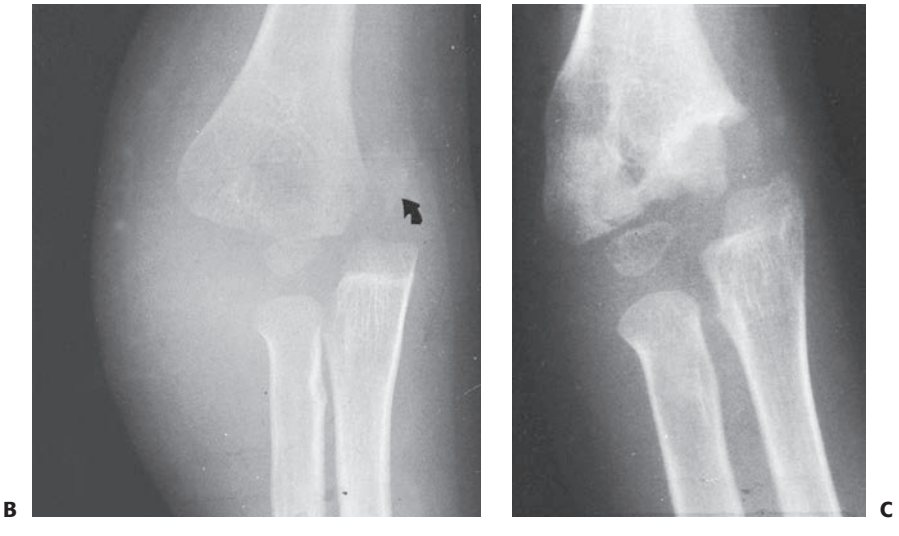

FIGURE 20-25 Osteonecrosis of the entire trochlea. **A:** In this type B deformity, loss of blood supply from both the medial and lateral vessels results in osteonecrosis of the entire medial crista along with a portion of the metaphysis. **B:** Radiograph of a 4-year-old boy who sustained a type II physeal fracture involving the entire distal humeral physis. In this injury film, there is a large metaphyseal fragment on the medial side (*arrow*). **C:** As shown by the appearance 5 months later, a mild varus deformity is present because of an incomplete reduction. The ossification in the medial metaphyseal fragment has disappeared.

FIGURE 20-26 A: Twelve-year-old girl who had supracondylar humerus fracture treated with closed reduction and pinning at age of 5. **B:** She presented after a fall at age of 12 with a medial condyle fracture which was treated with open reduction and internal fixation **(C).**

resulted in a varus deformity of the elbow, this deformity can be corrected by a supracondylar osteotomy with ulnar nerve transposition. The correction of the carrying angle may be aesthetic without functional improvement. Surgical treatment carries the risk of increased stiffness to the already limited elbow.

In our experience, small defects with minimal joint involvement can be observed.[25] In patients with extensive joint involvement, associated with loss of motion, elbow stiffness, or loose bodies, arthroscopic debridement may help transiently improve symptoms including pain and limited range of motion. As one would expect, symptoms commonly recur and long-term outcomes are unknown. Therefore in patients who have limited deformity and mild symptoms, arthroscopic debridement can prove to be useful, particularly if there is limited medial and lateral growth of the distal humerus remaining. It may be the only salvage option for symptomatic patients with significant deformity and subluxation of the radial head.

If there is growth remaining in the medial or lateral physis, physeal closure may be of benefit in some patients. Nwakama et al.[57] has suggested that surgical closure of the lateral and/or medial portions of the physis to prevent the progressive intracondylar notching leads to proximal ulnar migration. Unfortunately there are no studies that have outlined long-term follow-up from epiphysiodesis. However, we believe that this technique is beneficial in patients with open physes, a mild deformity, and a congruent radiocapitellar joint.

21 HUMERAL SHAFT AND PROXIMAL HUMERUS, SHOULDER DISLOCATION

Donald S. Bae

Introduction to Shoulder Dislocation

Historically, glenohumeral joint dislocations in skeletally immature patients were thought to be a rare occurrence.[171,179,256,443] Rowe's classic series of 500 glenohumeral joint dislocations from 1956 contained only eight patients under 10 years of age, though 99 patients were reportedly between 10 and 20 years old.[360] Other published series similarly have documented shoulder instability in adolescents without specific reference to physeal status.[148,276,282,318,356] Prior studies in collegiate athletes have documented the incidence of shoulder instability to be approximately 1 per 10,000 athlete-exposures, and the incidence of dislocations has been reported to be 1.69 per 1,000 person-years in young adult military personnel.[325,326] Although these demographic data cannot be directly extrapolated to the pediatric or adolescent population, they do provide some insight into the expected range of glenohumeral joint instability rates in young, active people.

While the exact incidence of traumatic glenohumeral joint instability in skeletally immature patients remains unknown, there appears to be a rising frequency with which these injuries are occurring in older children and adolescents. Potential etiologies for this trend include increasing participation in higher-demand and higher-energy activities, younger age at first sports participation, and greater awareness among patients, families, and care providers. It is important to remember, however, that ligamentous laxity and shoulder subluxation may be a normal, nonpathologic finding in otherwise asymptomatic children and adolescents.[54] Indeed, there is published information to suggest that physical examination signs of glenohumeral joint instability may be seen in up to 50% of otherwise asymptomatic adolescents.[120]

Assessment of Shoulder Dislocation

Mechanisms of Injury for Shoulder Dislocation

In general, both traumatic and atraumatic glenohumeral joint instability may be seen. In traumatic instability, the predominant direction of humeral head dislocation is anterior. Typically, an anteriorly directed force applied to the abducted and externally rotated shoulder results in anterior dislocation. These injury mechanisms may be seen with sports participation, altercations, motor vehicle collisions, and even simple falls onto an outstretched upper extremity.[35,188,300] The spectrum of injury includes an anterior labral tear (Bankart lesion), glenohumeral joint capsular stretch, compression injury to the posterior humeral head (Hill–Sachs lesion), and/or anterior glenoid rim fracture.

Posterior dislocations are less common, representing 5% or less of all traumatic glenohumeral instability. Typically patients dislocate with the affected shoulder forward flexed, internally rotated, and adducted. More commonly associated with higher-energy injury, posterior instability events may be seen after falls, motor vehicle collisions, seizures, or electroconvulsive therapy. As in adults, the diagnosis of posterior dislocation is often subtle, and a high index of suspicion is needed to avoid untimely or missed diagnosis.[105,110,169,315,432]

Atraumatic shoulder instability is common in children and adolescents. These situations are characterized by initially painless glenohumeral dislocation without antecedent or causative trauma, and may be more commonly seen in patients with systemic ligamentous laxity and multidirectional instability.[60] Often patients will report instability symptoms of other parts of the body, including the patellofemoral, ankle, and hip joints. Associations with connective tissue disorders may be seen, such as Ehlers–Danlos or Marfan syndrome. Atraumatic instability may be voluntary or involuntary, and both are thought to arise from selective firing of shoulder girdle muscles with inhibition of their antagonists (Fig. 21-1). Spontaneous reduction is common, and if sedation or anesthesia is utilized, the glenohumeral joint typically reduces without need for manipulation.[356]

Finally, there are some pediatric patients who sustain glenohumeral joint dislocation due to neuromuscular pathology. In cases of arthrogryposis, brachial plexus birth palsy, stroke, or cerebral palsy, muscle imbalance with or without glenohumeral joint dysplasia can lead to atraumatic dislocations, even in neonates or young children.[13,77,148,152,411,451,458] These situations must be distinguished from neonatal pseudodislocation, in which a traumatic displaced physeal fracture and radiographically unossified proximal humeral epiphysis may give the radiographic appearance of glenohumeral dislocation.

Associated Injuries with Shoulder Dislocations

The axillary nerve is commonly injured in association with shoulder dislocations. Because of its circuitous course around the proximal humerus and inferior to the glenohumeral joint, as well as its relative tethering at the quadrilateral space, the axillary nerve is usually stretched at the time of humeral head dislocation. As these are neuropraxic injuries, spontaneous recovery is typically seen, though recovery may take many months. In the event of complete axillary nerve injuries without spontaneous recovery after the expected period of time, the axillary nerve may be explored, repaired, grafted, or neurotized to provide return of deltoid motor function.[18,37,79,87,118,268] Similarly, injuries to the axillary artery, though rare, have been reported in association with shoulder dislocation.[18,87,301] Prompt fracture reduction with or without arterial reconstitution should be performed in cases of vascular insufficiency and ischemia.

While less common than in adults, concomitant fractures of the proximal humerus (e.g., lesser tuberosity, greater tuberosity) or scapula (e.g., coracoid process, glenoid) may be seen with shoulder dislocation.[76,109,355,436] (Fig. 21-2). Careful inspection of plain radiographs is needed to assess for associated bony injuries. While nondisplaced fractures may be effectively treated nonoperatively, displaced fractures may predispose to recurrent instability.[239]

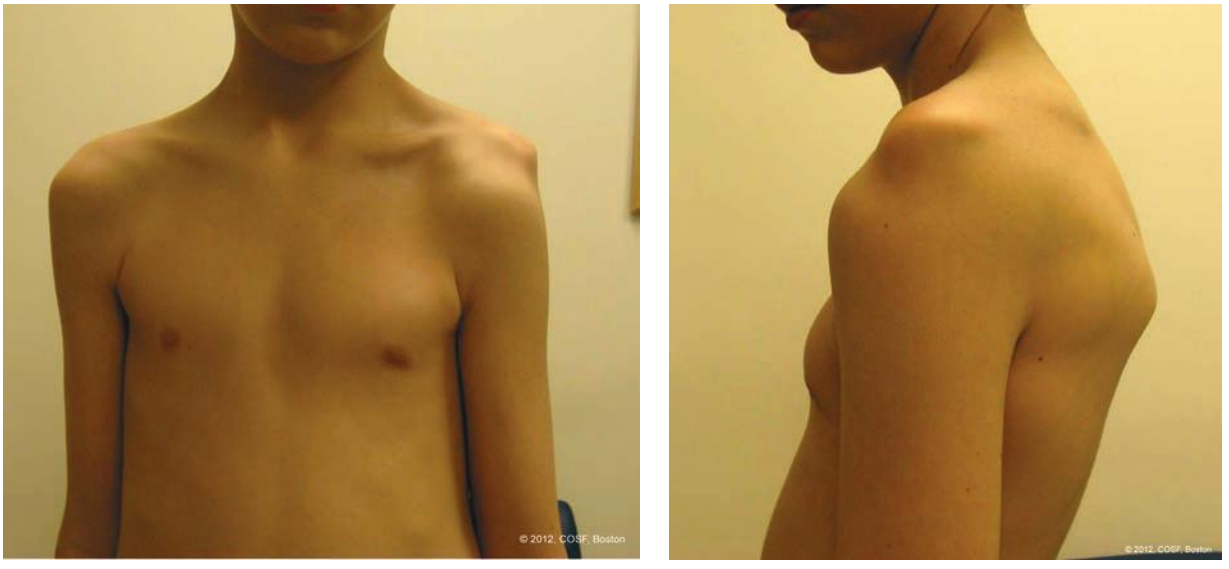

FIGURE 21-1 Clinical photographs of a preadolescent child with atraumatic multidirectional instability. **A:** Anterior view demonstrates obvious anteroinferior position of the humeral head. **B:** View of the lateral aspect depicts inferior humeral head position and the "sulcus" sign.

Signs and Symptoms of Shoulder Dislocations

In cases of traumatic anterior glenohumeral joint dislocations, patients will present with pain, swelling, and limited shoulder motion. Typically the limb is held in slight abduction and external rotation, and often the patient will support the affected extremity with the contralateral hand. Careful inspection will reveal abnormal contour of the shoulder, with a prominent acromion, flattened or concavity to the posterolateral shoulder girdle, and obvious prominence or fullness anteriorly in the area of the dislocated humeral head. Careful and comprehensive physical examination is critical to rule out concomitant neurologic injury. The axillary nerve is most commonly affected; sensation over the lateral aspect of the shoulder and deltoid muscle function is checked to assess axillary nerve function (Fig. 21-3). In cases in which there has been spontaneous reduction after an anterior instability event, the shoulder appears

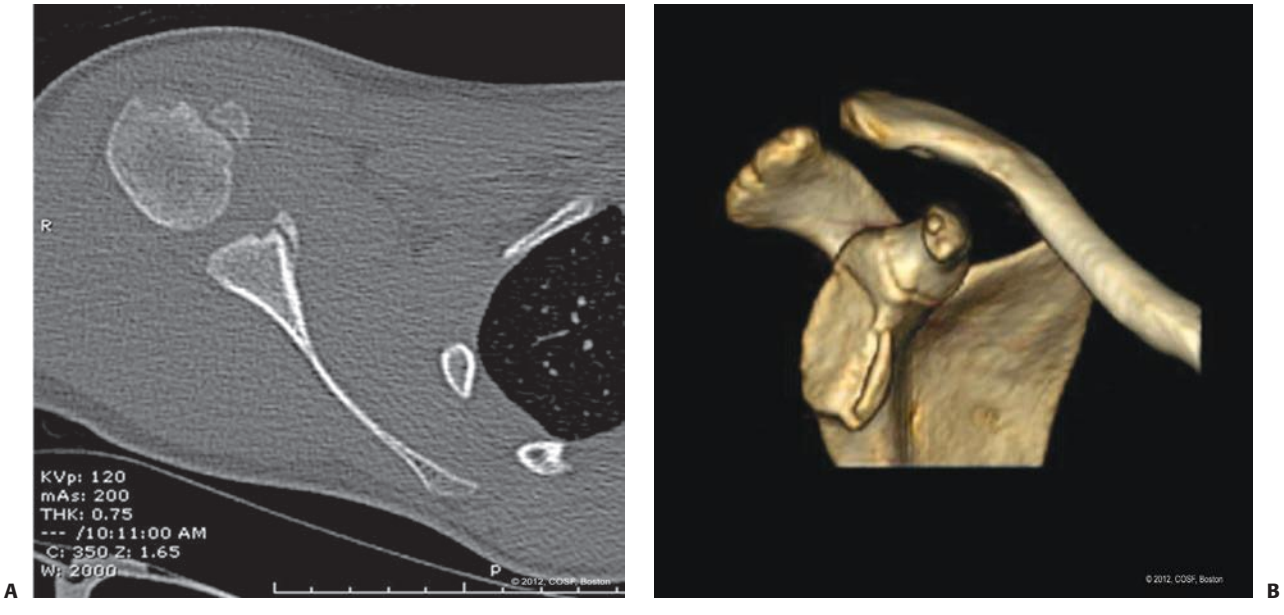

FIGURE 21-2 Computed tomography (CT) images of a 13-year-old male after traumatic anterior shoulder dislocation. Axial images **(A)** and three-dimensional reconstruction with subtraction of the humeral head **(B)** depict an anterior glenoid fracture (bony Bankart lesion).

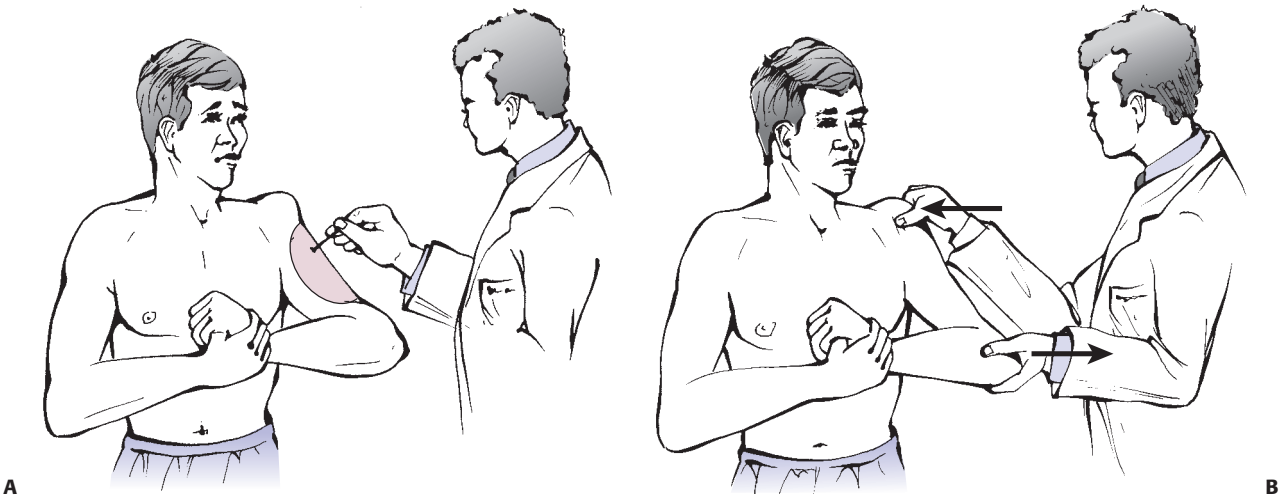

FIGURE 21-3 **A:** Sensory distribution for the axillary nerve important in anterior dislocation. **B:** Deltoid muscle can be tested in acute anterior dislocation by grabbing the muscle belly with the right hand while supporting the elbow with the left. The patient then can actively contract the deltoid by pushing the elbow against the examiner's hand while the examiner feels the muscle contraction.

more normal in contour and glenohumeral motion is typically preserved. Patients will be guarded in active motion especially above the shoulder line, resist extremes of abduction and external rotation, and the apprehension test will be positive.[122,263,368,427]

Conversely, patients with traumatic posterior dislocations will present with a painful adducted and internally rotated shoulder. There is often flattening or concavity to the anterior aspect of the shoulder girdle, with palpable fullness posteriorly. Prominence of the superomedial scapular angle (the so-called Putti sign) is often seen, and patients will resist attempts at passive shoulder motion. Inability to passively externally rotate the shoulder or supinate the forearm should alert the examiner to the possibility of a posterior glenohumeral joint dislocation. Again, a comprehensive examination is performed to evaluate for associated neurovascular deficits.

In neonates and infants, pseudodislocation may similarly present with pain, reluctance to move the affected upper limb, swelling, and asymmetric contour of the shoulder girdle. Occasionally crepitus due to motion at the fracture site may be appreciated with gentle, small arc range of motion.

Children and adolescents with atraumatic and/or multidirectional instability present quite differently. In addition to the lack of causative or antecedent trauma, these patients may not have pain with joint subluxation or dislocation (Fig. 21-1). Even with discomfort, patients will frequently report rapid resolution of pain after reduction. Examination will often elicit diffuse signs of ligamentous laxity, including hyperextension of the elbow, knee, and metacarpophalangeal joints.[307] Abnormally hyperelasticity and striae of the skin may be seen. Focused examination of the shoulder will demonstrate a positive sulcus sign and increased translation with anterior and posterior load-and-shift testing.[419] The sulcus sign refers to a concavity or indentation noted of the skin inferior to the acromion with manual longitudinal traction applied to the adducted arm (Fig. 21-4). Anterior and posterior load-and-shift tests are performed with the examiner standing behind or alongside the patient. While stabilizing the scapula with one hand, the humeral head is grasped and translated anteriorly and/or posteriorly with the examiner's other hand; translation of greater than 5 mm from center is thought to be an indicator of multidirectional instability. Though some patients are truly unstable in all directions, posterior-inferior dislocations are most common. This pattern may be elicited with forward flexion and slight adduction, with joint reduction achieved with abduction. Patients with voluntary instability may demonstrate their condition by contracting the anterior deltoid and internal rotators while inhibiting the antagonistic muscles.

FIGURE 21-4 Dramatic demonstration of inferior subluxation of the glenohumeral joint in a patient with multidirectional instability. The clinical correlate is the sulcus sign.

Imaging and Other Diagnostic Studies for Shoulder Dislocation

Radiographic evaluation should include orthogonal views of the shoulder to assess for direction of dislocation, congruency of subsequent joint reduction, and presence of associated bony injuries. Anteroposterior (AP) and axillary views are preferred (Fig. 21-5). In the acutely injured or anxious, uncomfortable child, alternative views including the transthoracic scapular Y, West Point lateral, or apical oblique projections may be performed.[69,144,156,400] AP views with the shoulder in internal rotation are not routinely required, but may allow for visualization of Hill–Sachs lesions of the humeral head.

In patients with recurrent instability or in whom the extent of injury needs to be assessed after the initial traumatic dislocation, advanced imaging may be performed. Magnetic resonance imaging (MRI) will provide visualization of chondral, labral, capsular, and musculotendinous pathology. The addition of intra-articular contrast improves sensitivity for labral pathology and provides more detailed information regarding capsular patulousness; this is particularly helpful in patients with persistent, functionally limiting multidirectional instability in whom surgical treatment is being considered (Fig. 21-6). While computed tomography (CT) and CT-arthrography are less helpful for soft tissue evaluation, they do provide the best modality to identify and quantify bony defects in the glenoid and humeral head.[75,101,227] (Fig. 21-7). In children and adolescents in whom a large portion of the glenoid is incompletely ossified, careful inspection of the glenoid contour is needed to avoid missing bony lesions. Loss of the normal sclerotic margin of the glenoid has been proposed as a sign of bony defects of the anterior glenoid rim.[210]

Radiographic evaluation of patients with atraumatic multidirectional instability is similar, though a few points deserve mention. Though plain radiographs are typically normal, patients with congenital glenoid hypoplasia will have subtle rounding or convexity to the glenoid fossa, with or without scapular neck dysplasia.[77,85,88,334] As cited above, MRI-arthrography is a useful tool in assessing the capsular laxity and presence of pathologic lesions of the labrum in these patients.

TABLE 21-1 Classification of Shoulder Instability

	Mechanism	Direction	Chronicity	Associated Conditions
Classification	Traumatic Atraumatic	Anterior Posterior Inferior Multidirectional	Acute Recurrent Chronic	None Neuromuscular Connective tissue

Classification of Shoulder Dislocations

In general, shoulder dislocations in children and adolescents are described according to the association with trauma, direction of instability, chronicity, and presence of underlying local or systemic disorders (Table 21-1). Characterizing shoulder dislocations according to these categories is important and influences treatment decision making.[11]

As noted in Table 21-1, shoulder dislocations may be traumatic or atraumatic in etiology. Direction of humeral instability may be anterior, posterior, inferior (luxatio erecta), or multidirectional. As in adults, perhaps 90% of traumatic dislocations in children and adults is anterior, with posterior dislocations occurring much less commonly and luxatio erecta described in case reports.[44,130,132,179,246,283,286,356] Furthermore, pathologic instability may include both subluxation or true dislocation. Dislocation refers to situations in which the humeral head moves completely out of the glenoid fossa, with no articular contact and often with locking of the humeral head on the anterior or medial rim of the glenoid. Subluxation is defined as an incomplete dislocation characterized by pain, a feel of "looseness" or "slipping," and/or a "dead" feeling to the affected limb. Even traumatic subluxations have been associated with structural injury to the glenoid labrum and Hill–Sachs lesions of the humeral head.[327] These conditions must be distinguished from ligamentous laxity, which is typically asymptomatic.

Chronicity is generally classified as being acute, recurrent, or chronic. While a single episode of dislocation denotes acute instability, recurrent instability refers to multiple episodes. Chronic instability refers to unrecognized or untreated shoulder dislocations in which the humeral head is not reduced, and may be seen with congenital or neuromuscular conditions in children.

The presence or absence of associated systemic conditions—including collagen disorders such as Ehlers–Danlos syndrome, or congenital/neuromuscular syndromes such as cerebral palsy—is also a key consideration in diagnosis and management.

Pathoanatomy and Applied Anatomy Relating to Shoulder Dislocation

The anatomic development, structure, and growth of the proximal humerus are described in the section on proximal humerus fracture. The glenoid is a shallow, concave fossa with which the humeral head articulates. The radius of curvature of the humeral head is approximately three times that of the glenoid. As the glenohumeral articulation lacks substantial bony constraint, the shoulder is afforded near global range of motion, facilitating placement of the hand in space and upper limb function.

Given the relatively unconstrained bony architecture, the glenohumeral joint relies primarily on soft tissue capsuloligamentous structures for stability. The cartilaginous labrum runs along the rim of the glenoid, deepening the concavity and conferring stability. The glenohumeral ligaments are confluent with the labrum and are thickenings of the joint capsule. The inferior glenohumeral ligament has both anterior and posterior components. The anteroinferior glenohumeral ligament is taught and biomechanically contributes most stability in shoulder abduction and external rotation. Disruptions of the anteroinferior glenohumeral ligament or anteroinferior labrum (Bankart lesion) are most commonly seen with anterior traumatic instability (Fig. 21-8). Furthermore, traumatic instability may also cause elevation of the anterior labrum with the periosteum of the anterior glenoid neck, resulting in the so-called anterior labroligamentous periosteal sleeve avulsion

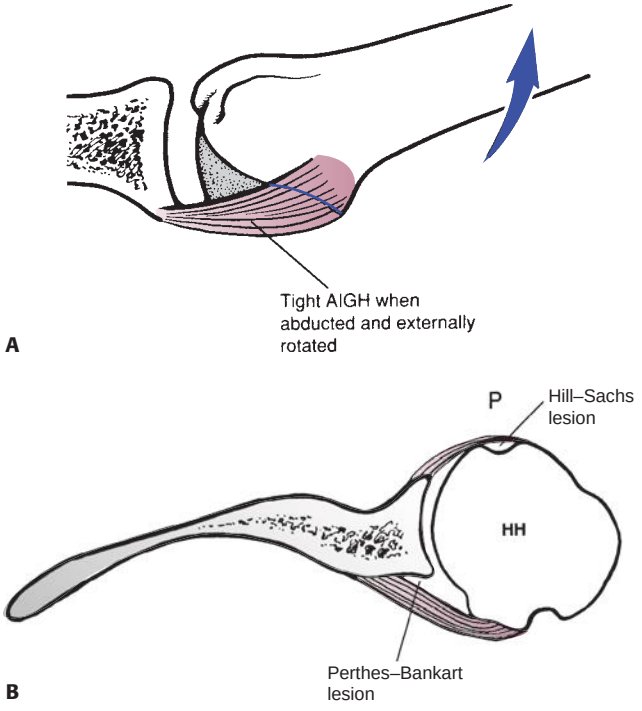

FIGURE 21-8 A: The tight anteroinferior glenohumeral ligament complex with the arm abducted and externally rotated. This ligament sling is the primary restraint against anterior instability of the shoulder. **B:** A cross section in the transverse plane through the glenohumeral joint demonstrates the common lesions associated with anterior instability of the shoulder: Hill–Sachs lesion, Perthes–Bankart lesion, and redundant anteroinferior glenohumeral ligaments. (HH, humeral head; P, posterior.)

(ALPSA).[309] The middle glenohumeral ligament is primarily responsible for stability in midabduction and external rotation, whereas the superior glenohumeral ligament resists inferior translation of the humeral head.

On the humeral side, the joint capsule inserts along the anatomic neck of the humerus, except for medially where the insertion lies more inferiorly along the proximal humeral metaphysis. Thus the proximal humeral physis is predominantly extracapsular, with exception of the very medial extent. Shoulder dislocation may result in detachment of the capsule from its humeral insertion, resulting in the so-called humeral avulsion of the glenohumeral ligament (HAGL) lesions.[463] Failure of recognition and repair of these HAGL lesions is a common cause of recurrent instability after surgical treatment.[341]

The glenohumeral joint is surrounded by the rotator cuff muscles, comprising the supraspinatus, infraspinatus, teres minor, and subscapularis. While rotator cuff tears are uncommon in children, these musculotendinous units form a force couple with the larger surrounding shoulder girdle muscles (deltoid, pectoralis major, teres major, and latissimus dorsi) and serve as important dynamic secondary stabilizers of the shoulder. The dynamic stabilizing effects of the rotator cuff muscles are largely the focus of nonoperative rehabilitative programs for young patients with glenohumeral instability.[52]

Treatment Options for Shoulder Dislocations

Nonoperative Treatment of Shoulder Dislocations

Indications/Contraindications

Treatment options continue to evolve for shoulder instability in children and adolescents, though remain based upon the classification system and considerations described above. Nonoperative treatment is typically recommended for acute traumatic dislocations as well as atraumatic multidirectional instability.

Closed reduction is performed for acute traumatic dislocations, and a host of reduction maneuvers have been described. Adequate analgesia and relaxation facilitates closed reduction, and both conscious sedation and intra-articular anesthetic injection have been advocated. Multiple reports have suggested that intra-articular lidocaine injection is as safe and effective as intravenous sedation, with less cost and shorter length of stays.[73,281,295,299,444] The method of traction–countertraction is advocated by many (Fig. 21-9). In this method, a bedsheet is looped around the axilla of the affected shoulder and passed superiorly and laterally to the contralateral shoulder. Longitudinal traction is applied to the affected upper extremity in line with the deformity, with countertraction provided by pull of the bedsheet. Steady, continuous traction will ultimately overcome the spasm of the shoulder girdle muscles, and the humeral head may be disimpacted and reduced. Others advocate modifications of the Milch maneuver.[96,292,293,317,399] In this technique, the patient is positioned supine and the affected limb supported. Gradual abduction and external rotation is used to achieve glenohumeral reduction. As this technique does not employ traction to overcome muscle spasm, it may be successfully performed without sedation.[237,366] Still others utilize the Stimson technique of reduction (Fig. 21-10).[413] With the patient in prone position and the affected limb hanging free over the edge of the stretcher, longitudinal traction is applied to the extremity by means of a weight attached to the wrist. As the spasm of the shoulder girdle muscles fatigues and is overcome, reduction is achieved spontaneously and relatively atraumatically. Additional scapular mobilization may assist with reduction using the Stimson technique [231,285]

Posterior dislocations may be similarly reduced with traction–countertraction maneuvers. Furthermore, the addition of a laterally directed force on the proximal humeral diaphysis may assist in achieving reduction.[297] In the rare inferior dislocations

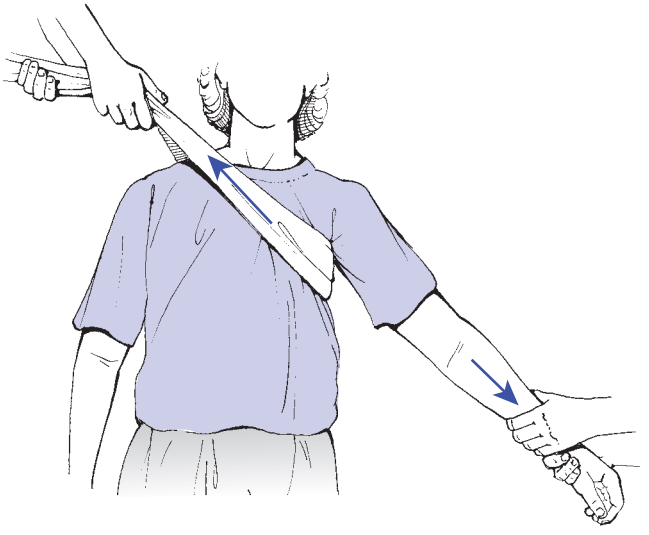

FIGURE 21-9 Techniques for closed shoulder reduction. A modification of the Hippocratic method uses a handheld sheet around the thorax to provide countertraction.

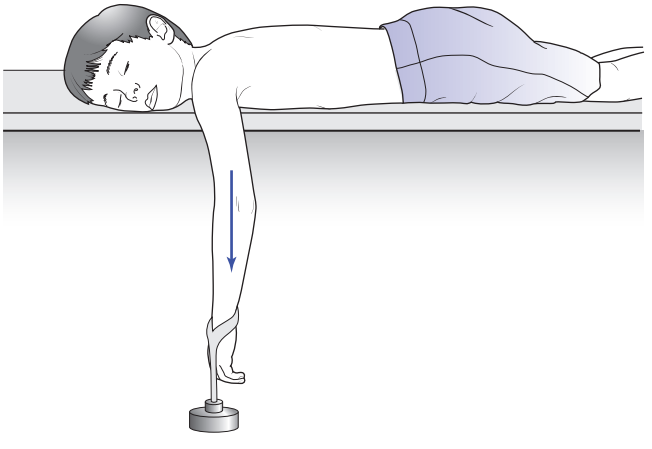

FIGURE 21-10 The Stimson technique for closed shoulder reduction. With the patient in prone position, weight is hung from the wrist to distract the shoulder joint. Eventually, with sufficient fatigue in the shoulder musculature, the joint can be easily reduced.

(or luxatio erecta), a two-step closed reduction maneuver has been advocated.[310] An anterior-directed force is applied to the humeral shaft, converting the inferior dislocation to an anterior one. Subsequent external rotation will then achieve glenohumeral reduction. Closed reduction is the definitive management of luxatio erecta in the majority of cases.[329]

Outcomes

Following closed reduction, patients are typically immobilized with a sling for comfort. There is no evidence that longer duration of sling immobilization with the shoulder in internal rotation reduces the risk of recurrent instability.[330] Recent work, however, has raised the question of whether immobilization with the shoulder in adduction and external rotation is preferred. Anatomically, 30 degrees or more of external rotation of the shoulder may tension the anterior soft tissues and "reduce" the torn anterior capsulolabral structures to a more anatomic position on the glenoid.[206,294] Dynamic MRI have demonstrated improved position of the displaced labrum with external rotation.[207,378,384,398] Subsequent clinical studies have demonstrated up to a 40% reduction in recurrent instability rates when external rotation bracing was utilized for 4 or more weeks.[204,205,418] These findings have not been universally reproducible; however, other investigators have failed to demonstrate reduction in recurrent instability with external rotation immobilization.[126,255,259,330,417] Regardless of the type or time of immobilization after reduction of acute dislocation, physical therapy is typically recommended to improve the dynamic stability conferred by the rotator cuff and adjacent shoulder girdle muscles.[52]

Despite successful closed reduction and subsequent rehabilitation, there is a high risk of recurrent instability, particularly in young, active patients.[284] The available literature, however, is limited in quantifying the true recurrent dislocation rates in children and adolescents. Much of the previously published information consists of retrospective case series of both adult and pediatric patients with limited follow-up.

Rowe[361] previously reported recurrent anterior instability in 100% of children less than 10 years of age and 94% of patients between 11 and 20 years. Marans et al.[276] similarly reported universal recurrent instability in their series of 21 children following traumatic dislocations. Wagner and Lyne[443] reported an 80% recurrence in 10 patients with open physes. In a series of nine patients who sustained traumatic instability at a mean age of 12.3 years, Elbaum et al.[118] similarly reported recurrent instability in 71%. In their review of 154 traumatic dislocations, Vermeiren et al.[435] found a 68% recurrence rate in patients less than 20 years of age. Higher rates of recurrent instability have been reported in higher-energy injuries as well as those associated with bony glenoid injuries.[291,349,354] Younger patients involved in overhead or contact sports have similarly been noted to have higher recurrent instability rates.[367]

Other reports, however, cite lower recurrence rates in younger patients. Rockwood[356] documented a 50% recurrence rate in patients between 13.8 and 15.8 years of age. Cordischi et al.[83] published their study of 14 patients between 10.9 and 13.1 years of age and reported that only three patients (21%) went on to surgical treatment for recurrent instability. In perhaps the largest study with the longest follow-up, Hovelius et al.[189] reported 25-year follow-up on 229 shoulder in 227 patients who sustained their first traumatic dislocation between 12 and 40 years of age. Of the 58 patients who sustained their primary dislocation between 12 and 19 years of age, 26% reported a single recurrence, and an additional 16% of shoulders stabilized over time (defined as no instability events in the last 10 years). Only 43% of patients underwent surgical stabilization procedures. Additional case reports and small case series exist of young patients without recurrent instability at midterm follow-up (Table 21-2).[121,171]

TABLE 21-2 Classification of Non-Operative Treatment for Shoulder Instability

Nonoperative Treatment	
Indications	**Relative Contraindications**
Primary dislocation in patients willing to undergo physical therapy and accept risks of recurrent instability	Large bony glenoid fracture
Multidirectional instability in setting of ligamentous laxity	

Operative Treatment of Shoulder Dislocations: Arthroscopic Bankart Repair

Indications/Contraindications

Surgical treatment is considered in patients with functionally limiting recurrent instability as well as in high-demand, overhead or contact athletes in whom the risk of recurrent instability after their primary event is unacceptably high. In general, patients considered for surgery should have failed attempts at physical therapy and rehabilitation. In patients with traumatic anterior shoulder dislocations, recurrent instability is due to injury to the anterior-inferior labrum and adjacent glenohumeral joint capsule and ligaments. Surgical treatment is focused on repairing the torn labrum to its anatomic location on the glenoid rim.

Surgical Procedure

Preoperative Planning. Presently, arthroscopic labral repair is the standard treatment for posttraumatic shoulder instability. Preoperative imaging should include plain radiographs of the affected shoulder to rule out associated bony lesions (e.g., glenoid fractures, Hill–Sachs lesions). MRI, with or without intra-articular contrast, is also helpful in determining the extent of labral injury and assessing for concomitant soft tissue injuries. Typical equipment required includes a standard 4-mm 30-degree arthroscope, arthroscopic cannulae, and surgical instruments used to mobilize and prepare the capsulolabral tissue (e.g., arthroscopic shavers, elevators, rasps, and suture passing devices). While a host of commercially available instruments are available, all provide the same fundamental arthroscopic capabilities. Suture anchors are also invaluable for arthroscopic labral repairs, and increasing the standard is to use bioabsorbable suture anchors for intra-articular procedures (Table 21-3).

TABLE 21-3 Bankart Repair for Shoulder Instability

Preoperative Planning Checklist

- OR Table: Standard table
- Position/positioning aids: Bean bag and distraction apparatus for lateral decubitus positioning; bean bag and arm holder for beach chair positioning
- Fluoroscopy location: N/A
- Equipment: 4-mm 30-degree arthroscope, arthroscopic cannulae, arthroscopic shaver, arthroscopic instruments to prepare tissue and pass sutures, bioabsorbable suture anchors, shoulder immobilizer
- Tourniquet (sterile/nonsterile): N/A

Positioning. In general arthroscopic stabilization may be performed in either the beach chair or lateral decubitus position (Fig. 21-11). Advantages of lateral decubitus position include ease of longitudinal and lateral distraction to assist in visualization and access to the axillary recess of the glenohumeral joint. Patients are placed with the unaffected shoulder down, allowing the thorax to fall posteriorly about 10 degrees, which will place the glenoid parallel to the ground. Care is taken to place an axillary roll and pad all bony prominences (e.g., contralateral fibular head) to avoid excessive or prolonged compression of the peripheral nerves. The entire affected limb and shoulder girdle are prepped and draped into the surgical field. The limb is placed in balanced suspension with about 40 degrees of abduction and 10 to 20 degrees of forward flexion, typically with 7 to

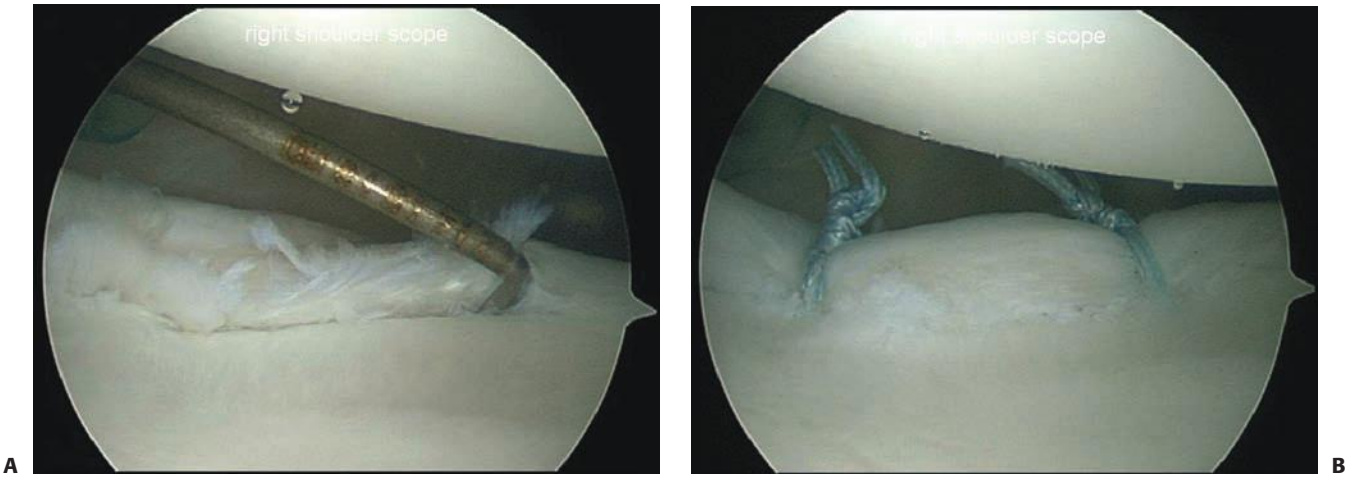

FIGURE 21-12 Arthroscopic Bankart repair. **A:** Arthroscopic image of an anterior labral tear in the right shoulder of a 16-year-old male. The patient is positioned in the lateral decubitus position. **B:** Arthroscopic appearance after anterior labral repair, demonstrating reapproximation of the labral tissue to the glenoid rim.

10 lb of longitudinal and lateral distraction with the assistance of a limb holder. This allows for circumferential access to the shoulder girdle. Furthermore, additional abduction–adduction and internal–external rotation may be employed during surgery for selective access and tensioning of soft tissues.

The modified beach chair position is also effective and commonly utilized. After placement of a roll or bump behind the patient between the scapulae, patients may be positioned with the affected limb and shoulder girdle off the edge of the table to allow circumferential access. The use of commercially available beach chairs, limb holders, and/or bean bags will assist with positioning.

Surgical Approach(es). The procedure begins with examination under anesthesia to assess pathologic instability anteriorly, posteriorly, and inferiorly. After glenohumeral joint is insufflated with sterile saline solution, a standard posterosuperior, anterosuperior, and anteroinferior arthroscopy portals are established. Viewing is traditionally performed from the posterosuperior portal, but moving the camera to the anterosuperior portal will allow for improved visualization of the anterior glenoid neck and anterior soft tissues, particularly in cases of long-standing instability where the labral and capsule have scarred in a more medial position.

Technique. Arthroscopic survey is performed to assess the extent of labral, capsular, and/or bony injury (Fig. 21-12). After confirmation of labral pathology, the capsulolabral complex is mobilized from its typical medial position using arthroscopic elevators. The glenoid rim and medial glenoid neck in the region of the labral tear is similarly prepared with arthroscopic rasps or shavers in efforts to debride fibrinous tissue and prepare a bleeding bony bed for biologic healing. In a sequential fashion, arthroscopic suture anchors are placed from inferior to superior and sutures are shuttled through the capsulolabral complex.[346,385,431] Knots are tied in a sequential fashion, reapproximating the labrum to its anatomic location and retensioning the soft tissues. While a host of commercially available devices and techniques may be utilized, all conform to the standard principles of soft tissue mobilization, glenoid preparation, and repair of the soft tissue to the glenoid rim, thus tensioning the anteroinferior capsule (Table 21-4).

Operative Treatment of Shoulder Dislocations: Latarjet Reconstruction

Indications/Contraindications

In patients with traumatic anterior shoulder dislocations, recurrent instability may also be due to bony fracture or bony insufficiency of the anteroinferior glenoid.[291,354] In these cases, soft tissue procedures alone may not address the underlying pathoanatomy and are prone to failure. Surgical treatment in these situations typically involves restoring or augmenting the

TABLE 21-4 Bankart Repair for Shoulder Instability

Surgical Steps

- Examination under anesthesia
- Establish arthroscopic portals
- Arthroscopic survey
- Mobilization of torn labrum and associated capsule
- Preparation of glenoid rim and glenoid neck
- Suture anchor placement in most inferior position of labral tear, just onto the chondral face of the glenoid
  - Shuttle sutures through the adjacent capsulolabral tissue, effectuating an inferior-to-superior and medial-to-lateral shift
- Tie arthroscopic knot
- Repeat anchor placement, suture passage, and knot tying sequentially in more superior positions along the glenoid
- Minimum of three anchors are utilized
- Skin closure of portals with simple sutures
- Application of sling-and-swathe

bony deficit of the glenoid. While several techniques have been advocated, transferring the coracoid process with its soft tissue attachments to the glenoid (the so-called Latarjet procedure) has increasingly become the standard of care.[331,336] Bony reconstructions such as the Latarjet procedure have also been advocated in patients with recurrent instability after prior failed soft tissue reconstruction.

In addition to providing additional bony support for the articulating humeral head, the Latarjet procedure also stabilizes the glenohumeral joint by virtue of the fact that the conjoined tendon remains attached to the tip of the coracoid during transfer. These soft tissues act as a "sling" and provide additional anteroinferior stability. Stability is further conferred by preservation of the musculotendinous fibers of the subscapularis. This "triple effect" has been touted by Patte and Debeyre.[99,331,445]

Surgical Procedure

Preoperative Planning. Though MRI is helpful in identifying and qualitatively assessing the extent of labral injury, Latarjet reconstructions are typically reserved for recurrent posttraumatic instability with associated glenoid loss; or, in those patients who have failed prior soft tissue stabilizations. In these situations, assessment of glenoid bone loss and possible engaging Hill–Sachs lesions is best done with CT with three-dimensional reconstructions (Fig. 21-7).

Most Latarjet reconstructions are performed via open deltopectoral approaches. Aside from the standard instruments and retractors used for open shoulder surgery, a few additional items are useful. A 90-degree oscillating saw blade will facilitate accurate and efficient coracoid osteotomy. Appropriate-sized cannulated screws—typically 4 mm in diameter and 34 to 40 mm in length—are used for fixation of the coracoid process to the anterior glenoid (Table 21-5).

Positioning. The modified beach chair position is effective and commonly utilized. A roll or bump is placed behind the patient between the scapulae, to allow for scapular positioning and improved access to the glenoid neck. Patients are positioned with the affected limb and shoulder girdle off the edge of the table to allow circumferential access. The use of commercially available beach chairs, limb holders, and/or bean bags assist with positioning.

Surgical Approach(es). A standard deltopectoral approach is utilized. The incision is placed slightly more medial and superior than traditional deltopectoral approaches to the shoulder, because of the need to expose the coracoid and medial glenoid neck. A vertical incision in Langer skin lines will maximize the aesthetics of the resultant scar. Superficial dissection will allow visualization of the deltopectoral interval, which is developed taking the cephalic vein laterally with the deltoid. Deep dissection will allow visualization of the coracoid process, conjoined tendon, clavipectoral fascia, and subscapularis muscles.

Technique. After initial dissection is performed, a spike Hohmann retractor is placed superiorly over the coracoid process, with its tip just anterior to the origin of the coracoclavicular (CC) ligaments. The shoulder is abducted and externally rotated, placing the coracoacromial (CA) ligament under tension. The CA ligament is then divided approximately 1 to 2 cm from the coracoid, leaving a cuff of tissue which will be used later for capsular reconstruction. The shoulder is then adducted and internally rotated. The pectoralis minor insertion is then released off the coracoid process, being careful to protect the brachial plexus which lies deep to the pectoralis minor. Following this, the coracoid is osteotomized at its flexure, or "knee," from medial to lateral. The use of commercially available 90-degree microsagittal saws will facilitate coracoid osteotomy. The coracoid is then freed from the remaining surrounding soft tissue attachments, including the deep coracohumeral ligament, and mobilized while protecting the origin of the conjoined tendon. The undersurface of the coracoid is decorticated to expose bleeding cancellous bone. Two drill holes (typically 3.5 to 4 mm) are made in the coracoid to facilitate subsequent screw placement. Overzealous mobilization or retraction of the freed coracoid process is avoided, as the musculocutaneous nerve enters the coracobrachialis approximately 4 to 5 cm distal.

Direction is then turned to glenoid preparation. With the shoulder in adduction and external rotation, the subscapularis is split in line with its muscle fibers between the superior two-thirds and inferior one-third. This muscle splitting technique preserves subscapularis integrity, contributing stability and minimizing iatrogenic injury to the axillary nerve. The plane between the subscapularis and underlying capsule is developed bluntly, and the glenohumeral joint line is identified. With the shoulder in neutral rotation, a vertical capsulotomy is made in the glenohumeral joint; this may be extended with a medial horizontal incision (in the shape of a sideways "T") for improved exposure of the anterior-inferior glenoid. With the shoulder internally rotated, a Fukuda or humeral head retractor is then placed into the glenohumeral joint. Exposure of the anterior-inferior glenoid neck is then performed via subperiosteal elevation or debridement of the scar tissue and prior bony Bankart fragments. The recipient bed on the glenoid is then decorticated until punctate bleeding is seen.

The coracoid process is then passed through the subscapularis split and its previously decorticated deep surface is approximated to the anterior-inferior glenoid neck. Care is made to position the coracoid bone block precisely; lateral overhang may result in joint incongruity and subsequent degenerative arthrosis or pain. After the coracoid is positioned, the previously placed

Preoperative Planning Checklist

- OR Table: Standard table
- Position/positioning aids: Modified beach chair position
- Fluoroscopy location: N/A
- Equipment: 90-degree oscillating saw, 3.5- or 4-mm cannulated screws
- Tourniquet (sterile/nonsterile): N/A

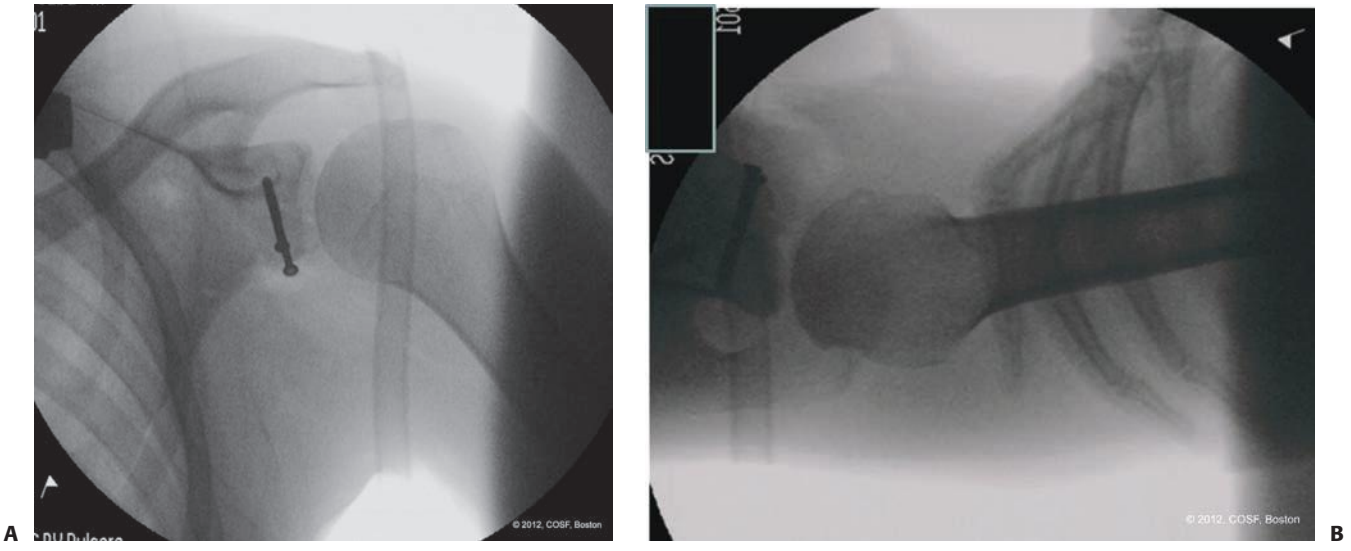

FIGURE 21-13 Intraoperative fluoroscopy images of the left shoulder following Latarjet reconstruction. **A:** Anteroposterior and **(B)** axillary projections depict screw fixation of the coracoid process, with care made not to lateralize the bone block.

drill holes are identified. Through these holes, the glenoid neck is drilled anterior to posteriorly in the path of anticipated screw passage. Measurements are taken, and screw fixation of the coracoid process to the glenoid is achieved with 3.5- or 4-mm screws (Fig. 21-13). Screws are typically 34 to 36 mm in older adolescents, though the size will vary according from patient to patient. The lateral portion of the glenohumeral capsule is then reapproximated to the cuff of prior CA ligament still attached to the coracoid, completing a capsular reconstruction. Wound closure is performed in layers including pectoralis major repair, though the subscapularis split need not be closed. Patients are placed in a sling and swathe postoperatively (Table 21-6).

TABLE 21-6 Latarjet Reconstruction for Shoulder Instability

Surgical Steps

- Deltopectoral approach
- Expose coracoid process
- Release CA ligament with shoulder in abduction, external rotation
- Release pectoralis minor with shoulder in adduction, internal rotation
  - Protect neurovascular structures deep to the pectoralis minor
- Osteotomize coracoid process
- Prepare undersurface of coracoid bone block and predrill holes
  - Avoid excessive retraction of coracoid to protect musculocutaneous nerve
- Split subscapularis at superior $^{2}/_{3}$–inferior $^{1}/_{3}$ interval
- Make glenohumeral joint arthrotomy
- Expose and prepare anterior-inferior glenoid neck
- Approximate coracoid bone block to prepared glenoid neck
- Avoid lateral overhang
- Screw fixation of bone block
- Wound closure in layers

Operative Treatment of Shoulder Dislocations: Arthroscopic Capsulorrhaphy

Indications/Contraindications

In patients with multidirectional instability which is painful and/or functionally limiting and has failed nonoperative treatment, arthroscopic capsulorrhaphy may be considered. As cited above, careful patient selection and preoperative counseling is critical, given the risk of recurrent instability and importance of postoperative therapy. Relative contraindications include patients with poorly controlled neuromuscular conditions, or those with cognitive or developmental delays limiting understanding and compliance with postoperative care.

Surgical Procedure

Preoperative Planning. Preoperative planning and equipment is similar to arthroscopic Bankart repair, as described above. MRI-arthrography is particularly useful, as it may demonstrate areas of capsular redundancy and guide selective capsulorrhaphy (Table 21-7).

TABLE 21-7 Arthroscopic Capsulorrhaphy for Shoulder Instability

Preoperative Planning Checklist

- OR Table: Standard table
- Position/positioning aids: Bean bag and distraction apparatus for lateral decubitus positioning; bean bag and arm holder for beach chair positioning
- Fluoroscopy location: N/A
- Equipment: 4-mm 30-degree arthroscope, arthroscopic cannulae, arthroscopic shaver, arthroscopic instruments to prepare tissue and pass sutures, bioabsorbable suture anchors, shoulder immobilizer
- Tourniquet (sterile/nonsterile): N/A

Positioning. Arthroscopic capsulorrhaphy may be performed either in the lateral decubitus or modified beach chair positions. Given the need for circumferential access around the glenoid and glenohumeral joint, the addition of laterally directed distraction is useful. This may be facilitated with the use of lateral traction, commercially available arm holders, or placement of a bump beneath the axilla.

Surgical Approach(es). Similar to arthroscopic Bankart repairs, the procedure begins with examination under anesthesia to assess pathologic instability anteriorly, posteriorly, and inferiorly. After glenohumeral joint is insufflated with sterile saline solution, standard posterosuperior, anterosuperior, and anteroinferior arthroscopy portals are established. Viewing is traditionally performed from the posterosuperior portal, but moving the camera to the anterosuperior portal and establishing a posterior working portal will allow for improved visualization and circumferential access to the glenohumeral joint capsule.

Technique. Arthroscopic survey is performed to assess the extent of capsular patulousness and rule out unrecognized labral and/or bony pathology (Fig. 21-14). As plication of the posterior capsule is typically more challenging, direction is first turned to the posterior aspect of the shoulder. The arthroscope is placed in the anterosuperior portal and a working portal established

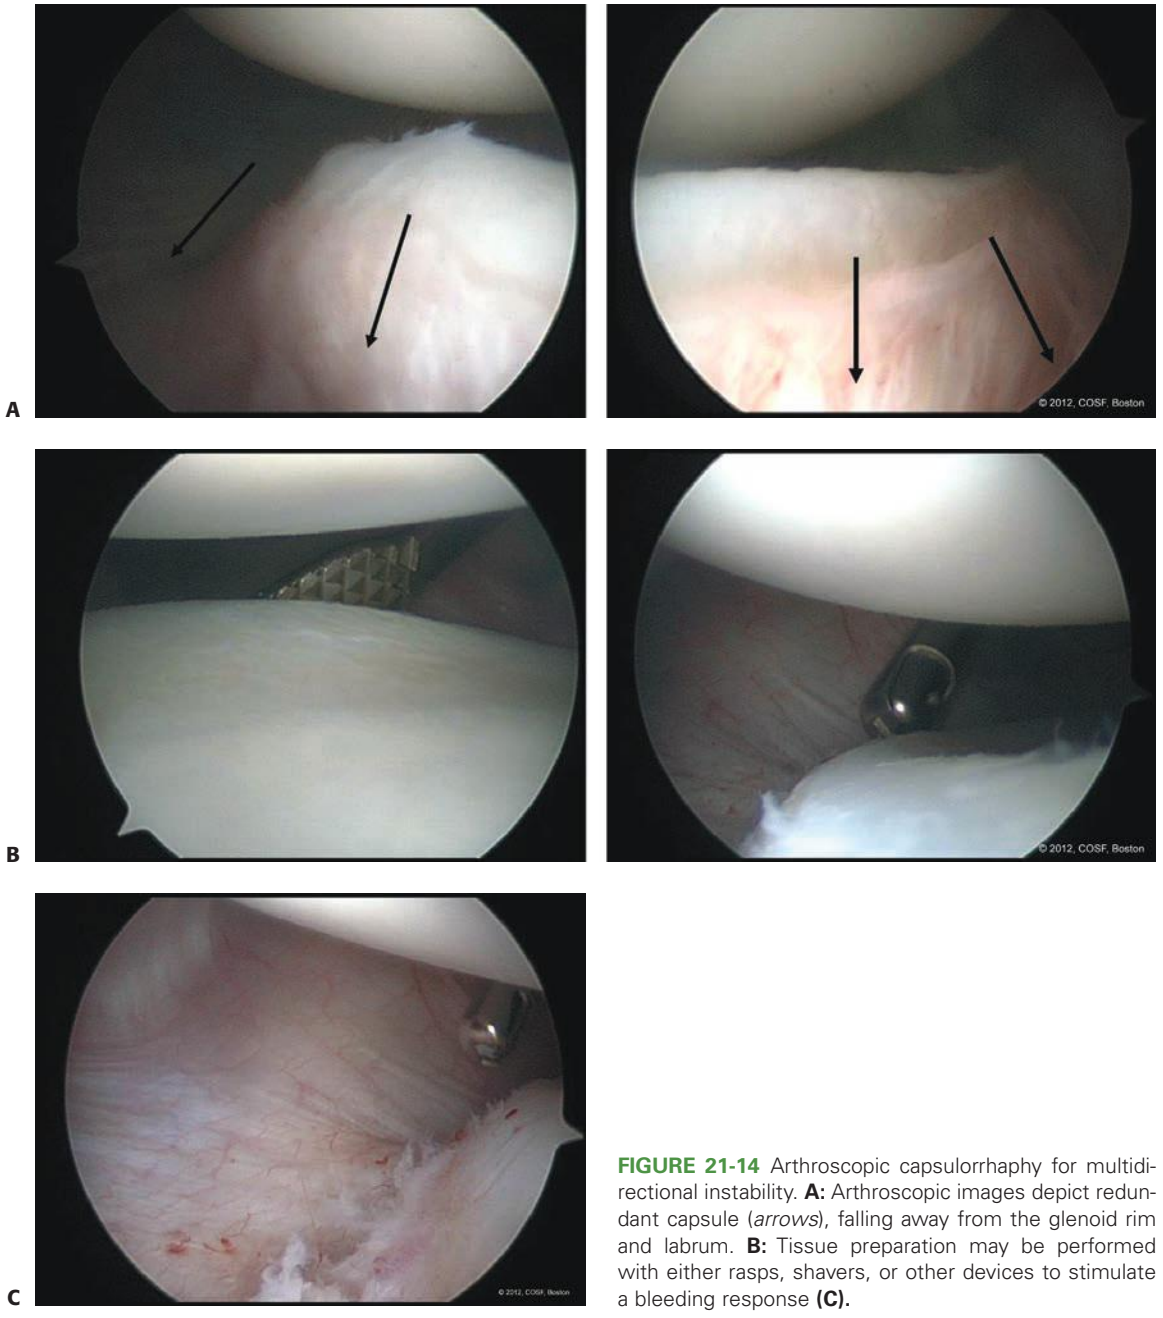

FIGURE 21-14 Arthroscopic capsulorrhaphy for multidirectional instability. **A:** Arthroscopic images depict redundant capsule (*arrows*), falling away from the glenoid rim and labrum. **B:** Tissue preparation may be performed with either rasps, shavers, or other devices to stimulate a bleeding response **(C).**

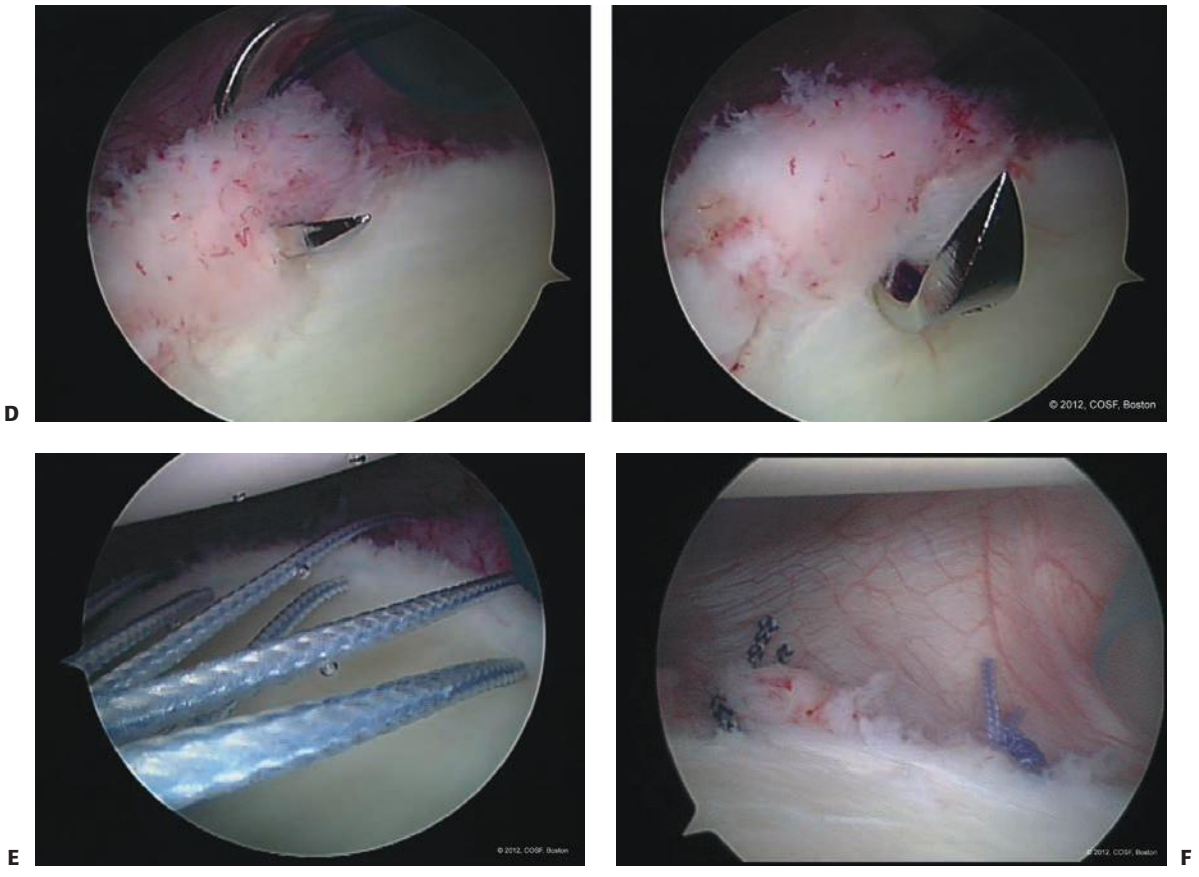

FIGURE 21-14 (*continued*) **D:** Suture passing devices are used in a "pinch-tuck" fashion to imbricate the redundant tissue. **E:** Arthroscopic view after posterior plication sutures have been passed. **F:** After sutures have been tied, note is made of plication of the capsule and loss of the capsular redundancy.

posteriorly. The redundant capsule adjacent to the glenoid rim is prepared using arthroscopic rasps or shavers until punctate bleeding is seen, in efforts to stimulate a healing response; care is made to avoid overzealous tissue preparation, as the tissue is thin and undesirable rents in the capsule may be created. Following this, imbricating sutures may be placed, beginning in the most inferior aspect of the joint. Typically this is performed by passing a suture through capsular tissue approximately 1 cm from the labrum, and then passing the suture a second time from the capsule through the chondrolabral junction. (Prior biomechanical studies have demonstrated that sutures passed through the chondrolabral junction of patients with an intact labrum is as strong as suture anchors).[342] This "pinch-tuck" suture will plicate the capsule when tied, reducing overall capsular volume. If knots are tied as the sutures are passed, the reduced capsular volume will often make subsequent suture placement more difficult; for this reason, consideration is made to pass all posterior sutures first before tying. After all posterior sutures are placed, they may be tied in sequential fashion from inferior to superior, completing the posterior capsulorrhaphy.

The arthroscope is then repositioned posteriorly and an accessory portal reestablished anterosuperiorly. The anteroinferior capsule is similarly prepared with rasps, shavers, or other instruments until punctate bleedings is seen. Plicating sutures are again passed in a "pinch-tuck" fashion, imbricating the redundant capsule to the intact glenoid labrum. These may be tied in series, completing the circumferential repair (Table 21-8).

Operative Treatment of Shoulder Dislocations: Open Capsulorrhaphy

Indications/Contraindications

Despite advances in arthroscopic surgical techniques, open soft tissue procedures may still be performed. Relative indications for open capsulorrhaphy include failed prior arthroscopic procedures, multidirectional instability in setting of capsular laxity without labral tear, and surgeon preference and/or experience. The principles of these procedures are similar to arthroscopic plication: Stability is conferred by tightening the redundant capsule, thus reducing joint volume and conferring stability.

Surgical Procedure

Preoperative Planning. Preoperative planning similar to procedures described above (Table 21-9).

Positioning. The modified beach chair position is utilized. Intraoperative positioning is aided by a limb holder.

Surgical Approach(es). A standard deltopectoral approach is utilized, with the skin incision beginning just lateral to the

TABLE 21-8 Arthroscopic Capsulorrhaphy for Shoulder Instability

Surgical Steps

- Examination under anesthesia
- Establish arthroscopic portals
- Arthroscopic survey
- Preparation and imbrication of posterior glenohumeral joint
  - Place arthroscope anterosuperiorly with working portal posteriorly
  - Stimulation of bleeding response in posterior capsule
  - Pass imbricating suture through capsule first, then through chondrolabral junction, beginning in most inferior position
  - May store sutures in anteroinferior portal to ease visualization and subsequent suture management
  - Pass additional plication sutures from inferior to superior
  - After all posterior sutures have been placed, tie in sequential fashion from inferior to superior
- Preparation and imbrication of anterior glenohumeral joint
  - Place arthroscope posteriorly and establish accessory portal anterosuperiorly
  - Stimulate redundant anterior capsule until bleeding response seen
  - Pass imbricating sutures through capsule and then chondrolabral junction, placating redundant tissue
  - Tie sutures as they are placed, inferiorly to superiorly
- Skin closure with simple sutures
- Application of sling-and-swathe

coracoid process and extending within Langer skin lines toward the axillary crease. The cephalic vein is typically retracted laterally with the deltoid. After the clavipectoral fascia is excised, the conjoined tendon is carefully retracted medially to avoid excessive traction to the musculocutaneous nerve. This will allow direct visualization of the subscapularis and underlying glenohumeral joint capsule.

Technique. After the subscapularis is exposed, the limb is placed in adduction and external rotation. The lesser tuberosity is palpated and identified. A subscapularis tenotomy may then be performed 2 to 3 cm medial to its insertion on the lesser tuberosity, leaving a cuff of tissue laterally to allow for subsequent repair. Traction sutures are placed on the subscapularis tendon, which may then be mobilized and separated from the underlying glenohumeral joint capsule. (In some situations, the upper two-thirds of the subscapularis may be divided, leaving a portion of the inferior musculotendinous unit intact.) Following this, T-shaped capsulotomy is created; a vertical incision is made laterally, with a subsequent transverse extension medially. The superomedial and inferomedial capsular flaps are then mobilized with suture tags. With the limb in the desired position of slight abduction and external rotation, the inferomedial limb is advanced and shifted superolaterally, repaired to the lateral capsule with multiple interrupted nonabsorbable sutures. The superomedial limb is then similarly advanced inferomedially and sewn to the lateral capsule, completing the capsulorrhaphy. Meticulous repair of the subscapularis tenotomy is performed with multiple braided nonabsorbable sutures. The subcutaneous tissues and skin are closed in layers, followed by application of a sling and swathe (Table 21-10).

TABLE 21-9 Open Capsulorrhaphy for Shoulder Instability

Preoperative Planning Checklist

- OR Table: Regular table
- Position/positioning aids: Modified beach chair position, limb holder if available
- Fluoroscopy location: N/A
- Equipment: Shoulder retractors, nonabsorbable braided sutures
- Tourniquet (sterile/nonsterile): N/A

TABLE 21-10 Open Capsulorrhaphy for Shoulder Instability

Surgical Steps

- Deltopectoral approach
- Excise clavipectoral fascia
- Gentle retraction of conjoined tendon
- Subscapularis tenotomy, leaving cuff of tissue on lesser tuberosity for subsequent repair
  - Mobilize subscapularis after placement of traction sutures
- Perform T-shaped capsulotomy
- Imbricate capsule, advancing inferomedial capsular flap superolaterally, followed by repair of the superomedial flap inferomedially
  - Position limb in slight abduction and ~30 degrees external rotation to avoid overtightening
- Careful repair of subscapularis tenotomy using heavy braided nonabsorbable sutures
- Layered wound closure
- Sling-and-swathe immobilization

Author's Preferred Treatment of Shoulder Dislocations

Children and adolescents with traumatic, anterior shoulder dislocations are treated with prompt closed reduction and sling immobilization. Radiographs are obtained to confirm adequacy of glenohumeral reduction and evaluate for possible bony glenoid fractures. In the majority of patients with purely soft tissue injuries—likely anterior-inferior labral tears—physical therapy is initiated following brief immobilization. Return to sports is limited until patients have restoration of motion, strength, and proprioception.[8]

Early in the post injury period, patients and families are counseled regarding the risk of recurrent instability. In high-risk patients (e.g., contact or overhead athletes) or patients for whom the risk of recurrent instability is judged to be unacceptable, arthroscopic Bankart repair may be performed after primary dislocation. In rare circumstances where patients wish to continue with high-risk activities despite known risk of recurrent instability (e.g., in-season

contact athlete), functional bracing with orthoses limiting abduction and external rotation may be utilized.

Patients with bony Bankart lesions are further assessed with CT, and quantification is made of glenoid deficiency. Given the high risk of recurrent instability in the setting of glenoid bone loss, patients with small marginal lesions are offered arthroscopic repair. Patients with larger bony glenoid lesions are treated with open reduction and internal fixation (ORIF) versus Latarjet reconstruction, depending upon the integrity of the bony fragment.

Surgical stabilization of adolescents with recurrent unidirectional instability is typically performed via arthroscopic capsulolabral repair. Preoperative imaging with MRI-arthrography will better define the extent of labral injury and rule out unrecognized or attritional glenoid insufficiency. Latarjet reconstructions are performed in cases of glenoid bone loss or recurrent instability failing prior arthroscopic stabilizations.

Patients with atraumatic multidirectional instability in the setting of ligamentous laxity or other systemic conditions (e.g., hypermobility, Ehlers–Danlos, etc.) are treated with physical therapy, emphasizing strength, proprioception, biofeedback, and neuromuscular retraining of the entire shoulder girdle. In select patients where there is persistent, painful or functionally limiting instability refractory to or precluding physical therapy, surgical treatment is considered. MRI-arthrography is obtained to characterize the extent and magnitude of capsular redundancy. Stabilization is performed via arthroscopic capsulorrhaphy, with appropriate postoperative immobilization and therapy (Fig. 21-15).

Postoperative Care

Postoperatively, patients are sling immobilized for 4-week postoperatively. During the third and fourth postoperative weeks, patients initiate pendulum exercises only. Formal supervised physical therapy is begun after the fourth postoperative week, limiting forward flexion and lateral abduction in the plane of the scapula to 90 degrees and external rotation to 30 degrees. After the sixth postoperative week, motion and strengthening are advanced as tolerated. Sports participation is generally limited for 6 months postoperatively, provided full motion and strength has been restored.

Potential Pitfalls and Preventative Measures

Potential pitfalls in the diagnosis and management of shoulder dislocations are described above. In general, early recurrent instability after nonoperative or surgical treatment is generally due to failure to recognize the pertinent pathoanatomy. Careful radiographic evaluation after primary or recurrent instability events is needed to recognize bony glenoid deficiency and guide appropriate management. Early

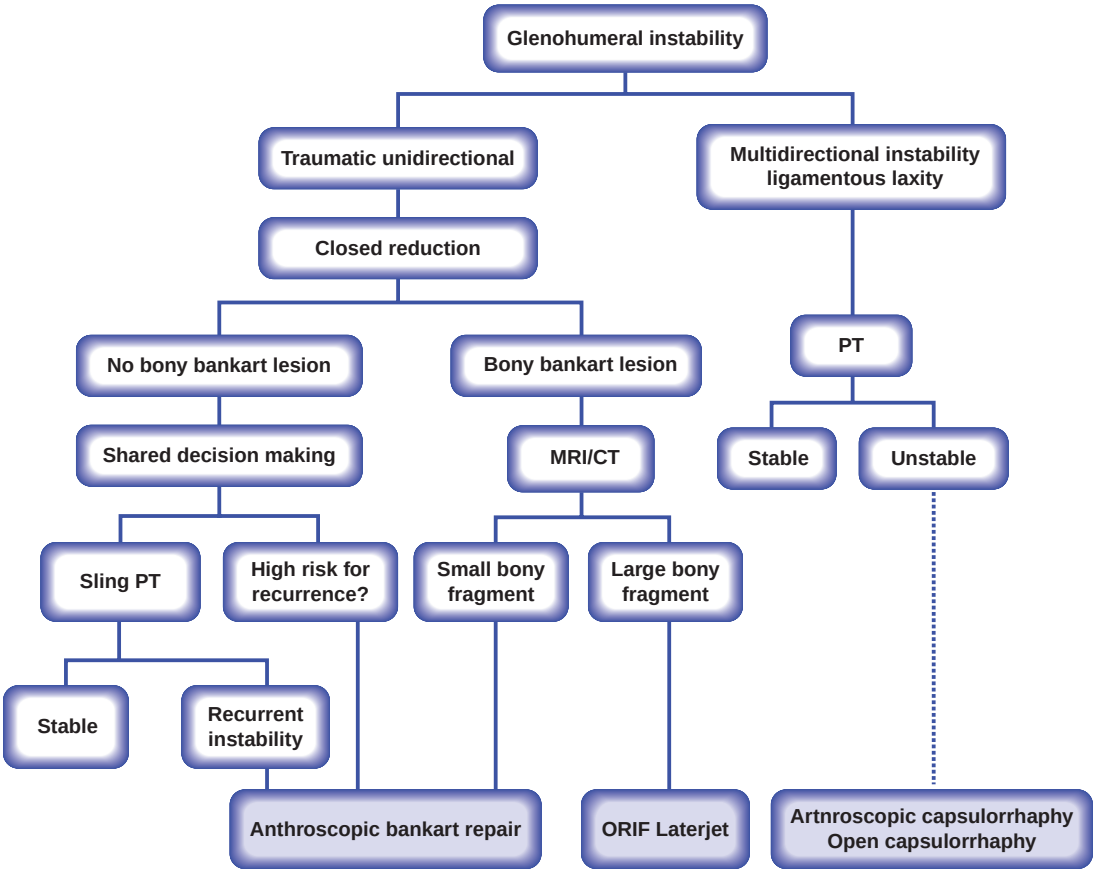

FIGURE 21-15 Proposed treatment algorithm for shoulder dislocation.

TABLE 21-11 Potential Pitfalls and Strategies for Prevention

Potential Pitfalls and Preventions

Pitfall	Preventions
Failure to identify bony glenoid fractures	Careful evaluation of injury and postreduction radiographs including MRI and/or CT imaging Use of orthogonal radiographic images, including axillary view
Early recurrent instability after arthroscopic stabilization	Appropriate recognition of glenoid deficiency or large, engaging Hill–Sachs lesion requiring bony reconstruction Meticulous preparation, mobilization of capsulolabral tissue, particularly in the setting of an ALPSA lesion Appropriate suture passage and knot security Appropriate recognition of HAGL lesions
Early recurrent instability after stabilization for multidirectional instability	Comprehensive counseling regarding importance of therapy and nonoperative treatment modalities Appropriate patient selection Meticulous soft tissue preparation and plication

recurrent instability after arthroscopic soft tissue procedures may be due to unrecognized glenoid deficiency, suboptimal mobilization and preparation of the capsulolabral tissue, untreated HAGL lesions, or technical errors in suture passage and knot security. Finally, recurrent instability after capsulorrhaphy for multidirectional instability may be due to unrecognized systemic connective tissue disorders, suboptimal tissue preparation and plication, or inappropriate patient selection (Table 21-11).

Treatment-Specific Outcomes

As noted above, there is limited published information regarding the results of surgical stabilization for glenohumeral instability in children and adolescents. Much of the current understanding of the treatment outcomes is derived from applications of the adult experiences. A number of general observations may be gleaned from review of the existing retrospective case series. First, there has been an increase in the incidence of glenohumeral instability in younger patients, perhaps because of increasing activities and younger age of first sports participation, with expectation for high recurrence rates with nonoperative treatment alone.[100,149,189,420] Second, arthroscopic repairs have become increasingly common and preferred over open stabilization procedures.[275,349] Third, surgical stabilization of Bankart lesions safely and effectively improves shoulder stability, with the risk of recurrence reduced to 5% to 20%.[1,61,247] Castagna et al.[61] reported the results of 65 patients between 13 and 18 years of age, treated with arthroscopic capsulolabral repair, all of whom were overhead or contact athletes. At mean 5-year follow-up, shoulder motion was restored and 81% had returned to their preinjury level of sports participation. Recurrent instability was reported in 21%, and recurrence was associated with choice of sports participation. In a report of 32 arthroscopic stabilizations in 30 patients under 18 years of age, Jones et al.[214] similarly reported high functional outcomes, though recurrent instability was noted in 12% to 19% of patients. Finally, bony procedures including the Latarjet coracoid transfer is safe and effective, with low risk of recurrent instability.[21,191,193]

Management of Adverse Outcomes and Unexpected Complications Related to Shoulder Dislocations

Adverse outcomes and complications occur infrequently with glenohumeral instability. As noted above, vascular injury is exceedingly rare, and the majority of neurologic injuries associated with traumatic dislocations represent neurapraxic traction injuries to the axillary nerve or brachial plexus, with expectation of spontaneous resolution over time. Nerve repairs or reconstructions are rarely needed and reserved for patients who fail to demonstrate progressive spontaneous recovery.

Chondrolysis has been increasingly reported in patients undergoing arthroscopic stabilizations for glenohumeral instability. Recent reports suggest that use of intra-articular analgesics (e.g., indwelling intra-articular pain catheters) are associated with chondrolysis, and for this reason are currently contraindicated.[377,382,403,457] Similarly, unexpected joint degeneration has been reported after thermal capsulorrhaphy and loose metallic suture anchors, likely related to thermal injury and third body wear of the articular cartilage, respectively.[82,107,150,216] Cartilage loss in a young, skeletally immature shoulder is a disastrous and yet unsolved complication. Avoidance of excessive heat and proper placement of bioabsorbable suture anchors may minimize these adverse events. Judicious placement of bone grafts and internal fixation, such as in the Latarjet procedure, is also critically important to minimize risk of early arthrosis (Table 21-12).[192]

Summary, Controversies, and Future Directions Related to Shoulder Dislocations

In summary, glenohumeral instability is common in children and adolescents. While closed reduction is easily performed after

TABLE 21-12 Shoulder Dislocations

Common Adverse Outcomes and Complications

Recurrent instability
Neurovascular injury
Chondrolysis
Arthrosis

acute dislocations, there is a high risk of recurrent instability. In appropriately selected patients, arthroscopic or open soft tissue and/or bony stabilization procedures are safe and effective.

There is ongoing debate and controversy surrounding the indications for surgical stabilization after primary traumatic dislocation in the child or adolescent. Proponents of primary surgery point to the safety and efficacy of predominantly arthroscopic procedures in reducing recurrence risk and restoring stability and return of function. Furthermore, there is some evidence suggesting recurrent dislocations may lead to more extensive labral tears, development of glenoid insufficiency, and even arthrosis.[190,219] Many argue that surgical stabilization should be performed in higher-risk patients (e.g., young athletes involved in contact sports).[67,233] A recent expected-value decision analysis supports primary arthroscopic stabilization if recurrence risk above 32% and utility value of surgical intervention remains above 6.6.[33] Further investigation of the natural history of recurrent glenohumeral instability as well as prospective randomized trials of surgical versus nonoperative treatment is needed in the pediatric patient population.

Finally, as more information regarding the frequency and clinical significance of bony glenoid and humeral head defects becomes available, clarification of the indications for bony augmentation procedures (e.g., coracoid transfer, bone grafting) is needed. This is particularly relevant given the persistent risks of recurrent instability after arthroscopic Bankart repairs and the promising longer-term studies regarding the results of bony procedures.[75,191,193,210,227]

Introduction to Proximal Humerus Fractures

Proximal humeral fractures are relatively uncommon injuries, with an estimated annual incidence of 1.2 to 4.4 per 1,000, and representing less than 5% of all childhood fractures.[26,182,203,240,241,358,464] Given the metaphyseal location, thick periosteum, and proximity to the proximal humeral physis, there is tremendous healing and remodeling potential of proximal humerus fractures. Furthermore, given the robust, near universal motion about the glenohumeral joint, little functional impairment may be seen even in cases of considerable bony malalignment. For these reasons, most proximal humeral fractures are amenable to nonoperative treatment.

Assessment of Proximal Humerus Fractures

Mechanisms of Injury for Proximal Humerus Fractures

Proximal humerus fractures occur through a number of characteristic injury mechanisms. Birth-related fractures of the proximal humerus are not uncommon.[250,397] In general, hyperextension and/or rotational forces imparted on the upper limb during labor and delivery result in failure through the proximal humeral physis or metaphysis (Fig. 21-16).[95,155,163,167,250,272,397] Risk factors include difficult delivery, macrosomia, and breech presentation, but are not entirely predictive.[56,136,212,397] Indeed, proximal humerus fractures may occur during vaginal delivery of infants of all weights and sizes, implicating other maternal and perinatal factors.

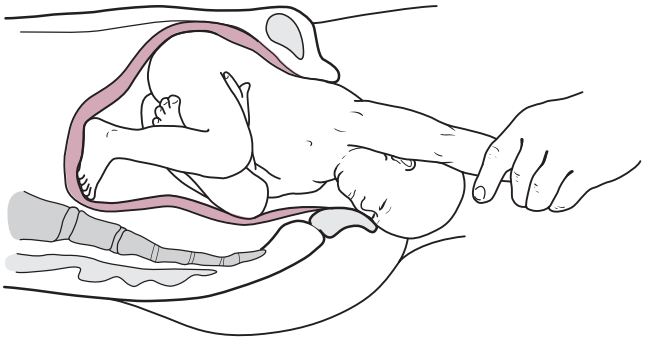

FIGURE 21-16 Hyperextension or rotation of the ipsilateral arm may result in a proximal humeral or physeal injury during birth.

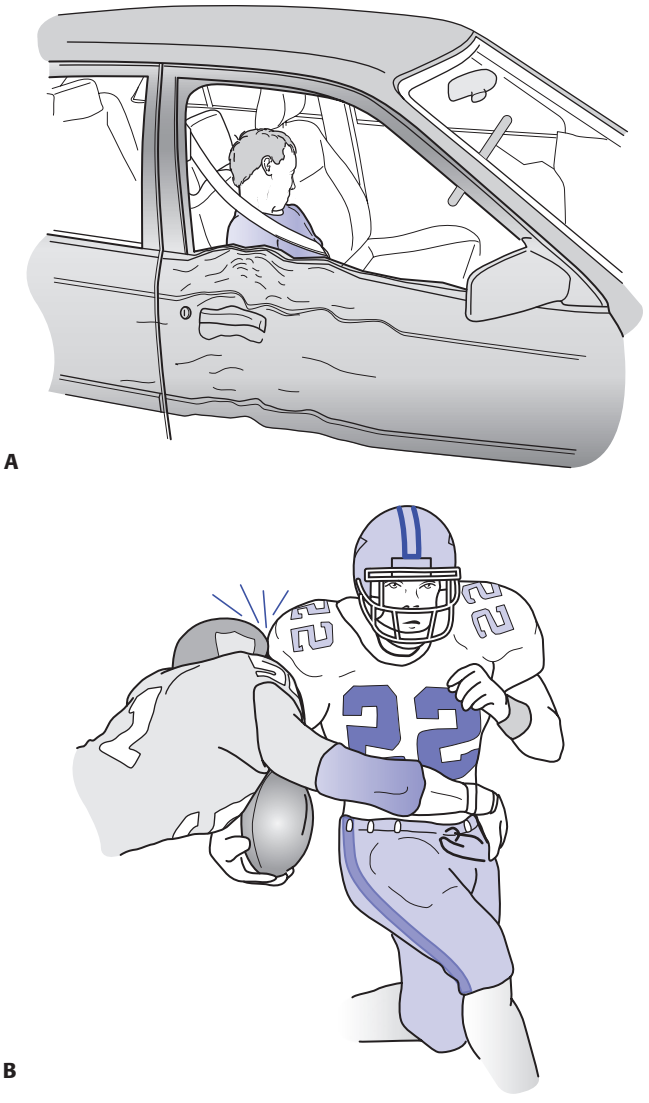
In older children and adolescents, proximal humerus fractures are typically sustained from traumatic mechanisms, such as sports-related activities or motor vehicle collisions (Fig. 21-17). Direct trauma to the anterior or posterior aspect of the proximal humerus may result in fracture.[95,308,402] More commonly, indirect trauma via forces imparted on the upper limb during falls or nonphysiologic positioning may result in a proximal humeral fracture.[3,43,402] Indeed, Williams[460] postulated six distinct mechanisms by which proximal humerus fractures may be sustained: Forced extension, forced flexion, forced extension with lateral or medial rotation, and forced flexion with lateral or medial rotation. Fractures may occur at the level of the proximal metaphysis or physis.

Furthermore, the proximal humerus is a common location of pathologic fractures in children. Benign—such as unicameral or aneurysmal bone cysts—and much less often malignant lesions (osteogenic sarcoma), commonly involve the proximal humerus and may first present in the setting of pathologic fracture.[2,235,323,353] Neuropathic conditions including Arnold–Chiari malformation, myelomeningocele, or syringomyelia have also been implicated in pathologic fractures of the proximal humerus.[19,264] Finally, radiation therapy to the shoulder girdle may result in bony abnormalities predisposing to proximal humerus fracture.[115]

Finally, proximal humerus fractures may be seen in the setting of nonaccidental trauma and child abuse.[133,289,390] For this reason, careful assessment including comprehensive history and physical examinations are needed when assessing infants and young children with proximal humerus fractures.

Associated Injuries with Proximal Humerus Fractures

Fractures of the proximal humerus may have concomitant dislocations of the glenohumeral joint, particularly with high-energy mechanisms of injury.[80,133,154,231,311,316,449,432] Glenohumeral joint dislocation may be anterior, posterior, or inferior, and concomitant intra-articular or apophyseal avulsion fractures may be seen.[303,359,404,455] All patients with proximal humerus fractures should be evaluated for concomitant glenohumeral joint reduction with appropriate radiographic imaging. A high index of suspicion is needed to avoid delayed or missed diagnosis. Ipsilateral fractures of the upper limb have also been reported, emphasizing the importance of a comprehensive physical examination and imaging of the entire humerus or upper limb as appropriate.[159,209,269,322]



A

B

FIGURE 21-17 A: Motor vehicle crashes may result in proximal humeral fracture due to blunt trauma to the shoulder region. **B:** Blunt trauma from contact sports may result in fracture of the proximal humerus in children.

Given the proximity to the brachial plexus and axillary vessels, proximal humerus fractures may be associated with neurovascular injury. Axillary nerve, radial nerve, and total brachial plexus palsies have been reported in the setting of displaced proximal humerus fractures.[10,112,199,432,438] These are typically seen in valgus injuries, in which the distal diaphyseal segment displaces medially and proximally into the region of the brachial plexus. While spontaneous neurologic recovery is seen in the majority of patients within 9 to 12 months, patients may develop a profound neurogenic pain syndrome.[199] Proximal humerus fractures associated with arterial injury and vascular insufficiency require emergent reduction and/or stabilization and vascular repair.[168,453] Associated injuries to the thorax, including rib fractures and pneumothorax, have also been reported.

Signs and Symptoms of Proximal Humerus Fractures

In neonates, the signs and symptoms of proximal humerus fractures may be subtle. Rarely will ecchymosis, swelling, or deformity be clinically apparent. Care providers will often report irritability or "fussiness" with handling or motion of the affected extremity. Often the absence of spontaneous movement of the upper limb—so-called "pseudoparalysis"—will alert the examiner to an underlying fracture.

In older children and adolescents, the clinical diagnosis is more obvious. Patients will present with pain, swelling, ecchymosis, and/or limited shoulder motion after traumatic injury. The limb is typically held against the body in adduction and internal rotation, and patients will guard against passive or active movement. Inspection will reveal asymmetry in the contour of the shoulder girdle compared with the contralateral, uninjured extremity. Subtle skin puckering may be seen, suggestive of soft tissue interposition in severely displaced fractures.[97] Careful evaluation of neurovascular status is critical to rule out concomitant nerve or vessel injury. Even in patients with considerable pain and guarding, axillary nerve function (sensation over the lateral deltoid, abduction of the shoulder) may be adequately assessed. Similarly brachial plexus integrity may be assessed by distal motor sensory function without moving the injured limb.

Patients with associated posterior glenohumeral joint dislocation will posture with internal rotation and have limited or extremely painful passive external rotation. Associated fracture-dislocations involving the greater tuberosity and luxation erecta will present with extreme abduction of the shoulder and elbow flexion.[132,230] Fractures of the lesser tuberosity and/or subscapularis disruption may be more subtle in presentation, though patients will have weak internal rotation, a positive lift-off sign, and often increased passive external rotation.[254,359,396,436,442]

Imaging and Other Diagnostic Studies for Proximal Humerus Fractures

The proximal humeral epiphysis is not radiographically apparent until approximately 6 months of age, limiting the diagnostic utility of plain radiographs in the evaluation of neonates and infants.[234,321] In these very young patients, ultrasonography may provide meaningful diagnostic information.[46,127,194] MRI may also help distinguish between proximal humeral fracture and other potential causes of pseudoparalysis, such as osteomyelitis, septic arthritis, or glenohumeral joint instability in the setting of brachial plexus birth palsy, though MRI requires conscious sedation or general anesthesia.

Subtle signs of proximal humerus fracture in infants include asymmetric positioning of the proximal humeral metaphysis in relationship to the scapula and acromion, particularly when compared to images of the contralateral shoulder. In patients with posteriorly displaced physeal fractures, the so-called "vanishing epiphysis" sign has been used to describe the apparent absence of the small epiphyseal ossification center, which lies behind the proximal metaphysis (Fig. 21-18).[224,376]

In older patients and adolescents, plain radiographs will confirm the diagnosis and characterize fracture pattern and

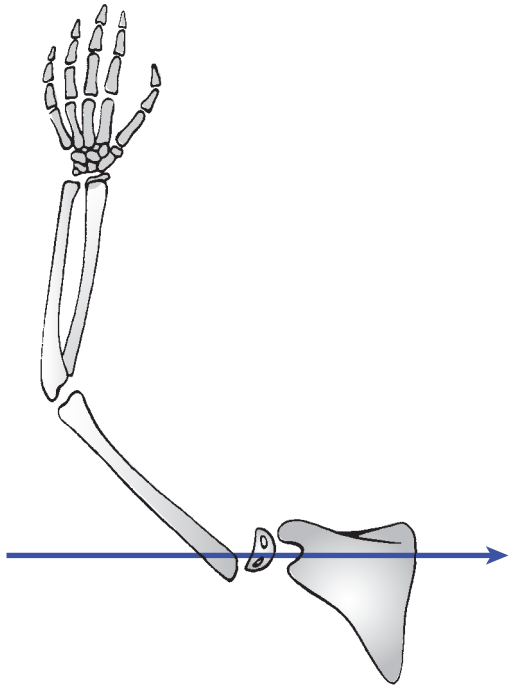


FIGURE 21-18 Vanishing epiphysis sign.

FIGURE 21-19 Proximal humeral metaphyseal fracture in a 5-year-old male.

displacement. Orthogonal views are necessary, and ideally AP and axillary views are obtained to assess for concomitant lesser tuberosity fracture or glenohumeral joint dislocation.[416,436] In appropriate axillary images, the humeral head normally resides between the acromion and coracoid process, concentrically reduced within the glenoid. Given the difficulty in obtaining axillary radiographs in the acutely injured child, a host of alternative radiographic views have been proposed, including the transthoracic scapular Y view, apical oblique view, and other variations.[144,400] In unusual situations in which adequate plain radiographs cannot be obtained, CT or MRI may be utilized. These advanced imaging modalities are particularly useful in cases of posterior glenohumeral fracture-dislocations, intra-articular fractures, or occult fractures.[26,154,365,423,424,442]

Classification of Proximal Humerus Fractures

Metaphyseal proximal humerus fractures occur most commonly in children between 5 and 12 years of age, and may be described according to their radiographic displacement and angulation (Fig. 21-19). It has been hypothesized that rapid metaphyseal growth and thus relative porosity of the proximal humeral metaphysis contributes to the predilection to fracture in this age group.[95]

Physeal fractures are classified according to the Salter–Harris classification (Fig. 21-20).[370] Salter–Harris I injuries denote fractures through the physis and most commonly occur in patients under 5 years of age.[95,333] Salter–Harris II fractures exit through the metaphysis, often associated with an anterolateral bony fragment, and are more commonly seen in older children and adolescents.[51,95,127,333] Salter–Harris III fractures are relatively rare and have been associated with concomitant

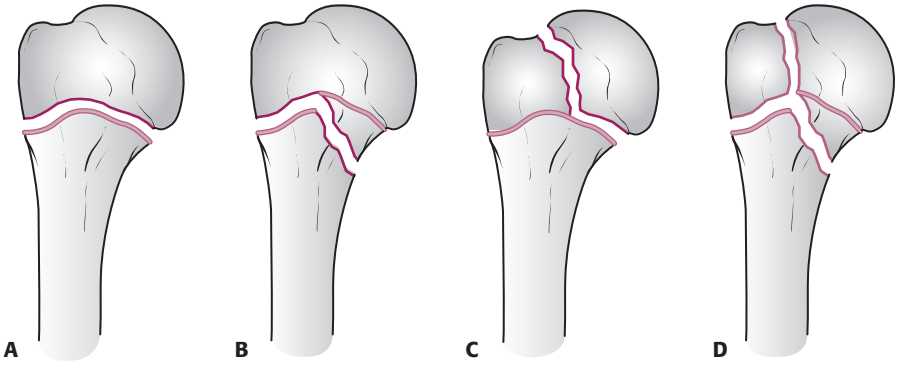

FIGURE 21-20 Physeal fractures of the proximal humerus. **A:** Salter–Harris type I. **B:** Salter–Harris type II. **C:** Salter–Harris type III. **D:** Salter–Harris type IV.

glenohumeral dislocation. Salter–Harris IV fractures have not been reported in children.

Neer and Horwitz[308] proposed a classification system for pediatric proximal humerus fractures based upon the amount of fracture displacement. In grade I fractures, there is up to 5 mm of displacement. Grade II fractures are displaced up to one-third of the cortical diameter of the humeral diaphysis. Grade III injuries have up to two-third displacement. Grade IV fractures have greater than two-thirds cortical diameter displacement. Angulation and malrotation are not specifically categorized in this classification system.

Pathoanatomy and Applied Anatomy Relating to Proximal Humerus Fractures

Care of proximal humerus fractures in children and adolescents is challenging for a number of reasons. First, given the robust remodeling potential in skeletally immature patients, there are variations in what is deemed "acceptable" deformity. Fracture reduction is often difficult, owing to the small size and deep location of the humeral head as well as the deforming muscle insertions on both the proximal and distal fracture fragments. Multiple reduction maneuvers and fixation options have been proposed, adding complexity to nonoperative or surgical decision making. Finally, the proximity of the zone of injury to adjacent neurovascular structures results in the potential for associated injuries and surgical risks. All of these considerations must be reconciled with evolving patient and family expectations regarding pain control, healing time, and functional return. For these reasons, understanding of the applied anatomy and pathoanatomy of proximal humerus fractures is critical.

The proximal humeral epiphysis does not become radiographically apparent until approximately 6 months of age.[234,321] Furthermore, the greater and lesser tuberosities have their own distinct secondary centers of ossification, which become visible at 1 to 3 years and 4 to 5 years of age, respectively.[321,372] The greater and lesser tuberosities coalesce between 5 and 7 years of age, and subsequently fuse to the rest of the humeral head between 7 and 13 years of age.

The proximal humeral physis ultimately contributes 80% of the longitudinal growth of the humerus.[40,339,340] There is some variation over time, however, as the proximal humeral physis contributes 75% of longitudinal growth of the humerus prior to 2 years of age, but up to 90% of growth after the age of 11 years. Generally, the proximal humeral physis closes at 14 to 17 years of age in females and between 16 and 18 years of age in males.[40,339,340,407]

The articular surface of the humeral head encompasses the medial aspect of the epiphysis as well as the proximal medial corner of the metaphysis (Fig. 21-21). The capsule of the glenohumeral joint correspondingly surrounds the articular surface. However, the proximal humeral physis is extracapsular and thus susceptible to injury. Indeed, most fractures of the proximal humerus involve the physis.[51,95,333] As with other growth plate injuries, proximal humeral physeal fractures typically occur through the zone of hypertrophy and provisional calcification, sparing the resting and proliferative zones. For these reasons, the typical Salter–Harris I and II injuries have tremendous remodeling potential and have a low risk of subsequent growth disturbance.[22,95,370]

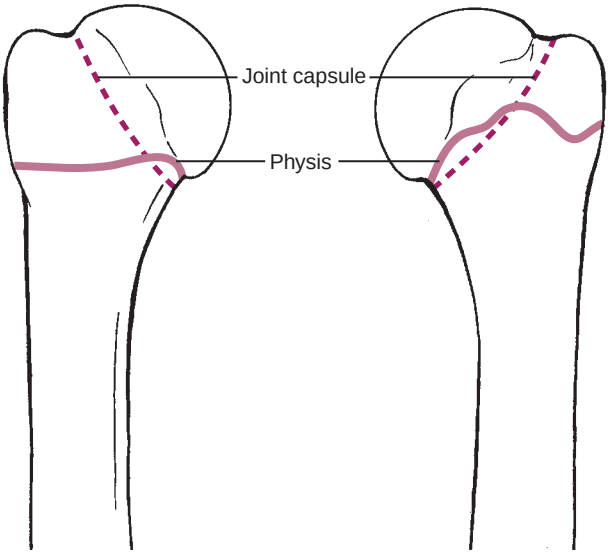

FIGURE 21-21 The anatomy of the proximal humerus.

The periosteum is thick and strong along the posteromedial aspect of the proximal humerus, but relatively weak anterolaterally, allowing for fracture fragment displacement. In cases of displaced fractures, interposed periosteum may block reduction attempts.[95,111,267]

A number of muscles insert on the proximal humerus, influencing fracture pattern, location, and characteristic displacement. Understanding of these dynamic influences is critical for successful fracture reduction. The subscapularis inserts anteriorly on the lesser tuberosity, whereas the supraspinatus, infraspinatus, and teres minor attach to the greater tuberosity and posterosuperior epiphysis. The deltoid tubercle lies more distally along the lateral aspect of the humeral diaphysis, and the pectoralis major and latissimus dorsi muscles insert along the anteromedial aspect of the metaphysis. In patients with physeal or metaphyseal fractures proximal to the pectoralis major insertion, the humeral head is abducted, flexed, and externally rotated by the action of the rotator cuff muscles, whereas the distal humeral diaphyseal segment is typically displaced proximally, medially, and into internal rotation. In metaphyseal fractures between the pectoralis major and deltoid insertions, the proximal fragment is adducted by the pull of the pectoralis major and the distal segment is pulled proximally and into abduction by the deltoid. For diaphyseal fractures distal to the deltoid insertion, the proximal fracture fragment is abducted by the deltoid and flexed by the pectoralis major, and the distal fragment is displaced proximally and medially by the biceps and triceps. Rarely, the subscapularis muscle may lead to displacement of an isolated fracture of the lesser tuberosity.

The vascularity of the proximal humerus arises from the axillary artery and its branches. In particular, the anterior and

posterior humeral circumflex arteries supply the proximal humerus, whereas the humeral head derives most of its vascular supply from the arcuate artery, a branch of the ascending branch of the anterior humeral circumflex artery.[142,238] The posterior humeral circumflex artery supplies only a portion of the greater tuberosity and posteroinferior humeral head.[142]

Of the neurologic structures, the axillary nerve is the closest and most at risk in fractures and fracture-dislocations of the proximal humerus.[10,432] The axillary nerve arises from the posterior cord of the brachial plexus before it traverses the anterior aspect of the subscapularis muscle and passes just inferior to the glenohumeral joint. From there it passes through the quadrilateral space to innervate the deltoid and teres minor muscles and to supply sensation to the lateral aspect of the shoulder.

Treatment Options for Proximal Humerus Fractures

Nonoperative Treatment of Proximal Humerus Fractures

Indications/Contraindications

Given their tremendous remodeling potential as well as the robust compensatory motion afforded by the shoulder joint, the vast majority of proximal humerus fractures may be treated by nonoperative means. Birth-related fractures of the proximal humerus may be successfully treated with simple pinning of the sleeve to the body or stockinette sling-and-swathe immobilization. Closed reduction is rarely needed in infants, and while ultrasonography may be utilized to confirm alignment, advanced imaging is almost always unnecessary. In these infants, healing is rapid and robust, typically within 2 to 3 weeks, and there is little concern for long-term aesthetic differences or functional limitations.[95,163,212,251,397]

Nondisplaced or minimally displaced fractures (Neer–Horwitz grades I and II) in older children and adolescents may also be treated with simple sling-and-swathe immobilization, with or without additional splinting (Fig. 21-22). After confirmation of radiographic healing, patients may advance to motion and strengthening, with anticipation of excellent long-term results.[53,95] Similarly, stress fractures of the metaphysis or physis—such as seen from repetitive overuse sports activities, neurologic conditions, metabolic bone disease, or local radiation therapy—may be successfully treated with rest, activity modification and/or simple sling immobilization.[45,93,115,261,425,426]

With increasing age and skeletal maturity, remodeling capacity diminishes; therefore, the amount of "acceptable" deformity changes with age. Given the remodeling potential in patients less than 11 years of age, good-to-excellent results have been reported with nonoperative treatment regardless of fracture displacement.[95,243,308,402] Immobilization options include sling-and-swathe, Velpeau thoracobrachial bandages, hanging arm casts, and shoulder spica casts in the "saluting" and "Statue of Liberty" positions.[53,95,163,243]

There continues to be controversy, however, regarding what constitutes "acceptable" alignment in pediatric proximal humerus fractures, particularly in older children and adolescents. Much of the available information comes from historic retrospective case series, with little or no comparative outcome data available. Traditional recommendations have divided treatment recommendations according to patient age and fracture displacement (Table 21-13).[23,111,390,393] In patients less than 5 years of age, up to 70 degrees of angulation and 100% displacement is deemed acceptable. In patients between 5 and 11 years of age, 40 to 70 degrees of angulation and 50% to 100% displacement may be accepted. And in patients greater than 12 years of age with less growth and remodeling potential, less than 40 degrees and 50% translation should be accepted. Though these guidelines are generally accepted, appropriate clinical judgment weighing individual patient and provider factors should be made on a case-by-case basis.[23,95,111,243] For example, in overhead athletes requiring maximal shoulder abduction and forward flexion, less varus or apex anterior angulation may be

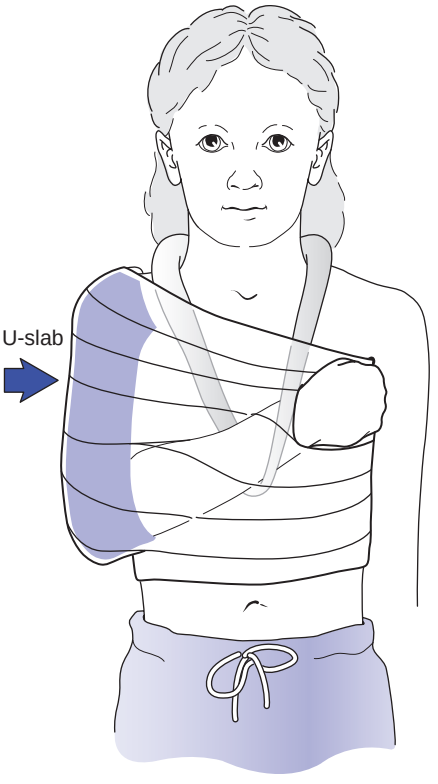

FIGURE 21-22 Sling-and-swathe for immobilization of proximal humeral fracture.

TABLE 21-13 Acceptable Alignment of Proximal Humerus Fractures

Age	Angulation	Displacement
<5 y	70 degrees	100%
5–11 y	40–70 degrees	50–100%
>12 y	<40 degrees	<50%

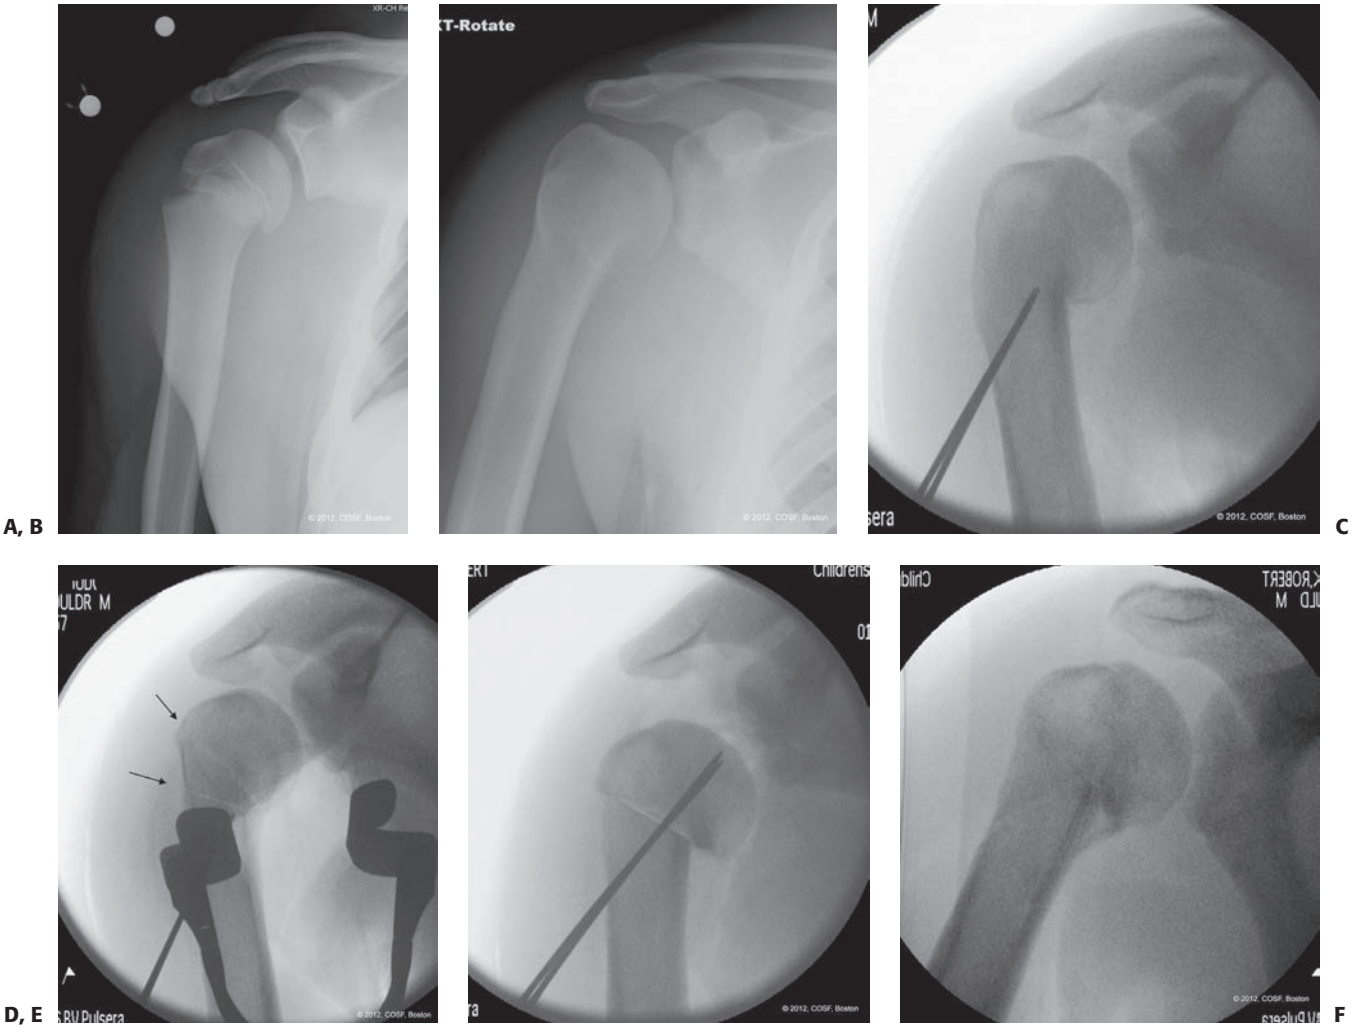

FIGURE 21-23 **A:** AP radiograph of a minimally displaced right proximal humeral physeal fracture in a 14-year-old male. **B:** Follow-up radiographs depicting humerus varus, characterized by a decreased neck-shaft angle and high-riding greater tuberosity resulting in limited shoulder abduction and bony impingement. **C:** Intraoperative image during corrective osteotomy, depicting percutaneous pin placement. **D:** Converging osteotomies (*arrows*) are made to create a lateral closing wedge osteotomy. **E:** Osteotomy fixed using percutaneous pins and a tension-band fixation construction. **F:** Follow-up radiographs demonstrating bony healing and restoration of more normal proximal humeral alignment.

acceptable, given concerns regarding acromial impingement and bony blocks to glenohumeral motion (Fig. 21-23).

In patients older than 11 years, fracture reduction and immobilization is recommended for Neer–Horwitz grade III and IV injuries with unacceptable alignment.[23,95,243,308,393] While a host of reduction maneuvers have been described, all adhere to the fundamental principles of reversing the deformity and counteracting the deforming forces. Most fractures may be reducing by applying longitudinal traction to the distal brachium, followed by abduction, flexion, and external rotation; this technique essentially brings the distal diaphyseal segment to the displaced humeral head. Often, initial adduction and internal rotation to relax the pectoralis major, followed by posteriorly directed pressure on the humeral diaphysis to correct the apex anterior angulation, will facilitate reduction.[208] Alternatively, reduction may be achieved by abduction, flexion to 90 degrees, and external rotation.[308] Still others advocate placing the limb in 135 degrees abduction and slight (30 degrees) flexion, followed by longitudinal traction and manual manipulation of the fracture fragments.[43,212] In cases of physeal fractures, gentle manipulation with the assistance of conscious sedation or general anesthesia should be considered to avoid excessively forceful manipulation and minimize the risk of iatrogenic physeal disturbance. After reduction, fracture stability needs to be assessed. Often the intact periosteum will stabilize the reduction and allow for immobilization at the patient's side. Typically, immobilization with sling-and-swathe or Velpeau thoracobrachial bandage is sufficient.[95]

Some fractures may not be reducible, because of soft tissue interposition at the fracture site. Potential structural barriers

to fracture realignment include the adjacent periosteum, glenohumeral joint capsule, and long head of biceps tendon.[23,111,131,208,249,251,267,439] In these situations, open reduction via a limited anterior deltopectoral approach may be needed to obtain appropriate reduction. Even in cases in which the bony alignment is improved to "acceptable" parameters but not anatomic, fracture healing and functional return may be expected; indeed, good functional results have been reported in patients with Neer–Horwitz grade III and IV injuries who were reduced to grade I or II displacement.[111,198]

There is additional controversy regarding the optimal management of the older adolescent who undergoes successful fracture reduction. Loss of reduction following initial manipulation has been reported to be as high as 50% in older adolescents, suggesting that internal fixation should be considered when caring for older patients with severely displaced injuries.[95,111,308] Again, there is no prospective or comparative data to inform us regarding the utility or cost-effectiveness of internal fixation in these situations (Table 21-14).

Operative Treatment of Proximal Humerus Fractures

Indications/Contraindications

Surgical indications include open fractures, fractures associated with vascular injury, fractures in the multitrauma patient, displaced intra-articular fractures, displaced tuberosity fractures, and irreducible or unstable fractures in unacceptable alignment.[23,89,111,182,198,249,265,277,333,383,412,449]

A host of surgical treatment options have been advocated in these situations, and in general may be divided according to manner of reduction (closed vs. open) and type of fixation (pin fixation, intramedullary fixation, and plate-and-screw constructs).[23,70,71,89,95,111,125,208,308,345,362,381,393,466]

Surgical Procedure: Percutaneous Pin Fixation

Preoperative Planning. Percutaneous pin fixation is a common technique for the treatment of unstable proximal humerus fractures.[71,111,198] Appropriate preoperative planning includes orthogonal radiographic views of the proximal humerus—preferably AP and axillary views—to characterize the fracture pattern and displacement. Careful radiographic assessment should be made to identify associated bony lesions, as pathologic fractures due to unicameral bone cysts, aneurysmal bone cysts, and other benign and malignant lesions commonly occur in the proximal humerus. Preoperative evaluation should also include a careful neurovascular examination to rule out concomitant nerve palsy or vascular injury.

While terminally threaded pins are commonly used in adults, smooth pins are sufficient in pediatric patients given the bone quality, rapid healing, ease of implant removal, and typical simple extra-articular fracture patterns. The appropriate-sized implants should be determined in advance; typically smooth Kirschner (K)-wires between 0.0625 and 3/32 in in diameter are used. Cannulated screw fixation has been advocated by some, citing its minimal invasiveness, improved stability, and avoidance of complications commonly seen with smooth K-wires. However, given the concerns regarding potential physeal disturbance and need for staged implant removal, cannulated screw fixation is not typically utilized or necessary (Table 21-15).[71,452]

Positioning. Patient positioning should be predicated upon access to the shoulder girdle and upper limb and ease of fluoroscopic imaging. Use of the modified beach chair position will allow for easy manipulation, implant placement, and intraoperative imaging. In these cases, the fluoroscopy unit may be brought in from the head of the bed, allowing the surgeon to stand in the axilla or lateral to the affected shoulder and facilitating both AP and axillary views of the proximal humerus (Fig. 21-24). Alternatively, patients may be positioned supine on a radiolucent table with a bump placed under the ipsilateral pelvis or between the scapulae. With supine positioning, the fluoroscopy unit may be brought in from the ipsilateral or contralateral side of the table.

Surgical Approach(es). After adequate induction of general anesthesia, closed reduction is performed. Adequate muscle relaxation will facilitate fracture manipulation. In cases where closed reduction does not allow for adequate bony alignment, open reduction may be performed via a deltopectoral approach. As most physeal and metaphyseal fractures are extracapsular, the incision and deep dissection should be biased more inferiorly than standard approaches to the glenohumeral joint.

TABLE 21-14 Proximal Humerus Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Birth-related fractures	Open fractures
Younger patients with stable or minimally displaced fractures	Fractures with vascular or severe soft tissue injury
Stress fractures	Displaced intra-articular fractures Displaced tuberosity fractures Irreducible or unstable fractures in older adolescents with unacceptable alignment

Technique. After appropriate positioning, the shoulder girdle and ipsilateral upper limb is prepped and draped into the surgical field. Care is made to provide circumferential access to the shoulder region. Closed reduction maneuvers are performed, as described above. For most injuries, initial adduction and internal rotation will relax the deforming forces of the pectoralis major muscle, and subsequent posterior translation of the diaphyseal fragment will correct the apex anterior angulation. Following this, longitudinal traction and increasing abduction and flexion will reduce the angulation and displacement (Fig. 21-25). In cases of marked fracture instability, the reduction achieved may be lost when the arm is brought into an adducted and internally rotated position. In these situations, it may be advantageous to preplace the pins into the distal humeral fracture fragment first, then perform the appropriate reduction maneuver. Once the fracture is realigned, the pins may be simply passed across the fracture site into the proximal fragment, even with the shoulder abducted, external rotated, and/or flexed.

Once an adequate closed reduction has been achieved, the fracture is fixed with percutaneous smooth K-wires. Small stab incisions are made at or just proximal to the level of the deltoid tubercle, and careful blunt dissection is performed down to the lateral cortex of the humerus using a hemostat or narrow dissecting scissors. Injury to the axillary nerve may be avoided by

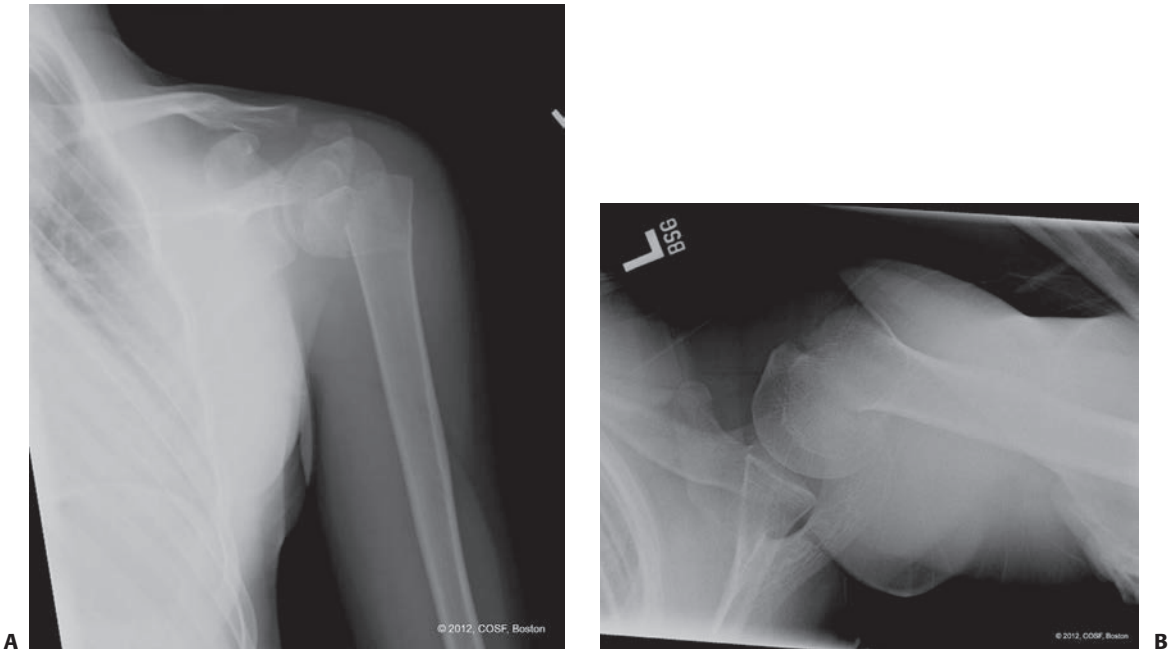

FIGURE 21-25 Percutaneous pin fixation. Injury AP **(A)** and views **(B)** of a proximal humerus fracture in a 12-year-old female. Note is made of excessive apex anterior angulation.

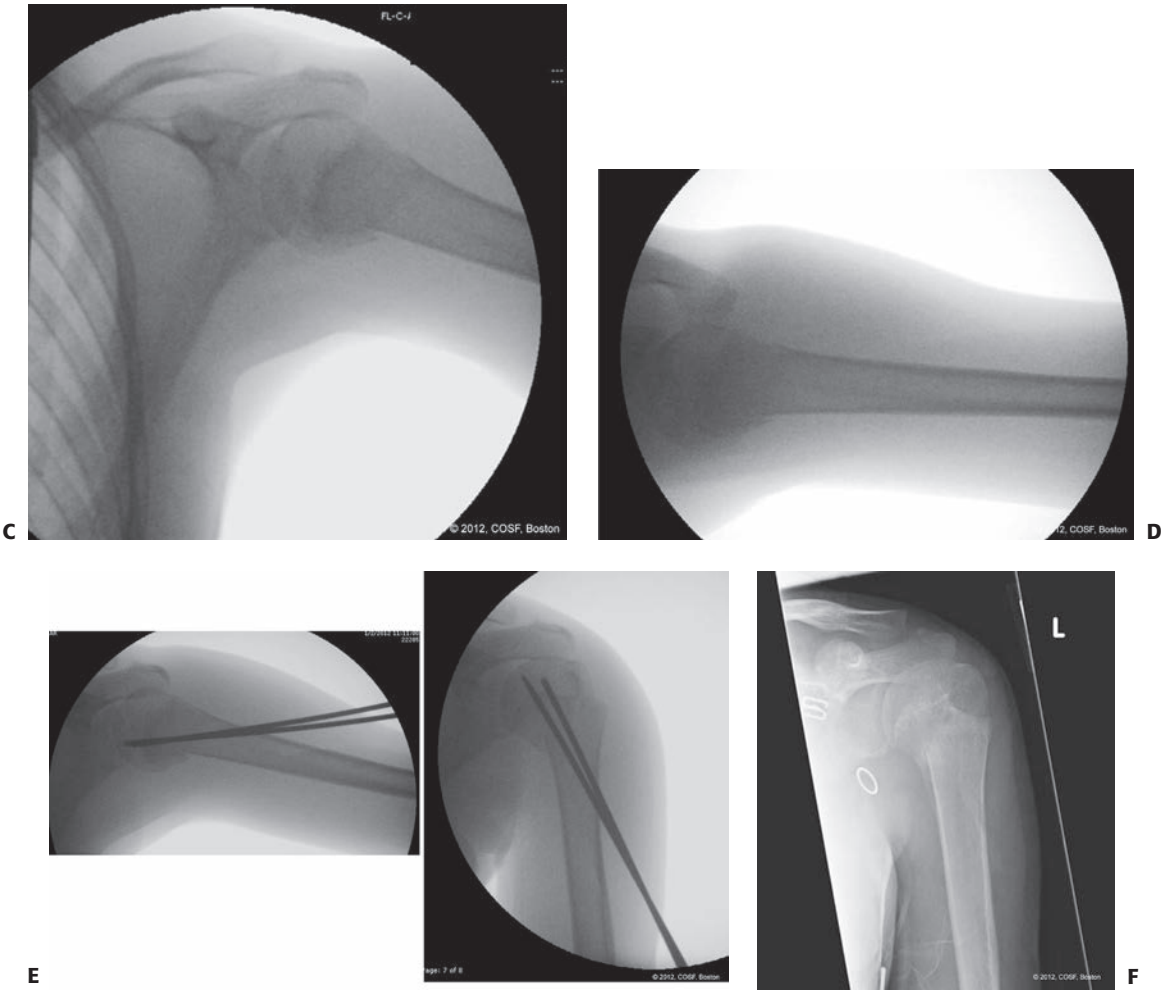

FIGURE 21-25 (*continued*) Intraoperatively, the fracture is closed reduced with traction, abduction **(C)** and correction of the apex anterior angulation **(D). E:** Postoperative alignment after percutaneous pinning. **F:** Follow-up radiograph demonstrates improved alignment and bony healing.

placing the entry points for percutaneous pinning two times the height of the articular surface distal to the most proximal edge of the humerus.[362] Data from computer modeling studies of pediatric proximal humerus fractures suggest that pins entering laterally 4.4 and 8 cm distal to the superior aspect of the humeral head at a coronal angle of 21 degrees allow for optimal pin placement.[288]

After the first pin is placed, multiplanar fluoroscopic views are obtained to confirm appropriate alignment and implant placement. Following this one or two additional pins are placed, again in a distal-lateral to proximal-medial direction. Care is made not to violate the subchondral surface of the humeral head and enter the glenohumeral joint. A drill hole at the entry site may make pin adjustment and placement easier and avoid inadvertent joint and/or adjacent soft tissue (brachial plexus) penetration. Once the desired alignment, depth, and stability is achieved, the pins are bent and cut either below the skin or outside the skin.[198] The limb is placed in a sling-and-swathe. Implants may be removed after radiographic evidence of healing is confirmed, typically 4 weeks after surgery.

Occasionally, additional fixation or assistance with closed reduction is needed. An antegrade pin entering the greater tuberosity and directed distally and medially may be considered, though is rarely necessary. These pins should be placed with the limb in external rotation and directed to a point at least 2 cm inferior to the most medial aspect of the articular surface.[362] As cited earlier, if closed reduction is not successful, open reduction via a deltopectoral approach may be utilized, with pinning techniques performed in a similar fashion (Table 21-16).

Surgical Procedure: Intramedullary Fixation

Preoperative Planning. Intramedullary nailing is a common technique in the treatment of pediatric proximal humerus fractures.[70,71,345,381,466] Unlike adults, in whom solid reamed antegrade nails have been used, intramedullary fixation in children and adolescents typically involves retrograde passage of multiple flexible titanium elastic nails, Rush rods, or Enders nails. Adequate AP and lateral radiographs of the proximal humerus should be reviewed to assess fracture location, pattern, and displacement. Again, careful preoperative evaluation should be

TABLE 21-16 Reduction and Percutaneous Pinning of Proximal Humerus Fractures

Surgical Steps

- Closed reduction
- Skin incisions at or proximal to deltoid tubercle
- Spreading through subcutaneous tissues to lateral humeral cortex
- Smooth K-wire fixation
- Fluoroscopic confirmation of alignment and implant placement
- Placement of additional K-wire(s)
- Final fluoroscopic evaluation
- Bent and cut pins beneath or outside the skin
- Sling-and-swathe immobilization

made to document neurovascular status, given the known risks of associate nerve injury. Appropriately sized flexible stainless steel or titanium intramedullary nails should be available. Similar to intramedullary fixation techniques of pediatric femur fractures, the selected nail diameter should be approximately 40% of the intramedullary canal dimension (Table 21-17).

Positioning. Patient positioning should be predicated upon access to the shoulder girdle and upper limb and ease of fluoroscopic imaging. Use of the modified beach chair position will allow for easy manipulation, implant placement, and intraoperative imaging. In these cases, the fluoroscopy unit may be brought in from the head of the bed, allowing the surgeon to stand in the axilla or lateral to the affected shoulder and facilitating both AP and axillary views of the proximal humerus. Alternatively, patients may be positioned supine on a radiolucent table with a bump placed under the ipsilateral pelvis or between the scapulae. With supine positioning, the fluoroscopy unit may be brought in from the ipsilateral or contralateral side of the table.

TABLE 21-17 Intramedullary Fixation of Proximal Humerus Fractures

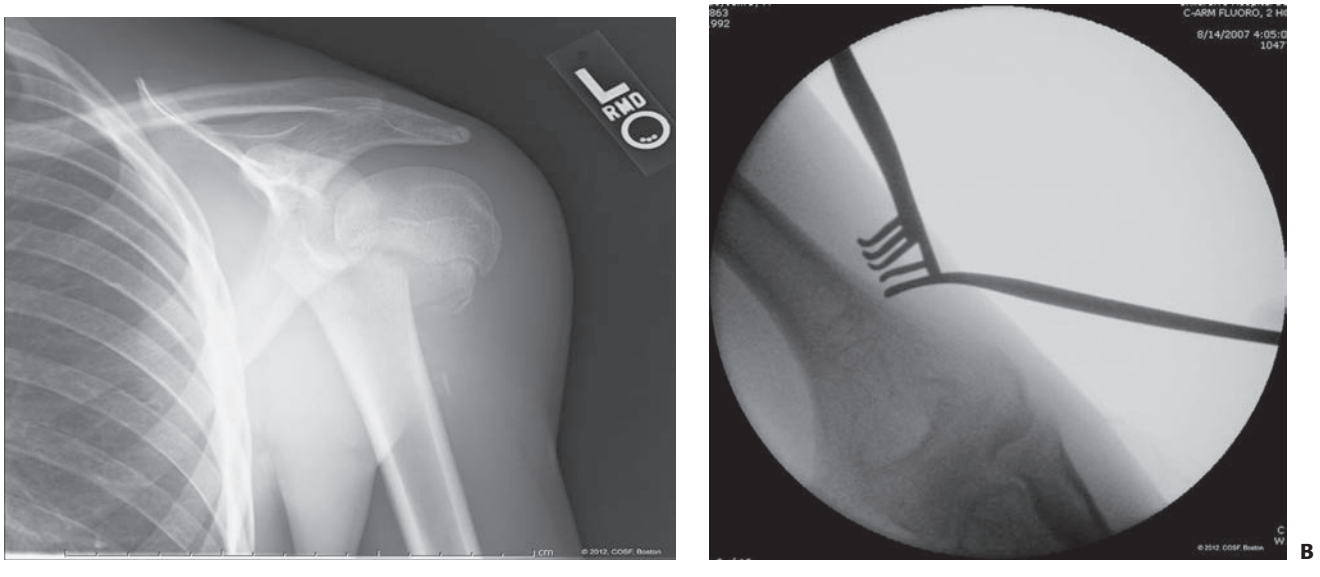
Surgical Approach(es). Again, closed reduction of the proximal humerus fracture is performed using the maneuvers described above. If inadequate realignment is achieved, open reduction may be performed via a limited deltopectoral approach.

Technique. Following fracture reduction, a longitudinal incision is made along the lateral column of the distal humerus at the level of the superior aspect of the olecranon fossa. Alternatively, medial column or posterior approaches may be utilized, splitting the triceps in the latter situation to gain access to the distal humerus and intramedullary canal above the olecranon fossa. Blunt dissection is performed through the subcutaneous tissues to the level of the distal humeral cortex (Fig. 21-26). Using a drill guide to protect the adjacent soft tissues, a 3.2- or 4.5-mm drill bit is used to create a cortical window in the lateral column; care is made to create this starting hole obliquely from distal-lateral to proximal-medial to facilitate subsequent nail passage. Appropriately sized intramedullary nails (typically 3 to 4 mm in diameter) are then prebent; if both nails are to be passed via a lateral entry point, one nail is bent in the shape of a gentle "C" and the other in the shape of a lazy "S" to allow for some divergence of the nail ends in the proximal fracture fragment. Nails are then passed into the lateral column



A B

FIGURE 21-26 Intramedullary fixation. **A:** Displaced proximal humerus fracture in an adolescent female. **B:** Blunt spreading is performed via a lateral incision along the distal humeral metaphysis.

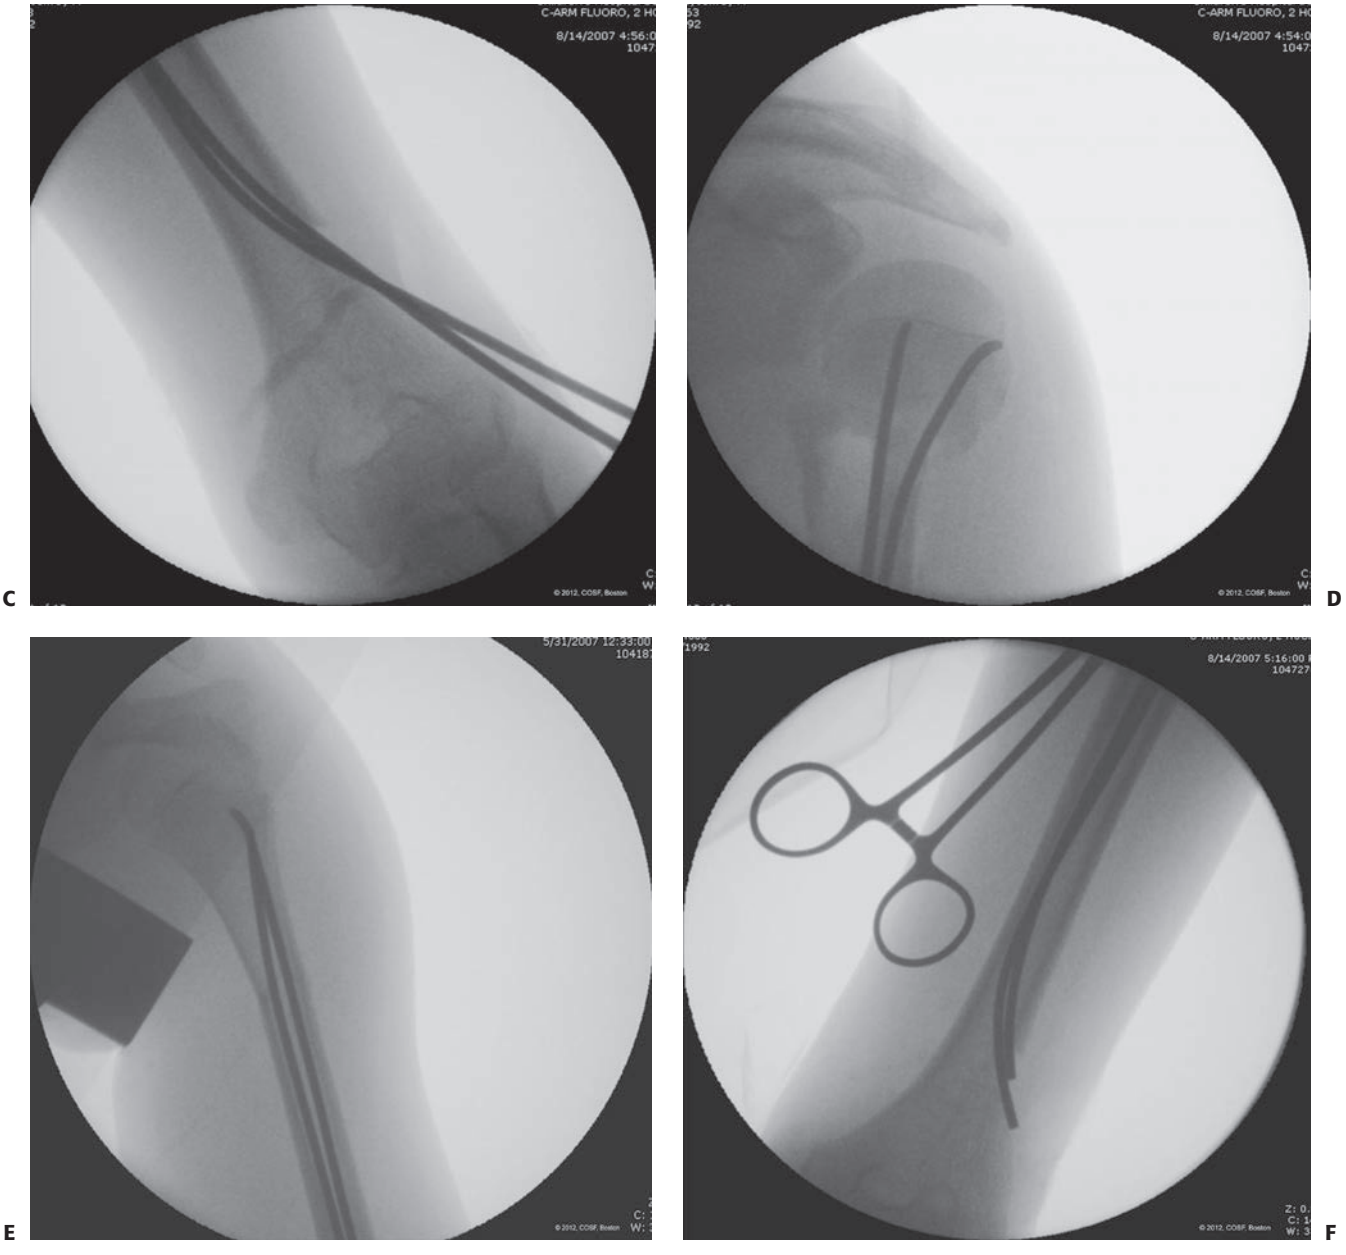


FIGURE 21-26 (*continued*) **C:** Precontoured flexible intramedullary nails are passed into the medullary canal. **D:** The implants traverse the fracture site and engage the humeral head. **E:** Rotation of the nails may be used to improve translation or angulation. **F:** Implants are cut beneath the skin.

entry site, through the intramedullary canal of the humerus, across the fracture site, and into the proximal fracture fragment. Typically, the nails must be gently impacted into the proximal humerus, with care to avoid distraction or further displacement at the fracture site. Fracture translation or angulation may be further corrected with nail rotation once the proximal fragment is engaged. Intraoperative fluoroscopy is utilized to confirm fracture alignment, stability, and implant placement. Nails are then cut beneath the skin with the distal ends flush against the metaphyseal flare to allow for subsequent removal but lessen the risk of nail irritation during fracture healing. Wound(s) are then closed, the dressing applied, and the upper extremity placed in sling-and-swathe immobilization (Table 21-18).

Surgical Procedure: Open Reduction Internal Fixation

Preoperative Planning. Open reduction and plate fixation is rarely necessary in the pediatric population, and typically reserved for cases of intra-articular extension, extensive fracture comminution, pathologic injuries, or severely displaced fractures in skeletally mature adolescents. Surgical principles follow established tenets of fracture fixation, with particular attention

TABLE 21-18 Intramedullary Fixation of Proximal Humerus Fractures

Surgical Steps

- Closed (or open) fracture reduction
- Incision along lateral column of distal humerus, at or proximal to olecranon fossa
- Alternatively, may use additional medial or posterior incisions and entry sites
- Blunt dissection to lateral humeral cortex
- Create cortical entry site with drill bit
- Precontour intramedullary nails
- Pass nails into intramedullary canal, across fracture site, and into proximal humeral fracture fragment
- Nail rotation to effectuate additional correction of translation/displacement
- Fluoroscopic confirmation of alignment and implant placement
- Bend and cut nails, leaving 2–3 cm flush along metaphyseal flare to allow subsequent removal
- Sling-and-swathe immobilization

to preservation of the vascularity to the humeral head and avoidance of iatrogenic neurologic injury. Though a host of anatomically precontoured plates are available, these commercially available implants do not often fit the adolescent patient, and standard small fragment plate-and-screw constructs will suffice.

Appropriate preoperative planning includes orthogonal radiographic views of the proximal humerus—preferably AP and axillary views—to characterize the fracture pattern and displacement. A careful neurovascular examination to rule out concomitant nerve palsy or vascular injury is imperative (Table 21-19).

Positioning. Similar to the procedures described above, patient positioning should allow near circumferential access to the shoulder girdle and ease of fluoroscopic imaging. Use of the modified beach chair position will allow for easy manipulation, implant placement, and intraoperative imaging. This semirecumbent position will also facilitate venous drainage and visualization. In these cases, the fluoroscopy unit may be brought in from the head of the bed, allowing the surgeon to stand in the axilla or lateral to the affected shoulder and facilitating both AP and axillary views of the proximal humerus.

Surgical Approach(es). A standard deltopectoral approach is typically used, as described above. As this procedure targets the proximal humeral metaphysis and diaphysis, rather than the glenohumeral joint, the incision is often biased distally. The approach is extensile and may be carried distally into an anterolateral or Henry approach to the proximal and middle humerus. Careful subperiosteal elevation of the deltoid and pectoralis major insertions will allow for adequate exposure of the metadiaphyseal humerus. Overzealous lateral retraction is avoided to prevent iatrogenic axillary neurapraxis. Great care should be taken to protect the ascending branch of the anterior humeral circumflex artery, which runs just lateral to the long head of biceps tendon.

TABLE 21-19 Reduction and Fixation of Proximal Humerus Fractures

Preoperative Planning Checklist

- OR Table: Standard
- Position/positioning aids: Modified beach chair position
- Fluoroscopy location: From head of table
- Equipment: Appropriately sized small fragment implants or site-specific implants; shoulder retractors if desired
- Tourniquet (sterile/nonsterile): Not applicable

Technique. After appropriate exposure is obtained, the fracture site is identified and cleared of fracture hematoma or any interposed soft tissue. Unlike adults, adolescent proximal humerus fractures tend not to be comminuted, and osteopenia is rare. The biceps tendon is a useful anatomic landmark, as the greater and lesser tuberosities lie lateral and medial to the biceps tendon, respectively. Anatomic fracture reduction may be achieved, and if needed provisional fracture fixation using smooth K-wires or fracture reduction clamps may be obtained. Following fracture realignment, internal fixation using appropriate plate-and-screw constructs is achieved. Careful intraoperative imaging will assist in proper screw placement within the humeral head and avoidance of intra-articular implant penetration. Typically six cortices of fixation into the distal fracture fragment are sufficient. After direct and fluoroscopic confirmation of appropriate alignment and stability, the wound is closed in layers and the affected limb placed in a sling.

As noted above, avulsion fractures of the lesser tuberosity may occur in adolescents. ORIF is recommended in patients with displaced injuries.[140,166,223,436] Similar patient positioning and surgical deltopectoral approach may be utilized. In general, the lesser tuberosity fracture fragment is easily identified, and the attachment of the subscapularis tendon and muscle are preserved. Once fracture site on the proximal humerus is defined and debrided, bioabsorbable suture anchors may be placed in the donor site. Heavy, nonabsorbable sutures are then passed through the undersurface of the lesser tuberosity fracture fragment, exiting superficially. The fracture is then reduced, and the previously passed sutures are tied down completing the repair (Table 21-20).

TABLE 21-20 Open Reduction and Fixation of Proximal Humerus Fractures

Surgical Steps

- Exposure via a deltopectoral approach
  - Identification of the biceps tendon
  - Protection of the ascending branch of the anterior humeral circumflex artery and axillary nerve
- Identify fracture fragments
  - Preserve soft tissue attachments
- Reduce fracture
  - In cases of intra-articular extension, reduce and fix humeral head fragment first
- Provisional fixation with K-wires
- Apply plate-and-screw fixation
- Layered wound closure
- Sling immobilization

Author's Preferred Treatment of Proximal Humerus Fractures

The majority of proximal humerus fractures in children and adolescents may be successfully treated nonoperatively. In infants with birth-related fractures, immobilization with a stockinette or pinning of the sleeve to the trunk is simple and effective. Radiographic assessment of healing is performed at 4 to 6 weeks of age; immobilization is discontinued with evidence of clinical and radiographic healing.

In children and adolescents with closed proximal humerus fractures in acceptable deformity (Table 21-13), simple sling immobilization is utilized. Serial radiographs are obtained to confirm adequate alignment. Bony union is typically obtained in 4 to 6 weeks, though clinically improvement and pain relief typically precedes radiographic healing. After confirmation of clinical and radiographic healing, range of motion and strengthening is advanced as tolerated.

In older children and adolescents with unacceptable radiographic alignment, initial closed reduction is performed with conscious sedation or general anesthesia. Careful radiographic evaluation of bony alignment and assessment of fracture stability is performed. Given the data suggesting that late displacement is a frequent occurrence following closed manipulation alone of severely displaced proximal humerus fractures in adolescents, *a low threshold exists for fracture stabilization.* For unstable injuries with deformity beyond what is anticipated to remodel with continued skeletal growth, fracture fixation is performed. Physeal fractures are treated with closed reduction and percutaneous smooth pin fixation; typically two retrograde pins will suffice. Pins may be bent and cut outside the skin, which facilitates subsequent removal and obviates the need for additional anesthesia. If pins are left outside the skin, patients are immobilized with sling-and-swathe to prevent pin migration or pin-tract complications. In patients with metaphyseal fractures—in which there is still some metaphyseal bone on the proximal fracture fragment—intramedullary nailing is preferred (Fig. 21-27). Using the technique described above, appropriate flexible titanium intramedullary implants are prebent and inserted via a lateral entry point. Intramedullary nails are cut and left beneath the skin; attention to the trajectory and location of nail entry will allow the ends of the nails to lie flush against the metaphyseal flare of the distal humerus, avoiding unnecessary soft tissue irritation. Patients are placed in sling-and-swathe immobilization.

In cases of open fractures with adequate soft tissue coverage, open reduction and either pin or intramedullary nail fixation is performed after thorough irrigation and debridement of the open wound. In cases associated with excessive fracture comminution, vascular insufficiency, or severe soft tissue loss, internal fixation with plate-and-screw constructs are considered. Open reduction is similarly performed in closed injuries in which an acceptable reduction may not be achieved with manipulation, typically because of interposed soft tissue (Fig. 21-28).[16,89,111,251,439]

Postoperative Care

Patients receiving nonoperative treatment of proximal humeral fractures are followed weekly with radiographs to ensure confirm maintenance of alignment. Once there is evidence of clinical and radiographic healing, gentle shoulder

pendulum and elbow range-of-motion exercises are begun. Immobilization is typically discontinued after 4 to 6 weeks. Sports participation is restricted until there is return of motion and strength, and patients/families are counseled regarding the risk of refracture.

Following surgical reduction and stabilization, sling immobilization is usually sufficient and continued until radiographic healing. With plate fixation, gentle pendulum and elbow range-of-motion exercises may be initiated once adequate comfort is achieved. In cases of intramedullary nail fixation, implants are typically removed at 6 months postoperatively.

Potential Pitfalls and Preventative Measures

While the principles of treatment are seemingly straightforward, proximal humerus fractures present a number of challenges and potential pitfalls, particularly in the adolescent with severe displacement. First, assessment of what constitutes "acceptable deformity" can be challenging in the older pediatric patient population. Though guidelines exist on what constitutes adequate bony alignment, these recommendations are based upon historical retrospective case series and expert opinion. The decision-making process is further challenged by changing patient functional demands and

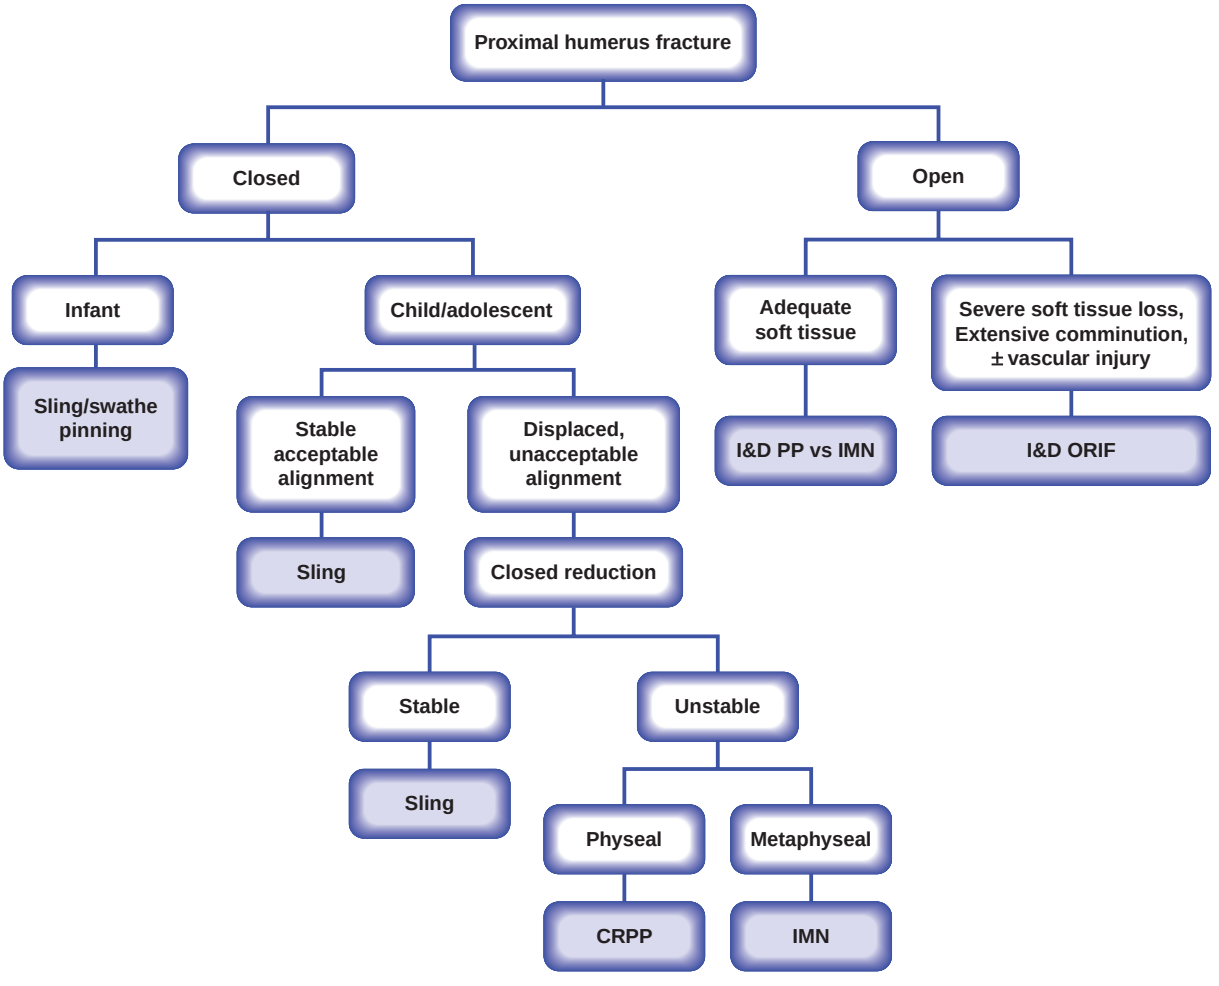

FIGURE 21-28 Proposed treatment algorithm for humeral shaft fracture.

evolving parent/family expectations. Careful characterization of radiographic alignment in the context of patient demands is needed to ensure optimal outcomes. For example, less than 40 degrees of varus may be deemed permissible, but might lead to limitations in abduction unacceptable to an overhead athlete. As in all pediatric orthopedics, care should be individualized to account for these considerations.

Second, when indicated, closed reduction of severely displaced proximal humerus fractures is challenging. Awareness of the deforming muscular forces, adequate analgesia or anesthesia, and appropriate fluoroscopic imaging will facilitate successful closed manipulations. In cases where acceptable reduction cannot be achieved, open reduction should be pursued, and any interposed periosteum or soft tissue extricated from the fracture site.

In addition, loss of reduction and further fracture displacement is common in older adolescents with severely displaced injuries. Careful assessment of fracture stability at the time of reduction and with serial radiographs is recommended. A low threshold should exist for percutaneous pin fixation or intramedullary nailing of severely displaced fractures to maintain bony alignment.

Furthermore, there are a number of potential pitfalls commonly encountered during surgical stabilization. Judicious percutaneous pin placement is imperative to avoid iatrogenic axillary nerve injury or inadvertent intra-articular penetration of the glenohumeral joint. Given the frequency with which pins cause soft tissue or infectious complications, adequate immobilization of the affected limb and timely pin removal are needed. Conversely, if intramedullary devices are used, appropriate entry point(s) and trajectory will prevent soft tissue irritation or migration of the implants (Table 21-21).

TABLE 21-21 Proximal Humerus Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Failure to recognize fracture pattern	Appropriate orthogonal imaging Avoid varus and apex anterior angulation Individualized treatment
Difficulty with closed reduction	Understand, reverse deforming muscle actions Adequate analgesia/anesthesia Orthogonal fluoroscopic imaging Transition to open reduction if interposed soft tissue
Loss of alignment after reduction	Routine fracture fixation after closed reduction of severely displaced injuries in adolescents Preset pins into the distal fracture fragment first, then perform the reduction, then pass the pins across the fracture site with the shoulder abducted and/or externally rotated
Implant-related complications	Correct insertion of percutaneous pins Sling-and-swathe immobilization if percutaneous pins left out of skin

Treatment-Specific Outcomes

Multiple published reports have suggested that surgical reduction and stabilization of displaced proximal humerus fractures is safe and effective in obtaining radiographic healing with improved bony alignment and minimal complications.[28,70,111,229] In patients with Neer–Horwitz grade III and IV injuries, improvement to grade I and II displacement may be expected.[111,198]

Kohler and Trillaud[229] have previously reported the clinical and radiographic outcomes of 52 patients at a mean of 5 years following proximal humerus fractures. Clinical results were "good" or "very good" in all cases, with little correlation to longer-term radiographic parameters. While the authors suggest that surgical intervention offers no advantages over nonoperative treatment, it should be noted that all surgical patients in their series underwent formal ORIF, with fixation including staples, pins, screws, and plate-and-screw constructs.

Beringer et al.[28] similarly advocated a nonoperative approach in their report of 48 patients with displaced proximal humerus fractures. All patients with longer-term follow-up reported no activity restrictions or limitations, and functional results did not correlate with radiographic findings. As three of the nine patients treated surgically had complications, the authors recommended nonsurgical treatment in the majority of cases.

Dobbs et al.[111] published their series of 29 patients treated for Neer–Horwitz grade III and IV fractures, of which 25 were treated with closed versus open reduction and pin or screw fixation. The majority of patients were greater than 15 years of age. Postoperatively, all patients improved to a grade I or II deformity, and there were no surgical complications. At a mean follow-up of 4 years, normal or near-normal motion and strength was seen in all patients. These findings support the efficacy and safety of surgical intervention for severely displaced injuries in older patients.

Chee et al.[70] presented their series of 14 patients, mean age 13 years, treated with single intramedullary flexible nail fixation for displaced proximal humerus fractures. All patients had full range of shoulder motion at final follow-up, supporting the authors' assertion that intramedullary fixation is effective in select patients.

To date, however, much of the available data comes from retrospective case series or limited comparative cohort studies, heavily weighted toward radiographic and/or physician-derived results. Little patient-derived functional outcomes data is available, and future prospective investigation assessing long-term results using validated outcomes instruments is needed to provide better insight into optimal management and potential adverse sequelae.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Proximal Humerus Fractures

While uncommon, complications of proximal humerus fractures may have considerable effect on shoulder girdle and upper limb function. Neurologic injury of the brachial plexus or peripheral

nerves may be seen, particularly in severely displaced valgus injuries and the rare fracture-dislocation.[10,112,199,432,438] Most nerve palsies are diagnosed at the time of injury and represent neurapraxic injuries rather than true nerve transections. In general, these neurologic deficits will resolve spontaneously over 6 to 12 months but may be associated with neurogenic pain in the affected limb during recovery.[199] In patients with persistent nerve deficits without clinical signs of spontaneous recovery in the expected period of time, electrodiagnostic studies (electromyography and nerve conduction velocities) may be considered to characterize the location and severity of neurologic deficit. In rare situations, exploration with neurolysis, nerve repair, nerve grafting, or nerve transfers (i.e., radial motor branch of long head of triceps to axillary motor) may be necessary.[10,79] In chronic or late-presenting situations, salvage procedures such as tendon transfers or proximal humeral osteotomies may be considered to improve shoulder and upper limb function.[84,181,222,335]

Vascular insufficiency is a rare but potentially devastating complication of proximal humerus fractures. Treatment is predicated on prompt reduction, fracture stabilization, and reassessment of vascularity. In cases of persistent distal ischemia, appropriate exploration and vascular repair or reconstruction is needed.[199]

Humerus varus is another potential complication of proximal humerus fractures in children and adolescents. Humerus varus is characterized by a humeral neck-shaft angle of less than 140 degrees, a greater tuberosity cephalad to the superior aspect of the humeral head, and a reduced distance between the articular surface of the humeral head and the lateral cortex of the humerus.[228] The resultant varus angulation and prominent greater tuberosity leads to limitations in shoulder forward flexion and lateral abduction. Potential etiologies include varus malunion as well as partial physeal arrest following proximal humeral physeal fracture. In cases of functionally limiting humerus varus, corrective osteotomy to restore more anatomic proximal humeral morphology may be performed (Fig. 21-23).[119,146,242,268,404,428]

Upper limb length discrepancy may similarly be seen as a late sequela of physeal fractures.[22,95,369] Though more commonly reported in patients following operative reduction, physeal disturbance is likely due to the trauma associated with the initial injury rather than surgical intervention. Furthermore, prior reports have suggested that limb length discrepancy is not correlated with the quality of initial fracture reduction.[22,308] Limb length inequality has similarly been reported in patients with pathologic fractures of the proximal humerus through unicameral bone cysts.[180,298,314] In patients with functional limitations or predicted upper limb length discrepancies of greater than 6 cm at skeletal maturity, limb-lengthening procedures may be considered.[187,248,332]

Osteonecrosis of the humeral head is much less common in children than adults.[278] In setting of confirmed osteonecrosis, revascularization and humeral head remodeling may be seen in skeletally immature patients, leading to satisfactory clinical outcomes.[449]

Finally, hypertrophic scar formation is commonly seen after surgical treatment of proximal humerus fractures, particularly following open reduction via a deltopectoral approach. Prior investigation has suggested this aesthetic difference may be psychologically troubling to adolescent patients.[131,145] For this reason, alternative, more aesthetic incisions in the axilla have been proposed.[157] Patients and families should be counseled about the possibility of hypertrophic scar formation from deltopectoral incisions or percutaneous pin sites prior to surgical intervention (Table 21-22).

Hypertrophic scar formation

Summary, Controversies, and Future Directions Related to Proximal Humerus Fractures

In summary, the majority of proximal humeral fractures may be effectively treated nonoperatively. In older adolescent patients with greater angulation and displacement, reduction and surgical stabilization is safe and effective in restoring radiographic alignment and shoulder motion. Future prospective, comparative investigation is needed to determine the criteria for reduction and fixation in older children and adolescents and characterize the patient-derived functional outcomes of these injuries in the long term.

Introduction to Humerus Shaft Fractures

The humeral diaphysis is the location of 20% or less of all pediatric humerus fractures and 5% or less of all childhood skeletal injuries.[72,257,358] The incidence is estimated to be between 12 and 30 per 100,000 per year, and more recent epidemiologic information from the United States suggests that this incidence has remained relatively constant despite population changes.[221,240,464] There is a bimodal distribution of ages of children who sustain humeral diaphyseal fractures, with the greatest frequency seen in infants and adolescents.[23]

Assessment of Humerus Shaft Fractures

Mechanisms of Injury for Humerus Shaft Fractures

Humeral shaft fractures may be due to a variety of injury mechanisms, each with its own set of clinical considerations.

Birth-related trauma is a frequent cause of humeral diaphyseal injury, with a reported incidence between 0.035% and 0.34%.[56,272] Macrosomia, breech presentation, and/or difficult delivery are thought to be potential risk factors. The humerus is at particular risk in situations where the upper limb is abducted above the newborn's head and must be delivered inferiorly after

version and extraction.[272] Similarly, humerus fractures may occur in cases of shoulder dystocia with rotational maneuvers or posterior arm delivery.[253] Cesarean section delivery is not necessarily protective, and any forceful extraction may impart enough energy to cause a humerus fracture.[29,57,351]

Nonaccidental trauma may also manifest as humerus fracture in a child. Indeed, 12% of all fractures and up to 60% of new fractures stemming from nonaccidental trauma affect the humerus.[266,390] While child abuse must be considered within the differential diagnosis of humeral diaphyseal fractures—particularly in children less than 3 years of age—only a minority of humeral shaft injuries in children are due to nonaccidental trauma.[390]

The most common mechanism of injury is direct or indirect force imparted upon the upper limb in the older child or adolescent. Direct blows to the brachium, falls onto an outstretched upper limb, motor vehicle collisions, and sports-related trauma may all result in diaphyseal fractures. Indeed, humeral shaft fractures have even been noted from throwing and other overuse activities, because of the rotational forces imparted upon the humerus during the throwing motion.[4,141,153,177,260,320,454]

Associated Injuries with Humerus Shaft Fractures

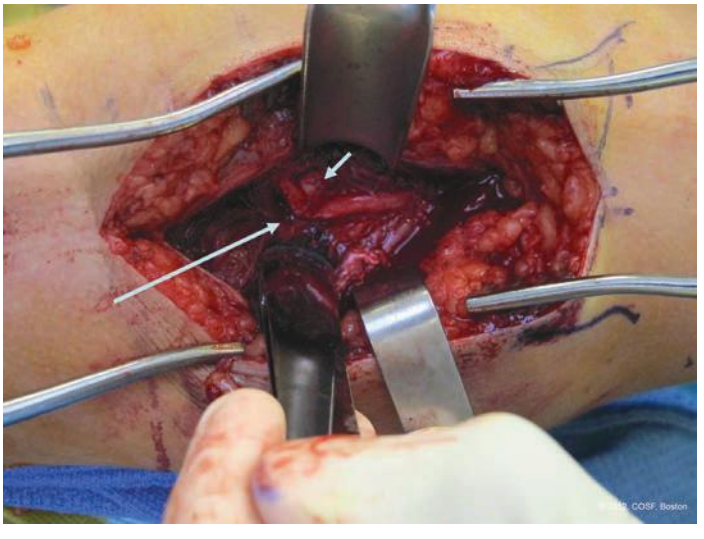
Radial nerve palsies are commonly associated with humeral diaphyseal fractures and raise a number of treatment considerations and controversies.[5,23,68,90,94,117,138,172,184,270,273,328,338,357,391,429] Owing to the anatomic proximity of the radial nerve to the mid- and distal humerus, the nerve may be contused, stretched, kinked, or rarely transected with the initial injury and/or fracture displacement.[433] Furthermore, a delayed palsy may occur due to compression secondary to scar tissue, fracture callus, and even bone formation. It has been estimated that up to 20% of adult and 5% of pediatric humeral diaphyseal fractures will have associated radial nerve palsies.[36,138,270,280,337,386,440]

Clinically, radial nerve palsies may be categorized into the time of presentation. Primary radial nerve palsies occur at the time of injury and are clinically apparent at first evaluation. Secondary radial nerve palsies refer to deficits presumably sustained at the time of fracture reduction or manipulation, in patients in whom radial nerve function was initially intact.

Most published information suggests that the potential for spontaneous nerve recovery is high, with 78% to 100% of patients regaining radial nerve function with observation alone.[6,36,41,42,50,108,117,138,147,262,328,337,338,371,386,440] Indeed, in cases in which the primary radial nerve palsies were treated with immediate or early exploration, the vast majority of the time the nerve is found to be intact, though contused or tented over the displaced fracture fragments (Fig. 21-29).[151,270,328,386,388,405,440] In children, it has been hypothesized that the thicker periosteum may confer a protective effect on the radial nerve, reducing the risk of traumatic laceration or incarceration within the fracture site.

Radial nerve exploration should be performed in instances of open humeral diaphyseal fractures in which surgical debridement and stabilization is to be performed. If a true radial nerve laceration is encountered, options include tagging the nerve ends for subsequent identification and repair versus immediate primary neurorrhaphy.[129,415,422] Given the distance to reinnervation from a high radial nerve palsy, earlier repair allows for the best anatomic and functional potential.[31]

A



B

FIGURE 21-29 **A:** AP radiograph of a 15-year-old female with an open humeral diaphyseal fracture and radial nerve palsy. **B:** Intraoperative radiograph depicting exposure via a lateral approach. (*continues*)

C

D

FIGURE 21-29 (*continued*) **C:** After irrigation, debridement, and plate fixation of the fracture, the nerve can be seen decompressed overlying the implant. **D:** Postoperative radiograph depicting bony healing and implant placement.

In cases of primary radial nerve palsy, recommendations have been made for observation and exploration at 8 weeks to 6 months if there is failure of adequate recovery.[5,6,94,108,186,280,337,338,391] While these time-based guidelines are helpful, each patient must be considered individually, adhering to fundamental principles.[32] In general, if there is failure of adequate recovery after the anticipated time—based upon the distance from the injury to distal points of reinnervation—surgical exploration should be considered. Prior physiologic studies have determined that following wallerian degeneration, nerve growth will occur at a rate on an average of 1 mm per day.[379,380,414,415] For high radial nerve palsies, spontaneous resolution should entail an advancing Tinel sign, with sequential return of radial wrist extensors, central wrist extensors, digital extensors, and thumb extensors. In cases of late exploration where radial nerve lacerations are encountered, sural nerve grafting may be performed, with anticipation of functional return.[31,128,319,434]

There continues to be controversy regarding the optimal management of secondary radial nerve palsy. If nerve function is lost after fracture manipulation, observation alone is still supported by published data suggesting that spontaneous recovery will occur in the majority of patients.[36,42,108,138,236,386] Others advocate early exploration because of liability concerns and late extraction from fracture callus is much more difficult than early decompression. If radial nerve function is lost during the later period of fracture healing, careful consideration should be made regarding whether the nerve is entrapped within scar tissue, fracture callus, or bone.[116,468] Radiographs may depict an oval lucency corresponding to the bony foramen through which the nerve is running, the so-called Matev sign.[113,196,441] In these situations, surgical exploration and decompression should be performed.

Signs and Symptoms of Humerus Shaft Fractures

Clinical signs and symptoms will vary considerably depending upon the patient age and mechanism of injury.

In infants in whom a birth-related humerus fracture is suspected, a careful pre- and perinatal history should be obtained, specifically evaluating for macrosomia, prolonged or difficult labor and delivery, and history of shoulder dystocia. Additional historical information—such as whether the newborn will nurse from each breast—may guide the care provider to the correct diagnosis. Clinically, these infants will exhibit pseudoparalysis of the affected limb, holding or splinting the arm against the side. As distal neurologic function is intact, the infant will spontaneously grasp and move the digits and wrist. There will be reproducible tenderness, motion, and crepitus at the fracture site, though often little swelling or ecchymosis.

In older children who sustain traumatic or sports-related fractures, a careful history will provide insight into the mechanism of injury and any associated trauma. Details regarding the position of the upper limb, direction of forces imparted, and energy of injury will aid in clinical diagnosis. Patients will typically present with pain, swelling, ecchymosis, and guarding of the affected limb, with or without obvious deformity. The arm is typically held tightly against the body as the patient guards and protects the injured limb. Physical examination should include careful inspection of the overlying skin to assess for open wounds, ecchymosis, and skin tenting or dimpling. A thorough neurovascular examination is critical, particularly to assess potential injury of the radial nerve.[41,42,184,312,319,337]

Imaging and Other Diagnostic Studies for Humerus Shaft Fractures

Plain radiographs of the humerus will confirm the diagnosis and should be performed in all cases of suspected humeral diaphyseal fractures (Figs. 21-30 and 21-31). Orthogonal views should be obtained, as nondisplaced or incomplete greenstick fractures may occur in children. Appropriate lateral radiographs will demonstrate overlap or superimposition of the posterior supracondylar ridges of the medial and lateral epicondyles.[151]

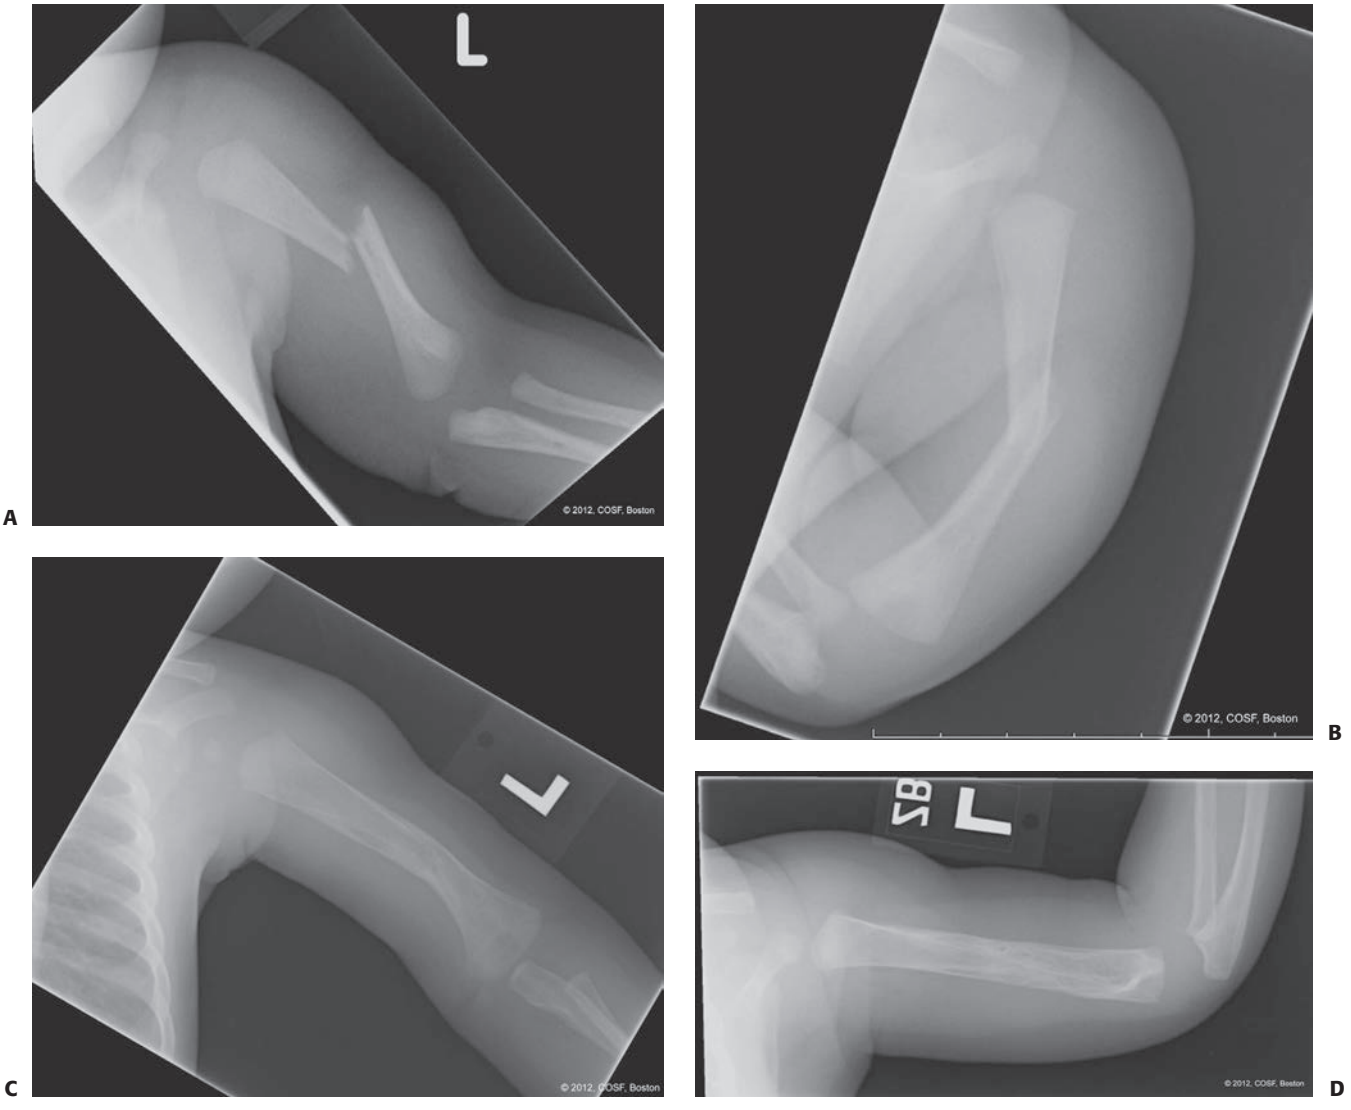

FIGURE 21-30 **A, B:** Radiographs depicting a humeral diaphyseal fracture in a 4-day-old infant with displacement and angulation. **C, D:** By 3 months of age, there is excellent bony healing and early remodeling.

In addition to confirming the diagnosis and characterizing its anatomic location and pattern, radiographs should be inspected for associated lesions to evaluate for possible pathologic fractures.[323,410,421] The humerus is a common site for both benign and malignant lesions in skeletally immature patients, and care should be taken to identify an associated condition.

"Floating elbow" injuries may occur, particularly in the setting of higher-energy mechanisms.[409] In patients with ipsilateral wrist or forearm pain or swelling, radiographic evaluation of the elbow and forearm will allow for diagnosis of these associated injuries.

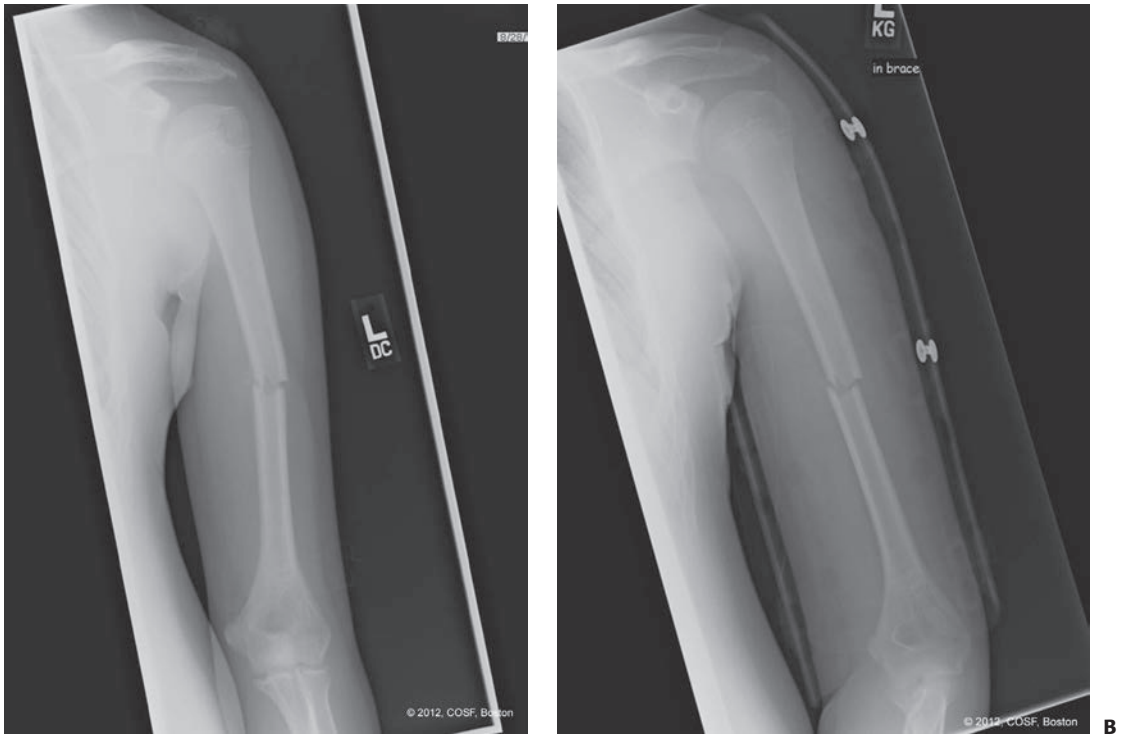
Finally, in cases of suspected nonaccidental trauma, a skeletal survey and bone scan may be performed to evaluate for the presence of other fractures at various stages of healing.

Classification of Humerus Shaft Fractures

Classification of humeral diaphyseal fractures remains largely descriptive. Anatomic location, fracture pattern, direction of displacement and/or angulation, and the presence of associated soft tissue or ipsilateral skeletal injuries are used. While a classification system has been proposed by the Association for Study of Internal Fixation for humeral shaft fractures in adults, this has not been universally applied to the pediatric patient population, and questions persist over its interobserver reliability and clinical utility.[213,303]

Pathoanatomy and Applied Anatomy Relating to Humerus Shaft Fractures

While the humerus is a long, tubular bone, a number of anatomic features are worthy of note. First, the middiaphyseal region is triangular in cross section and narrower than the adjacent proximal and distal metaphyseal regions. In children, the humerus is enveloped in thick periosteum and has a rich vascular supply; the primary nutrient artery enters at the



A B

FIGURE 21-31 **A:** AP radiograph of a minimally displaced humeral diaphyseal fracture in a 13-year-old male. **B:** Radiograph in fracture brace, demonstrating maintenance of alignment.

middiaphyseal level, though abundant accessory vessels supply the humeral shaft anteriorly and posteriorly.[59,139,151]

The deltoid tuberosity serves as the insertion of the deltoid and is located in the middiaphysis. The latissimus dorsi and teres major insert on the proximal aspect of the humerus, just medial to the bicipital groove. Conversely, the pectoralis major inserts along the anterior humerus lateral and distal to the bicipital groove. The coracobrachialis arises from the coracoid process and inserts along the middle third–distal third junction anteromedially. Distal and posterior to the deltoid tuberosity lies the so-called spiral groove, adjacent to which runs the radial nerve and from which the most proximal fibers of the brachialis originate. Similar to fractures of the proximal humerus, awareness of these muscle and soft tissue relationships help explain typical fracture displacement patterns and guide reduction maneuvers.

The anatomic path of the radial nerve deserves special attention, given the frequency with which the nerve is injured with humeral diaphyseal fractures.[456] While much of the published literature is derived from cadaveric data in adults, a few principles may be applied to the pediatric population. First, as the radial nerve arises from the posterior cord of the brachial plexus, it passes through the triangular interval, bounded by the teres major superiorly and the lateral and long heads of the triceps medially and laterally. The radial nerve is typically accompanied by the profunda brachii artery as it passes through the upper arm. The nerve travels along the spiral groove, but is typically not in direct contact with the posterior humeral cortex; instead, it is separated from the bone by muscular fibers.[58,456] In general, the radial nerve is located directly posterior to the humeral diaphysis at the level of the deltoid tuberosity, a useful anatomic relationship in cases of surgical fracture treatment. The radial nerve continues distally and laterally, where it pierces the lateral intermuscular septum to enter the anterior compartment. Distally at the elbow, it may be found reliably in the brachialis–brachioradialis intermuscular interval.

The ulnar nerve runs in the medial aspect of the posterior compartment and does not give off any motor branches above the elbow. The median nerve travels just medial to the brachial artery in the distal half of the brachium.

Treatment Options for Humerus Shaft Fractures

Nonoperative Treatment of Humerus Shaft Fractures

Indications/Contraindications (Table 21-23)

The vast majority of humeral diaphyseal fractures in children are amenable to nonoperative care.[103] As the upper limb is not weight bearing, anatomic alignment of the humerus is not necessary for functional restoration. Furthermore, shoulder motion, elbow flexion–extension, and forearm rotation may effectively compensate for mild-to-moderate humeral deformity. Finally, there is considerable remodeling potential for humeral deformity in skeletally immature patients; indeed, even up to 30 degrees may remodel in the adolescent population.[94] For these reasons, up to 20 to 30 degrees of varus, 20 degrees of apex anterior angulation, 15 degrees of internal rotation, and

TABLE 21-23 Humerus Shaft Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Birth-related fractures	Open fractures
Diaphyseal fractures with acceptable alignment	Associated vascular injury
Stress fractures	Diaphyseal fractures with unacceptable alignment
Benign pathologic fractures	

bayonet apposition with 1 to 2 cm of shortening is deemed acceptable.[94,225,347] As with all guidelines, these parameters for "acceptable deformity" must be taken into their historical context, and individualized decisions should be made regarding the function demands and treatment goals of each patient.

Birth-related fractures of the humeral diaphysis heal robustly and demonstrate profound remodeling potential. Indeed, 50% or greater remodeling may be seen within 1 to 2 years.[30] For this reason, simple immobilization to maximize comfort is sufficient, and no effort to achieve or maintain anatomic alignment is necessary.[183,197,394] A host of different treatment options have been proposed—ranging from sling-and-swathe, splinting, casting, traction, or simply pinning the sleeve of the affected arm to the body.[12,183,197,394] Concerns regarding immobilization and bony healing in excessive internal rotation may be addressed by immobilization of the upper extremity with elbow extension. This is particularly relevant in patients with concomitant brachial plexus birth palsies, in whom internal rotation contractures and external rotation weakness of the shoulder are common.[162,232,450]

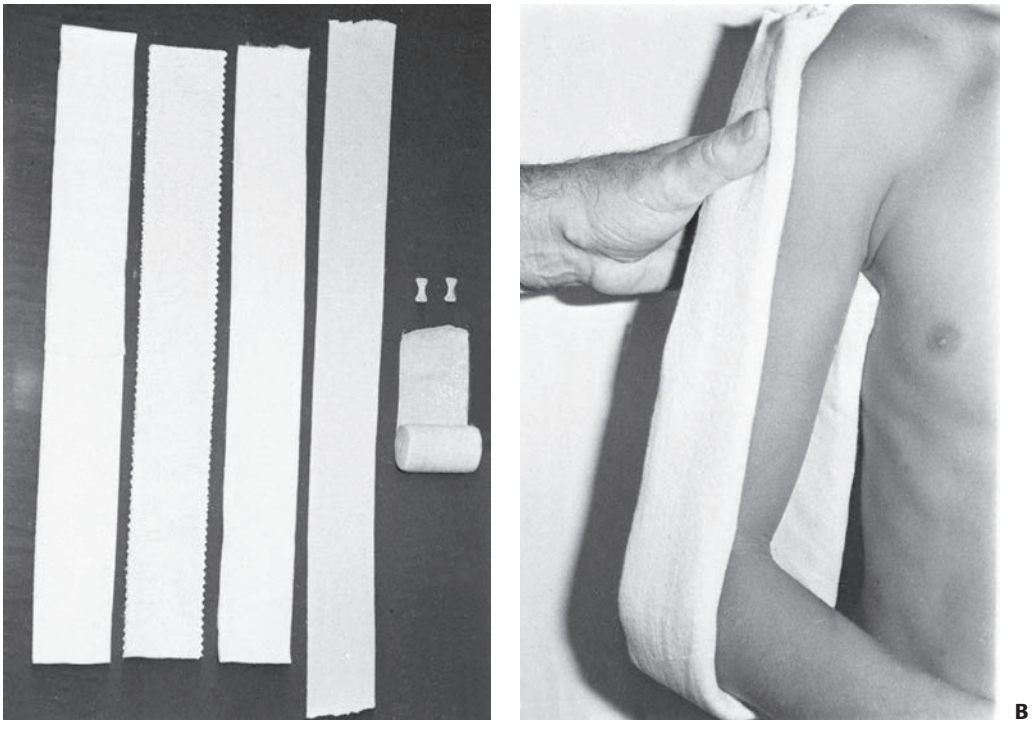
Stress fractures of the humerus do occur and almost universally heal with appropriate rest, time, and activity modification.[4,106,141,260,348,454] Failure to allow for symptom-free healing may result in fracture completion and displacement.[4]

Techniques

Sling-and-swath immobilization is simple, safe, and effective for incomplete and minimally displaced fractures.[347] It may also be utilized for displaced fractures, though does not control apex anterior or varus angulation well, particularly in active and/or obese patients.[173,347,406] While the weight of the upper limb may be well supported, some patients find sling-and-swathe immobilization uncomfortable because of persistent motion at the fracture site.

Techniques: Coaptation Splinting

Coaptation splinting (also referred to as U-plaster or sugartong splinting) has also been advocated in the treatment of humeral diaphyseal fractures.[38,471] The application of a coaptation splint is straightforward and is similar to that of sugartong splinting of the forearm (Fig. 21-32). A plaster splint, corresponding to



A **B**

FIGURE 21-32 Coaptation splints with collar and cuff. **A:** The material used for a sugartong arm splint is two pieces of cast padding rolled out to the length of the plaster-of-paris splint and applied to each side of the splint after it is wet. The splint is then brought into the tubular stockinette of the same width but 4 in longer than the splint. **B:** The plaster splint is applied to the arm from the axilla up to the tip of the acromion.

(*continues*)

C

D

FIGURE 21-32 (*continued*) **C:** As the plaster is setting, the splint is molded to the arm. An elastic bandage holds the splint in place. **D:** Stockinette is applied and attached to the wrist to form a collar-and-cuff sling.

the width of the brachium, is applied in a well-padded fashion from the acromion superolaterally, around the olecranon distally, and back up to the level of the axilla medially. The splint may be gently molded to the upper arm and secured in place with an elastic bandage or wrap. Efforts should be made to advance the superolateral extension of the splint to the level of the neck, in efforts prevent distal migration with gravity.[387] Others have recommended application of benzoin to the skin prior to splint placement and the use of a collar-and-cuff to prevent slippage.[183] Coaptation splinting has proven effective in children, and is particularly useful in the acute setting as the plaster slab may be molded comfortably to the swollen limb.[94,226] However, as the initial swelling subsides, refitting or transitioning to other methods of immobilization may be needed. Furthermore, coaptation splinting is not as effective as other forms of immobilization at effectuating or maintaining reduction in cases of severe initial displacement.[39,183]

Techniques: Traction

Both overhead and side-arm traction have been described for the treatment of humeral diaphyseal fractures.[183,195,437] Skin traction may be applied to the elbow, forearm, or hand. Alternatively, skeletal traction via an olecranon wingnut or transolecranon traction pin may be utilized.[15,27] Excessive or prolonged traction includes nonunion and elbow dislocation.[174,178] At present, because of patient and family demands, economic pressures, and wealth of alternative treatment options, the use of traction remains primarily of historic importance and is rarely utilized.

Techniques: Hanging Casting

Hanging arm casts utilize both immobilization and gravity to impart stability and longitudinal traction to humerus fractures.[53] Long above-elbow casts are applied to the affected limb and supported by a sling or collar-and-cuff. Adjustments in sling/cuff placement may allow for correction of coronal and sagittal plane deformity, though rotational alignment is poorly controlled. While reported results demonstrate efficacy with this technique, compliance may be limited due to pain and difficulty maintaining an upright position, particularly in very young patients.[412,461] Furthermore, concerns regarding shoulder and elbow stiffness and internal rotation contractures persist.[14,78,352]

Techniques: Functional Bracing

First described by Sarmiento et al.[374] in 1977, functional bracing of humeral diaphyseal fractures has been increasingly used in both children and adults.[17,24,65,161,252,306,389,446,447,469] In general, these functional braces confer a number of advantages over other nonoperative treatment options. In addition to providing external support via their clamshell design, when properly applied functional braces may effectuate and maintain fracture reduction due to the hydraulic effect to the surrounding soft tissues (Fig. 21-31). Furthermore, functional braces allow for elbow motion, minimizing the risk of late elbow contractures. While limited comparative information is available, there is data to suggest that functional bracing is superior to coaptation

splinting and equally effective as locked intramedullary nailing in appropriately selected patients.[389,447]

Prefabricated or custom-fit functional braces are used early in the course of treatment. Many patients will not tolerate functional bracing immediately, and are temporarily supported in a sling-and-swathe or coaptation splint until the initial swelling subsides. Serial clinical visits and radiographic assessment are needed to ensure adequate brace fit and maintenance of radiographic alignment. Functional braces may even be utilized for comminuted extra-articular fractures of the distal third of the humerus, though occasionally brace extensions may need to assist in coronal plane control.[211,373] By design, functional braces for humerus fractures are not as effective in controlling apex anterior angulation, nor are they meant to support weight bearing of the affected upper limb.

Operative Treatment of Humerus Shaft Fractures

Indications/Contraindications

In general, indications for surgical treatment of humeral diaphyseal fractures include open fractures, fractures with vascular injury, floating elbow injuries (Fig. 21-33) and failure to achieve adequate alignment with nonoperative means. In addition, multitrauma and secondary radial nerve palsies (i.e., those occurring after closed fracture manipulation in patients in whom the radial nerve was initially intact) are deemed by many as relative indications for surgical exploration and fracture fixation. A host of options exist for surgical fracture fixation, including ORIF using plate-and-screw constructs, intramedullary nailing, and external fixation.[104,175,324]

A B C

FIGURE 21-33 Floating elbow injury. **A:** AP radiograph depicting an open humeral diaphyseal fracture in a 10-year-old female. **B:** An ipsilateral radius fracture is also seen, consistent with a floating elbow injury. **C:** Postoperative radiograph after open irrigation and plate fixation of the humeral fracture. The radius fracture was also stabilized with internal fixation.

Surgical Procedure: Open Reduction Internal Fixation

Preoperative Planning. Preoperative planning for open reduction and plate-and-screw fixation includes appropriate AP and lateral radiographs of the humerus to assess fracture location, pattern, and displacement. The appropriate-sized implants should be determined in advance. While broad 4.5-mm dynamic compression plates are commonly utilized in adults, smaller 3.5 mm or semitubular plates are often used and sufficient for fixation of humeral diaphyseal fractures in children and adolescents, given the smaller size of the bone.[176,213,363] Furthermore, careful preoperative evaluation should be made to document neurovascular status, given the known risks of traumatic and iatrogenic radial nerve palsy associated with humeral diaphyseal fractures (Table 21-24).

Positioning. Patient positioning is dependent in part on the planned surgical approach. In most instances, supine positioning is sufficient. In older children and adolescents, the affected limb may be placed on a radiolucent hand table to provide adequate access to both the surgeon and fluoroscopy unit. In the very young child, the patient and injured extremity may be supported by a radiolucent fracture table. Even in cases in which a posterior surgical approach is to be utilized, supine positioning may be used with the limb adducted across the body. The fluoroscopy unit may be best positioned coming in from the head of the patient, allowing the surgeon to sit in the axilla and access the limb at all times.

Surgical Approach(es). A variety of different surgical approaches may be utilized. For distal humeral fractures, a posterior, triceps-splitting approach may be used.[91,185,305,459,473] Prone or lateral decubitus positioning may be helpful for this approach. After a posterior midline incision is made, dissection is performed down to the level of the triceps fascia, through the deep fascia. Skin flaps are elevated, exposing the triceps. The triceps tendon is split longitudinally in the midline, and this may be extended proximally in the interval between the long and lateral heads of the triceps. The deeper, medial head of the triceps may then be split and careful subperiosteal elevation is performed, exposing the humeral cortex. This approach is not extensile, and more proximal exposure is limited by the course of the radial nerve.

A traditional anterolateral approach is familiar to most surgeons and provides more extensile exposure.[25,130,185] In the supine position, a proximal deltopectoral incision is extended distally along the lateral aspect of the biceps. Proximally, the deltopectoral intermuscular interval is developed, retracting the cephalic vein laterally. More distally, the brachialis–brachioradialis interval is developed. Proximally, subperiosteal elevation will allow bony exposure. Distally, the brachialis muscle may be split longitudinally in the distal humeral shaft region, taking advantage of its dual innervation. The brachial artery and median and ulnar nerves are protected within the medial soft tissues. This exposure will not allow visualization or access to the radial nerve, which must be protected from overzealous retractor placement or drill/screw insertion posterior to the humerus.[467]

Alternatively, an extensile lateral or posterolateral approach will provide access to most of the humeral diaphysis as well as the radial nerve.[58,143,296] In the supine position, a lateral or posterolateral incision is created centered on the fracture site. Dissection is performed down to the level of the deep fascia and subcutaneous flaps elevated. The triceps fascia is incised just posterior to the lateral intermuscular septum, entering the posterior compartment of the brachium. The lateral head of the triceps is then elevated off the lateral intermuscular septum from distal to proximal. The radial nerve may then be identified, often surround by perineural fat, as it passes from the posterior to anterior compartments. Often the posterior antebrachial cutaneous nerve may be identified as it travels from proximal-posterior to distal-anterior more superficially; following this nerve proximally will allow for easy identification of the radial nerve proper. Other anatomic landmarks, including the apex of the triceps aponeurosis, have been utilized for radial nerve identification.[9] After the radial nerve is circumferentially dissected free, it may be isolated with a vessel loop and carefully retracted. Subperiosteal dissection will then allow for exposure of the humeral diaphysis.

Technique. After the diaphysis is exposed and radial nerve identified and retracted, the fracture site is identified. Fracture hematoma is evacuated and the cortical fracture edges defined. Reduction may be performed under direct visualization, with interdigitation of the fracture edges restoring longitudinal alignment and proper rotation. The fracture is then fixed using appropriately sized plates for age and size of patient (3.5-mm compression plates, single or double-stacked semitubular plates), ideally obtaining six cortices of fixation above and below the fracture site using 3.5-mm cortical screws. Intraoperative fluoroscopy may be utilized to confirm anatomic reduction and appropriate implant placement. If the fracture site occurs adjacent to the radial nerve, care must be made to slide the plate beneath the nerve and avoid iatrogenic injury or kinking (Table 21-25).

TABLE 21-24 ORIF of Humerus Shaft Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent table or regular table with radiolucent hand table
- Position/positioning aids: Supine
- Fluoroscopy location: From head of table as needed
- Equipment: 4.5 mm, 3.5 mm, or semitubular plates and screws
- Tourniquet (sterile/nonsterile): Sterile, if needed

TABLE 21-25 ORIF of Humerus Shaft Fractures

Surgical Steps

- Expose humeral diaphysis
- Identify and retract radial nerve, when applicable
- Anatomic reduction of humeral fracture
- Apply lateral plate, with care to protect the radial nerve
- Six cortices of fixation above and below the fracture site
- Layered wound closure
- Splint or cast immobilization

TABLE 21-26 IM Nailing of Humerus Shaft Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent table or regular table with radiolucent hand table extension
- Position/positioning aids: Supine
- Fluoroscopy location: From head of bed
- Equipment: Stainless steel or flexible titanium intramedullary nails, ideally 40% of intramedullary canal diameter
- Tourniquet (sterile/nonsterile): None

Surgical Procedure: Intramedullary Fixation

Preoperative Planning. Preoperative planning for intramedullary nailing includes appropriate AP and lateral radiographs of the humerus to assess fracture location, pattern, and displacement. Again, careful preoperative evaluation should be made to document neurovascular status, given the known risks of traumatic and iatrogenic radial nerve palsy associated with humeral diaphyseal fractures. (In cases of radial nerve palsy, consideration should be given for formal open reduction and plate fixation, given the ability to simultaneously explore and decompress the radial nerve.) Appropriately sized flexible stainless steel or titanium intramedullary nails should be available. Similar to intramedullary fixation techniques of pediatric femur fractures, the selected nail diameter should be approximately 40% of the intramedullary canal dimension (Table 21-26).

Positioning. In the majority of cases, supine positioning is sufficient. In older children and adolescents, the affected limb may be placed on a radiolucent hand table to provide adequate access to both the surgeon and fluoroscopy unit. In the very young child, the patient and injured extremity may be supported by a radiolucent fracture table. The fluoroscopy unit may be best positioned coming in from the head of the patient, allowing the surgeon to sit in the axilla and access the limb at all times.

Surgical Approach(es). A theoretical advantage of intramedullary nailing of humeral diaphyseal fractures is the ability to achieve stable realignment via closed or indirect fracture reduction and minimally invasive implant placement. Reduction and stabilization may be achieved with efficiently, without need for extensive surgical dissection.[81,102,165,392] A host of surgical approaches may be utilized. Intramedullary implants (Enders nails, Rush rods, flexible titanium nails) may be inserted via a posterior approach. Through a small posterior incision and triceps-splitting approach to the posterior humeral cortex just proximal to the olecranon fossa, an oval corticotomy may be made, large enough to accommodate passage of two nails. Nails may then be inserted retrograde through this combined entry point. While two nails may be sufficient, some have advocated the Hackethal or "bouquet" technique, in which the canal is progressively filled with multiple pins to confer additional rigidity (Fig. 21-34).[160] This may be particularly useful in cases of segmental, comminuted, or pathologic fractures.

Alternatively, intramedullary nails may be placed via the lateral and/or medial columns of the distal humerus[258,290] Small incisions may be made overlying the distal lateral and/or medial columns, at or above the level of olecranon fossa. Oval corticotomies are created at the site of nail entry to facilitate implant passage. Others have proposed insertion through the lateral and medial epicondyles via small drill holes. Care is made to retract and protect the posteromedial soft tissues—including the ulnar nerve—if a medial entry point is chosen. Nails may then be passed into the intramedullary canal and in a retrograde fashion to the fracture site.

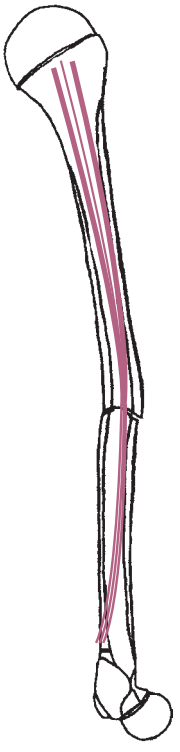


FIGURE 21-34 The Hackethal technique involves multiple smooth pins placed up the humeral shaft through a cortical window just above the olecranon fossa. The pins are placed until the canal is filled.

Once fracture reduction is achieved, intramedullary nails may be atraumatically passed into the canal of the proximal fragment. Fluoroscopic guidance is helpful, and efforts should be made to avoid repeated false passage of the nails into the adjacent soft tissues. In general, two nails are sufficient, provided they are of appropriate diameter and symmetrically contoured to allow for appropriate angular correction and rotational control.[244,245,290]

While the experience in adults is well documented, at present there are limited indications for solid reamed intramedullary nailing of humeral diaphyseal fractures in skeletally immature patients. This is in part because of the risks of physeal disturbance, shoulder impingement, and the relative narrow dimensions of the intramedullary canal in younger patients.[86,164,202,279,344,350,357,430]

Technique. Patients are positioned in the supine position. The appropriate-sized intramedullary implants (titanium elastic nails, Enders nails, Rush rods) are placed over the brachium, and fluoroscopy is utilized to determine the anticipated length of the

intramedullary nail. The nails are then prebent into a gentle bow, with the apex centered at the level of the fracture site. If lateral column entry site only is to be used, the nails should be contoured into the shape of a "C" and "S" to maximize spread (and thus stability) at the level of the fracture site while still allowing for medial and lateral engagement of the proximal humeral metaphysis. If both medial and lateral column entry sites are planned, each nail will be prebent into the shape of a "C."

A longitudinal incision is then created over the palpable lateral (and medial) column, just proximal to the olecranon fossa. Tourniquet control is not typically necessary. While epicondylar entry sites have been described, these have been associated with more frequent nail back-out.[165] Dissection is performed down to the level of the cortex. A small periosteal window may be elevated. Drill bits or awls may be used to create a cortical entry point, with care taken to orient the obliquity of the cortical tunnel along the anticipated trajectory of the nail. The intramedullary devices are then passed into the intramedullary canal of the distal fracture fragment to the level of the fracture. Fracture reduction is achieved through gentle closed manipulation, restoring length and correcting the angular deformity in the coronal and sagittal planes. Once fracture reduction is achieved, intramedullary nails may be atraumatically passed into the canal of the proximal fragment. A small bend at the leading tip of the intramedullary implant will facilitate engagement of the proximal fracture fragment. Fluoroscopic guidance is helpful, and efforts should be made to avoid repeated false passage of the nails into the adjacent soft tissues. In general, two nails are sufficient, provided they are of appropriate diameter and symmetrically contoured to allow for appropriate angular correction and rotational control.[244,245,290]

The implants are passed proximally into the proximal fragment until they lie 1 to 2 cm from the proximal humeral physis. At this time, the nails may be cut distally, leaving approximately 2 cm of length outside the cortex. If the nails were inserted with appropriate obliquity, the cut distal end of the nail will lie flush against the flare of the distal humeral metaphysis, avoiding symptomatic implant prominence yet still allowing for reliable implant retrieval. The entry wounds are closed in layers, and a long posterior splint, coaptation splint, or simple sling is applied (Table 21-27).

TABLE 21-27 IM Nailing of Humerus Shaft Fractures

Surgical Steps

- Measure anticipated diameter and length of intramedullary nails
- Precontour intramedullary nails
- Create entry sites along lateral (and medial) column(s) of distal humerus
- Create cortical entry points for subsequent nail passage
- Introduce intramedullary nails and pass proximally to level of fracture site
- Closed reduction of humerus
  - Fluoroscopic assistance
- Pass nails into intramedullary canal of proximal fragment, avoiding excessive false passage and trauma to the adjacent soft tissues
- Pass nails up to 1 to 2 cm distal to the proximal humeral epiphysis
- Bent and cut intramedullary nails beneath the skin
- Application of splint or sling after wound closure

Surgical Procedure: External Fixation

Preoperative Planning. External fixation remains a treatment option for humeral shaft fractures, particularly in critically ill multitrauma patients or patients with severe open fractures associated with extensive soft tissue injury and/or bone loss.[62,98,217,220,343,364,401] Preoperative planning includes appropriate AP and lateral radiographs of the humerus to assess fracture location, pattern, displacement, and/or bone loss. Thorough documentation of preoperative neurovascular status is needed. For the multitrauma patient, communication with other care providers is important for care coordination and prioritization of injury treatment. In cases of severe soft tissue injury, appropriate consultation with plastic surgeons is recommended; this will allow for guidance regarding appropriate pin placement and planning of ultimate soft tissue coverage, if needed. Appropriately sized external fixator pins and bars should be available. While unilateral constructs are sufficient in most situations to provide stability, multiplanar or ring fixators may be employed, particular if there are plans for subsequent lengthening, bone transport, or deformity correction (Table 21-28).

Positioning. Patients may be positioned supine with the limb supported by a radiolucent table or hand table. Fluoroscopy units may be positioned on the ipsilateral side of the table, coming from the head or foot. Coordination should be made with other care providers in the multitrauma patient to allow adequate access to all anatomic regions necessitating care.

Surgical Approach(es). Surgical approaches are dictated by fracture characteristics, concomitant wounds and soft tissue injuries, and plans for future interventions. For a standard unilateral construct, pins may be inserted using percutaneous approaches via small incisions and careful spreading through the underlying soft tissues. Understanding of the cross-sectional anatomy of the brachium is important to avoid potential neurovascular injury.

Technique. Once the patient is positioned and the fracture location and pattern identified, the configuration of the ultimate external fixator construct is determined. Biomechanically, maximal spread of pins in both the proximal and distal fracture fragments will allow for the most rigid construct. If a unilateral frame

TABLE 21-28 External Fixation of Humerus Shaft Fractures

Preoperative Planning Checklist

- OR Table: Radiolucent table
- Position/positioning aids: Supine
- Fluoroscopy location: Ipsilateral side of table
- Equipment: Appropriate-sized external fixation pins, bars, rings
- Tourniquet (sterile/nonsterile): N/A

TABLE 21-29 External Fixation of Humerus Shaft Fractures

Surgical Steps

- Identify fracture location and pattern
- Preassemble external fixator frame with planned pin-to-bar/ring clamps
- Small stab incisions made in skin at desired pin sites
- Blunt dissection through the subcutaneous tissues to level of humeral cortex
- Insert threaded pins (should be coplanar if unilateral fixator used)
- Provisionally connect the pins to the bar/ring
- Reduce or realign fracture
- Tighten pin-to-bar/ring connections
- Evaluate final alignment and construct with fluoroscopy or full-length radiographs of the humerus

is to be applied, preassembly of the bar with pin-to-bar clamps may facilitate coplanar placement of pins; indeed, the pin-to-bar clamps may be utilized as a "drill guide" during pin placement.

In a sequential fashion, the skin is incised at the site of pin placement and gentle, blunt dissection is performed through the subcutaneous tissues to the level of the humeral cortex. Appropriately sized threaded pins may then be drilled into the humerus, and use of cannulae or drill guides will protect the adjacent soft tissues and minimize the risk of iatrogenic neurovascular injury. This is particularly true for the radial nerve when lateral pins are placed in the mid- to distal diaphysis.

After pins are placed and connected to the external fixator bar, the fracture may be aligned in the desired position and stabilized. The addition of a second bar, while not always necessary, will improve bending rigidity of the construct (Table 21-29).

Author's Preferred Treatment of Humerus Shaft Fractures

The majority of humeral shaft fractures in children and adolescents may be successfully treated nonoperatively. In infants with birth-related fractures, immobilization with a stockinette or pinning of the sleeve to the trunk is simple and effective. Radiographic assessment of healing is performed at 4 to 6 weeks of age; immobilization is discontinued after confirmation of clinical and radiographic healing.

In children and adolescents with closed humeral diaphyseal fractures, stable injuries (e.g., torus or minimally displaced greenstick fractures) may be treated with simple sling immobilization. Patients with displaced fractures typically present with considerable pain, swelling, and ecchymosis. In these situations, gentle fracture realignment of the fracture may be performed with conscious sedation or general anesthesia, followed by application of a well-molded coaptation splint. Patients may be transitioned to a fracture brace at 1 to 2 weeks post injury, after the initial swelling and discomfort has subsided. Serial radiographs are obtained to monitor fracture alignment and bony healing. Bony union is typically obtained by 6 weeks, after which immobilization is discontinued and activities advanced.

Similar nonoperative treatment is advocated for patients with closed injuries and acceptable alignment who present with radial nerve palsies. Even after bony union is achieved, serial clinical checks are performed monthly to monitor nerve recovery. An advancing Tinel sign and sequential motor recovery, beginning with wrist extension and progressing to digital and thumb extension, portend a favorable prognosis and spontaneous recovery. In general, nerve regeneration progresses 1 mm per day, and calculation of the distance from the fracture site to the sites of distal muscle innervation will allow for prediction of time to motor recovery. Surgical exploration with radial nerve decompression, repair, or reconstruction is considered after 3 to 6 months without evidence of any neurologic recovery.

Surgical intervention is indicated in cases of open fractures, fractures with vascular or severe soft tissue injury, and fractures in unacceptable alignment. Surgery is also considered for patients with failure of appropriate radial nerve recovery or new radial nerve palsies after fracture manipulation.

For most humeral diaphyseal fractures proximal to the distal metadiaphysis and without intercondylar extension that are treated surgically, formal open reduction and plate fixation is preferred. An extensile lateral or posterolateral approach is used, as it allows safe access to up to 90% of the humeral diaphysis.[143] As surgery is often performed in the setting of radial nerve palsy, the lateral approach confers the additional advantage of allowing identification, mobilization, and/or repair of the radial nerve.[58,143,296]

Intramedullary nailing may be considered in patients without preoperative radial nerve palsy and transverse or short oblique (i.e., "length stable") fracture patterns. While the principles of intramedullary fixation are well established and the results well documented, closed nailing does not allow for visualization or decompression of the radial nerve (Fig. 21-35).

Postoperative Care

Patients receiving nonoperative treatment of humeral diaphyseal fractures are followed weekly with radiographs in splint or fracture brace to ensure adequate fit, monitor neurovascular function, and confirm radiographic alignment. In patients with associated radial nerve palsies, evaluation for an advancing Tinel sign and sequential motor recovery is performed. Once there is evidence of clinical and radiographic healing, gentle shoulder pendulum and elbow range-of-motion exercises are begun. Immobilization is typically discontinued after 6 weeks. Sports participation is restricted until there is return of motion and strength, and patients/families are counseled regarding the risk of refracture.

Following surgical reduction and stabilization, sling immobilization is usually sufficient and continued until radiographic healing. With plate fixation, gentle elbow range-of-motion exercises may be initiated once adequate comfort is achieved. In cases of intramedullary nail fixation, implants are typically removed at 6 months postoperatively.

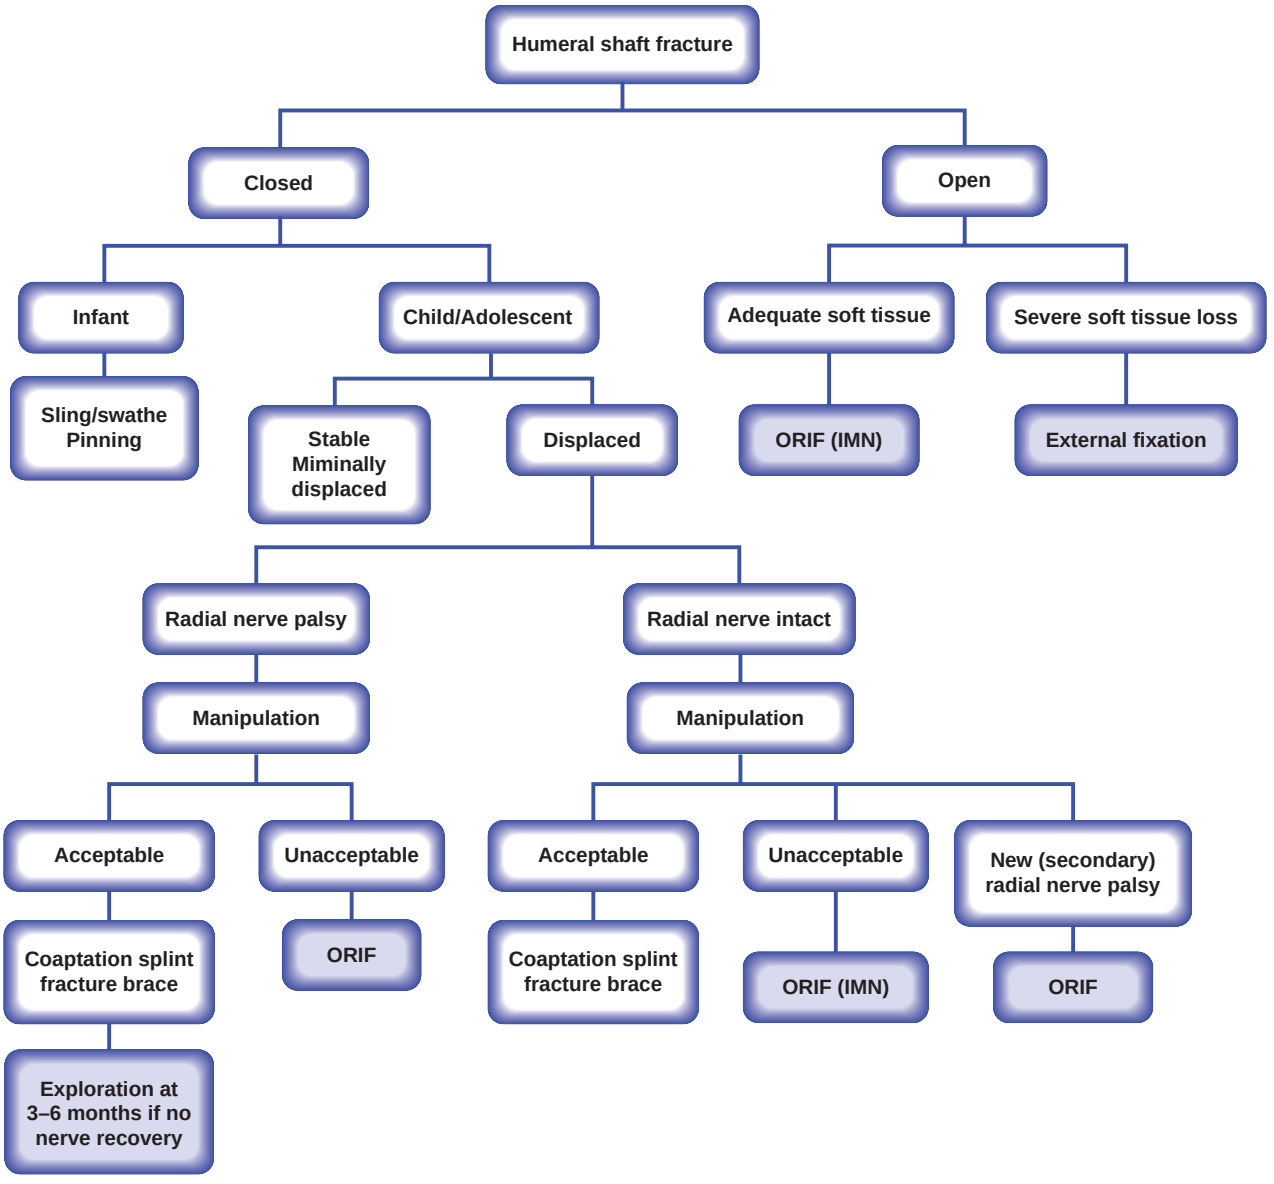

FIGURE 21-35 Author's preferred treatment algorithm for humeral shaft fractures.

Potential Pitfalls and Preventative Measures

While the techniques described above are well established, a number of potential pitfalls may be encountered during the treatment of diaphyseal fractures. First, nonoperative treatment of distal diaphyseal fractures may be challenging, given the anatomic location and relative limited amount of distal humerus that may be incorporated into a fracture brace or splint.[124] In these situations, use of medial and lateral extensions of conventional fracture brace may be needed to provide better control of coronal plane and rotational alignment. Alternatively, long arm casts or long posterior splints may be utilized to provide stability and maintain alignment until clinical and radiographic healing occurs. Careful clinical and radiographic monitoring is needed, due to the tendency for varus malalignment and the limited capacity for remodeling of very distal humeral deformity.[48]

Similarly, surgical treatment of *distal* diaphyseal fractures may provide several challenges (Fig. 21-36).[124] Closed reduction and percutaneous pinning techniques commonly used for supracondylar humerus fractures may not provide adequate stability, as the more proximal fracture location results in medial and lateral entry pins that cross at the fracture site (Fig. 21-37). This may result in longer operative times, loss of fixation with late deformity, and loss of motion. Alternative treatments include open plating or intramedullary nailing via medial and lateral epicondyle entry sites (Fig. 21-38). With a medial epicondylar entry, the ulnar nerve needs to be identified and protected. When open plate or intramedullary nail fixation is chosen, consideration

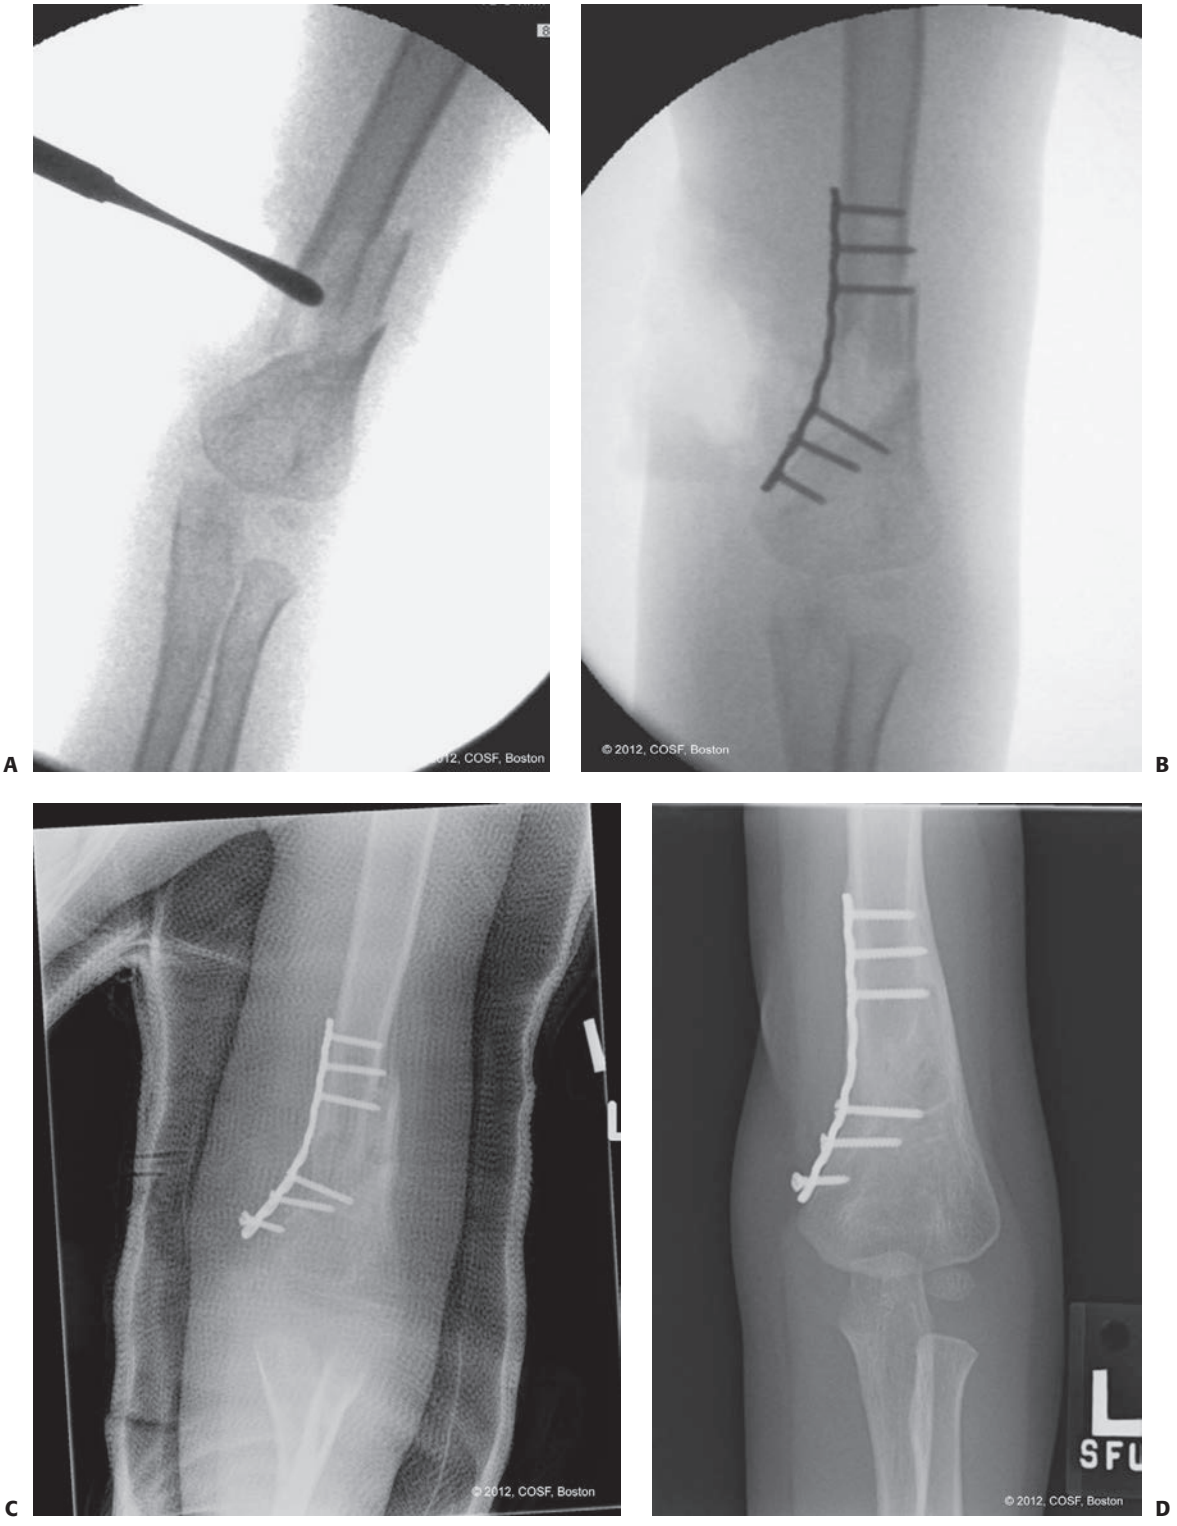

FIGURE 21-36 **A:** Intraoperative image depicting a comminuted, open distal humerus fracture in a 3-year-old male after a motorcycle injury. **B:** Intraoperative image after lateral column plate fixation, sparing the distal humeral physes. **C:** Given single column fixation, some loss of fixation is seen. Internal fixation was supplemented with spica cast immobilization. **D:** Final radiographs demonstrate appropriate bony healing and alignment.

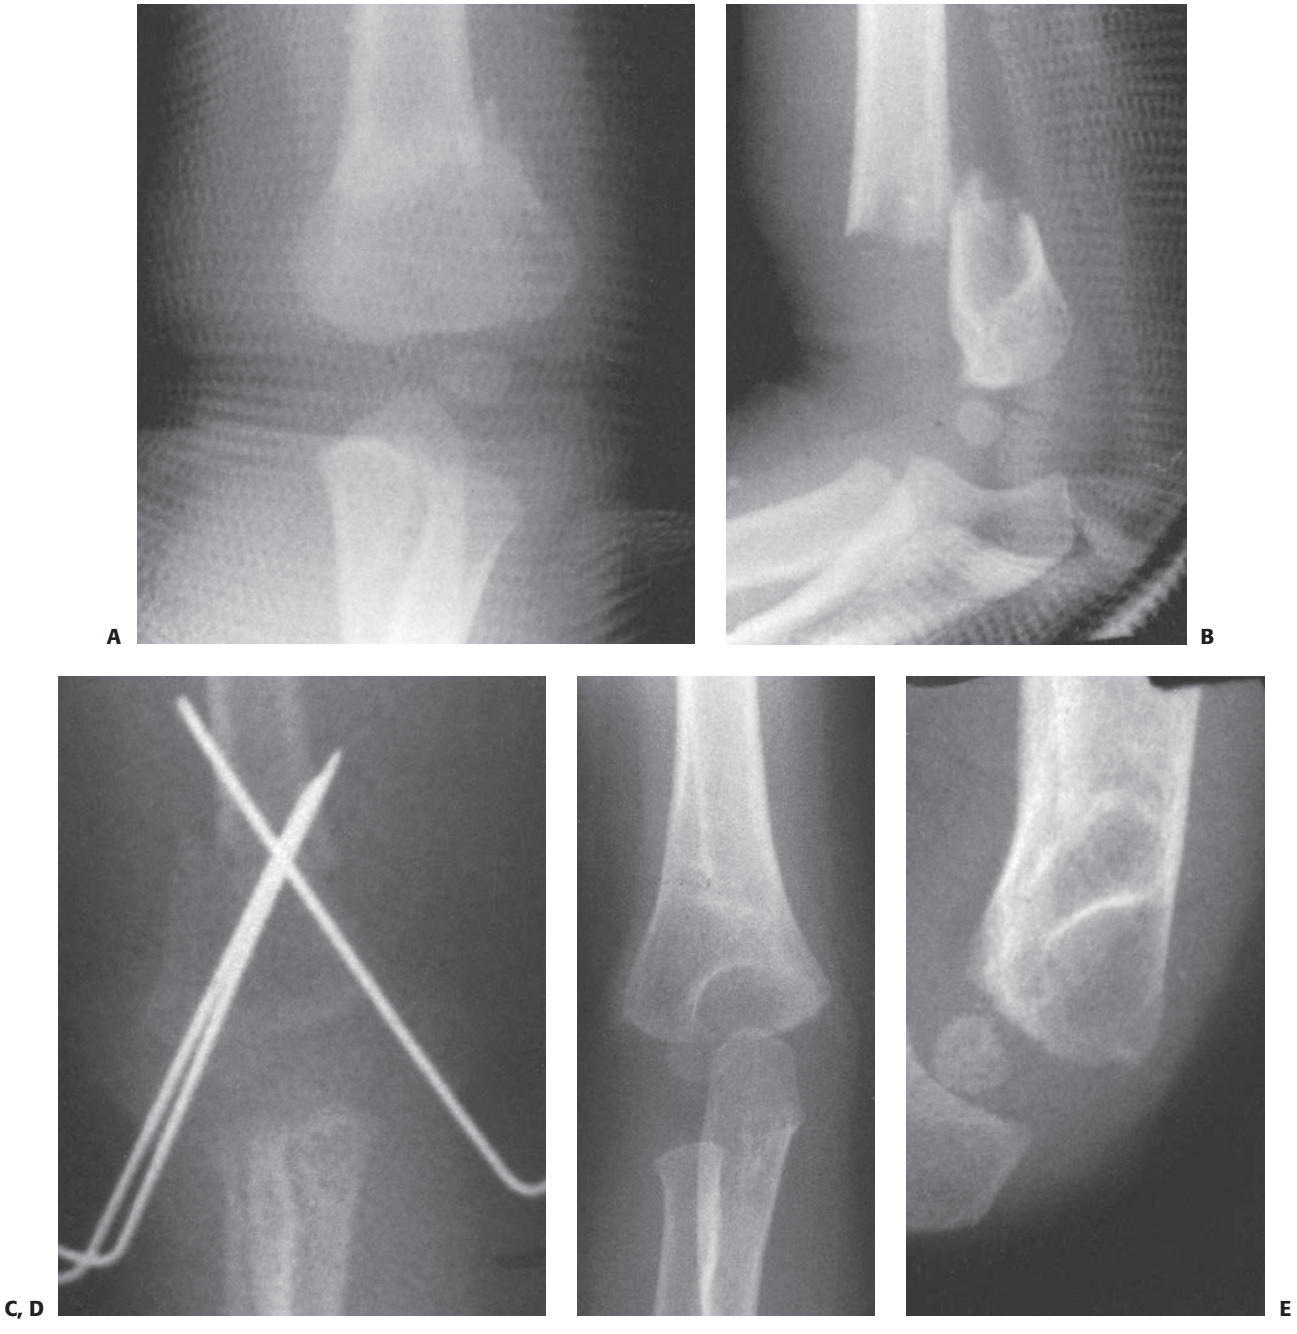

FIGURE 21-37 **A, B:** Distal humeral diaphyseal fracture in an 18-month old treated with closed reduction and percutaneous pinning. **C:** The pins cross at the fracture site with decreased stability and some loss of position. **D, E:** The ultimate outcome was good.

should be made for stabilization of both the medial and lateral columns to provide maximal control and minimize risk for late instability. In cases where bicolumnar fixation is not possible, supplementation with long arm casts or other external immobilization is suggested.

During ORIF via a lateral or posterolateral approach, care of the radial nerve is paramount. Identification of the posterior brachial cutaneous nerve and/or the characteristic fat stripe along the lateral aspect of the triceps will enable radial nerve identification during surgical exposures. Often the radial nerve must be mobilized to allow for implant placement between the humeral cortex below and the radial nerve above. Adequate direct visualization of plate placement and screw insertion is imperative to minimize the risk of iatrogenic nerve injury (Fig. 21-39).

Finally, a few maneuvers may aid in the intramedullary nailing of humeral diaphyseal fractures. Lateral column entry provides easy surgical access and minimizes risk to the ulnar

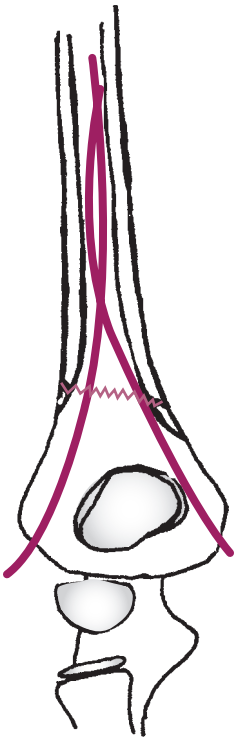

FIGURE 21-38 Ideally, pin fixation for distal humeral diaphyseal–metaphyseal junction fractures involves pins placed in intramedullary fashion up the medial and lateral columns.

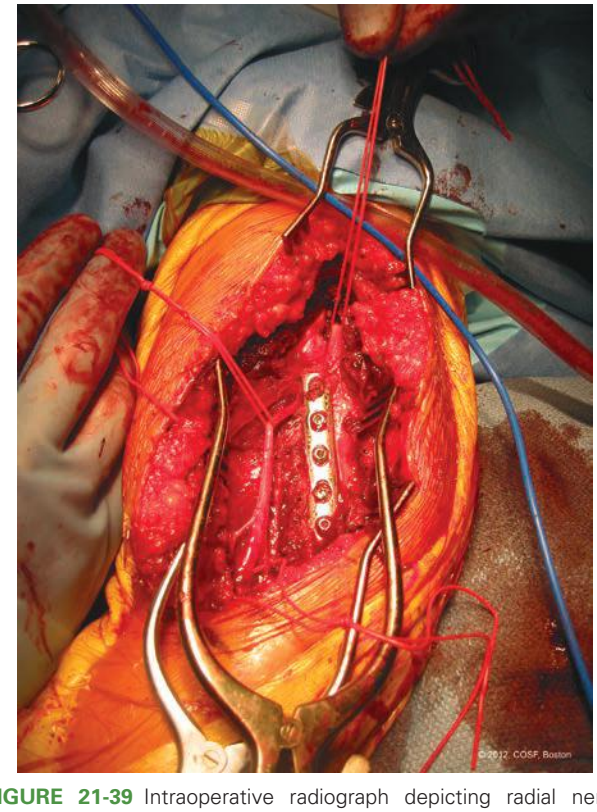

FIGURE 21-39 Intraoperative radiograph depicting radial nerve placement beneath a previously applied lateral plate.

TABLE 21-30 Humerus Shaft Fractures

Potential Pitfalls and Preventions

Pitfall	Preventions
Malalignment of distal fractures (nonoperative)	Extensions of fracture brace Use of long arm casts/splints
Malalignment of distal fractures (surgical)	Avoid percutaneous pinning Use of plates or IM nails Bicolumnar fixation Supplement with cast/splint immobilization
Radial nerve injury during ORIF	Careful dissection and mobilization Position plate beneath nerve Direct visualization of plate/screws
Complications of IM nailing	Lateral entry above olecranon fossa Appropriate vector for nail insertion

nerve. If this is chosen, nails should be precontoured into the shape of a "C" and "S" to allow for maximal spread at the fracture site and engagement of the proximal humeral fracture fragment. Creating the cortical entry point above the olecranon fossa with the appropriate distal-lateral to proximal-medial vector will allow the nail to sit against the metaphyseal flare of the lateral column when cut; this will facilitate subsequent retrieval and minimize the soft tissue irritation commonly caused by epicondylar entry points (Table 21-30).

Treatment-Specific Outcomes

Overall, reported clinical results are good after surgical treatment of humeral diaphyseal fractures using both intramedullary nailing and open plate fixation techniques.[25,86,114,165,175,202,304,344,357,412,430,462,470,472]

Management of Expected Adverse Outcomes and Unexpected Complications Related to Humerus Shaft Fractures

Radial nerve palsies are commonly seen with humeral diaphyseal fractures. As discussed above, these nerve injuries may be primary or secondary. Secondary radial nerve injuries may result from a host of mechanisms, including excessive fracture manipulation resulting in neurapraxia, nerve incarceration within the fracture site or subsequent fracture callus, or rarely direct nerve injury or transection during fracture manipulation or implant placement. These inadvertent neurologic complications may be seen with both nonoperative and surgical treatment. There continues to be controversy regarding the initial management of immediate secondary nerve palsies, though it is clear that failure of spontaneous recovery after an appropriate period of observation should prompt surgical exploration, decompression, and/or nerve reconstruction.[134,448] In addition

to radial nerve injuries, ulnar and median nerve injuries have been reported.[218,271,408]

Compartment syndrome of the brachium is relatively rare, in part because of anatomic differences in fascial strength, ability to avoid extreme positioning during fracture immobilization, and fracture characteristics.[34,55,135,158,302] Patients with associated ipsilateral upper extremity fractures or vascular injuries are at highest risk.

Vascular injuries, including brachial artery transection, are uncommon but mandate prompt evaluation and intervention to restore vascularity to the upper limb.[47,274,287] In cases in which vascular repair or reconstruction is needed, fracture stability with external or internal fixation is needed to protect and facilitate vascular repair.

Functionally limiting malunion is uncommon in pediatric humeral diaphyseal fractures. As cited previously, 20 to 30 degrees of varus and 20 degrees of apex anterior angulation may be accepted, with often little aesthetic differences and functional consequence.[94,119,225,347,409] Up to 15 degrees of internal rotation is also well tolerated.[94] Patients younger than 6 years of age will remodel most angular deformity, and obese patients—though more prone to malunion given the challenges of immobilization—may hide their resultant deformity better.[186,313,363] Because of the remodeling potential, compensatory motion at the shoulder, elbow, and forearm, and lack of functional deficits, corrective osteotomies for humeral diaphyseal malunions are rarely necessary.

While more commonly reported in adults, nonunion of humeral diaphyseal fractures may rarely occur in children and adolescents (Fig. 21-40).[74,137] Risk factors may include excessive soft tissue injury, vascular insufficiency, segmental bone defects, or underlying bone abnormalities, such as osteogenesis imperfecta. Treatment principles for humeral nonunion in children have been extrapolated from adult orthopedics.[20,66,123,170,184,303,465] In cases of hypertrophic nonunions, treatment is predicated on provision of bony stability, typically with ORIF. In cases of atrophic nonunions, ORIF with debridement of the pseudarthrosis back to bleeding bone and use of autogenous bone grafting is advised.[178] Alternatively treatments include external fixation or Ilizarov technique.[49,63,200,201,395] In cases of pathologic fractures or systemic bone abnormalities—such as osteogenesis imperfecta—intramedullary implants are preferred.[137] In rare situations, a vascularized fibula graft is appropriate to provide bony alignment, stability, and healing.[215]

FIGURE 21-40 Radiograph depicting an atrophic humeral diaphyseal nonunion in a skeletally mature adolescent previously treated with screw and cerclage wire fixation of an open humeral diaphyseal fracture.

TABLE 21-31 Humerus Shaft Fractures

Common Adverse Outcomes and Complications

Radial nerve palsy
Malunion
Nonunion
Limb length discrepancy
Stiffness

Limb length discrepancy may result from prior humeral diaphyseal fracture, though clinically up to 6 to 8 cm of shortening may be well tolerated without functional loss. As with other long bone fractures, overgrowth may occur following humerus fracture, though the magnitude is often minimal (less than 1 cm).[173,375] In cases of considerable limb length discrepancy and functional compromise, humeral lengthening via distraction osteogenesis using unilateral or multiplanar ring fixators may be performed.[63,64,92,332]

Finally, while loss of shoulder and/or elbow motion is common with both nonoperative and surgical treatment of humeral diaphyseal fractures in adults, persistent stiffness is uncommon in pediatric patients.[7,178] Judicious initiation of early range of motion will aid to minimize the risk of this complication (Table 21-31).

Summary, Controversies, and Future Directions Related to Humerus Shaft Fractures

In summary, the vast majority of humeral diaphyseal fractures may be effectively treated nonoperatively. In older patients with greater deformity, surgical reduction and stabilization will result in reliable bony healing and improved radiographic alignment. Controversy continues regarding the optimal management of secondary radial nerve palsies as well as the relative indications for intramedullary nailing versus open reduction and plate fixation of displaced humeral shaft fractures. Future prospective, comparative investigation is needed to determine the optimal surgical management of these injuries.

22 CLAVICLE AND SCAPULA FRACTURES: ACROMIOCLAVICULAR AND STERNOCLAVICULAR INJURIES

Joshua M. Abzug and Peter M. Waters

Introduction to Midshaft Clavicle Fractures

The clavicle is the most commonly fractured bone in children, representing 5% to 15% of all pediatric fractures.[109] The most common location for a clavicle fracture is the midshaft of the bone, accounting for up to 80% of fractures.[109,112,116,123] Despite this high incidence, little literature exists regarding management and outcomes of pediatric clavicle fractures. Much of the literature cited throughout this chapter is therefore extrapolated from scientific studies performed regarding either adult or adolescent clavicle fractures. However, with the increasing trend for operative fixation in adults, more scientific investigations regarding the management of clavicle fractures in children are being performed.

Assessment of Midshaft Clavicle Fractures

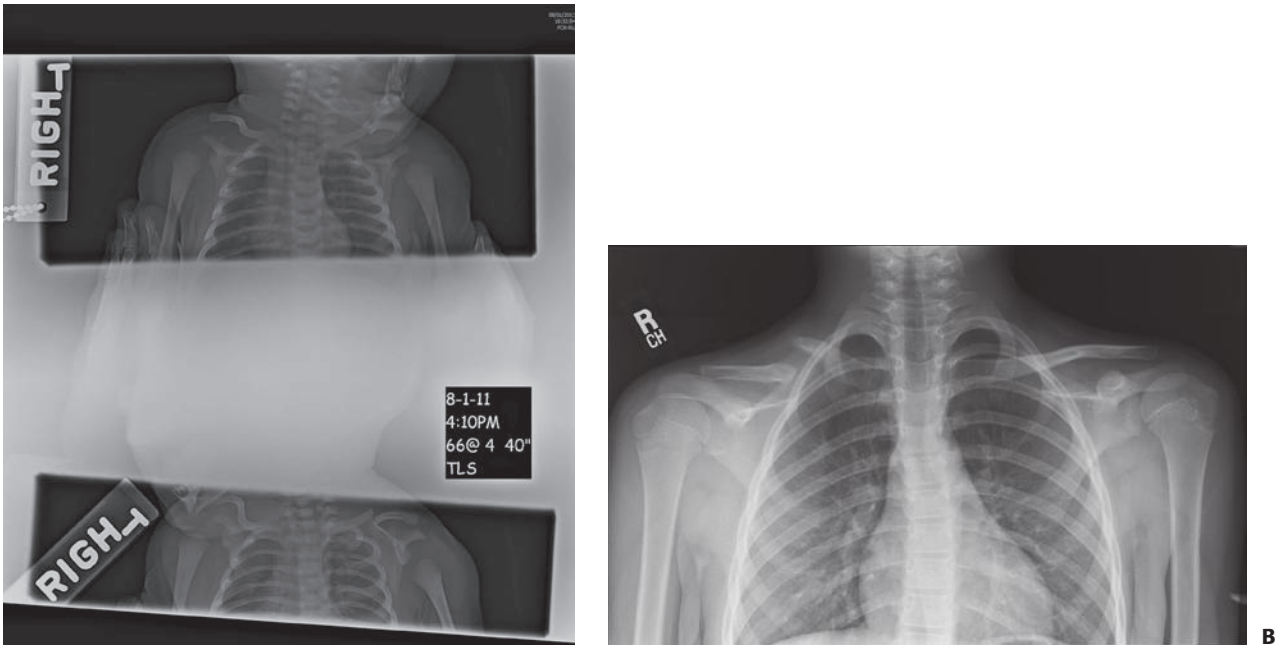
Mechanisms of Injury for Midshaft Clavicle Fractures

Clavicle fractures are frequent in children of all ages, from birth to skeletal maturity, with different mechanisms of injury resulting in the fracture based on age. Infants can sustain a clavicle fracture during the birthing process, especially those that are large for gestational age or those involved in difficult deliveries.[15,60,78] Additional risk factors include a lower mean head to abdominal circumference ratio and a prior history of the mother having a previous child with macrosomia.[60]

Neonatal clavicular fractures have been cited as one of the most frequent complications of natural delivery.[30,67,70,81,113,122] However, there is no uniform screening method for determining whether or not a fracture occurred and therefore the exact incidence of neonatal clavicle fractures remains unknown. The incidence has been reported to be as high as 4.4%, but the true incidence may be even higher.[81] Clavicle fractures due to birth trauma need to be distinguished from the rarer congenital pseudarthrosis of the clavicle, which is generally seen on the right side except in dextrocardia (Fig. 22-1).

The anterior shoulder, typically the right side, is the most likely location where the clavicle fracture occurs, as babies are typically in the left occiput anterior (LOA) position.[60] In addition, this is the most common side of injury in neonatal brachial plexus palsy. Therefore, when an infant sustains a clavicle fracture during the birthing process and limited motion is present about the affected extremity, it is unknown if the child has a concomitant brachial plexus injury or is not moving their arm secondary to the pain associated with the fracture, a so-called pseudopalsy. Once the fracture heals, typically in 1 to 3 weeks in a newborn, repeat assessment of the brachial plexus should be performed to distinguish pseudopalsy from a nerve injury.

The exact mechanism for sustaining the clavicle fracture during the birthing process remains unknown. It is likely related to lateral compression of the shoulder girdle against the pelvis. However, neonatal clavicle fractures have also been shown to occur during cesarean sections.[60]



A B

FIGURE 22-1 **A:** Radiograph of a left midshaft clavicular fracture in an infant sustained during the birthing process. (Courtesy of Joshua M. Abzug, MD.) **B:** Neonatal pseudarthrosis of the clavicle. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

Toddlers who sustain clavicle fractures may sustain the injury due to a fall from a height or injuries sustained during child abuse.[22,70,114] In a series of children aged 4 years or younger, children abused had an incidence of clavicle fractures of approximately 4% compared to only about 1% in the control group.[114]

School age clavicle fractures occurring in children are typically the result of a fall where the child sustains a lateral compressive force to the shoulder.[131] Typical activities include falls off of playground equipment, falls from bicycles, and sporting activities. Alternatively, a direct blow to the clavicle can lead to fracture in a child; however, this mechanism is less common. The common fall onto an outstretched hand does not typically transmit enough force to the clavicle to sustain a fracture.[64]

Adolescents sustain clavicle fractures due to similar mechanisms as school age children as well as due to high-energy mechanisms or competitive athletics. Motor vehicle and all-terrain vehicle (ATV) accidents are common high-energy mechanisms in adolescents that can result in either isolated clavicular fractures or clavicular fractures associated with polytrauma similar to adults.[73,116] High-level competitive athletes also commonly sustain clavicle fractures due to collision sports, such as football, or much less commonly, due to repetitive, high-intensity training leading to a stress fracture.[1] Specific sporting activities that can lead to stress fractures include rowing, diving, baseball, and gymnastics, among others.[1,140,147]

The proposed mechanism leading to a clavicular stress fracture is excessive cyclic scapular protraction and retraction leading to clavicular fatigue.[1] Excessive motion at the sternoclavicular and acromioclavicular (AC) joints transfers the forces to the clavicle itself, with the end result being these forces exceeding the ultimate tensile strength of the clavicle.[1] This most commonly occurs in athletes who rapidly increase their training program.

Associated Injuries with Midshaft Clavicle Fractures

Injuries that are associated with clavicle fractures depend on the age of the child with the fracture. Neonates can have a concomitant neonatal brachial plexus palsy. The most common type of neonatal brachial plexus palsy is an injury affecting C5 and C6 with resultant limited shoulder movement, elbow flexion, forearm supination, and wrist extension.[46] Differentiation between a pseudopalsy, the child not moving their arm secondary to the clavicle fracture itself, and a concomitant neonatal brachial plexus palsy can be made by 3 to 4 weeks of age, as the pain from the fracture will be markedly decreased. Toddlers who sustain clavicle fractures as a result of nonaccidental trauma are likely to sustain concomitant fractures, such as fractures of the rib, tibia/fibula, humerus, or femur, intracranial bleeding, eye contusions, retinal hemorrhage, and burns.[28,114] Lastly, adolescents involved in high-energy mechanisms of injury can have associated polytrauma including injury to surrounding structures or vital organs. Concomitant rib fractures, scapula fractures, pneumothorax, brachial plexus injury, or subclavian vessel injury may be present.[64] Abdominal, head, spine, and/or lower extremity trauma can also occur.

FIGURE 22-2 Photographs depicting skin tenting from a displaced, segmental left diaphyseal clavicle fracture. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide.* Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

Signs and Symptoms of Midshaft Clavicle Fractures

Clavicle fractures in neonates commonly present after difficult deliveries with decreased active movement about the shoulder region, crying upon passive movement of the shoulder and entire upper extremity, swelling, crepitation, and an asymmetrical bony contour. The Moro (startle) reflex, (a newborn reflex in which a noise or sudden movement causes the baby to extend their neck, arms, and legs followed by pulling the arms and legs back in), may be decreased as well.[60] Presence of limited digit motion or Horner syndrome (ptosis, miosis, and anhydrosis) indicates the presence of a more serious concomitant brachial plexus birth palsy with injury affecting the lower portions of the brachial plexus.

Toddlers who sustain clavicle fractures associated with suspected abuse should undergo a complete head-to-toe survey, as if they were a trauma patient, looking for concomitant injuries and/or signs of abuse. This includes a thorough neurologic evaluation, an ophthalmologic examination, and a skeletal survey to look for corner fractures or additional fractures in various stages of healing.

Examination of a child or adolescent with a clavicle fracture includes looking for deformity, swelling, and ecchymosis about the affected clavicle. Any tenting of the skin (Fig. 22-2) or open wounds should be noted. In addition, one should look at the lateral aspect of the shoulder for an abrasion or erythema, as this is most commonly the site of impact. Inspection may also demonstrate some drooping of the involved side as the scapula appears internally rotated and the shoulder appears shortened compared to the contralateral side. If significant swelling is present, this may be difficult to recognize.[64]

Pain about the entire shoulder girdle is typically present, however significant tenderness to palpation is present overlying the fracture itself. Crepitus, with any attempt of active or passive range of motion, may be present. As noted above, concomitant injury to the brachial plexus may occur, especially the ulnar nerve because of its location adjacent to the middle third of the clavicle. Therefore, a thorough neurologic examination is required for all patients who sustain clavicular fractures. This includes assessing motor and sensory function throughout the entire upper extremity. It may be difficult to have a child in pain perform certain functions necessary to complete the neurologic evaluation; however, it is imperative to be patient and repeat the examination as often as necessary to obtain the necessary information.

Because of the location of the subclavian vessel, a thorough vascular examination is also necessary, especially in patients involved in high-energy mechanisms of injury. The vessel can spasm or have a thrombosis from blunt trauma. Assessment of the radial pulse should be symmetric and if there is any concern for injury of the vessel, further diagnostic evaluation with advanced imaging should be performed.

Imaging and Other Diagnostic Studies for Midshaft Clavicle Fractures

Initial imaging of a suspected clavicle fracture includes plain radiographs of the clavicle in two projections. Typically, a standard anteroposterior (AP) radiograph and a 45-degree cephalic tilt view are obtained (Fig. 22-3). These images provide visualization of the shoulder girdle region as well as the upper lung fields, both of which should be assessed for additional injuries. However, if clinical suspicion is present for additional injuries, dedicated series of the suspected part(s) should be obtained. Rarely is advanced imaging necessary to evaluate the clavicle fracture as displacement, the fracture pattern, and any presence of comminution can be assessed on the plain films. In cases of high-energy mechanisms, the trauma team typically obtains a chest CT scan which can be used to further evaluate the clavicle fracture.

Classification of Midshaft Clavicle Fractures

Clavicle fractures are usually described based on the location of the fracture, the fracture pattern, and the presence or absence

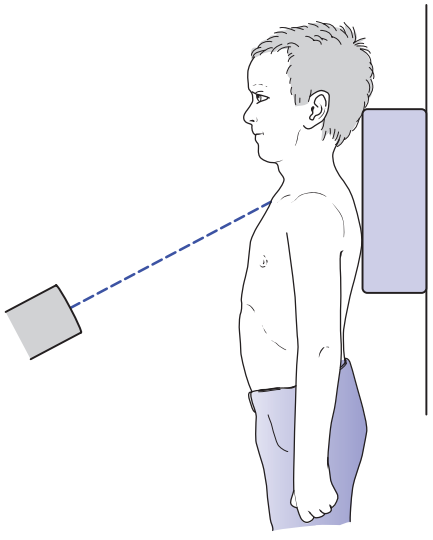


FIGURE 22-3 Depiction of a 45-degree cephalic tilt to obtain an additional view of the clavicle.

of displacement. Thus, clavicle fractures are either medial, midshaft, or lateral; nondisplaced or displaced; open or closed; comminuted or simple. Additional classification schemes have been proposed to evaluate adult clavicle fractures but none are widely utilized, as they are either purely descriptive of fracture location[3] or cumbersome with multiple types and subtypes.[43,123]

Outcome Measures for MIdshaft Clavicle Fractures

No outcome scores are specifically utilized to assess results following pediatric clavicle fractures. Outcome measures utilized are typically patient satisfaction, range of motion, pain, fracture union, and complications. Additional outcome measures assessed have included the Disability of the Arm, Shoulder, and Hand (DASH) Score, the QuickDASH, the simple shoulder test, and the Constant Shoulder Score. Radiographic criteria evaluating shortening and/or vertical displacement have also been utilized to assess results.

Pathoanatomy and Applied Anatomy Relating to Midshaft Clavicle Fractures

The clavicle, also referred to as the collar bone, is an S-shaped bone that lies along the subcutaneous border of the anterior aspect of the shoulder girdle. An anterior convexity is present medially to permit the passage of the brachial plexus and axillary vessels from the neck region into the upper arm, whereas laterally there is an anterior concavity.

Development of the clavicle begins at five and a half weeks' gestation via intramembranous ossification and by 8 weeks, the bone has developed into its S shape configuration.[45] Postnatally, the clavicle continues to grow at a steady rate until age 12, increasing approximately 8.4 mm per year.[92] After 12 years of age, the clavicle grows approximately 2.6 mm per year in females and 5.4 mm per year in males. Thus, 80% of the final clavicle length is reached by age 9 in females and age 12 in males.[92]

Medially the clavicle articulates with the sternum, forming the sternoclavicular joint, whereas laterally the bone ends in an articulation with the acromion, forming the AC joint. The medial inferior aspect of the clavicle is the site of attachment of the costoclavicular ligament, whereas laterally on the inferior aspect there is the conoid tubercle and trapezoid line, the sites of attachment for the conoid and trapezoid ligaments, respectively. All of these ligaments slant posteriorly as they approach the clavicle and therefore when the clavicle elevates and the ligaments are put on stretch, the clavicle rotates posteriorly. In addition, these ligaments provide significant stability at both ends of the clavicle, thus making fractures in the middle third of the clavicle more likely.

The pectoralis major originates from the medial aspect of the clavicle as well as the sternum and inserts onto the humerus at the intertubercular groove whereas the deltoid originates from the lateral aspect of the clavicle as well as the acromion and scapular spine to insert onto the humerus at the deltoid tuberosity. In addition, the sternocleidomastoid and sternohyoid muscles originate from the clavicle whereas the trapezius and subclavius insert onto the clavicle.

Treatment Options for Midshaft Clavicle Fractures

Nonoperative Treatment of Midshaft Clavicle Fractures

Indications/Contraindications

The mainstay of treatment of pediatric and adolescent clavicle fractures is nonoperative, allowing the fracture to form callous and heal in situ, even if significant displacement is present (Fig. 22-4).[8] It is well agreed upon that nondisplaced or minimally displaced fractures, defined as displacement less than 1.5 to 2 cm, should be treated nonoperatively. Fractures that should proceed directly to operative intervention include open fractures, fractures with associated skin tenting, and fractures with associated neurovascular injury (Table 22-1).

Techniques

Nonoperative treatment of clavicle fractures is performed by immobilizing the child's shoulder girdle, typically with a sling. Alternatively, a figure-of-eight dressing or shoulder immobilizer can be utilized; however, these are more cumbersome and have not been shown to provide improved results. Neonates who

sustain a clavicular fracture during the birthing process, can have immobilization performed utilizing a swath technique, such as placing Webril followed by an ACE bandage around the torso and arm.

Follow-up radiographs are obtained at 4-week intervals until fracture union occurs. Once union is present and the child's motion and strength have returned to normal, the child is permitted to resume activities as tolerated. Calder et al. have suggested that follow-up radiographs are unnecessary in pediatric patients given the near universal expected fracture healing rate in a child. However, we routinely obtain radiographs until union is established to assess return to sports with decreased refracture risk.[25]

Outcomes

Despite the high incidence of pediatric clavicle fractures and the fact that the vast majority of these fractures are treated nonoperatively, little data exist regarding the outcomes of these injuries. Union rates from 95% to 100% have been reported with nonoperative treatment.[52,74,138] Most nondisplaced fractures have union by 4 to 8 weeks of time, whereas displaced fractures take longer, approximately 10 weeks.[138]

Overall, the vast majority of patients have excellent outcomes and are able to return to their activities without limitations. A small percentage of patients treated nonoperatively with significant fracture displacement may have subjective complaints of pain with prolonged activity, easy fatigability, axillary pain, or drooping shoulders with bony prominence.[138] Bae et al. evaluated a group of 16 patients with displaced (>2 cm) mid-diaphyseal clavicle fractures treated nonoperatively. All fractures united with no meaningful loss of shoulder motion or abduction–adduction strength by isokinetic testing. The vast majority of patients had low DASH and pain Visual Analog Scores (VAS) that were very low, means of 4.9 and 1.6 respectively. Only one patient out of 16 required a corrective osteotomy.[8] The authors concluded that routine surgical fixation for displaced, nonsegmental clavicle fractures may not be justified based upon concerns regarding shoulder motion and strength alone. Further investigation is required to determine the risk factors and causes of pain and functional compromise in the minority of pediatric patients with symptomatic malunions. In contrast, the adult literature has shown that patients with significantly displaced midshaft fractures treated nonoperatively compared to plate fixation have significantly worse Constant shoulder scores, DASH scores, higher rates of nonunion, longer times to union, and more symptomatic malunions.[26]

Operative Treatment of Midshaft Clavicle Fractures

Indications/Contraindications

Absolute indications for operative treatment of clavicle fractures in the pediatric and adolescent population is limited but includes open fractures, fractures with significant skin tenting/compromise (Fig. 22-5), comminuted fractures in which the central fragment is markedly displaced, and fractures associated with neurovascular injury. Additional relative indications may include floating shoulder injuries and fractures associated with polytrauma. Floating shoulder injuries involving midshaft clavicle fractures and fractures of the glenoid neck can

FIGURE 22-5 Radiograph of a segmental right diaphyseal clavicle fracture causing skin tenting and subsequent compromise. Note the vertical nature of the segmental fragment. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide.* Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

be treated by ORIF of the clavicle alone as ligamentotaxis will reduce the other fracture via the coracoclavicular ligament.[9]

Fractures with significant displacement that are treated nonoperatively in adults have been shown to subsequently heal with a malunion that can cause changes to shoulder mechanics. These alterations have been shown at times to lead to pain with overhead activities, decreased strength, and decreased endurance.[58,93] Therefore, multiple studies have investigated the benefit of operative fixation versus nonoperative management of displaced midshaft clavicle fractures. A recent meta-analysis evaluating the results of randomized clinical trials that compared nonoperative and operative treatment in adults found a significantly higher nonunion and symptomatic malunion rate in the nonoperative group. In addition, patients treated with operative intervention had earlier functional return.[94] It is unclear whether this data is transferable to the adolescent. Clearly the young child, especially less than age 8 years, has the potential to remodel a foreshortened, displaced fracture.

Surgical Procedure for Midshaft Clavicle Fractures

Preoperative Planning

As with any procedure that will utilize implants, it is imperative to have the desired hardware available before proceeding to the operating room. Options for treatment of pediatric and adolescent clavicle fractures include anatomically designed clavicle plates, standard nonlocking and locking plates, and intramedullary devices including pins, wires, screws, and elastic nails.

Intramedullary fixation has the potential benefits of requiring less soft tissue stripping at the fracture site, better cosmesis with smaller skin incisions, easier hardware removal, less potential for hardware irritation, and less bony weakness following hardware removal compared to plate fixation. However, the ability to resist torsional forces is less with intramedullary fixation compared to plating which can result in fracture of the intramedullary implant (Fig. 22-6). Furthermore, the potential for the intramedullary device to migrate is a major concern for many surgeons, thus limiting usage.

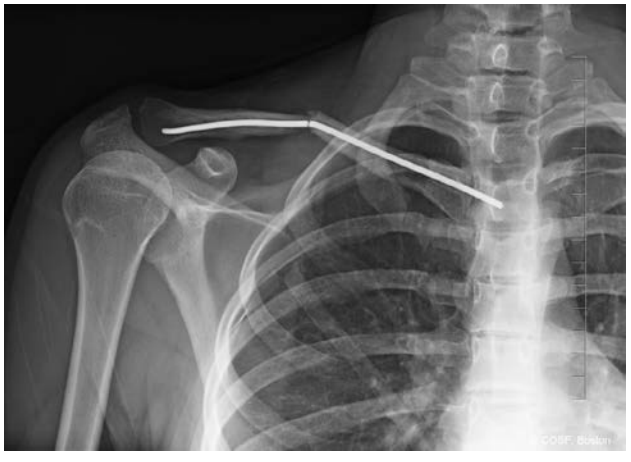

FIGURE 22-6 Radiograph of a right midshaft clavicular fracture treated with an intramedullary elastic nail, which subsequently went on to fracture. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

TABLE 22-2 ORIF of Midshaft Clavicle Fractures

Preoperative Planning Checklist

OR Table: Standard OR table capable of going into beach chair position

Position/positioning aids: Supine beach chair position with head and neck tilted away
Bump placed behind the scapula

Fluoroscopy location: Contralateral to fracture

Equipment: Surgeon's choice of implant

Tourniquet (sterile/nonsterile): None

Draping: Shoulder girdle, entire clavicle and ipsilateral limb is prepped and draped into the field to allow for visualization traction and manipulation
Medially the contralateral sternoclavicular joint should be included in the operative field

If plate fixation is being planned, one must determine what the preferred location of the plate will be, anteroinferior or superior. Anteroinferior plates have the advantage of performing drilling in a posterosuperior direction, thus the drill is not directed toward the surrounding neurovascular structures. In addition, the plate is less prominent in this location. Superior placement of the plate is technically easier and allows for better resistance of the biomechanical forces acting to displace the fracture (Table 22-2).

Positioning

Options for positioning during open reduction and internal fixation or intramedullary fixation of clavicle fractures include utilizing the beach chair position or having the patient supine. With either position, a bump is placed behind the scapula to aid in reducing the fracture.

Surgical Approach(es)

Open reduction and internal fixation is performed via a direct surgical approach to the clavicle is performed by utilizing a skin incision that follows Langer lines. In an attempt to avoid wound problems, by having the incision directly over the plate, and to improve cosmesis, one can incise the skin on the inferior aspect of the clavicle.[32] Once the skin is incised, electrocautery is utilized to divide the platysma, fascia, and periosteum in line with the skin incision. During this process, it is important to identify and protect the cutaneous supraclavicular nerves as they cross the clavicle. Subperiosteal dissection is then carried out to expose the fracture site while ensuring maintenance of the soft tissue attachments to any malrotated or segmental fracture fragments.

Intramedullary fixation is performed by making a similar approach utilizing a small incision over the fracture site to expose only the ends of fracture fragments. An additional percutaneous incision is placed over the superolateral part of the clavicle to place the intramedullary device in an antegrade manner.

Technique

Once the fracture site and fragments are exposed, bone holding forceps are utilized to reduce the fracture. If there is a segmental fracture, a separate interfragmentary screw may be used to reduce the fracture from three-parts to two-parts. The fracture is then anatomically reduced and clamped. Areas of comminution are accounted for. Either an anatomic clavicle plate or a small pelvic reconstruction plate is contoured to allow for rigid internal fixation. The plate is subsequently applied in the desired location and either direct visualization alone or fluoroscopic imaging in multiple planes is utilized to assess the reduction, screw placement and length. Following placement of the plate, the periosteum is closed while still protecting the supraclavicular nerves. Layered closure including a meticulous skin closure is then performed to reduce the chance of wound complications and permit the best cosmetic outcome possible. The patient is then placed in a sling or shoulder immobilizer.

Intramedullary fixation is performed by exposing the fracture ends and then drilling the distal segment retrograde through the canal, exiting the posterior lateral cortex. Drilling of the medial segment is then performed, ensuring no violation of the anterior medial cortex occurs. The device can be placed retrograde through the canal to exit through the posterior-lateral hole and subsequently the skin. Fracture reduction can now be performed and the intramedullary device can be advanced antegrade across the fracture site. Many devices have mechanisms, such as washers or nuts, that can now be applied in an attempt to prevent migration of the device or allow for fracture compression.

Author's Preferred Treatment of Midshaft Clavicle Fractures

The vast majority of pediatric and adolescent clavicle fractures are treated nonoperatively with immobilization for 3 to 4 weeks. Patients then undergo home or formal rehabilitation to restore range of motion and strength before resuming full activities. Operative treatment is performed for open fractures, fractures with skin compromise, fractures associated with neurologic or vascular injury, and significantly displaced fractures in athletes (Fig. 22-7).

We utilize the beach chair position and make our skin incision approximately 1 cm inferior to the clavicle. Following exposure of the fracture fragments, reduction is performed utilizing bone

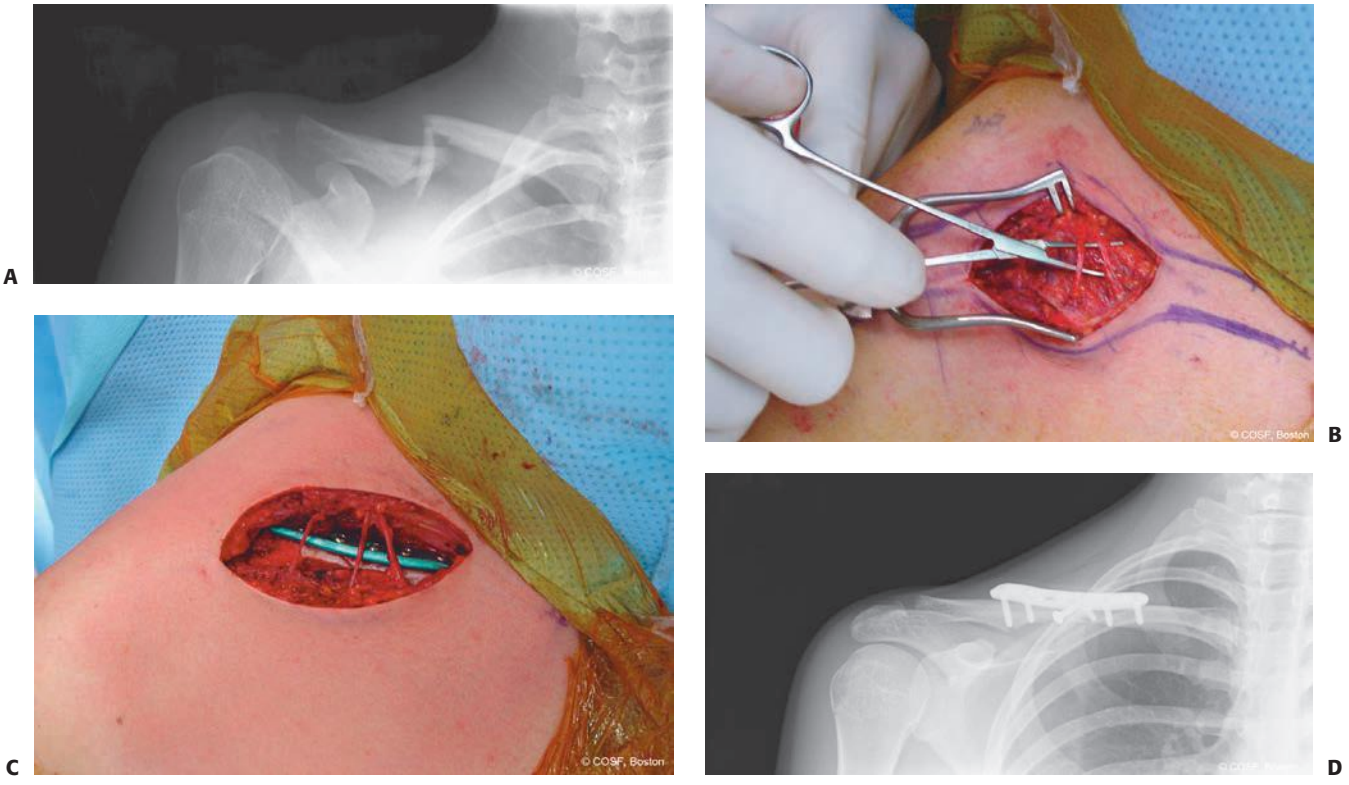

FIGURE 22-7 **A:** Radiograph of a displaced, segmental right diaphyseal clavicle fracture. **B:** Incision in line with Langer lines, ensuring protection of the supraclavicular cutaneous nerves as the exposure is performed. **C:** Plate placement on the superior aspect of the clavicle while preserving the supraclavicular cutaneous nerves. **D:** Postoperative radiograph of the anatomically reduced fracture. Note the interfragmentary screw that was utilized to convert this fracture from three fragments to two. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide.* Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

holding forceps. It is imperative to restore the length and contour of the clavicle during the reduction process. This may require utilization of smooth wires, suture, or interfragmentary screws. Once the reduction is near anatomic, the plate is applied on the superior aspect of the clavicle. During drilling and screw placement, we protect the surrounding neurovascular structures by placement of a malleable retractor inferior to the clavicle. Following plate placement, fluoroscopic imaging and/or direct visualization is utilized to assess the fracture reduction and screw lengths. The wound is then thoroughly irrigated and the periosteum closed. A meticulous subcuticular closure is then performed to obtain the best cosmetic result possible and decrease the chance of wound complications. Sterile dressings are applied followed by placement of the patient into either a sling or shoulder immobilizer.

Postoperative Care for Midshaft Clavicle Fractures

Whether open reduction and internal fixation or intramedullary fixation is performed, the patient is placed in a sling or shoulder immobilizer for 3 to 4 weeks. At that point, clinical examination is utilized to assess tenderness at the fracture site and radiographs in two planes are obtained to assess bony healing. If the examination and radiographs are consistent with healing, the patient is permitted to begin range-of-motion activities followed by strengthening once the bone is fully healed. Full activity can be resumed once the range of motion and strength are returned to baseline levels.

Potential Pitfalls and Preventive Measures for Midshaft Clavicle Fractures

The most dreaded intraoperative complication would be damage to a neurovascular structure or creation of a pneumothorax. Both of these exceedingly rare iatrogenic complications can be prevented by utilizing meticulous technique during the exposure of the fracture fragments and drilling/screw placement during the plate application. When exposing the fracture fragments, it is imperative to stay subperiosteal to create a layer between the bone and surrounding neurovascular structures. Subsequently, retractors can be placed in this layer and direct visualization can be utilized during the drilling and screw placement process to avoid damaging the neurovascular structures.

Maintenance of soft tissue attachments to comminuted or malrotated small fragments will aid the surgeon in the reduction process. Furthermore, if these fragments are completely devoid of soft tissue attachments, devitalization may cause bony union to be delayed or not occur.

Wound complications can be prevented by utilizing the inferior skin incision rather than a direct approach to the clavicle. In addition, a meticulous closure at the end of the procedure will permit the best cosmetic outcome while minimizing the chance of wound issues.

Treatment-Specific Outcomes for Midshaft Clavicle Fractures

The majority of available data for the treatment of pediatric and adolescent midshaft clavicle fractures is retrospective in nature involving preadolescents and adolescents. Mehlman et al. performed a retrospective review of 24 children with a mean age of 12 years who underwent operative treatment of completely displaced clavicle shaft fractures. In their series, there were no nonunions and no infections. Twenty-one of the 24 patients were able to return to unrestricted sports activity. Three complications were reported including two patients who had scar sensitivity and one patient who had a transient ulnar nerve neurapraxia. All patients underwent hardware removal on an elective basis.[95]

Namdari et al. also performed a retrospective review of 14 skeletally immature patients who underwent open reduction and internal fixation of displaced midshaft clavicle fractures. No nonunions occurred in the cohort but eight patients had numbness about the surgical site. Four patients had their hardware removed.[101]

Vander Have et al. have performed the only comparative study to date evaluating nonoperative versus operative treatment of midshaft clavicle fractures in adolescents. The authors retrospectively reviewed 43 fractures of which 25 were treated nonoperatively and 17 were treated operatively. No nonunions occurred in either group but five symptomatic malunions occurred in the nonoperative group, four of which were treated with a corrective osteotomy. All complications in the operative group were related to prominence of the hardware. Return to full activities occurred faster, by approximately 4 weeks, in the operative group compared to the nonoperative group.[138]

Although the Vander Have study showed a high rate (20%) of symptomatic malunion, with many requiring corrective osteotomy, in the nonoperative group, Bae et al. have recently reported that the vast majority of significantly displaced (>2 cm) diaphyseal clavicle fractures treated nonoperatively result in an asymptomatic malunion that does not require corrective osteotomy. Of the 16 fractures studied, all united in a malunited position with only one requiring a corrective osteotomy. The mean DASH score was low at 4.9 and the mean pain VAS was 1.6. No significant loss of strength or motion was present.[8]

Management of Expected Adverse Outcomes and Unexpected Complications Related to Midshaft Clavicle Fractures

Patients who have prominence of their hardware can be successfully treated by removal of their hardware.[95,101,138] If a patient initially treated by nonoperative measures develops a symptomatic malunion, corrective osteotomy has been shown to be successful in eliminating symptoms (Fig. 22-8).[138] In the Vander Have series, all patients who underwent corrective osteotomy of their malunion went on to union and resolution of their symptoms.[138] Only one nonunion has been reported in the pediatric and adolescent literature to date.[107] Treatment can be successfully performed by subsequent open reduction and internal fixation with a stable construct. On rare occasion, a vascularized bone or corticoperiosteal flap may be necessary (Fig. 22-9, Table 22-3).

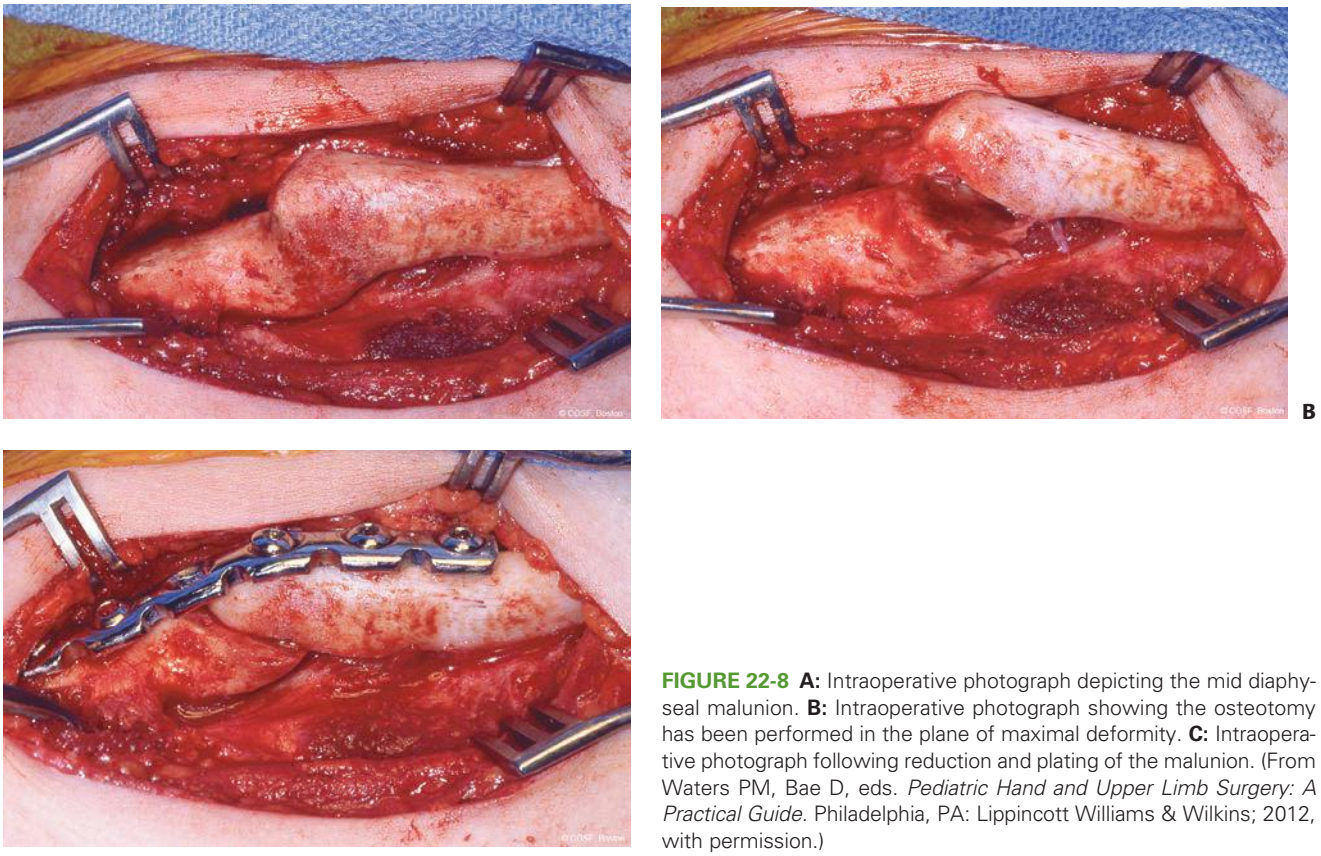

FIGURE 22-8 **A:** Intraoperative photograph depicting the mid diaphyseal malunion. **B:** Intraoperative photograph showing the osteotomy has been performed in the plane of maximal deformity. **C:** Intraoperative photograph following reduction and plating of the malunion. Summary, Controversies, and Future Directions Related to Midshaft Clavicle Fractures

The vast majority of pediatric and adolescent midshaft clavicle fractures can be treated successfully with nonoperative measures. Open reduction and internal fixation should be performed for open fractures, fractures with skin compromise, and fractures with nerve or vascular injury. In addition, recent literature has suggested a faster return to activities utilizing open reduction and internal fixation of markedly displaced (>2 cm) or segmental fractures in older patients. Future prospective studies will need to be performed to determine the potential benefits and complications of operative fixation versus nonoperative treatment in adolescents.

Introduction to Distal Clavicle Fractures

Distal clavicle fractures account for 10% to 30% of all clavicle fractures, thus making it the second most common site for a clavicle fracture.[124] Minimal studies exist regarding the treatment and outcomes of these fractures for pediatric and adolescent patients. Therefore, the information presented here will mainly be extrapolated from the adult literature and our experience.

Assessment of Distal Clavicle Fractures

Mechanisms of Injury for Distal Clavicle Fractures

Akin to midshaft clavicle fractures, distal clavicle fractures are typically the result of a direct blow to the shoulder girdle or a fall onto the distal aspect of the clavicle.[124,131] Direct blows typically occur in adolescents involved in collision-type sports such

FIGURE 22-9 Radiograph of a healed clavicle fracture following treatment of a symptomatic nonunion with a vascularized fibula graft. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

TABLE 22-3 ORIF of Midshaft Clavicle Fractures

Surgical Steps

1. Skin incision approximately 1 cm inferior to the clavicle in line with Langer lines
2. Electrocautery through platysma, fascia, and periosteum directly onto the clavicle while avoiding injury to the supraclavicular cutaneous nerves
3. Expose fracture site in a subperiosteal manner while preserving soft tissue attachments to malrotated and comminuted fragments
4. Reduce fracture fragments utilizing bone holding forceps
5. Apply plate in desired location
6. Assess reduction and screw lengths with direct visualization or fluoroscopic imaging in multiple planes
7. Close periosteum
8. Meticulous skin closure
9. Apply sling or shoulder immobilizer

Intramedullary Fixation of Midshaft Clavicle Fractures

Surgical Steps

1. Skin incision overlying the fracture site in line with Langer lines
2. Electrocautery through fascia and periosteum directly onto the clavicle while avoiding injury to the supraclavicular cutaneous nerves
3. Expose fracture site in a subperiosteal manner while preserving soft tissue attachments to malrotated and comminuted fragments
4. Drill the medial segment of the fracture in preparation for device placement while ensuring no violation of the anterior medial cortex occurs
5. Drill distal fragment medullary canal and then posterior lateral cortex so that the drill can be visualized just beneath the skin
6. Make a percutaneous skin incision where the drill is tenting the skin
7. Place intramedullary device in a retrograde manner through fracture site to exit through posterior lateral skin incision
8. Reduce fracture fragments
9. Advance device antegrade across the fracture
10. Place device-specific mechanisms, if available, to prevent migration or permit compression
11. Close periosteum
12. Meticulous skin closure
13. Apply sling or shoulder immobilizer

as football or lacrosse. When a fall is the mechanism of injury, direct contact from the ground is made against the acromion with the arm typically held in an adducted position. The force is transmitted from the acromion across the AC joint to the distal end of the clavicle.

Associated Injuries with Distal Clavicle Fractures

Common injuries associated with distal clavicle fractures include additional fractures about the shoulder girdle including proximal humerus and scapular fractures, thus constituting a floating shoulder-type injury. In addition, rib fractures, lung injuries including contusions, and brachial plexus injuries may occur concomitantly. Lastly, cervical spine injuries must be ruled out in collision or high-energy mechanisms of injury.

Signs and Symptoms of Distal Clavicle Fractures

Patients who sustain distal clavicle fractures present with pain about the involved shoulder especially with any attempt at movement of the arm. Paresthesias may be present if a concomitant brachial plexus injury occurred or there is swelling causing injury to the supraclavicular nerves.

Physical examination should begin by observing for obvious swelling, ecchymosis, and/or skin tenting. Palpation of the entire upper extremity, hemithorax, and cervical spine should be performed to identify the location of maximal tenderness as well as additional areas that may have sustained a concomitant injury. A complete neurovascular examination should be performed to evaluate for rare brachial plexus injury. Patients involved in high-energy mechanisms should have a complete head-to-toe survey performed by the orthopedic physician as well as either a member of the trauma team or the emergency room physician.

Imaging and Other Diagnostic Studies for Distal Clavicle Fractures

Initial imaging should be performed by obtaining plain radiographs of the shoulder including a true AP view and an axillary lateral view. In addition, a Zanca view can be obtained to better assess the AC joint for intra-articular involvement. This is performed by aiming the x-ray beam in 10 to 15 degrees of cephalic tilt.[149] A CT scan will be diagnostic of intra-articular fractures, which may require operative intervention for best results.

Classification of Distal Clavicle Fractures

The most commonly utilized classification scheme for distal clavicle fractures is that proposed by Neer and modified by Craig.[33,104] This classification scheme includes five types based on the relationship of the fracture line to the coracoclavicular ligaments, the AC ligaments, and the physis. Most lateral clavicle fractures in the skeletally immature are periosteal disruptions in which the bone displaces away from the periosteal sleeve whereas the ligaments remain attached to the intact inferior portion of the periosteum.

Type I fractures occur distal to the coracoclavicular ligaments but do not involve the AC joint. Minimal displacement occurs due to the proximal fragment being stabilized by the intact coracoclavicular ligaments and the distal fragment being stabilized by the AC joint capsule, the AC ligaments, and the deltotrapezial fascia.

Type II fractures are subdivided into type IIA and type IIB fractures, with type IIA fractures occurring medial to the coracoclavicular ligaments and type IIB fractures occurring between the coracoclavicular ligaments with concomitant injury to the conoid ligament. In type IIA injuries, the proximal fragment loses the stability provided by the coracoclavicular ligaments and displaces superiorly out of the periosteal sleeve. In contrast,

the distal fragment remains stable because of the attachments of the AC joint capsule, AC ligaments, and the coracoclavicular ligament(s). This remains true for type IIB fractures as well, because even though the conoid ligament is disrupted, the trapezoid ligament remains attached.

Type III fractures occur distal to the coracoclavicular ligaments and extend into the AC joint. As these fractures do not disrupt the ligamentous structures, minimal displacement is the norm.

Type IV fractures occur in skeletally immature patients and involve a fracture medial to the physis. The epiphysis and physis remain uninjured and attached to the AC joint. However, significant displacement can occur between the physis and metaphyseal fragment, as the coracoclavicular ligaments are attached to the physis. This is especially true if the periosteal sleeve is disrupted. In essence, this is analogous to a type IIA fracture.

Type V fractures have a fracture line that leaves a free-floating inferior cortical fragment attached to the coracoclavicular ligaments with an additional fracture line dividing the distal clavicle from the remainder of the clavicle. Therefore, neither the proximal nor distal fragment is attached to the coracoclavicular ligaments. The end result is instability with the potential for significant displacement of the distal end of the proximal fragment.

Outcome Measures for Distal Clavicle Fractures

No specific outcome score exists in isolation for distal clavicle fractures. Therefore, outcomes are described based on union rates and subjective patient outcomes. Adult-oriented outcome measures have been individually utilized in various studies, including the Constant Score, the American Shoulder and Elbow Surgeons (ASES) score, and the Medical Outcomes Study 36-Item Short Form. However these have not been used universally and none of them have been validated in the pediatric or adolescent populations.

Pathoanatomy and Applied Anatomy Relating to Distal Clavicle Fractures

The distal aspect of the clavicle forms the articulation with the scapula via the AC joint. Ligamentous connections between this portion of the clavicle and the scapula include the AC ligaments and coracoclavicular ligaments. The coracoclavicular ligaments include the trapezoid ligament, located more laterally with an attachment to the distal clavicle approximately 2 cm from the AC joint, and the conoid ligament, located more medially with an attachment to the distal clavicle approximately 4 cm from the AC joint.[120] The presence of these ligamentous attachments and the acromioclavicular joint capsule permit fluid scapulothoracic motion.[11]

Stability of the clavicle in the horizontal/AP plane is provided by the AC ligaments whereas stability in the vertical/superoinferior plane is provided by the coracoclavicular ligaments.[44] This stability permits the definition of the coracoclavicular space, the space between the coracoid process and the undersurface of the clavicle, which should be 1.1 to 1.3 cm.[16]

Treatment Options for Distal Clavicle Fractures

Nonoperative Treatment of Distal Clavicle Fractures

Indications/Contraindications

The majority of distal clavicle fractures in the pediatric and adolescent population can be managed nonoperatively with immobilization alone as long as significant displacement is not present. Typically, this is universally true for type I and type III fractures. However, types II, IV, and V fractures may have significant displacement with subsequent skin tenting or instability present about the shoulder girdle. Contraindications to nonsurgical management include open fractures, fractures associated with skin compromise, and fractures with concomitant neurovascular injury requiring surgical intervention. Displaced fractures in the pediatric and adolescent population (types II, IV, and V) should be treated on an individual basis depending on the patient's age, the amount of displacement, and the patient's activities (Table 22-4).

Techniques

Patients are placed in either a sling or shoulder immobilizer for approximately 3 to 4 weeks and then allowed to begin active range of motion. Radiographs are taken at the 3- to 4-week follow-up visit to ensure adequate healing is occurring and there has been no further displacement.

Outcomes

Nonoperative treatment of nondisplaced or minimally displaced distal clavicle fractures typically has excellent outcomes with successful union occurring and patients able to return to full activities. However, types I and III fractures have been shown to go on to delayed-onset symptomatic AC joint arthrosis in the adult literature.[103]

Treatment of significantly displaced distal clavicle fractures is somewhat controversial due to a relatively high nonunion rate reported in the adult literature. In a retrospective review performed by Neer,[102] he documented that all patients with

TABLE 22-4 Midshaft Clavicle Fractures

Potential Pitfalls and Preventions

Pitfall	Prevention
Neurovascular injury/ pneumothorax	Utilize subperiosteal dissection Place retractors inferiorly when drilling from superior to inferior direction
Delayed union/ nonunion	Maintain soft tissue attachments to comminuted or malrotated fragments
Malunion	Maintain soft tissue attachments to comminuted or malrotated fragments Anatomically reduce and stabilize segmental fractures

type II distal clavicle fractures treated nonoperatively, had either a delayed union (67%) or a nonunion (33%). Edwards et al.[37] treated 20 patients with type II distal clavicle fractures nonoperatively and had a 45% delayed union rate and a 30% nonunion rate. Additional studies have shown similar nonunion rates ranging from 25% to 44% for type II fractures treated nonoperatively.[110,124,125,127] In contrast, all type II fractures treated surgically with open reduction and internal fixation have gone on to union.[37,102,127]

Operative Treatment of Distal Clavicle Fractures

Indications/Contraindications

Absolute indications for operative treatment of distal clavicle fractures include open fractures, fractures with significant skin compromise, displaced intra-articular extension, and fractures with associated neurovascular injuries that require operative intervention. Additional relative indications may include significantly displaced fractures in competitive athletes and adolescents, entrapment in the trapezius muscle, floating shoulder-type injuries, and patients with polytrauma.

Surgical Procedure for Distal Clavicle Fractures

Preoperative Planning

It is necessary to determine preoperatively what the plan for fixation is going to be as numerous techniques can be performed to stabilize the distal clavicle. Ideally, multiple options are available at the time of surgical intervention including various nonabsorbable suture options, Dacron tape, and locking plates, such as anatomic clavicle plates and hook plates. The position the patient will be in during the procedure needs to be discussed with the anesthesiologist and operating room staff, especially if the beach chair position is being utilized (Table 22-5).

Positioning

The patient can be positioned in either the beach chair position with the head and neck tilted away or supine on a radiolucent table. With either position, a bump should be placed behind the scapula. The entire shoulder girdle, beginning at the medial edge of the clavicle, and entire limb should be prepped and draped in the operative field to allow for movement of the limb which facilitates fracture reduction and fixation. A sterile area above the shoulder adjacent to the head is maintained to allow for the surgeon to work both inferior and superior to the clavicle and shoulder.

TABLE 22-5 Midshaft Clavicle Fractures

Common Adverse Outcomes and Complications
Hardware prominence
Malunion
Nonunion
Wound complications

Surgical Approach(es)

A slightly curved incision in Langer skin lines over the distal third of the clavicle and AC joint should be made. Once the skin is divided, the subcutaneous tissue, fascia, and periosteum are incised to maintain a thick flap. Subperiosteal dissection is then carried out from nonfractured clavicle out to the fracture site to expose the fracture fragments.

Technique

Fixation with low-profile anatomic distal locking plates or hook plates can be utilized for skeletally mature adolescents as appropriate (Fig. 22-10). Younger patients may require utilization of modular hand instrumentation or mini-fragment locking plates (Synthes, Inc., West Chester, PA). Distal radius plate fixation has also been suggested by placement of the 2.4-mm locking screws in the distal clavicle fragment.[68]

The implant choice will depend on the age and size of the patient, as well as the size and location of the fracture fragments. Larger patients and fragments will permit fixation with low-profile locking plates, whereas smaller fragments may require fixation with suture, Kirschner wire fixation, or even a hook plate. Kirschner wire fixation should be supplemented with a dorsal tension band, utilizing either suture or wire. Threaded wires are used to lessen the risk of migration.[6,69,82,87]

Additional fixation of the coracoclavicular ligaments has been suggested to decrease the chance of nonunion in adults. This has been performed utilizing suture or Dacron tape with or without additional fixation.[47,143] In addition, arthroscopic techniques, utilizing suture, the Tightrope system (Arthrex, Naples, FL) or a double-button device, to stabilize the coracoclavicular ligaments have also been reported in adults.[14,29,111,117] Some authors have proposed placement of a screw between the coracoid and clavicle, however this requires screw removal following fracture union.[10,37,39,65,86,148] Neither of these techniques are used very often in children or adolescents because of the periosteal insertion of the ligaments. Once the periosteum is repaired, the ligaments usually are stable (Table 22-6).

Author's Preferred Treatment of Distal Clavicle Fractures

Our preferred technique is to treat the vast majority of distal clavicle fractures in the pediatric and adolescent populations with nonoperative measures. Patients are placed into a sling

TABLE 22-6 Distal Clavicle Fractures

Nonoperative Treatment	
Indications	**Relative Contraindications**
Nondisplaced and minimally displaced fractures (type I and type III fractures)	Open fractures Fractures with associated skin compromise Fractures with concomitant neurovascular injury requiring surgical intervention

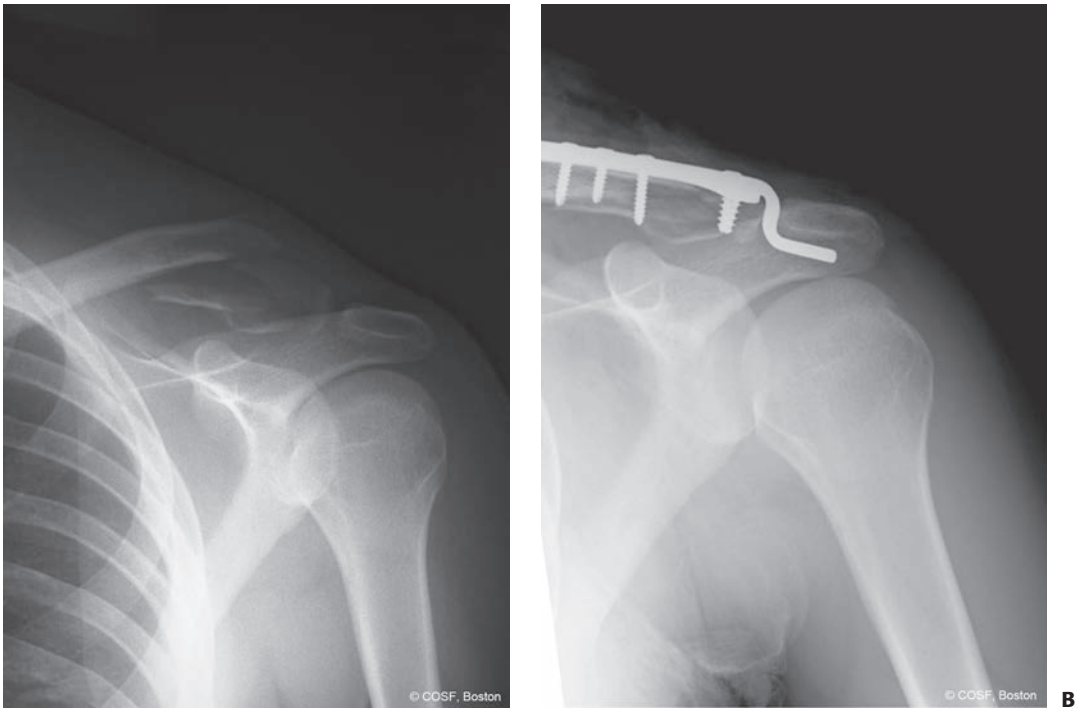

FIGURE 22-10 **A:** Radiograph of a displaced intra-articular lateral clavicle fracture where the lateral aspect of the medial fragment was entrapped in the trapezius muscle. **B:** Postoperative radiograph demonstrating fixation utilizing a hook plate. Removal of the implant is planned. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

or shoulder immobilizer for 3 to 4 weeks and then advanced to active range of motion, presuming union has occurred. Operative intervention is reserved for open fractures, fractures with skin compromise, fractures with associated neurovascular injury requiring operative intervention, displaced intra-articular fractures and significantly displaced fractures, especially those displaced posteriorly with entrapment in trapezius muscle.

A direct approach to the fracture site is performed utilizing a Langer skin line. Following sharp incision of the skin, electrocautery is utilized to divide the subcutaneous tissue, fascia, and periosteum. A freer elevator or similar blunt instrument is then used to elevate the periosteum off of the clavicle while preserving the AC and coracoclavicular ligament attachments. The fracture fragments are then exposed and irrigated free of hematoma and debris in preparation for reduction.

Fixation of a distal clavicle fracture is ideally performed utilizing a plate and screw construct, assuming there is enough bone laterally for stable fixation. In older adolescents, we utilize anatomically contoured distal clavicular locking plates when feasible. If the fragment is too small for these implants, we attempt to perform fixation utilizing mini-fragment or modular hand-locking plates (Synthes, Inc., West Chester, PA). We do not routinely supplement our plate fixation with suture around the coracoid and clavicle unless the fixation was marginal. The periosteal repair is generally sufficient for ligamentous and soft tissue stability.

If plate fixation is not an option, interosseous suture fixation of the fracture fragments is performed (Fig. 22-11). We have not found it necessary to place suture around the coracoid and clavicle to obtain union in the pediatric and adolescent populations. Hook plates are only utilized as a last resort, as they require a second procedure for removal. However, they are available during all procedures, in case adequate fixation is unable to be obtained without them. Generally the hook plate would be used in an appropriately sized adolescent.

Postoperative Care

Postoperatively, patients are placed in a sling or shoulder immobilizer for 4 to 6 weeks. Postoperative mobilization is dependent on age and psychological maturity of the patient as well as rigidity of the fixation. When safe, immobilization is removed several times a day for pendulum exercises. Following union of the fracture, active shoulder range of motion and strengthening is initiated. Contact sports participation is usually avoided for 3 months.

Potential Pitfalls and Preventive Measures for Distal Clavicle Fractures

Nonunion or hardware failure can occur if there is inadequate fixation of the distal clavicular fragment or excessive activity early. In addition, it is imperative to avoid screw penetration into the AC joint, which can be assessed with direct visualization and/or utilizing fluoroscopy in multiple planes.

Treatment-Specific Outcomes for Distal Clavicle Fractures

Operative treatment of distal clavicle fractures has excellent results with regard to union rates, especially in children and adolescents. The main concern is hardware complications. Utilization of smooth wires about this region has led to migration of the wires into areas including the lung, abdomen, spine, trachea, and vascular structures. Avoid smooth wires if possible; leave them out of skin and remove them early if used.[85,118,137] Furthermore, tension band wiring is prone to symptomatic hardware requiring a second procedure for removal. Using ethibond suture as a tension band lessens the risk of hardware irritation but suture granulomas can also be irritating and require subsequent removal at times.[79]

Union rates with plate fixation have been reported to be as high as 100%.[25,45] Studies comparing techniques for treatment of very distal fractures have found that hook plate usage in adults yields better results with regard to return to work and sports participation while having a lower complication rate.[42,79] However, we would advocate removal of the hook plate in an adolescent when the fracture is healed to avoid secondary complications.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Distal Clavicle Fractures

The most common complication of treatment of distal clavicle fractures is related to symptomatic hardware, which is easily remedied by removal of hardware. Nonunion and symptomatic malunions are best managed by performing open reduction and internal fixation of the fracture. If necessary, the distal fragment can be excised and the AC joint can be reconstructed utilizing a modified Weaver–Dunn procedure, where the coracoacromial ligament is transferred to the distal end of the remaining clavicle (Table 22-7).[5]

TABLE 22-7 ORIF of Distal Clavicle Fractures

Preoperative Planning Checklist

OR Table: Standard operating room table capable of being put into beach chair position

Position/positioning aids: Beach chair position with head and neck tilted away or supine

Bump placed behind the scapula. Leave plenty of sterile standing space above the shoulder adjacent to the head

Fluoroscopy location: Contralateral side of fracture

Equipment: Nonabsorbable suture, Dacron tape, anatomic clavicle plates, hook plates, mini fragment or modular hand locking plates

Tourniquet (sterile/nonsterile): None

Draping: Entire shoulder girdle region and ipsilateral limb is prepped and draped into the field to allow for traction and manipulation

Medially the contralateral sternoclavicular joint should be included in the operative field

Summary, Controversies, and Future Directions Related to Distal Clavicle Fractures

The majority of literature available on distal clavicle fractures is for the adult population. Typically, if a child or adolescent sustains a fracture in this region, immobilization alone is sufficient to obtain a successful outcome. In older adolescents and highly competitive athletes, operative intervention may be warranted. Utilization of a plate and screw construct typically yields excellent results with a rapid return to function, a very high union rate, and a low complication rate. Further studies evaluating the treatment and outcomes of these fractures in adolescents are needed.

Introduction to Scapula Fractures

Scapula fractures are uncommon accounting for 1% of all fractures in adults with an even lower incidence in children.[51,134] Fractures involving the scapular body are most common accounting for approximately 45% of fractures. The remainder of fractures involve the glenoid neck (25%), glenoid cavity (10%), acromion process (8%), coracoid process (7%), and scapular spine (5%).[91,134] Very rarely, scapulothoracic dissociation can occur and has been reported in two separate case reports involving children, one child 8 years old and the other 11 years old.[4,106] Because of the low incidence of scapular fractures, mostly case report and retrospective small case series literature exist on their treatment and outcomes in the pediatric and adolescent populations.

Assessment of Scapula Fractures

Mechanisms of Injury for Scapula Fractures

When scapula body fractures occur in children they are likely the result of either high-energy mechanisms, such as a fall from a height or motor vehicle accidents, or the result of nonaccidental injury.[22] Bullock et al.[22] showed that scapula fractures had the highest risk of abuse for any fracture other than rib/sternum fractures and when they were present, they were more than twice as likely to be associated with child abuse than not.

Glenoid fractures most commonly occur due to a direct force on the lateral shoulder, such as occurs during a fall or a collision sport. The force is transmitted to the humeral head, which then is driven into the glenoid surface.[24] An alternative mechanism of injury is a fall onto a flexed elbow.[84] The position of the arm at the time of injury will determine whether an anterior or posterior rim fracture occurs.[98]

Acromion fractures occur due to a direct blow to the lateral aspect of the shoulder, which typically occurs during a fall or a collision in sport.[91] It is imperative to recognize that complete failure of the epiphyses to fuse is a normal anatomic variant known as os acromiale, and should not be mistaken for a fracture.[83] If necessary, comparison radiographs with the contralateral side can be obtained to evaluate for this.

Coracoid fractures occur due to the pull of either the AC ligaments or the conjoint tendon. When the AC ligaments avulse the coracoid from the remainder of the scapula, the fracture occurs at the physis through the base of the coracoid and upper quarter of the glenoid.[57] In contrast, when the conjoint tendon avulses the coracoid from the scapula, the fracture occurs through the tip of the coracoid.[34]

Associated Injuries with Scapula Fractures

Whether scapula fractures occur due to high-energy mechanisms or nonaccidental trauma, associated injuries are common, including life-threatening injuries. Such injuries include closed head injuries, pneumo- or hemothorax, rib fractures, ruptured viscera, and concomitant long-bone fractures.[51,62,134] Almost half of all children admitted to the hospital for nonaccidental trauma have at least one fracture and approximately one-third had a diagnosis of contusion.[22] Concomitant neurovascular injury may also occur involving the brachial plexus, subclavian artery/vein, or axillary vessels. Lastly, additional fractures or dislocations can occur about the shoulder girdle, leading to a floating shoulder.

Signs and Symptoms of Scapula Fractures

Because of the large amount of force required to sustain a scapula fracture, a complete head-to-toe survey should be performed by either the trauma team or emergency room physician. Associated rib fractures or lung injury may cause difficulty breathing, whereas ruptured viscera will lead to an acute abdomen. In cases of suspected nonaccidental trauma, a complete evaluation needs to be performed including a head CT scan, an ophthalmologic examination, a skeletal survey, and a social work consultation.

Patients with scapula fractures will often complain of significant pain about their chest, back, and shoulder region. Numbness may be present because of concomitant brachial plexus injury or significant swelling. Observation for significant swelling and ecchymosis should begin the examination. Subsequently, a complete neurovascular examination of the involved upper extremity is necessary. Palpation should then be performed to determine the location of maximal tenderness as well as additional areas of tenderness, as concomitant shoulder girdle fractures can be present. A secondary survey should be performed by the orthopedic surgeon to ensure there are no additional musculoskeletal injuries.

Imaging and Other Diagnostic Studies for Scapula Fractures

Scapula fractures may initially be discovered on the chest x-ray obtained during the trauma work-up; however, additional imaging is necessary to fully evaluate the fracture. Plain radiographs including true AP and lateral scapula views as well as a glenohumeral axillary view should be obtained when a scapula fracture is suspected. In addition, because of the significant amount of overlying bony and soft tissue structures, a CT scan will enable the surgeon to fully understand the fracture pattern. The addition of reconstructions, including three-dimensional reconstructions, will aid in preoperative planning if operative intervention is being considered.

Classification of Scapula Fractures

Scapula fractures are classified according to the fracture location within the scapula; body, glenoid cavity, glenoid neck, acromion, or coracoid. In addition, scapulothoracic dissociation is a term utilized to describe complete separation of the scapula from the posterior chest wall.

Glenoid neck fractures are further classified based on their displacement and angulation. A type I fracture is displaced less than 1 cm and angulated less than 40 degrees, whereas a type II fracture has more than 1 cm of displacement and is angulated greater than 40 degrees.[50] Type I fractures account for 90% of glenoid neck fractures.[2,150]

Glenoid cavity fractures are classified into six types based on the location of the fracture within the glenoid cavity and their severity (Fig. 22-12).[49,61] Type I fractures involve either the anterior (type Ia) or posterior (type Ib) aspect of the glenoid rim. Type II fractures have a transverse fracture line that divides the superior and inferior aspects of the glenoid and then exits inferiorly through the lateral scapular border. Types III and IV fractures also begin with a fracture line dividing the superior and inferior aspects of the glenoid, but type III fractures exit superiorly near or through the scapular notch and type IV fractures exit medially through the medial border of the scapula. Type V fractures have more than one fracture line involving a combination of types II to IV and are further subclassified into a, b, and c. Type Va fractures are a combination of type II and IV fractures; type Vb fractures are a combination of types III and IV fractures; and type Vc fractures are a combination of types II, III, and IV fractures. Lastly, type VI fractures are severely comminuted fractures.

Outcome Measures for Scapula Fractures

No specific outcome measures exist for the evaluation of scapula fractures. Results in the adult literature utilize subjective complaints of pain, fracture displacement, residual deformity, nonunion, and development of posttraumatic arthritis as determinants for success.[38,72,77,89,108] Specific pediatric outcomes have not been developed but the goals of outcome are the same: Restoration of motion, function, and strength without long-term limitations and/or pain.

Pathoanatomy and Applied Anatomy Relating to Scapula Fractures

The scapula is a flat bone on the posterior aspect of the chest wall, covered almost entirely by muscle due to it having 17 muscular attachments on it. Only the dorsal aspect of the scapular spine and acromion are subcutaneous, thus the remainder of the bone is deep and well protected from low-energy mechanisms of injury. Three articulations occur with the scapula; the acromion articulates with the clavicle at the AC joint; the proximal humerus articulates with the glenoid at the glenohumeral joint; and the posterior chest wall articulates with the anterior scapula to make up the scapulothoracic articulation.

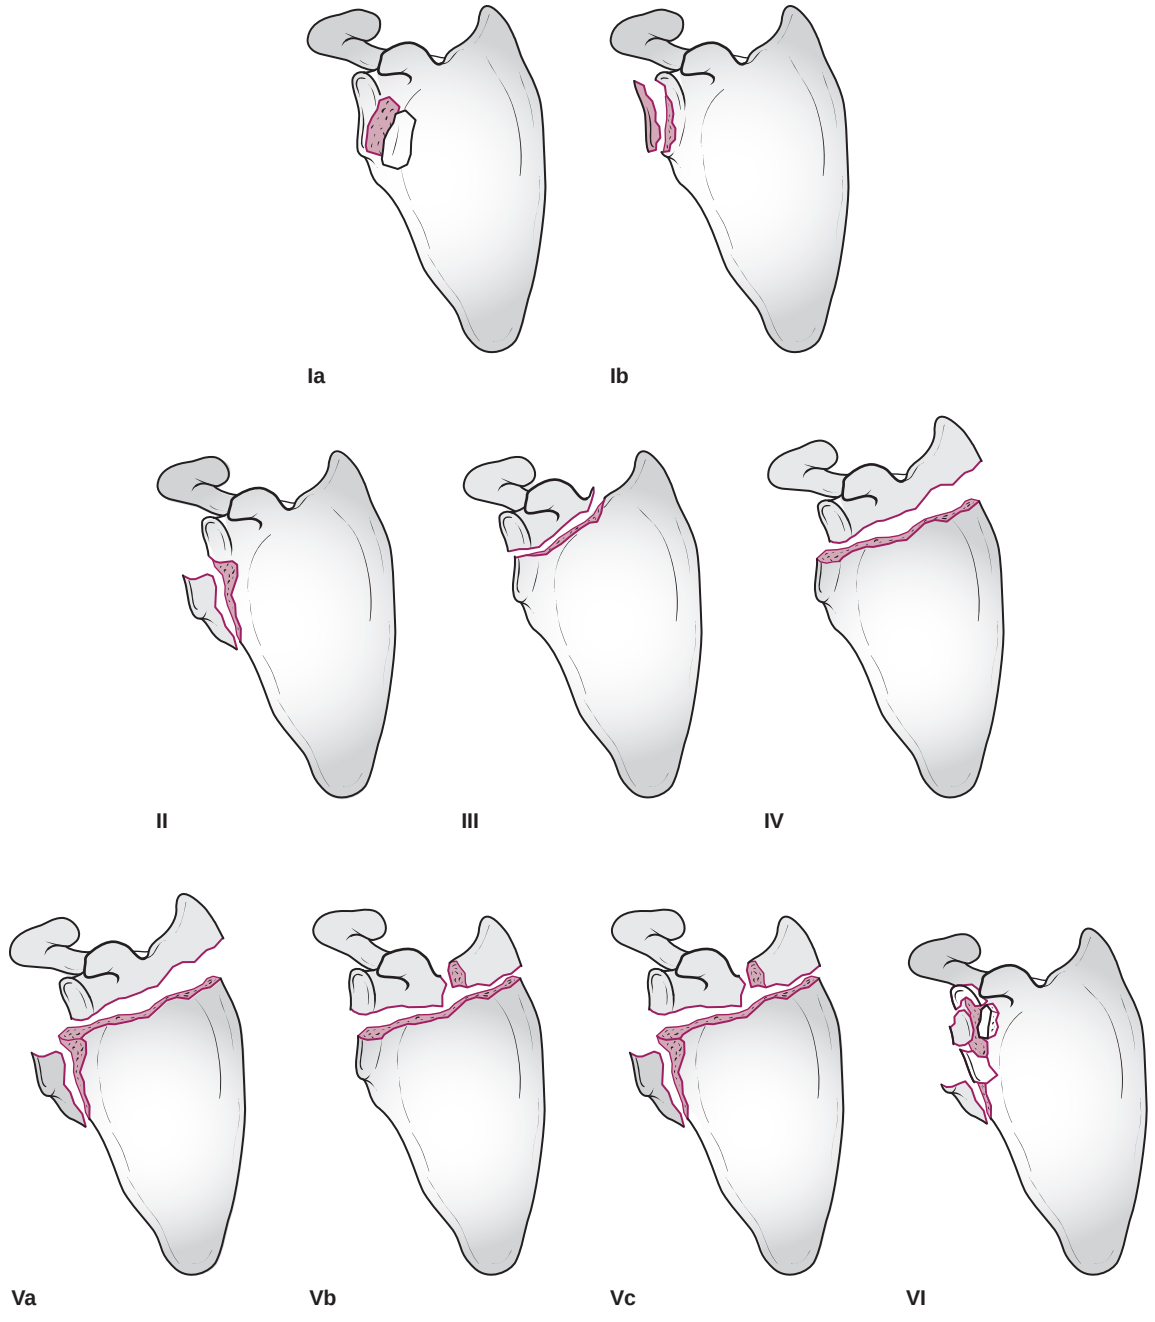

FIGURE 22-12 Schematic depicting the six types of glenoid cavity fractures.

Treatment Options for Scapula Fractures

Nonoperative Treatment of Scapula Fractures

Indications/Contraindications

The vast majority of scapula fractures can be treated nonoperatively with immobilization alone, no matter what part of the scapula the fracture involves. Exceptions include open fractures, fractures with associated neurovascular injuries requiring operative intervention, scapulothoracic dissociation, large glenoid rim fractures with associated proximal humerus subluxation/dislocation, type II glenoid neck fractures, and glenoid cavity fractures with displacement greater than 5 mm.[2,4,72,106] All of these are very rare in children but need not be missed (Table 22-8).

Techniques

A sling or shoulder immobilizer is utilized for 3 to 6 weeks depending on patient, injury severity, and healing. When there is sufficient healing and reduction in pain, rehabilitation

TABLE 22-8 ORIF of Distal Clavicle Fractures

Surgical Steps

1. Skin incision over distal 1/3 of clavicle and acromion in line with Langer lines
2. Electrocautery through subcutaneous tissue, fascia, and periosteum directly onto the clavicle
3. Expose fracture site in a subperiosteal manner while preserving the acromioclavicular and coracoclavicular ligaments
4. Reduce fracture fragments with reduction clamps and temporary Kirschner wire fixation if necessary
5. Apply plate on superior aspect of clavicle
6. Assess reduction and screw lengths with direct visualization and/or fluoroscopic imaging in multiple planes
7. Repair periosteum to tighten coracoclavicular and acromioclavicular ligaments. Rarely apply supplemental fixation to coracoclavicular ligaments utilizing suture around coracoid and clavicle if fixation is marginal
8. Irrigate wound and close periosteum
9. Meticulous skin closure with absorbable suture
10. Apply sling or shoulder immobilizer

progresses from pendulum exercises to full range of motion and strengthening. Return to sports is usually 8 to 12 weeks after injury.

Outcomes

No large studies exist regarding the outcomes of children treated for scapula fractures. In the adult literature, the vast majority of patients obtain fracture union and have minimal to no pain with good functional outcomes expected.[51,108] Similarly most reports indicate children do well with this rare injury.

Operative Treatment of Scapula Fractures

Indications/Contraindications

Operative indications for scapula fractures are limited in the pediatric and adolescent populations but include open fractures, fractures with associated neurovascular injuries requiring operative intervention, scapulothoracic dissociation, large glenoid rim fractures with associated proximal humerus subluxation/dislocation, type II glenoid neck fractures, coracoid process fractures with greater than 2 cm of displacement, and glenoid cavity fractures with displacement greater than 5 mm.[2,4,72,106] Floating shoulder injuries involving the midshaft of the clavicle and the glenoid neck can be treated by ORIF of the clavicle as the glenoid neck will reduce via ligamentotaxis provided by the intact coracoclavicular ligament.[9] Similarly, floating shoulder injuries involving fractures of the glenoid neck, midshaft of the clavicle, and scapula spine will heal by ORIF of the clavicle and scapula spine due to ligamentotaxis provided by the intact coracoclavicular and/or coracoacromial ligaments.[9] Nonoperative management with immobilization should be used for the remainder of injuries.

TABLE 22-9 Distal Clavicle Fractures

Potential Pitfalls and Preventions

Pitfall	Prevention
Nonunion/hardware failure	Ensure adequate fixation in distal fragment Supplement fixation with suture and prolonged immobilization until healed
Screw penetration into acromioclavicular joint	Directly visualize joint and utilize fluoroscopy in multiple planes following plate fixation

Surgical Procedure for Scapula Fractures

Preoperative Planning

The position of the patient and necessary implants will depend on which part of the scapula is fractured. Typically, it is necessary to utilize plates that can be bent and twisted to match the shape of the scapula. Advanced imaging with three-dimensional reconstruction is helpful in planning for open reduction and internal fixation of scapula fractures (Table 22-9).

Positioning

Patient positioning will depend on the location of the fracture within the scapula and subsequently the approach being utilized. If anterior exposure is necessary, the patient is placed in the beach chair position and a standard deltopectoral approach is performed. Posterior exposure is performed by having the patient in the lateral decubitus position in a bean bag, allowing the shoulder and trunk to droop slightly forward.

Surgical Approach(es)

Anterior access to the glenoid and coracoid is performed through a standard deltopectoral approach. An incision is made along the deltopectoral groove from the coracoid proximally and carried 10 to 15 cm distally. Sharp dissection is carried out through the skin and the cephalic vein is identified in the deltopectoral groove. Subsequently, the deltoid is retracted laterally and the pectoralis major medially. The cephalic vein can be taken in either direction. Deep, the short head of the biceps and the coracobrachialis are identified and retracted in a medial direction. Access to the anterior aspect of the shoulder joint is now easily obtained. Typically, to have adequate exposure of the glenoid, the subscapularis must be taken down and a retractor placed in the glenohumeral joint to retract the humeral head.

If a posterior approach to the glenoid is being performed, a vertical incision is made overlying the posterior glenoid and full-thickness skin flaps are raised. Exposure of the glenoid is performed by splitting the deltoid longitudinally in line with its fibers. The infraspinatus and teres minor are now visible. These muscles can be partially or completely detached, or the interval between them can be utilized, depending on the amount of exposure necessary. Alternatively, a transverse incision can be performed along the length of the scapula spine, extending to the posterior corner of the acromion. The deltoid

TABLE 22-10 Distal Clavicle Fractures

Common Adverse Outcomes and Complications

Hardware prominence
Hardware migration
Nonunion
Symptomatic malunion

is then detached from its origin on the scapular spine and the plane between the deltoid and infraspinatus is identified and developed. Identification of the teres minor is now performed and the plane between the teres minor and infraspinatus is developed. By retracting the infraspinatus superiorly and the teres minor inferiorly, the posterior aspect of the glenoid and scapula neck is now exposed. The glenohumeral joint capsule can be incised longitudinally along the edge of the scapula to gain access to the joint.

Technique

Displaced glenoid neck fractures are approached through the posterior approach with placement of a plate along the posterior aspect of the glenoid and extending down along the lateral angle of the scapula. Operative treatment of type Ib, type II, and type IV glenoid cavity fractures is also performed via a posterior approach. The infraspinatus can remain attached during fixation of type Ib fractures whereas detachment is necessary for types II and IV fractures. Fixation of type Ib fragments is typically performed utilizing two interfragmentary screws whereas types II and IV fractures typically require plate and screw fixation.

An anterior deltopectoral approach is utilized to perform ORIF of types Ia and III glenoid cavity fractures as well as coracoid fractures displaced greater than 2 cm. Fixation is achieved with interfragmentary screws for type Ia and large coracoid process fractures if the fragment is large enough whereas plate and screw fixation is typically necessary for type III fractures. Alternatively, suture anchors can be utilized to stabilize type Ia fragments and small coracoid process fractures can be reattached with the conjoint tendon utilizing heavy nonabsorbable suture placed in a Bunnell fashion through the tendon and passed through a drill hole in the intact coracoid process. Arthroscopic fixation of type Ia fractures can also be performed by utilizing suture anchor fixation to the intact labral attachment of the fragment (Table 22-10).[133]

Author's Preferred Treatment for Scapula Fractures

The vast majority of pediatric and adolescent scapula fractures are treated nonoperatively with immobilization for 3 to 4 weeks followed by pendulum exercises and progressed to active range of motion as tolerated. This includes scapula body fractures, acromion fractures, coracoid process fractures, and glenoid neck and cavity fractures without significant displacement. Operative treatment is reserved for open fractures and glenoid cavity fractures with significant size and/or displacement leading to glenohumeral subluxation/dislocation. Coracoid process fractures displaced greater than 2 cm are also treated with open reduction and internal fixation.

Our preference is to perform arthroscopic reduction of type Ia glenoid cavity fractures and open reduction and internal fixation for the remainder of glenoid cavity fractures and glenoid neck fractures requiring operative fixation. We routinely obtain three-dimensional CT scans to aid in preoperative planning and determination of the best surgical approach to utilize based on the fracture pattern.

Postoperative Care for Scapula Fractures

Postoperatively, patients are placed in a sling or shoulder immobilizer for 3 to 6 weeks. Subsequently, pendulum exercises are performed followed by advancement to active range of motion based on radiographic union and pain. Strengthening and contact sports are not permitted for a minimum of 3 months postoperatively.

Potential Pitfalls and Preventive Measures for Scapula Fractures

Care must be taken during ORIF when retracting structures about the shoulder region as vigorous retraction can damage neurovascular structures. For example, the musculocutaneous nerve is at risk during excessive medial retraction about the glenohumeral joint/coracoid.

It is necessary to obtain a near-anatomic reduction of the articular surface during ORIF of glenoid cavity fractures as residual displacement greater than 2 mm leads to poorer outcomes.[72,89] Furthermore, failure to reduce large glenoid cavity fragments may lead to persistent glenohumeral subluxation/dislocation (Table 22-11).

Treatment-Specific Outcomes for Scapula Fractures

No data exists regarding the outcomes of pediatric and adolescent patients treated with ORIF for scapula fractures. The adult literature has demonstrated that the results of operative fixation of glenoid cavity fractures depend on near-anatomic restoration of joint alignment. If residual incongruity is less than 2 mm, good-to-excellent results can be expected for 80% to 90% of patients. Furthermore, posttraumatic arthritis will be minimal.[72,89]

TABLE 22-11 Scapula Fractures

Potential Pitfalls and Preventions

Pitfall	Prevention
Neurovascular injury	Avoid overvigorous retraction
Persistent glenohumeral subluxation/dislocation	Obtain near anatomic (<2 mm incongruity) of glenoid cavity fragments

TABLE 22-12 Scapula Fractures

Common Adverse Outcomes and Complications
Nonunion
Symptomatic malunion
Glenohumeral subluxation/dislocation

Management of Expected Adverse Outcomes and Unexpected Complications Related to Scapula Fractures

Nonunion and symptomatic malunion can occur following treatment of scapular body fractures nonoperatively.[40,88,97] Nonunions can be addressed by performing open reduction and internal fixation with good-to-excellent results expected. In addition, significant displacement associated with glenoid neck fractures has been shown to be a poor prognostic indicator. Therefore, fixation of fractures with more than 1 cm of displacement or angulation greater than 40 degrees will yield improved outcomes.[38,77,108] Lastly, large glenoid rim fractures should be addressed operatively to prevent subluxation/dislocation of the glenohumeral joint (Table 22-12).

Summary, Controversies, and Future Directions Related to Scapula Fractures

Scapula fractures are rare injuries that occur due to high-energy mechanisms or nonaccidental trauma. Conservative treatment with immobilization yields excellent outcomes in the vast majority of cases. However it is important to recognize fractures that can potentially lead to adverse outcomes and complications. Advanced imaging with CT scans, including three-dimensional reconstruction, can aid the surgeon by providing better understanding of the fracture pattern. Operative fixation should be performed for fractures about the glenoid with significant displacement or those leading to glenohumeral subluxation/dislocation. Because of the rarity of these fractures, it is likely that future multicenter studies will be necessary to provide information regarding the best treatments and their outcomes for pediatric and adolescent scapula fractures.

Introduction to Acromioclavicular Dislocations

While AC dislocations are common in adults, they are rare in children. Injuries that appear to disrupt the AC joint in a child may actually be an epiphyseal separation of the distal clavicle termed a "pseudodislocation," rather than a true AC joint disruption.[126] However, adolescents can sustain true AC dislocations, especially those involved in competitive sports participation.[35,71] Treatment of these injuries, especially complete dislocations, remains somewhat controversial and is based on individual patient demands.

Assessment of Acromioclavicular Dislocations

Mechanisms of Injury for Acromioclavicular Dislocations

Acromioclavicular joint injuries typically occur due to a direct blow to the acromion with the shoulder adducted, as can occur during collision sports, or due to a fall onto the superolateral aspect of the shoulder. The result of this blow is inferior and medial movement of the acromion while the clavicle remains stable because of the sternoclavicular joint ligaments.[121] Propagation of the force to the coracoclavicular ligaments and deltotrapezial fascia can occur following complete disruption of the AC ligaments.[126] Indirect force can also result in injury to the AC joint, as occurs during a fall onto an outstretched hand or elbow.[128]

Assocaited Injuries with Acromioclavicular Dislocations

As with any injury to the shoulder region, the entire shoulder girdle must be examined for a concomitant injury. Anterior sternoclavicular dislocations or additional scapula, humerus, or clavicle fractures can occur simultaneously if enough force was present at the time of impact. In addition, brachial plexus or cervical spine injuries may be present, especially if the injury occurred during a collision sport, such as football.

Signs and Symptoms of Acromioclavicular Dislocations

Patients with AC dislocations usually complain of pain in the shoulder region localized to the AC joint area. Numbness and tingling may be present because of swelling or concomitant cervical spine/brachial plexus injury. Sometimes, they only complain of a "bump" in the region.

The physical examination should begin by observation of the shoulder region with the patient in an upright position, which permits the weight of the arm to make any deformity more apparent. Swelling, ecchymosis, abrasions, and skin tenting should be noted. Palpation overlying the AC joint will cause significant discomfort and should be reserved until the end of the examination. Additional areas that should be palpated first include the proximal humerus, the midshaft and medial clavicle, the sternoclavicular joint, and the cervical spine. A thorough neurologic examination should be performed to assess for concomitant brachial plexus or cervical spine injury. Most displaced distal clavicle fractures are malpositioned superiorly and have both visual and palpable deformities. However, some displace posteriorly, get entrapped in the trapezius muscle, and have a palpable prominence and tenderness medial and posterior to the acromion. These type IV injuries may be hard to diagnose unless examined specifically.

Once an AC injury is suspected, the joint should be assessed for stability if possible. Typically this needs to be done after the acute pain has subsided, approximately 5 to 7 days following the injury. Horizontal and vertical stabilities can be assessed and potentially the joint can be reduced by closed means. This is performed by stabilizing the clavicle with one hand and using

the other hand to place an upward force under the ipsilateral elbow. Once the joint is reduced in the coronal plane, the midshaft of the clavicle can be grasped and translated in an anterior and posterior direction to assess horizontal stability.[128]

Imaging and Other Diagnostic Studies for Acromioclavicular Dislocations

Plain radiographs are the initial imaging modality of choice and should include a true AP view of the shoulder, an axillary lateral view of the shoulder, and a Zanca view to better visualize the AC joint. The Zanca view is performed with the patient in an upright position, allowing the injured arm to hang by the weight of gravity, and aiming the x-ray beam 10 to 15 degrees cephalad.[149] In addition, stress views can be performed, to differentiate between types II and III injuries, by having the patient hold a weight in their hand. The posterior fracture dislocation (type IV) is often difficult to recognize by plain radiographs and may require a CT scan for accurate diagnosis.

Classification of Acromioclavicular Dislocations

The classic description of acromioclavicular injuries for adults is that of Tossy et al.[136] and Allman[3] which was subsequently modified by Rockwood (Fig. 22-13).[144] Type I injuries have normal radiographs with the only finding being tenderness to palpation over the AC joint due to a sprain of the AC ligaments. Type II injuries have disruption of the AC ligaments and a sprain of the coracoclavicular (CC) ligaments. The radiographs show a widened AC joint with slight vertical displacement demonstrated by a mild increase in the coracoclavicular space. Type III injuries have disruption of the AC and CC ligaments with the radiographs showing the clavicle displaced superiorly relative to the acromion by 25% to 100% the width of the clavicle. Type IV injuries have disruption of the AC and CC ligaments as well as the deltopectoral fascia which allows for the clavicle to be posteriorly displaced into or through the trapezius muscle. Type V injuries have disruption of the AC and CC ligaments as well as the deltopectoral fascia with concomitant injury to the deltoid and trapezius muscle attachments to the clavicle. These injuries present with the clavicle displaced greater than 100% and lying in the subcutaneous tissue. Type VI injuries have disruption of the AC ligaments and deltopectoral fascia, but the CC ligaments remain intact. This occurs due to a high-energy mechanism of injury that causes the shoulder to be hyperabducted and externally rotated. The end result is that the clavicle lies subacromial or subcoracoid, with a resultant decrease in the coracoclavicular distance seen on radiographs.

The classification mentioned above has been modified for the pediatric and adolescent populations as true AC injuries are rare during skeletal immaturity compared to fractures of the distal clavicle.[35] Typically, the clavicle itself displaces out of the periosteal sleeve, leaving the periosteum attached to the coracoclavicular and AC ligaments. The resultant clavicle injuries are then analogous to the six types described for the adult classification.

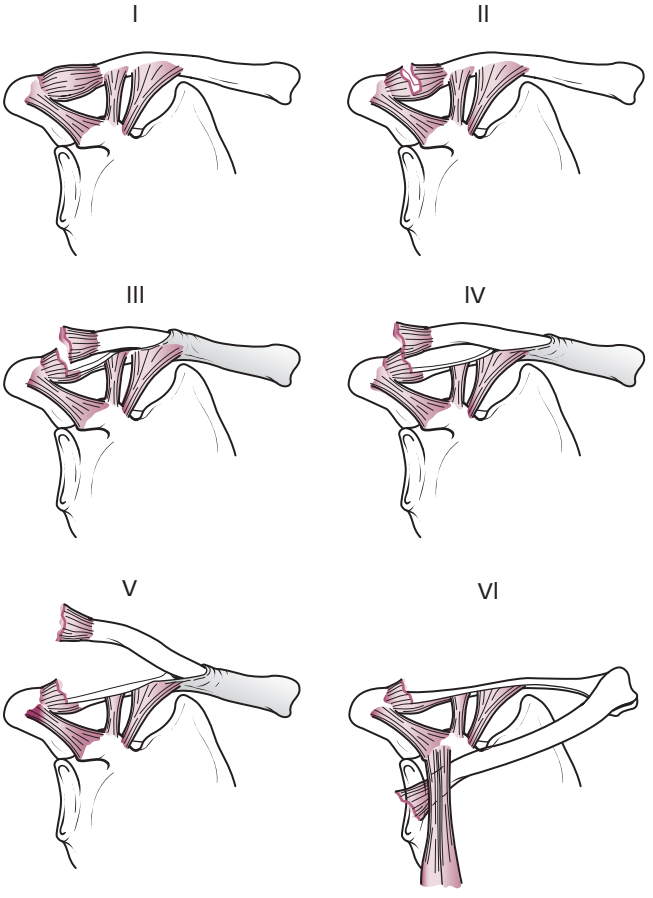

FIGURE 22-13 Schematic depicting the Rockwood classification of acromioclavicular joint injuries.

Outcome Measures for Acromioclavicular Dislocations

No outcome scores exist that specifically assess the results of pediatric and adolescent AC injuries or any injury about the shoulder. However, numerous adult shoulder and upper extremity outcome scores are available to assess these injuries in older adolescents. Typically, results of AC injuries have been reported based on subjective outcomes, the development of AC osteoarthritis, and range of motion.

Pathoanatomy and Applied Anatomy Relating to Acromioclavicular Dislocations

The AC joint is formed by the distal end of the clavicle and medial aspect of the acromion with a fibrocartilaginous disk between them. It is an important contribution to the superior shoulder suspensory complex, a bone–soft tissue ring composed of the glenoid, coracoid, coracoclavicular ligaments, distal clavicle, AC joint, and acromion (Fig. 22-14). This complex maintains a normal relationship between the scapula, upper extremity, and axial skeleton to permit fluid scapulothoracic motion. While the clavicle does rotate some relative to the acromion through the AC joint, the majority of motion occurs synchronously.[41]

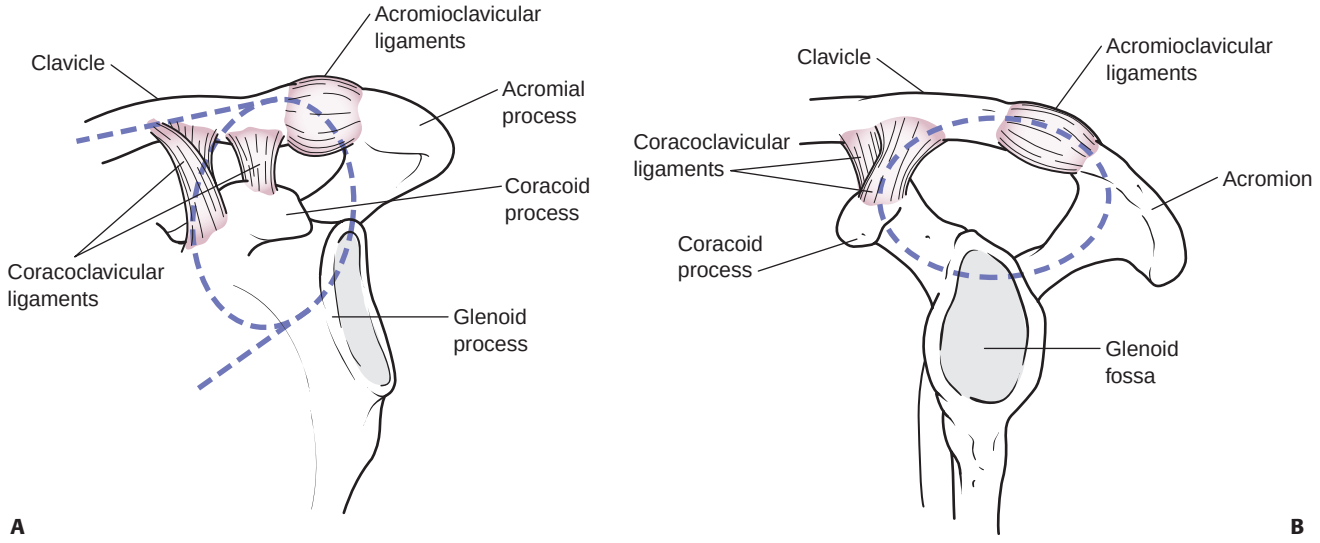

FIGURE 22-14 Schematic of the superior shoulder suspensory complex. **A:** Frontal view. **B:** Lateral view.

The ligamentous structures about the AC joint provide the vast majority of stability with a smaller component provided by the muscular attachments of the anterior deltoid onto the clavicle and trapezius onto the acromion. Horizontal stability is provided by the AC ligaments that reinforce the joint capsule, mainly the posterior and superior ligaments.[75] Vertical stability is provided by the coracoclavicular ligaments, including the conoid ligament medially and trapezoid ligament laterally.[44] The normal distance between the coracoid and the clavicle, the coracoclavicular space, should be 1.1 to 1.3 cm.[16]

Treatment Options for Acromioclavicular Dislocations

Nonoperative Treatment of Acromioclavicular Dislocations

Indications/Contraindications

Nonoperative treatment of types I and II AC injuries is uniformly accepted. However, treatment of type III injuries remains somewhat controversial. The vast majority of types IV, V, and VI injuries should be treated surgically to reduce the AC joint and restore stability to the superior shoulder suspensory complex. Absolute contraindications to nonoperative treatment include open injuries and injuries with associated neurovascular injury requiring operative intervention (Table 22-13).

TABLE 22-13 Acromioclavicular Dislocations

Nonoperative Treatment

Indications	Relative Contraindications
Type I injuries	Open injuries
Type II injuries	Injuries with associated neurovascular injuries requiring operative treatment

Techniques

Nonoperative treatment is performed utilizing immobilization in a sling or shoulder immobilizer for 2 to 4 weeks. Following the period of immobilization and resolution of the pain, patients are gradually progressed from pendulum exercises to active range of motion. Strengthening is begun once range of motion is equal to the uninjured side. Contact sports are avoided for 3 months following injury to allow for complete ligamentous healing and for prevention of converting an incomplete injury (type II) to a complete injury (type III).[128]

Outcomes

Little published data exists regarding the nonoperative treatment of types I and II injuries in the pediatric and adolescent populations. The adult literature has demonstrated a 9% to 30% rate of pain and limitation of activities with closed treatment of type I injuries and a 23% to 42% rate for closed treatment of type II injuries, some of which required surgical intervention.[17,100] Children and adolescents seem to do better in terms of pain and restoration of function but it has not been studied extensively.

Treatment of type III injuries remains controversial because of the outcomes demonstrated in the adult literature. Bannister et al.[12] found that injuries with 2 cm or more of displacement treated nonsurgically had 20% good or excellent results compared to 70% in the surgically treated group. However, a study involving athletes and laborers with type III injuries treated nonoperatively showed that they were able to recover adequate strength and endurance to return to their preinjury activities.[146] A meta-analysis by Phillips et al.[115] supported nonoperative treatment of type III injuries as patients treated surgically had a higher complication rate, with patients treated nonoperatively able to return to work and preinjury activities faster.

Operative Treatment of Acromioclavicular Dislocations

Indications/Contraindications

Indications for operative treatment of AC injuries include complete disruptions of the joint, leading to true dislocations in adolescents or fracture dislocations in the pediatric population, mainly types IV, V, and VI injuries. The most common operative indication in the young is a type IV injury with displacement and entrapment in the trapezius muscle posteriorly. In addition, an injury that is open or has a concomitant neurovascular injury requiring operative intervention should be treated operatively. As noted above, the treatment of type III injuries is somewhat controversial.

Surgical Procedure for Acromioclavicular Dislocations

Preoperative Planning

Treatment of AC injuries surgically requires planning to ensure that the appropriate equipment is available. If implants are being utilized, these may include a hook plate, cannulated screws, Kirschner wires, or heavy nonabsorbable suture. Reconstruction of the ligaments, however, requires either planning to obtain hamstring autograft or having allograft available (Table 22-14).

Positioning

Whether open reduction or ligament reconstruction is being performed, the beach chair position is utilized. A bump is placed behind the scapula to bring the acromion into a more anterior position.

Surgical Approach(es)

A direct approach to the AC joint is utilized by making an incision along the lateral clavicle and anterior aspect of the joint in Langer skin lines. Sharp dissection is carried out through the skin only. Subsequently, electrocautery is utilized the remainder of the way down to bone so that hemostasis and dissection can occur simultaneously. It is easiest to incise the periosteum of the distal clavicle and acromion before entering the joint. It is imperative to avoid disruption of the coracoclavicular ligaments in type VI injuries as they are intact. The AC and coracoclavicular ligaments as well as the deltopectoral fascia are disrupted in types II, IV, and V injuries in the skeletally mature; they are attached to the periosteum in younger patients.

TABLE 22-14 ORIF of Acromioclavicular Dislocations

Preoperative Planning Checklist

OR Table: Standard table able to go into beach chair position

Position/positioning aids: Beach chair position with adequate sterile space above the shoulder adjacent to the head

Fluoroscopy location: Contralateral side

Equipment: Implants may include hook plate, cannulated screws, Kirschner wires, heavy nonabsorbable suture, hamstring autograft, allograft

Tourniquet (sterile/nonsterile): None

Technique

Once the dissection has exposed the AC joint, an open reduction of the joint is performed. Type IV injuries necessitate carefully extracting the distal clavicle from the trapezius muscle, type V injuries require reducing the distal clavicle from the subcutaneous tissue, and type VI injuries require removing the distal clavicle from beneath the coracoid process. Once the distal clavicle is reduced to the level of the acromion, temporary pin fixation may be necessary to hold the reduction. As the periosteum is torn but still attached to the acromion, once the clavicle is reduced simple repair of the periosteum and ligamentous structures may be all that is required in the pediatric population.

If the patient is older and a hook plate is being utilized, the lateral end of the plate is placed deep to the acromion and the medial side is placed on the clavicle, which will facilitate joint reduction and maintenance of the reduction. Bicortical screws are now placed into the clavicle to hold the plate in place.

Ligament reconstruction and/or augmentation have been performed, via various methods as the primary method of treatment for the injury in adults. Fortunately these operations are rare in the acute setting for adolescents. More often these reconstructions are in chronic, painful AC separations in adults. Both semitendinosus autograft and allograft can be used as a loop around the coracoid and clavicle[66] or placed through bone tunnels in the coracoid and clavicle and secured with interference screws.[90] The interference screws are placed at the locations of the coracoclavicular ligaments in an attempt to restore normal anatomy.

Coracoclavicular screw placement or loops of heavy nonabsorbable suture/Dacron tape around the coracoid and clavicle has also been described to treat AC injuries, either by itself or in conjunction with ligament reconstruction.[19] Screw placement requires removal whereas the loop technique can lead to suture cutout or aseptic foreign body reactions.[18,132] The modified Weaver Dunn procedure has been performed in arthritic situations by resecting the distal end of the clavicle, detaching the coracoacromial ligament from the deep surface of the acromion, and transferring it to the distal end of the clavicle. Again, this is very rarely performed in children and adolescents (Table 22-15).

Author's Preferred Treatment of Acromioclavicular Dislocations

We treat all types I and II AC injuries as well as the vast majority of type III injuries, nonoperatively with immobilization in a sling or shoulder immobilizer for 2 to 4 weeks followed by early restoration of range of motion. Contact sports are avoided for at least 3 months. The vast majority of types IV, V, and VI injuries are treated operatively. Once the distal clavicle is exposed, we determine whether repair of the periosteum and ligamentous structures surrounding the clavicle is sufficient or if a plate is required. The vast majority can be treated with periosteal repair over the reduced clavicle. Most often operative

TABLE 22-15 ORIF of Acromioclavicular Dislocations

Surgical Steps

1. Skin incision in Langer line directly anterior to acromioclavicular joint
2. Electrocautery down to distal clavicle and acromion
3. Reduce acromioclavicular joint
4. Repair periosteum and ligamentous structures and assess stability
5. Utilize hook plate if joint remains unstable, for segmental fractures, or intra-articular fractures
6. Place lateral end of hook plate under acromion and facilitate AC joint reduction by placing medial part of plate on clavicle
7. Place bicortical screws in medial part of hook plate
8. Irrigate wound and close
9. Plate removal 2–3 months postoperatively

repair is for type IV fracture-dislocations with entrapment in the trapezius. Hook plates are most commonly utilized in older patients with fractures that are either segmental or intra-articular. Following plate placement, the periosteum and ligamentous structures are repaired.

Postoperative Care for Acromioclavicular Dislocations

Postoperatively patients are placed in either a sling or shoulder immobilizer for 4 to 6 weeks. Pendulum exercises are then begun followed by gentle active range of motion below shoulder level for 6 to 8 weeks. At 8 weeks full active range of motion is permitted. If a hook plate or coracoclavicular screw was placed, it is removed with sufficient healing, usually at approximately12 weeks. Contact sports are avoided for a minimum of 3 months following operative intervention.

Potential Pitfalls and Preventive Measures for Acromioclavicular Dislocations

One of the biggest pitfalls when treating AC injuries is failure to recognize a type IV injury. Although types V and VI injuries are fairly obvious on AP plain radiographs, type IV injuries because of their posterior displacement may not be readily apparent. Furthermore, lateral views may be inadequate or difficult to obtain, thus making it easy to miss a type IV injury. A high index of clinical suspicion, careful examination, and often a CT scan are necessary for accurate diagnosis and appropriate surgical treatment (Table 22-16).

TABLE 22-16 Acromioclavicular Dislocations

Potential Pitfalls and Preventions

Pitfall	Prevention

Common Adverse Outcomes and Complications

Posttraumatic arthritis
Persistent instability
Symptomatic hardware
Pin migration
Persistent pain
Suture cutout
Aseptic foreign body reaction

Treatment-Specific Outcomes for Acromioclavicular Dislocations

No studies have specifically evaluated the treatment of AC injuries in the pediatric and adolescent populations. In our experience, operative treatment of types IV, V, and VI injuries has yielded excellent outcomes in the majority of patients. Restoration of joint congruity and stability permits rapid return to function. However, we do not have long-term data to determine how many patients develop degenerative arthritis.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Acromioclavicular Dislocations

Development of degenerative arthritis can be treated by distal clavicle resection. However, the results of this are not favorable if the coracoclavicular ligaments are disrupted as instability will ensue.[31] Persistent instability following closed treatment of an AC joint injury can be treated with ligament reconstruction or augmentation.

Complications related to open reduction include migration of pins, symptomatic hardware, and persistent pain. As noted earlier, usage of synthetic material can lead to suture cutout or aseptic foreign material reaction. Any technique that passes material around the coracoid may lead to coracoid fracture or injury to the musculocutaneous nerve (Table 22-17).

Summary, Controversies, and Future Directions Related to Acromioclavicular Dislocations

AC injuries are relatively rare in the pediatric and adolescent populations. The injury patterns are classified similar to the adult population. However, in the young, the periosteum tears permitting the clavicle to displace while the periosteal attachment to the acromion and coracoid remain intact. Treatment can be immobilization alone for injuries that are not widely displaced, but operative intervention should be performed for significantly displaced injuries. Restoration of normal anatomy by reduction of the AC joint, suture repair of the periosteum,

and ligamentous repair as needed can yield excellent outcomes in the pediatric population while avoiding utilization of metal implants. Future studies are necessary to assess outcomes of these injuries in the pediatric and adolescent populations.

Introduction to Sternoclavicular Fracture-Dislocations

Injuries to the sternoclavicular joint are rare, representing less than 5% of shoulder girdle injuries.[27,63] These injuries occur secondary to high-energy mechanisms and therefore can be associated with life-threatening complications. Historically, treatment by observation has occurred in the pediatric and adolescent populations. More recent trends are to operatively reduce and stabilize acute posterior fracture-dislocations to restore anatomy and improve functional outcomes.

Assessment of Sternoclavicular Fracture-Dislocations

Mechanisms of Injury for Sternoclavicular Fracture-Dislocations

A significant amount of force is required to disrupt the sternoclavicular joint because of the numerous surrounding ligaments as well as the stability provided by the rib cage. Therefore, high-energy mechanisms, such as motor vehicle accidents and sports participation, result in greater than 80% of injuries.[21,105,141] Motor vehicle collisions, the most common mechanism of injury, may result in either an anterior or posterior force across the joint with a resultant anterior or posterior dislocation or fracture/dislocation.[56,96] A direct lateral blow to the shoulder with the shoulder extended will result in the more common anterior dislocation. Posterior dislocations can result from indirect force transferred to the shoulder girdle when the shoulder is adducted and flexed. Alternatively, a posteriorly directed blow, such as would occur when someone is jumped on while lying supine or kicked while on the ground, is another mechanism for development of a posterior dislocation during sports participation.[53] Of note, most cases of anterior sternoclavicular instability are atraumatic and associated with ligamentous laxity.

Associated Injuries with Sternoclavicular Fracture-Dislocations

Due to the high-energy mechanisms that cause posterior sternoclavicular injuries, associated chest wall injuries due occur such as rib fractures. In addition, the trachea, esophagus, lungs, or great vessels may be compressed. Patients may also experience a brachial plexopathy. Very rarely, the entire clavicle may dislocate from both the sternoclavicular joint and AC joint, thus constituting a floating shoulder. It is imperative to carefully evaluate the entire shoulder girdle for concomitant fractures or dislocations.

Signs and Symptoms of Sternoclavicular Fracture-Dislocations

Patients who sustain sternoclavicular joint injuries present with complaints of pain localized to the sternoclavicular joint. Additional subjective complaints may include shortness of breath, dyspnea, dysphagia, odynophagia, or hoarseness.[142] If an associated brachial plexopathy is present, patients may report the presence of paresthesias and/or weakness in the ipsilateral arm.

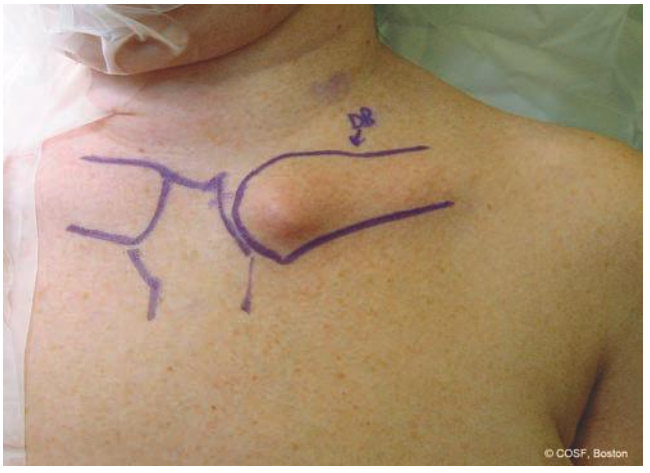

FIGURE 22-15 Clinical photograph demonstrating an anterior sternoclavicular dislocation. This was more easily identified once the patient was lying supine. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

Objective evaluation will demonstrate a significant amount of swelling and ecchymosis present, so much so, that it may be difficult to determine the direction of the dislocation.[53] Anterior dislocations may exhibit prominence of the medial clavicle, which is more easily appreciated with the patient supine (Fig. 22-15).[53] In contrast, the corner of the sternum may be palpable in cases of posterior dislocation, as the medial clavicle is displaced posteriorly.[105] However, at times, the posterior fracture dislocation can be more subtle than expected as the swelling can mimic normal sternoclavicular alignment on cursory examination.

Passive range of motion of the ipsilateral shoulder will cause pain and may elicit the sensation of instability. It is imperative that a formal trauma team or emergency room physician evaluation occurs to rule out associated life-threatening injuries. Signs of venous congestion and arterial insufficiency to the involved extremity or neck region may be present due to compression of vessels.

Imaging and Other Diagnostic Studies for Sternoclavicular Fracture-Dislocations

As with any injury, plain radiographs are the initial imaging modality performed. The routine AP chest radiograph may demonstrate asymmetry of the sternoclavicular articulations or clavicle lengths. However, these studies can be quite difficult to interpret because of the overlap of the medial clavicle, lungs, ribs, sternum, and spine (Fig. 22-16).

Specific radiographic views to evaluate the sternoclavicular joint have been described to overcome these obstacles. Heinig described a tangential view of the sternoclavicular joint which is obtained by laying the patient supine and placing the cassette behind the opposite shoulder. The beam is then angled coronally, parallel to the longitudinal axis of the opposite clavicle (Fig. 22-17A).[55] Hobbs[59] proposed taking a 90-degree

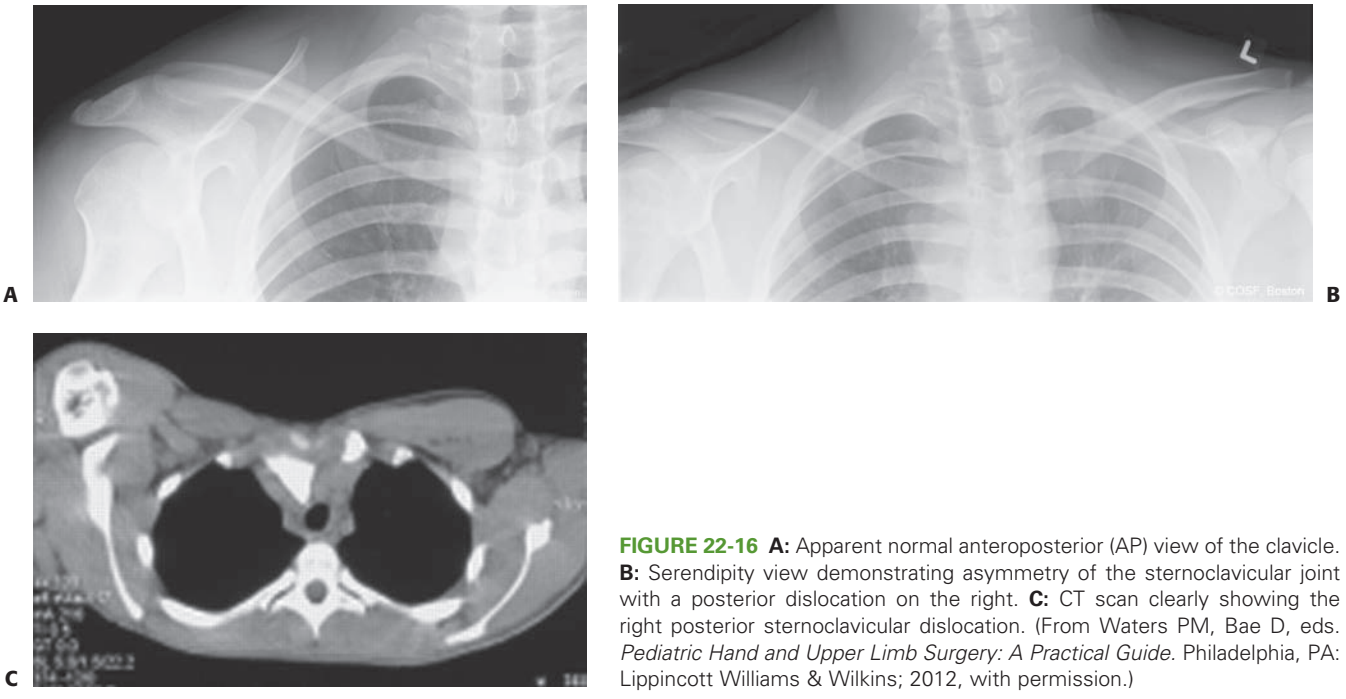

FIGURE 22-16 **A:** Apparent normal anteroposterior (AP) view of the clavicle. **B:** Serendipity view demonstrating asymmetry of the sternoclavicular joint with a posterior dislocation on the right. **C:** CT scan clearly showing the right posterior sternoclavicular dislocation. FIGURE 22-18 **A:** Serendipity radiograph showing a left posteriorly dislocated sternoclavicular joint. Note that the affected side appears inferiorly displaced. **B:** CT scan of the same patient clearly showing the left posterior dislocation.

cephalocaudal lateral view, by having the patient seated and flexed over a table while the beam is directed through the cervical spine (Fig. 22-17B). Lastly, the serendipity view described by Rockwood is performed by placing the cassette behind the chest and angling the x-ray beam 40 degrees cephalad while it is centered on the sternum, thus providing a view of both sternoclavicular joints (Fig. 22-17C).[145] In cases of anterior dislocation, the affected side will appear superiorly displaced, whereas in cases of posterior dislocation, the affected side will appear inferiorly displaced (Fig. 22-18).

Despite these described plain radiographic views, the easiest way to evaluate the sternoclavicular joint is with computed tomography which provides a three-dimensional view of the joint (Fig. 22-19). In addition to assessment of the sternoclavicular joint, one can evaluate the adjacent soft tissue structures including the esophagus, trachea, lungs, and brachiocephalic vessels. Distinction between a physeal fracture and a true dislocation may also be possible if the secondary center has ossified.

Magnetic resonance imaging can also be utilized to evaluate the sternoclavicular joint as well as the surrounding soft tissues. The integrity of the costoclavicular ligaments and intra-articular disk may be possible.[53] Despite the potential to gain additional information, CT scan is recommended over MRI scan to evaluate acute injuries because of its speed and availability.

Classification of Sternoclavicular Fracture-Dislocations

Sternoclavicular dislocations are classified based on the direction of displacement, anterior or posterior, as well as the chronicity of the injury, acute or chronic. The injury needs to be defined as a dislocation (displacement between the epiphysis and the sternum) or a fracture (displacement through the physis with the epiphysis still articulating with sternum). In addition, a sprain, rather than a true dislocation, may occur leading to subluxation.

Outcome Measures for Sternoclavicular Fracture-Dislocations

No specific outcome scores exist that specifically evaluate sternoclavicular joint injuries. Results reported have assessed subjective complaints of pain, recurrence of instability, return to function, and utilization of adult shoulder outcome measures, such as the ASES score, the simple shoulder test, and Rockwood scores.

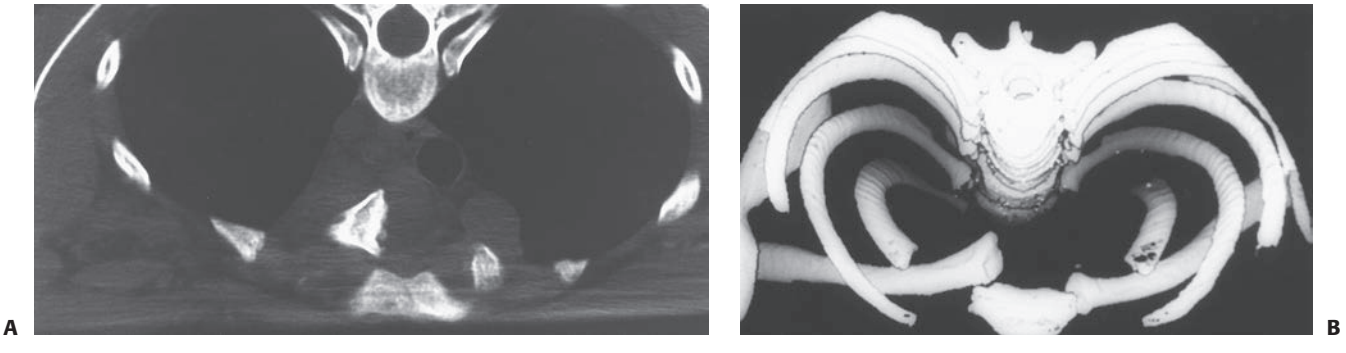

FIGURE 22-19 **A:** CT scan showing a posterior dislocation of the right sternoclavicular joint. **B:** Three-dimensional reconstruction makes the injury more apparent.

Pathoanatomy and Applied Anatomy Relating to Sternoclavicular Fracture-Dislocations

The sternoclavicular joint is a true diarthrodial joint comprising the medial clavicle and clavicular notch of the sternum. Thus, this joint is the only connection between the axial skeleton and the upper extremity. However, less than 50% of the clavicular head articulates with the clavicular notch of the sternum, resulting in little bony congruity. Stability is therefore provided by the multiple ligamentous and muscular attachments, including the sternocleidomastoid, pectoralis major, and sternohyoid muscles. The ligamentous structures include anterior and posterior sternoclavicular ligaments which reinforce the joint capsule as well as the interclavicular (connects both medial ends of the clavicle) and costoclavicular ligaments (between the inferior aspect of the clavicle and the superior costal cartilage of the adjacent rib). In addition, there is an intra-articular disk that is attached to the superior-posterior part of the clavicular articular surface and inferiorly to the costocartilaginous junction of the first rib (Fig. 22-20). The greatest amount of stability with regard to anterior translation is provided by the posterior capsule and sternoclavicular ligaments. The greatest stability with regard to posterior translation is provided by the posterior capsule.[129,130]

The medial epiphysis of the clavicle does not ossify until approximately 18 to 20 years of age, and closes between 22 and 25 years of age. Therefore, sternoclavicular injuries occurring in pediatric and adolescent patients are difficult to discern radiographically between fractures and dislocations. Operative treatment of posterior sternoclavicular injuries has taught us that dislocations and physeal fractures have near equivalent incidence rather than the previous teaching that most posterior sternoclavicular injuries were physeal fractures. Although the medial physis contributes approximately 80% of longitudinal growth of the clavicle, the degree of remodeling possible from a physeal fracture is uncertain. Clearly remodeling cannot occur with a dislocation.

TABLE 22-18 Sternoclavicular Dislocations

Nonoperative Treatment

Indications	Relative Contraindications
Atraumatic anterior dislocations	Acute posterior dislocations with associated neurovascular injury, dyspnea, dysphagia, odynophagia, or hoarseness

Treatment Options for Sternoclavicular Fracture-Dislocations

Nonoperative Treatment of Sternoclavicular Dislocations

Indications/Contraindications

An atraumatic anterior dislocation should be treated nonoperatively. Some have advocated closed reduction maneuvers be performed for acute posterior fracture-dislocations due to potential stability of reduction and/or remodeling of the medial clavicle.[80,145] Acute posterior dislocations with associated neurovascular injury, dyspnea, dysphagia, odynophagia, or hoarseness should clearly be treated with open reduction. We advocate that all posterior fracture-dislocations should be treated operatively (Table 22-18).

Techniques

Closed treatment of a nondisplaced injury consists of sling immobilization for approximately 3 weeks followed by gradual return to activities. Attempted closed reduction of anterior dislocations can be performed by placing a posteriorly directed force over the medial clavicle as the scapula is retracted by utilization of a bump placed between the shoulders. Subsequently, the patient is placed in a figure-of-eight strap or Velpeau-type sling for 6 weeks.[53] Successful reduction can often be obtained; however, recurrent instability is common.

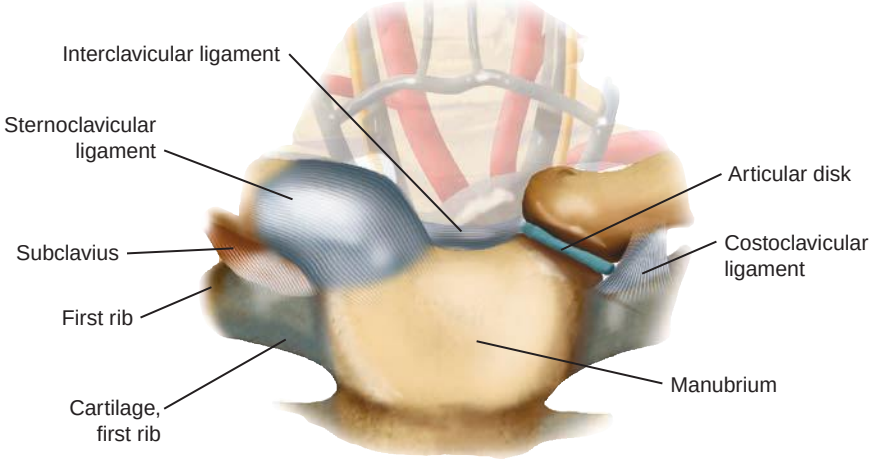

FIGURE 22-20 Schematic drawing of the sternoclavicular joint. Note the numerous ligamentous structures that provide stability. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

Closed reduction of a posterior dislocation is performed by placing the patient supine on an operating room table with a thick bump placed between the scapulae to extend the shoulders and the involved arm off the edge of the table. The ipsilateral arm is then abducted in line with the clavicle, with traction applied, while an assistant applies countertraction and stabilizes the patient. Traction is continued and increased and the arm is brought into extension as the joint reduces.[53] Alternatively, the arm can be placed in adduction while posterior pressure is applied to the shoulder which levers the clavicle over the first rib to permit reduction of the joint.[20] If these maneuvers fail, a sterile towel clip can be used to percutaneously grasp the medial clavicle and draw it anteriorly while traction is applied to the ipsilateral limb. An audible snap is typically noted as the joint reduces.[53]

Closed reductions of posterior sternoclavicular injuries are at risk for mediastinal hemorrhage and hemodynamic compromise. Therefore, closed reductions are performed in the controlled setting of the operating suite with vascular surgery standby. In addition, the orthopedic concern with closed reduction is recurrent instability.[48,54,142]

Outcomes

The majority of patients treated with immobilization alone for anterior dislocations yield good outcomes, despite the high rates of recurrent instability.[36] Those patients that develop symptoms following closed treatment of anterior dislocations may achieve relief of symptoms with physical therapy to promote scapular retraction and avoid provocative positions. If therapy is unsuccessful, ligament reconstruction can be performed with reasonable outcomes anticipated.[7,23,129]

Posterior fracture-dislocations that are reduced by closed means have been reported by some to be stable following reduction[54] whereas others have shown recurrent instability does occur.[48,54,,142] If the reduction is maintained over time, return to full activities can be expected in the majority of patients.

Operative Treatment of Sternoclavicular Fracture-Dislocations

Indications/Contraindications

Although many surgeons have attempted closed treatment of posterior fracture-dislocations with either immobilization alone or closed reduction followed by immobilization, recurrent instability can occur leading to symptomatic patients who require operative intervention.[13] Therefore, the majority of patients with acute traumatic posterior sternoclavicular fracture-dislocations are currently treated operatively. Operative intervention provides symptomatic relief, restores anatomy, and decreases the chance of late complications including recurrent instability and degenerative arthritis.[142]

Additional indications for operative treatment include patients with symptomatic acute or chronic anterior dislocations who have failed conservative measures and symptomatic patients with chronic posterior dislocations. Contraindications to operative intervention include those patients with asymptomatic anterior dislocations or patients with atraumatic recurrent anterior instability.

Surgical Procedure for Sternoclavicular Fracture-Dislocations

Preoperative Planning

It is imperative to be familiar with the anatomy surrounding the sternoclavicular joint as well as the bony articulation of the medial clavicle and clavicular notch of the sternum. Having a general surgeon or thoracic surgeon available to assist the orthopedic surgeon in case of hemodynamic compromise is essential during the reduction maneuver or open reduction (Table 22-19).

Positioning

Patients undergoing any procedure involving the sternoclavicular joint are placed in the modified beach chair position with a large bump or rolled towel placed between the scapulae to provide scapular retraction. The entire limb and hemithorax including the contralateral sternoclavicular joint, medial clavicle and chest is prepped and draped into the operative field. The sternum to upper abdomen is prepped and draped in case an emergency median sternotomy is required (Fig. 22-21).

Surgical Approach(es)

A transverse incision is made through the skin from the medial aspect of the clavicle over the ipsilateral sternoclavicular joint

FIGURE 22-21 Intraoperative photograph showing the area that should be prepped and draped into the sterile field. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide.* Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

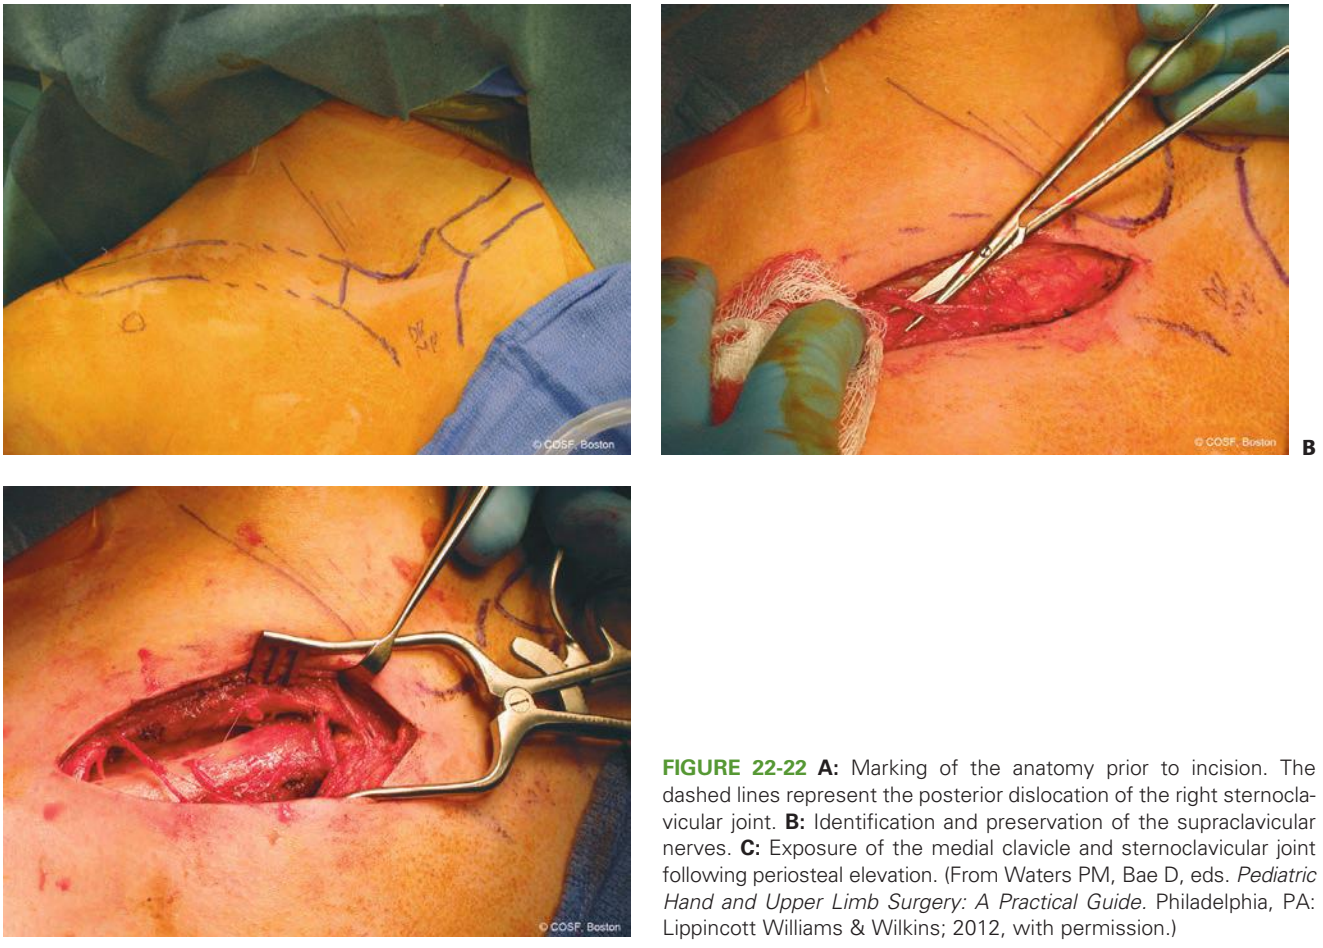

FIGURE 22-22 **A:** Marking of the anatomy prior to incision. The dashed lines represent the posterior dislocation of the right sternoclavicular joint. **B:** Identification and preservation of the supraclavicular nerves. **C:** Exposure of the medial clavicle and sternoclavicular joint following periosteal elevation. (From Waters PM, Bae D, eds. *Pediatric Hand and Upper Limb Surgery: A Practical Guide*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012, with permission.)

in Langer lines. The subcutaneous tissue and platysma are divided, utilizing electrocautery. The supraclavicular nerves are protected if in the operative field. The periosteum of the mid portion of the clavicle is elevated and a bone clamp is applied to the clavicle for control. The anterior periosteum is delicately divided over the posteriorly displaced clavicle until either the epiphysis or sternum is reached depending on whether it is a dislocation or a physeal fracture (Fig. 22-22). Typically, the posterior periosteum of the clavicle and the posterior joint capsule are intact, providing a protective layer between the bony injury and mediastinal structures.

Technique

Following exposure of the physeal fracture or sternoclavicular dislocation, a gentle reduction is performed utilizing the aid of a fracture reduction clamp. Once the clavicle is brought anteriorly, it is important to converse with the anesthesiologist to ensure that the patient remained hemodynamically stable. An anatomic reduction is now performed ensuring that the clavicular head is anatomically seated in the clavicular notch of the sternum.

Following anatomic reduction of either the fracture or dislocation, drill holes are made in the anterior metaphysis and epiphysis of the clavicle in cases of a fracture or the anterior epiphysis and sternum in cases of a dislocation. Placement of malleable retractors between the bone and posterior periosteum is helpful in preventing the drill from entering the mediastinum. Heavy nonabsorbable suture is then passed in a figure-of-eight fashion to provide the necessary stability (Fig. 22-23). The periosteum is then reapproximated with heavy suture to provide added stability, especially with a true dislocation as it provides indirect repair of the costoclavicular and sternoclavicular ligaments. Stability is now assessed by ranging the ipsilateral shoulder and limb. Once stability is satisfactory, the wound is irrigated and closed in sequential layers (Table 22-20).

Author's Preferred Treatment for Sternoclavicular Fracture-Dislocations

We treat acute atraumatic anterior dislocations with immobilization alone for 1 to 4 weeks followed by gradual return to function. If patients experience recurrent instability, therapy is initiated. Operative intervention is reserved for patients with persistent symptoms and typically involves reconstruction of the ligaments.

Acute posterior dislocations are treated operatively with open reduction and internal fixation. Chronic posterior dislocations that are symptomatic are treated with ligament

TABLE 22-20 ORIF of Sternoclavicular Fracture-Dislocations

Surgical Steps

1. Prep and drape entire limb and hemithorax including contralateral sternoclavicular joint, chest, and upper abdomen
2. Transverse skin incision in Langer lines from the diaphysis of the clavicle to the sternoclavicular joint
3. Divide subcutaneous tissue and platysma in line with skin incision. Protect the supraclavicular nerves.
4. Expose clavicle and sternum and incise periosteum working from lateral to medial on clavicle and from midline to lateral on sternum
5. Evaluate the sternoclavicular joint to determine whether a true dislocation or physeal fracture occurred
6. Reduce dislocation/fracture with aid of a fracture reduction clamp
7. Converse with anesthesia to ensure hemodynamic stability of patient
8. Place drill holes in anterior epiphysis and metaphysis for physeal fractures or anterior epiphysis and sternum for dislocations
9. Pass heavy nonabsorbable suture in a figure-of-eight fashion and tie
10. Reapproximate periosteum with heavy suture
11. Irrigate and close wound in sequential layers
12. Immobilize patient in sling and swathe or shoulder immobilizer

reconstruction utilizing allograft. At times, medial clavicle resection is required in painful chronic dislocations that have deformity of the bone and early arthritis of the joint.

Postoperative Care for Sternoclavicular Fracture-Dislocations

Postoperatively patients are placed in either a sling and swathe or shoulder immobilizer for 4 to 6 weeks. Subsequently, range-of-motion exercises are begun. Strengthening is permitted at 3 months postoperatively. Return to sports is dependent on full motion and strength, usually 3 to 6 months postoperatively.

Potential Pitfalls and Preventive Measures for Sternoclavicular Fracture-Dislocations

It is imperative to be familiar with the sternoclavicular bony alignment as overreduction of the clavicle into the clavicular notch of the sternum can occur. In addition, utilization of Dacron tape may cause osteolysis. Pins may migrate and therefore should be avoided.[85,119,139] (Table 22-21).

Treatment-Specific Outcomes for Sternoclavicular Fracture-DIslocations

The outcomes following open reduction and internal fixation of posterior sternoclavicular dislocations or medial clavicle physeal

TABLE 22-21 Sternoclavicular Dislocations

Potential Pitfalls and Preventions

Pitfall	Prevention
Overreduction of clavicle into clavicular notch of sternum	Be knowledgeable about the bony anatomy of the sternoclavicular joint
Osteolysis from Dacron	Utilize heavy nonabsorbable suture
Kirschner wire migration	Avoid Kirschner wires

fractures in pediatric and adolescent patients have been quite favorable in the vast majority of reported cases.[13,48,76,135,142] In a retrospective review by Waters et al.,[142] all patients treated with open reduction and suture fixation of their posterior sternoclavicular joint fracture dislocation had restoration of joint stability and shoulder motion with full return to activities. Similar findings were reported by Goldfarb et al.[48] with all patients returning to their preinjury function including sports participation.

Management of Expected Adverse Outcomes and Unexpected Complications in Sternoclavicular Fracture-Dislocations

Recurrent instability following acute repair is relatively rare but can occur, especially if the sternoclavicular joint is overreduced. Patients will present with persistent pain and a sense of instability. Treatment with ligament reconstruction can be performed utilizing semitendinosus autograft or allograft passed in a figure-of-eight fashion similar to the suture utilized during the acute repair. Ideally the tendon is passed on the "instability side" to minimize the risk of recurrent instability occurring again.

Alternatively, as a salvage procedure, medial clavicle resection arthroplasty can be performed with supplemental ligament reconstruction or soft tissue interposition. Approximately 1 cm of medial clavicle is excised in an oblique fashion to preserve the inferior ligamentous attachments. The intra-articular disk can be passed into the medullary canal of the clavicle by detaching its superior end while preserving the inferior attachments. Sutures are passed through drill holes in the superior clavicle and tied over a bony bridge (Fig. 22-24). Additional

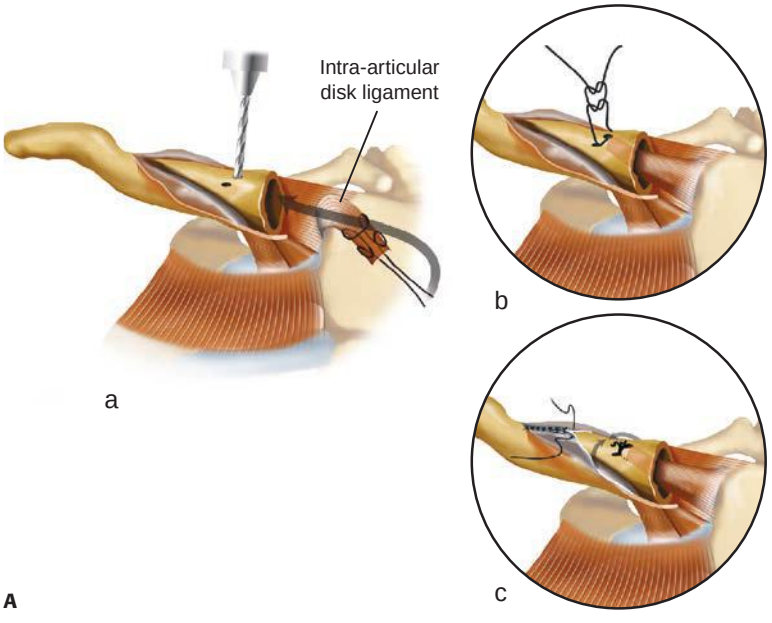

FIGURE 22-24 **A:** Schematic demonstrating the technique of medial clavicular resection arthroplasty. **B:** Intraoperative photograph of a patient with recurrent anterior sternoclavicular instability with resultant pain due to a deformed and irreducible clavicular head. **C:** Intraoperative photograph following medial clavicular head resection and intramedullary passage of the intra-articular disk ligament. TABLE 22-22 Sternoclavicular Dislocations

Common Adverse Outcomes and Complications

Persistent pain

Recurrent instability

stability can be provided by sutures passed between the costoclavicular ligament and the clavicle.

The results of treatment for recurrent anterior instability have been reported by Bae et al. in a retrospective review. Sixty percent of patients had stable, pain-free joints following the procedure. No patients developed instability following their treatment.[7] Many still had some minor limitations of function or persistent pain (Table 22-22).

Summary, Controversies, and Future Directions Related to Sternoclavicular Fracture-Dislocations

Although sternoclavicular joint injuries are relatively rare, they do occur, even in the pediatric and adolescent populations. As high-energy mechanisms cause sternoclavicular injuries, associated damage to critical mediastinal structures can occur and therefore a thorough evaluation is necessary to avoid missing an associated life-threatening injury. The majority of anterior dislocations can be treated with immobilization alone whereas acute posterior injuries are typically treated with operative intervention yielding good results. However, future investigation into the natural history of posterior dislocations treated nonoperatively is necessary to determine who should undergo immediate operative intervention and who should undergo either observation alone or have a closed reduction performed.

23 CERVICAL SPINE INJURIES IN CHILDREN

William C. Warner Jr. and Daniel J. Hedequist

Cervical Spine Injury

Cervical spine fractures in children are rare, accounting for only 1% of pediatric fractures and 2% of all spinal injuries.[7,10,105,115,116,135,141,157,171,220,252,281] The incidence is estimated to be 7.41 in 100,000 per year[191]; however, that may be misleading because some injuries are not detected or are detected only at autopsy. Aufdermaur[16] examined the autopsied spines of 12 juveniles who had spinal injuries. All 12 had cartilage endplates that were separated from the vertebral bodies in the zone of columnar and calcified cartilage, similar to a Salter–Harris type I fracture, although clinically and radiographically, a fracture was suggested in only one patient. Only radiographs at autopsy showed the disruption, represented by a small gap and apparent widening of the intervertebral space.[16]

Cervical spine injuries in children younger than 8 years of age occur in the upper cervical spine, whereas older children and adolescents tend to have fractures involving either the upper or lower cervical spine.[219,221,222] The upper cervical spine in children is more prone to injury because of the anatomic and biomechanical properties of the immature spine.[313,314] The immature spine is hypermobile because of ligamentous laxity, and the facet joints are oriented in a more horizontal position; both of these properties predispose children to more forward translation. Younger children also have a relatively large head compared to the body, which changes the fulcrum of motion of the upper cervical spine. All of these factors predispose younger children to injuries of the upper cervical spine; with age, the anatomic changes lead to an increased prevalence of lower cervical spine injuries.

Cervical spine injuries associated with neurologic deficits are infrequent in children, and when incomplete there tends to be a better prognosis for recovery in children than in adults.[22,60,75,76,212,298,306] Complete neurologic deficits, regardless of patient age, tend to have a poor prognosis for any recovery and may be indicative of the severity and magnitude of injury.[79,158,208,230] Death from cervical spine injuries tends to be related to the level of injury and the associated injuries. Higher cervical spine injuries (e.g., atlantooccipital dislocation) in younger children are associated with the highest mortality rate.[26,215,216] Children with significant cervical spine injuries also may have associated severe head injuries, leading to an increase in mortality. In a study of 61 pediatric deaths related to spinal cord injuries, 89% of fatalities occurred at the scene, and most were related to high cervical cord injuries in patients who had sustained multiple injuries.[119]

Assessment of Cervical Spine Injury

Mechanisms of Injury for Cervical Spine

The mechanism of injury in the cervical spine varies with age. Infants are at risk during birth and early development because of their lack of head control. Most cervical spine injuries in infants not related to birth trauma are caused by child abuse and often involve the spinal cord.[16] In young children, most cervical spine injuries result from motor vehicle accidents or being struck by a vehicle, although injuries have been reported after seemingly low-energy falls from heights less than 5 ft.[32,111,197] As children become adolescents, the prevalence of sporting injuries increases as does the prevalence of athletic-related spinal cord injury without radiographic abnormality (SCIWORA).[42,162]

Associated Injuries with Cervical Spine

Patients with suspected cervical spine injuries need to be thoroughly evaluated for other injuries. Facial injuries as well as traumatic brain injuries are commonly seen with cervical spine injuries, due to the anatomical proximity of these body regions. Vigilance must be high for noncontiguous spine fractures, as well as other orthopedic injuries. Inconsolable children need particular attention, with a thorough search for noncontiguous spine fractures or other associated injuries.

Spinal Cord Injury

Careful radiographic evaluation is helpful in the workup of these patients. MRI may show a spinal cord lesion that often is some distance from the vertebral column injury. As many as 5% to 10% of children with spinal cord injuries have normal radiographic results.[115,132]

Spinal cord injuries are rare in children. Ranjith et al.[241] reviewed spinal injuries at the Toronto Hospital for Sick Children over 15 years and found that children constituted a small percentage of the patients with acquired quadriplegia or paraplegia. He found that paraplegia was three times more common than quadriplegia. When a spinal cord injury is suspected, the neurologic examination must be complete and meticulous. Several examinations of sensory and motor function may be necessary.

Spinal column and spinal cord injury can occur during birth, especially during a breech delivery.[168,211] Injuries associated with breech delivery usually are in the lower cervical spine or upper thoracic spine and are thought to result from traction, whereas injuries associated with cephalic delivery usually occur in the upper cervical spine and are thought to result from rotation. Skeletal spine injury from obstetric trauma is probably underreported because the infantile spine is largely cartilaginous and difficult to evaluate with radiographs, especially if the injury is through the cartilage or cartilage–bone interface.[16] A cervical spine injury should be considered in an infant who is floppy at birth, especially after a difficult delivery. Flaccid paralysis, with areflexia, usually is followed by a typical pattern of hyperreflexia once spinal cord shock is over. Brachial plexus palsy also may be present after a difficult delivery and warrants cervical spine radiographs and an MRI. It is unclear whether cesarean section reduces spinal injury in neonates[179]; however, Bresnan and Abroms[38] noted that neck hyperextension in utero (star-gazing fetus) in breech presentations is likely to result in an estimated 25% incidence of spinal cord injury with vaginal delivery and can be prevented by cesarean section delivery.

Immature neck musculature in infants and toddlers increases the risk for cervical spine injury. Distraction-type injuries to the upper cervical spine have been reported in infants in forward-facing car seats. During sudden deceleration maneuvers, the head continues forward while the remainder of the body is strapped in the car seat, resulting in injury.[59,108] Child abuse is probably one of the most frequent causes of spinal injury in infants. Swischuk[288] in 1969 and Caffey[50] in 1974 described a form of child abuse they termed the shaken baby syndrome. This whiplash type stress can cause not only fracture to the spinal column and spinal cord injury, but intracranial and intraocular hemorrhages as well. The cerebral and spinal insult can result in death or retardation and permanent visual and hearing defects. In autopsy studies, Shulman et al.[273] found atlantooccipital and axial dislocations, and Tawbin[290] found a 10% incidence of brain and spinal injuries.

Spinal Cord Injury Without Radiographic Abnormality (SCIWORA)

SCIWORA, a syndrome first brought to the attention of the medical community by Pang and Wilberger,[220] is unique to children. This condition is defined as a spinal cord injury in a patient with no visible fracture or dislocation on plain radiographs, tomograms, or CT scans.

A complete or incomplete spinal cord lesion may be present, and the injury usually results from severe flexion or distraction of the cervical spine. SCIWORA is believed to occur because the spinal column (vertebrae and disk space) in children is more elastic than the spinal cord and can undergo considerable deformation without being disrupted.[46,291] The spinal column can elongate up to 2 in without disruption, whereas the spinal cord ruptures with only a quarter-inch of elongation.

SCIWORA also may represent an ischemic injury in some patients, although most are believed to be due to a distraction-type injury in which the spinal cord has not tolerated the degree of distraction but the bony ligamentous elements have not failed. Aufdermaur[16] suggested another possibility: a fracture through a pediatric vertebral endplate reduces spontaneously (much like a Salter–Harris type I fracture), giving a normal radiograph appearance, although the initial displacement could have caused spinal cord injury.

SCIWORA abnormalities are more common in children under 8 years of age than in older children,[220,228,252,304] perhaps because of predisposing factors such as cervical spine hypermobility, ligamentous laxity, and an immature vascular supply to the spinal cord. The reported incidence of this condition varies from 7% to 66% of patients with cervical spine injuries.[219,220,321]

Delayed onset of neurologic symptoms has been reported in as many as 52% of patients in some series.[194,220] Pang and Pollack[219] reported 15 patients who had delayed paralysis after their injuries. Nine had transient warning signs such as paresthesia or subjective paralysis. In all patients with delayed onset of paralysis, the spine had not been immobilized after the initial trauma, and all were neurologically normal before the second event. This underlines the importance of diligent immobilization of a suspected spinal cord injury in a child. Approximately half of the young children with SCIWORA in reported series had complete spinal cord injuries, whereas the older children usually had incomplete neurologic deficit injuries that involved the subaxial cervical spine.[12,17,121,194]

Signs and Symptoms of Cervical Spine Injuries

The most common presenting symptom in patients with cervical spine injuries is pain localized to the cervical region. Other complaints, such as headache, inability to move the neck, subjective feelings of instability, and neurologic symptoms, all warrant complete evaluation. Infants may present with unexplained respiratory distress, motor weakness, or hypotonia, which warrant further evaluation. Patients with head and neck trauma, distraction injuries, or altered levels of consciousness are at high risk for a cervical spine injury and need to be thoroughly evaluated before obtaining cervical spine clearance.[42] The presence of an occult cervical spine injury in an uncooperative or obtunded patient needs to be considered because of the frequency of SCIWORA in the pediatric population.[220,252]

Imaging and Other Diagnostic Studies for Cervical Spine Injuries

Plain Radiographs

Plain radiographs are the standard first step for evaluating the cervical spine in children.[207] There currently is no consensus regarding whether or not all pediatric trauma patients require cervical spine films. The presence of tenderness and a distraction injury are the most common clinical presentations of a cervical spine injury.[302] While some studies have shown that plain radiographs are of low yield in patients without evidence of specific physical findings, the burden remains on the treating physician to clear the cervical spine.[9,69,169,175] Clearly, patients with tenderness, distraction injuries, neurologic deficits, head and neck trauma, and altered levels of consciousness need to have a complete set of cervical spine radiographs. Initial radiographs should include an anteroposterior view, open-mouth odontoid view, and lateral view of the cervical spine. Patients who are deemed unstable in the emergency room and are not able to tolerate multiple radiographs should have a cross-table lateral view of the cervical spine until further radiographs can be taken.[40] The false-negative rates for a single cross-table radiograph have been reported to be 23% to 26%, indicating that complete radiographs are necessary when the patient is stable.[19,266]

Flexion and extension radiographs may further aid the evaluation of the cervical spine, but these views are unlikely to be abnormal when standard views show no abnormalities. These views are helpful, however, in ruling out acute ligamentous injury.[240] We recommend flexion and extension views in an alert patient with midline tenderness who has normal plain films of the cervical spine. These views should be taken only with a cooperative and alert child; they should not be used in obtunded or uncooperative patients, nor should they be done by manually placing the child in a position of flexion and extension.

Evaluation of cervical spine radiographs should proceed with a knowledge of the anatomic ossification centers and variations that occur in children. Each vertebral level should be systematically evaluated, as should the overall alignment of the cervical spine with respect to the anterior and posterior aspects of the vertebral bodies, the spinolaminar line, and the interspinous distances. The absence of cervical lordosis, an increase in the prevertebral soft tissue space, and subluxation of C2 on C3 are all anatomic variations that may be normal in children.[50] Ossification centers also may be confused with fractures, most commonly in evaluation of the dens. The presence of a synchondrosis at the base of the odontoid can be distinguished from a fracture based on the age of the patient and the location of synchondrosis well below the facet joints. Knowledge of these normal variants is useful in evaluating plain radiographs of the cervical spine in children (Table 23-1).

Radiographic Evaluation of Specific Areas of the Spine

Atlantooccipital Junction. The atlantooccipital interval remains the most difficult to assess for abnormalities, partly because of the difficulty in obtaining quality radiographs and partly because of the lack of discrete and reproducible landmarks. The distance between the occipital condyles and the facet joints of the atlas should be less than 5 mm; any distance of more than this suggests an atlantooccipital disruption.[70,231] The foramen magnum and its relationship to the atlas also are useful in detecting injuries of the atlantooccipital region. The anterior cortical margin of the foramen magnum is termed the basion, whereas the posterior cortical margin of the foramen magnum is termed the opisthion. The distance

TABLE 23-1 Normal Ossification Centers and Anomalies Frequently Confused with Injury

Avulsion Fracture	
	Apical ossification center of the odontoid. Secondary ossification centers at the tips of the transverse and spinous processes
Fracture	
	Persistence of the synchondrosis at the base of the odontoid
	Apparent anterior wedging of a young child's vertebral body
	Normal posterior angulation of the odontoid seen in 4% of normal children
Instability	
	Pseudosubluxation of C2–C3
	Incomplete ossification, especially of the odontoid process, with apparent superior subluxation of the anterior arch of C1
	Absence of the ossification center of the anterior arch of C1 in the first year of life may suggest posterior displacement of C1 on the odontoid
	Increase in the atlanto–dens interval of up to 4.5 mm
Miscellaneous	
	Physiologic variations in the width of the prevertebral soft tissue due to crying misinterpreted as swelling due to edema or hemorrhage
	Overlying structures such as ears, braided hair, teeth, or hyoid bone. Plastic rivets used in modern emergency cervical immobilization collars can simulate fracture line
	Horizontally placed facets in the younger child, creating the illusion of a pillar fracture
	Congenital anomalies such as os odontoideum, spina bifida, and congenital fusion or hemivertebrae

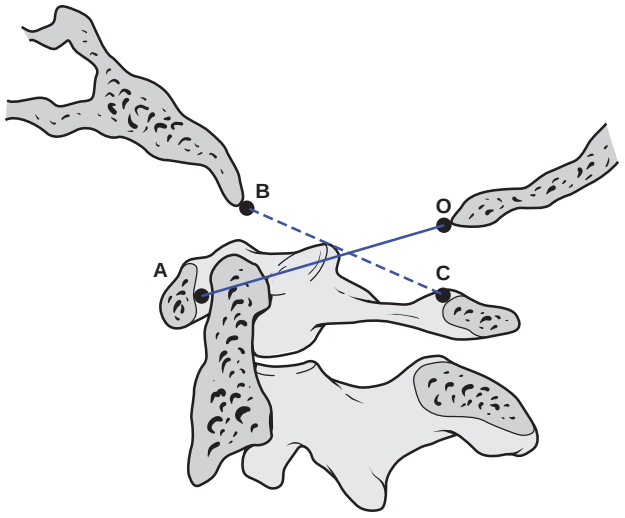

FIGURE 23-1 The Powers ratio is determined by drawing a line from the basion (*B*) to the posterior arch of the atlas (*C*) and a second line from the opisthion (*O*) to the anterior arch of the atlas (*A*). The length of the line BC is divided by the length of the line OA, producing the Powers ratio. (From Lebwohl NH, Eismont FJ. Cervical spine injuries in children. In: Weinstein SL, ed. *The Pediatric Spine: Principles and Practice*. New York, NY: Raven, 1994, with permission.)

between the basion and the tip of the dens should be less than 12 mm as measured on a lateral radiograph.[44] The Powers ratio (Fig. 23-1) is used to assess the position of the skull base relative to the atlas and is another way of evaluating the atlantooccipital region. To determine this ratio, a line is drawn from the basion to the anterior cortex of the posterior arch of C1, and this distance is divided by the distance of a line drawn from the opisthion to the posterior cortex of the anterior arch of C1. The value should be between 0.7 and 1; a higher value indicates anterior subluxation of the atlantooccipital joint and a lower value indicates a posterior subluxation. The problem lies in the fact that the basion is not always visible on plain radiographs. The Wackenheim line, which is drawn along the posterior aspect of the clivus, probably is the most easily identified line to determine disruption of the atlantooccipital joint. If the line does not intersect the tip of the odontoid tangentially and if this line is displaced anteriorly or posteriorly, disruption or increased laxity about the atlantooccipital joint should be suspected.

Atlantoaxial Joint. The atlanto–dens interval (ADI) and the space available for the spinal canal are two useful measurements for evaluation of the atlantoaxial joint (Fig. 23-2). The ADI in a child is considered normal up to 4.5 mm, partly because the unossified cartilage of the odontoid, which is not seen on plain films, gives an apparent increase in the interval. At the level of the atlantoaxial joint, the space taken up is broken into Steel's rule of thirds: one-third is occupied by the odontoid, one-third by the spinal cord, and one-third is free space available for the cord. These intervals also are easily measured on flexion and extension views and are helpful in determining instability. In children, extension views give the appearance of subluxation of the anterior portion of the atlas over the unossified dens, but this represents a pseudosubluxation and not instability.[52,66]

Upper Cervical Spine. Anterior displacement of one vertebral body on another may or may not indicate a true bony or

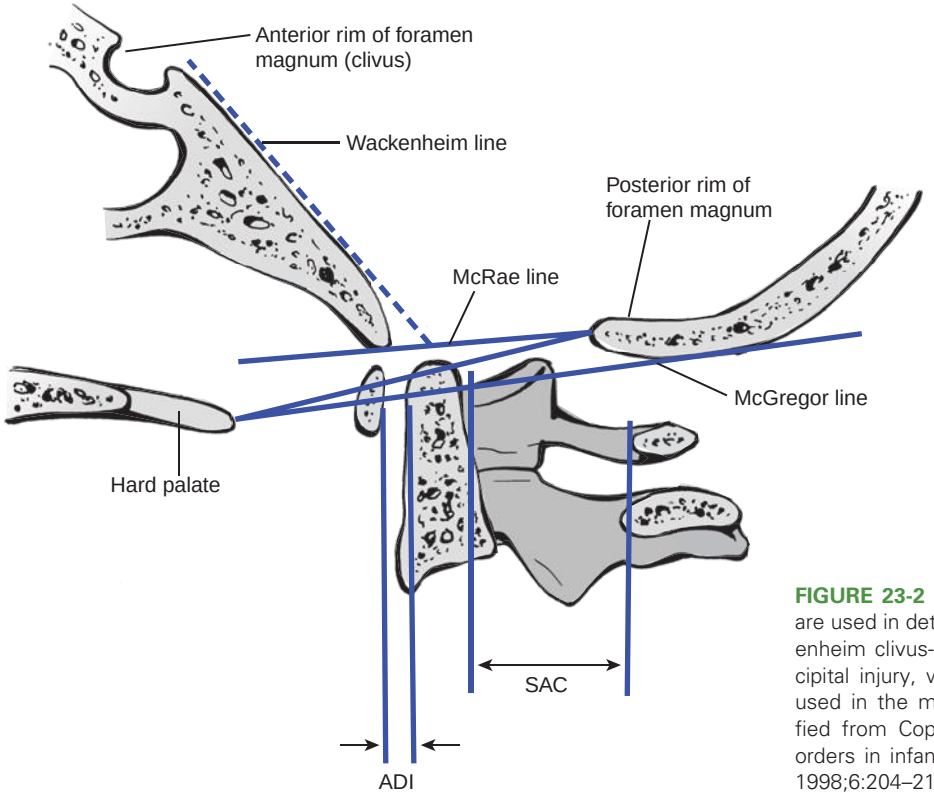

FIGURE 23-2 The ADI and the space available for cord are used in determining atlantoaxial instability. The Wackenheim clivus-canal line is used to determine atlantooccipital injury, while the McRae and McGregor lines are used in the measurement of basilar impression. (modified from Copley LA, Dormans JP. Cervical spine disorders in infants and children. *J Am Acad Orthop Surg*. 1998;6:204–214.)

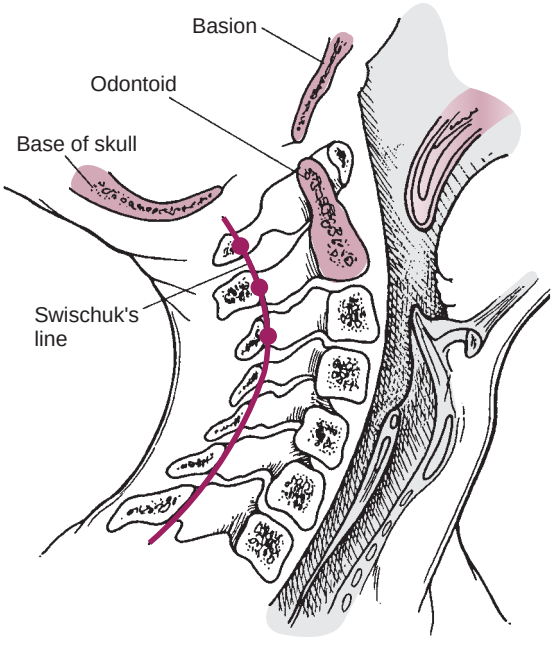

FIGURE 23-3 The spinolaminar line (Swischuk line) is used to determine the presence of pseudosubluxation of C2 on C3. (From Copley LA, Dormans JP. Cervical spine disorders in infants and children. *J Am Acad Orthop Surg.* 1998;6:201–214, with permission.)

ligamentous injury. Displacement of less than 3 mm at one level is a common anatomic variant in children at the levels of C2 to C3 and C3 to C4. This displacement is seen on flexion radiographs and reduces in extension. The posterior line of Swischuk and Rowe[287] has been described to differentiate pathologic subluxation from normal anatomic variation; this line is drawn from the anterior cortex of the spinous process of C1 to the spinous process of C3 (Fig. 23-3). The anterior cortex of the spinous process of C2 should lie within 3 mm of this line; if the distance is more than this, a true subluxation should be suspected (Fig. 23-4). Widening of the spinous processes between C1 and C2 of more than 10 mm also is indicative of a ligamentous injury and should be evaluated by further imaging studies.[3]

Lower Cervical Spine. Lateral radiographs of the cervical spine should be evaluated for overall alignment. The overall alignment can be evaluated by the continuous lines formed by the line adjoining the spinous processes, the spinolaminar line, and the lines adjoining the posterior and anterior vertebral bodies (Fig. 23-5). These lines should all be smooth and continuous with no evidence of vertebral translation at any level. Loss of normal cervical lordosis may be normal in children, but there should be no associated translation at any level.[304] The interspinous distance at each level should be evaluated and should be no more than 1.5 times the distance at adjacent levels; if this ratio is greater, an injury should be suspected. There are calculated norms for the interspinous distances in children, and any value greater than two standard deviations above normal is indicative of a ligamentous injury.[168] The measurement of soft tissue spaces is important in evaluating any evidence of swelling or hemorrhage, which may be associated with an occult injury. The normal retropharyngeal soft tissue space should be less than 6 mm at C3 and less than 14 mm at C6. These spaces may be increased in children without an injury who are crying at the time of the radiograph, because the attachment of the pharynx to the hyoid bone results in its forward displacement with crying, producing an apparent increase in the width of these spaces. These radiographs must be taken with the patient quiet and repeated if there is any doubt.

Special Imaging Studies

Most cervical spine injuries in children are detected by plain radiographs.[10] Most ligamentous injuries can be identified on

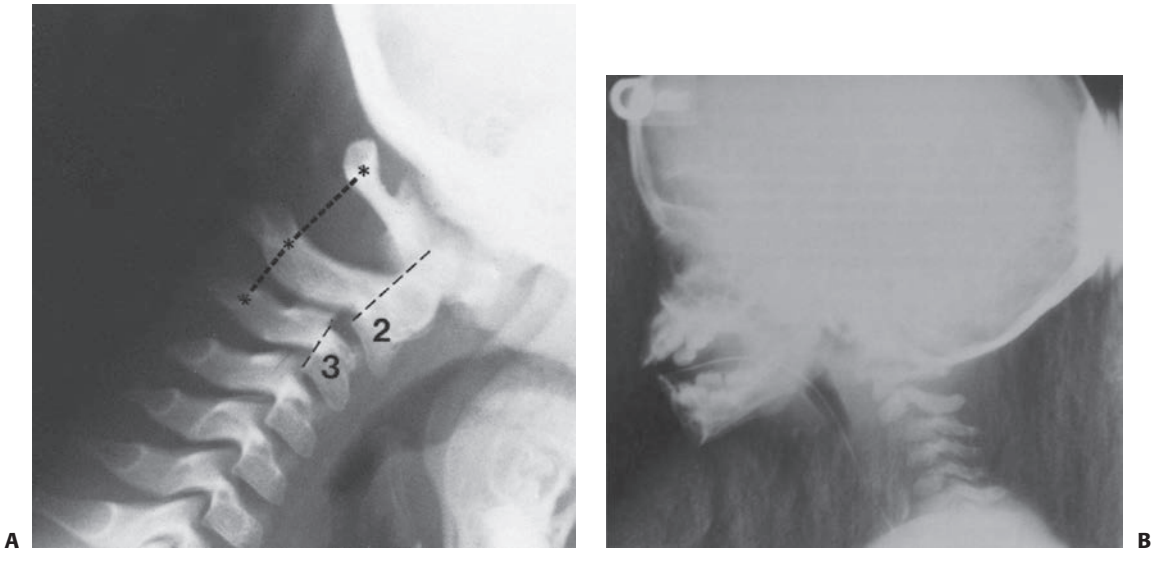

FIGURE 23-4 **A:** Pseudosubluxation of C2 on C3. In flexion, the posterior element of C2 should normally align itself with the posterior elements C1 and C3. The relationship of the body of C2 with the body of C3 gives the appearance of subluxation; however, the alignment of the posterior elements of C1 to C3 confirms pseudosubluxation. **B:** True subluxation.

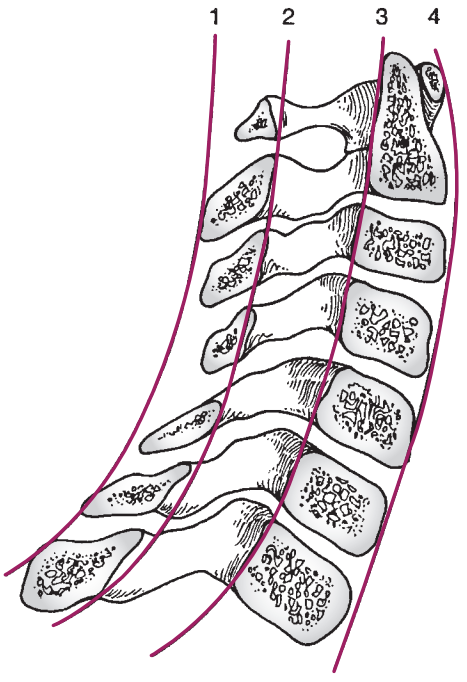

FIGURE 23-5 Normal relationships in the lateral cervical spine: *1,* spinous processes; *2,* spinolaminar line; *3,* posterior vertebral body line; *4,* anterior vertebral body line. (From Copley LA, Dormans JP. Cervical spine disorders in infants and children. *J Am Acad Orthop Surg.* 1998;6: 204–214, with permission.)

FIGURE 23-6 Anterior translation with patient on a spine board.

flexion and extension views of the cervical spine in a cooperative and alert patient. The roles of computed tomography (CT) imaging and magnetic resonance imaging (MRI) continue to evolve in the evaluation of trauma patients.[55]

Plain radiographs remain the standard for initial evaluation of the pediatric cervical spine; CT imaging as an initial diagnostic study is associated with an increase in radiation with no demonstrable benefit over plain radiographs.[2] However, when CT imaging is used in children, a few salient points should be kept in mind. First, the proportion of a child's head to his or her body is greater than that of an adult, so care must be taken not to position the head in flexion to obtain the scan, which could potentiate any occult fracture not seen on plain films (Fig. 23-6). Second, the radiation doses for CT imaging are significantly higher than for plain radiographs, and CT protocols for children should be used to limit the amount of radiation. Although axial views are standard, coronal and sagittal formatted images and three-dimensional reconstruction views provide improved anatomic detail of the spine and can be obtained without any additional radiation to the patient.[129,184] In patients with head injuries, the cervical spine can be included in the CT image of the head to reduce the number of plain films necessary to rule out an occult spinal injury.[155]

MRI has become increasingly useful in evaluating pediatric patients with suspected cervical spine injuries (Fig. 23-7), especially for ruling out ligamentous injuries in patients who cannot cooperate with flexion and extension views.[93] The advantages of an early MRI are the ability to allow mobilization if no injury is

FIGURE 23-7 MRI depicts injury to the cervical cord and upper cervical spine.

present and the early detection of an unrecognized spinal fracture to allow proper treatment. MRI also is useful in evaluating patients with SCIWORA. MR angiography (MRA) has replaced standard arteriography for evaluation of the vertebral arteries in patients with upper cervical spine injuries who have suspected arterial injuries.[224] MRI also remains the best imaging modality for evaluating injuries of the intervertebral disks and is especially useful to detect disk herniation in adolescent patients with facet joint injuries that may require operative reduction.

Classification of Cervical Spine Injuries

There is currently no fracture classification for pediatric cervical spine injuries. Fractures are defined by the level of injury as well as whether there is an associated bony injury or ligamentous injury. The presence of ligamentous injuries is more common in younger children whereas subaxial cervical injuries are more common toward skeletal maturity, and fractures may then be classified using adult fracture classifications. Classifications for specific fractures are discussed later in the chapter.

Pathoanatomy and Applied Anatomy Relating to Cervical Spine Injury

Understanding the normal growth and development of the cervical spine is essential when treating a child with a suspected cervical spine injury. This will allow the physician to differentiate normal physes or synchondroses from pathologic fractures or ligamentous disruptions and will alert the physician to any possible congenital anomalies that may be mistaken for a fracture.

Upper Cervical Spine

At birth, the atlas is composed of three ossification centers, one for the body and one for each of the neural arches (Fig. 23-8). In approximately 20% of individuals, the ossification center for the anterior arch is present at birth; in the remainder they appear by 1 year of age. Occasionally, the anterior arch is bifid, and the body may be formed from two centers, or it may fail to completely form. The posterior arches usually fuse by 3 years of age; however, occasionally the posterior synchondrosis between the two arches fails to fuse, resulting in a bifid arch. The neurocentral synchondroses that link the neural arches to the body close by 7 years of age. They are best seen on an open-mouth odontoid view and should not be mistaken for fractures.[50] The canal of the atlas is large enough to allow for the rotation that is necessary at this joint as well as some forward translation.[52] The vertebral arteries are about 2 cm from the midline and run in a groove on the superior surface of the atlas. This must be remembered during lateral dissection at the occipital–cervical junction. The ring of C1 reaches about normal adult size by 4 years of age.[10]

The axis develops from at least four separate ossification centers: one for the dens, one for the body, and two for the neural arches (Fig. 23-9). Between the odontoid and the body of the axis is a synchondrosis or vestigial disk space that often is mistaken for a fracture line. This synchondrosis runs well below the level of the articular processes of the axis and usually fuses at 6 to 7 years of age, although it may persist as a sclerotic line until 11 years of age.[52] The most common odontoid

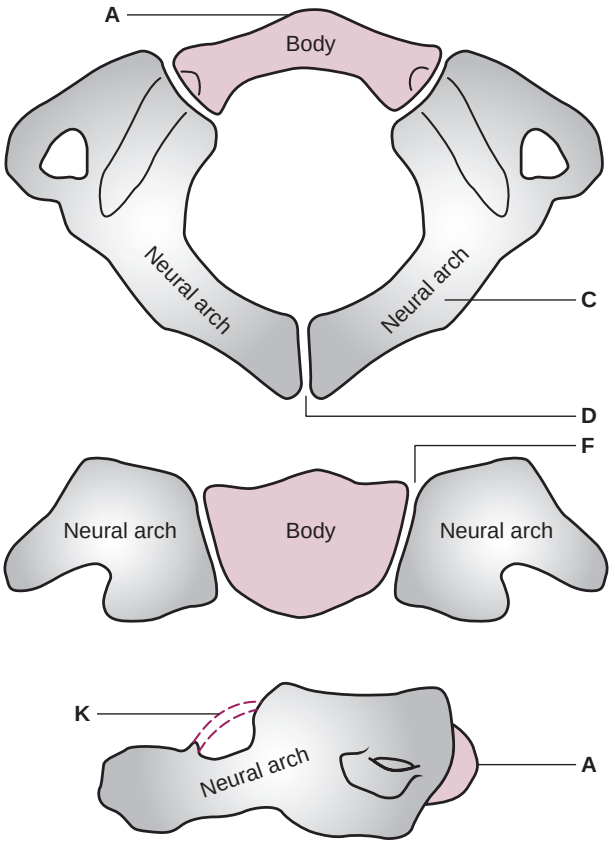

FIGURE 23-8 Diagram of C1 (atlas). The body (*A*) is not ossified at birth, and its ossification center appears during the first year of life. The body may fail to develop, and forward extension of neural arches (*C*) may take its place. Neural arches appear bilaterally about the seventh week (*D*), and the most anterior portion of the superior articulating surface usually is formed by the body. The synchondrosis of the spinous processes unites by the third year. Union rarely is preceded by the appearance of the secondary center within the synchondrosis. Neurocentral synchondrosis (*F*) fuses about the seventh year. The ligament surrounding the superior vertebral notch (*K*) may ossify, especially in later life. (From Bailey DK. Normal cervical spine in infants and children. *Radiology*. 1952;59: 713–714, with permission.)

fracture pattern in adults and adolescents is transverse and at the level of the articular processes. The normal synchondrosis should not be confused with this fracture; the synchondrosis is more cup-shaped and below the level of the articular processes. After 7 years of age, the synchondrosis should not be present on an open-mouth odontoid view; a fracture should be considered if a lucent line is present after this age. The neural arches of C2 fuse at 3 to 6 years of age; these are seen as vertical lucent lines on the open-mouth odontoid view. Occasionally, the tip of the odontoid is V-shaped (dens bicornum), or a small separate summit ossification center may be present at the tip of the odontoid (ossiculum terminale). An os odontoideum is believed to result from a history of unrecognized trauma. The differentiation between an os odontoideum and the synchondrosis of the body is relatively easy because of their relationships to the level of the C1 to C2 facet (Fig. 23-10).

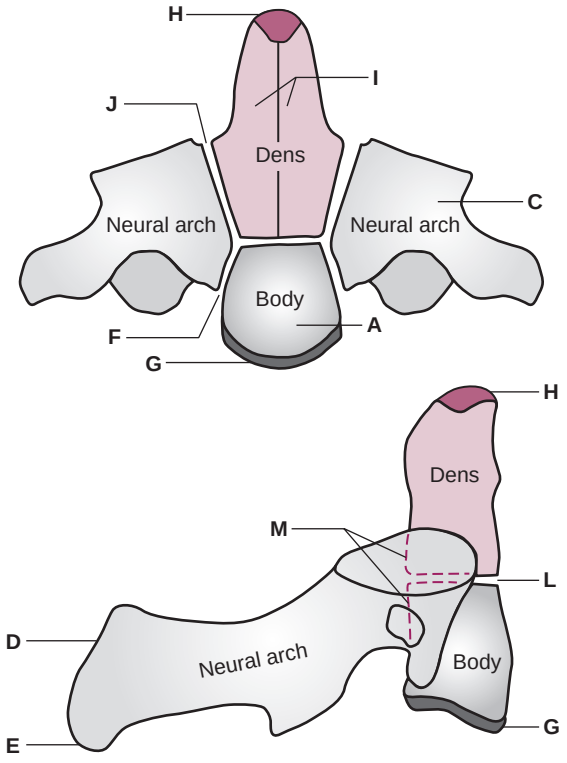

FIGURE 23-9 Diagram of C2 (axis). The body (*A*) in which one center (occasionally two) appears by the fifth fetal month. Neural arches (*C*) appear bilaterally by the seventh fetal month. Neural arches fuse (*D*) posteriorly by the second or third year. Bifid tip (*E*) of spinous process (occasionally a secondary center is present in each tip). Neurocentral synchondrosis (*F*) fuses at 3 to 6 years. The inferior epiphyseal ring (*G*) appears at puberty and fuses at about 25 years of age. The summit ossification center (*H*) for the odontoid appears at 3 to 6 years and fuses with the odontoid by 12 years. Odontoid (dens) (*I*). Two separate centers appear by the fifth fetal month and fuse with each other by the seventh fetal month. The synchondrosis between the odontoid and neural arch (*I*) fuses at 3 to 6 years. Synchondrosis between the odontoid and body (*L*) fuses at 3 to 6 years. Posterior surface of the body and odontoid (*M*). (From Bailey DK. Normal cervical spine in infants and children. *Radiology*. 1952; 59:713–714, with permission.)

The arterial supply to the odontoid is derived from the vertebral and carotid arteries. The anterior and posterior ascending arteries arise from the vertebral artery at the level of C3 and ascend anterior and posterior to the odontoid, meeting superiorly to form an apical arcade. These arteries supply small penetrating branches to the body of the axis and the odontoid process. The internal carotid artery gives off cleft perforators that supply the superior portion of the odontoid. This arrangement of arteries and vessels is necessary for embryologic development and anatomic function of the odontoid. The synchondrosis prevents direct vascularization of the odontoid from C2, and vascularization from the blood supply of C1 is not possible because the synovial joint cavity surrounds the odontoid. The formation of an os odontoideum after cervical trauma may be related to this peculiar blood supply (Fig. 23-11).

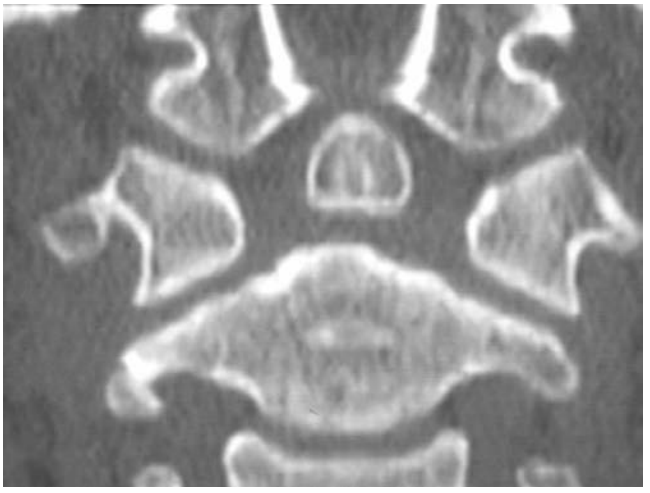

FIGURE 23-10 CT scan showing presence of an os odontoideum. Note the position of the os well above the C1 to C2 facets. The scan also shows the vestigial scar of the synchondrosis between the dens and the body below the C1 to C2 facet.

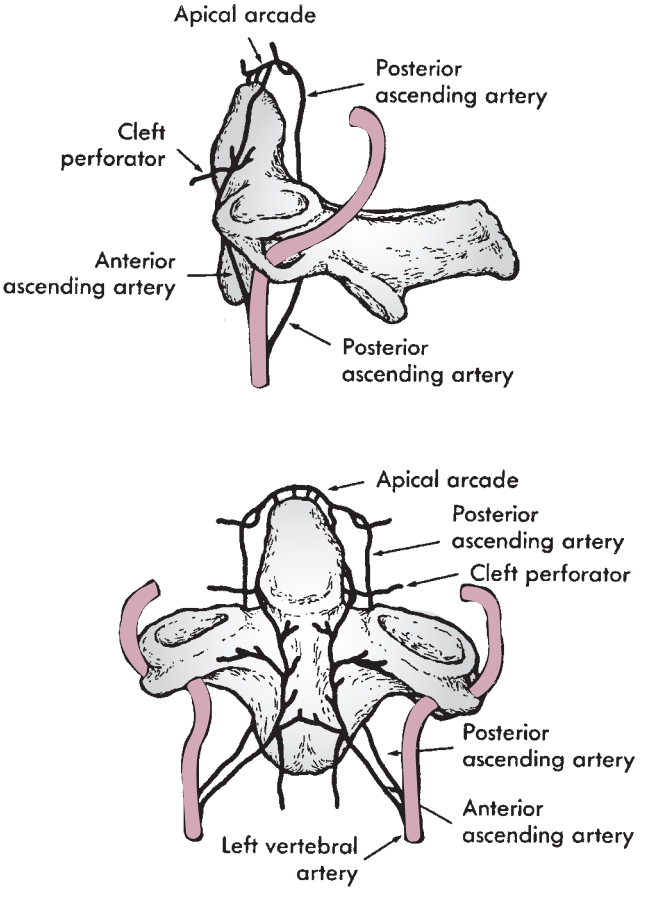

FIGURE 23-11 Blood supply to odontoid: posterior and anterior ascending arteries and apical arcade. (From Schiff DC, Parke WW. The arterial supply of the odontoid process. J Bone Joint Surg Am 1973;55:1450–1464, with permission.[258])

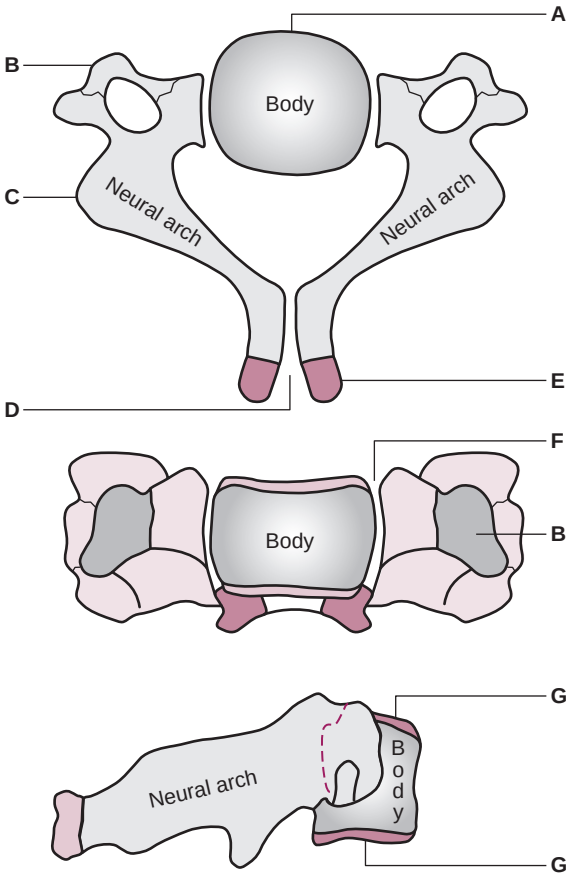

FIGURE 23-12 Diagram of typical cervical vertebrae, C3 to C7. The body (*A*) appears by the fifth fetal month. The anterior (costal) portion of the transverse process (*B*) may develop from a separate center that appears by the sixth fetal month and joins the arch by the sixth year. Neural arches (*C*) appear by the seventh to ninth fetal week. The synchondrosis between spinous processes (*D*) usually unites by the second or third year. Secondary centers for bifid spine (*E*) appear at puberty and unite with spinous process at 25 years. Neurocentral synchondrosis (*F*) fuses at 3 to 6 years. Superior and inferior epiphyseal rings (*G*) appear at puberty and unite with the body at about 25 years. The seventh cervical vertebra differs slightly because of a long, powerful, nonbifid spinous process. (From Bailey DK. Normal cervical spine in infants and children. *Radiology*. 1952; 59:713–714, with permission.)

Lower Cervical Spine

The third through seventh cervical vertebrae share a similar ossification pattern: a single ossification center for the vertebral body and an ossification center for each neural arch (Fig. 23-12). The neural arch fuses posteriorly between the second and third years, and the neurocentral synchondroses between the neural arches and the vertebral body fuse by 3 to 6 years of age. These vertebrae normally are wedge-shaped until 7 to 8 years of age.[16,170,239] The vertebral bodies, neural arches, and pedicles enlarge by periosteal appositional growth, similar to that seen in long bones. By 8 to 10 years of age, a child's spine usually reaches near adult size and characteristics. There are five secondary ossification centers that can remain open until 25 years of age.[169] These include one each for the spinous processes, transverse processes, and the ring apophyses about the vertebral endplates. These should not be confused with fractures.

The superior and inferior endplates are firmly bound to the adjacent disk. The junction between the vertebral body and the endplate is similar to a physis of a long bone. The vertebral body is analogous to the metaphysis and the endplate to the physis, where longitudinal growth occurs. The junction between the vertebral body and the endplate has been shown to be weaker than the adjacent vertebral body or disk, which can result in a fracture at the endplate in the area of columnar and calcified cartilage of the growth zone, similar to a Salter–Harris type I fracture of a long bone.[16] The inferior end plate may be more susceptible to this injury than the superior endplate because of the mechanical protection afforded by the developing uncinate processes.[31]

The facet joints of the cervical spine change in orientation with age. The angle of the C1 to C2 facet is 55 degrees in newborns and increases to 70 degrees at maturity. In the lower cervical spine, the angle of the facet joints is 30 degrees at birth and 60 to 70 degrees at maturity. This may explain why the pediatric cervical spine may be more susceptible to injury from the increased motion or translation allowed by the facet joint orientation.

Increased ligamentous laxity in young children allows a greater degree of spinal mobility than in adults. Flexion and extension of the spine at C2 to C3 are 50% greater in children between the ages of 3 and 8 years than in adults. The level of the greatest mobility in the cervical spine descends with increasing age. Between 3 and 8 years of age, the most mobile segment is C3 to C4; from 9 to 11 years, C4 to C5 is the most mobile segment, and from 12 to 15 years, C5 to C6 is the most mobile segment.[4,231] This explains the tendency for craniocervical injuries in young children.

Several anomalies of the cervical spine may influence treatment recommendations. The atlas can fail to segment from the skull, a condition called occipitalization of the atlas, and can lead to narrowing of the foramen magnum, neurologic symptoms, and increased stresses to the atlantoaxial articulation, which often causes instability. Failure of fusion of the posterior arch of C1 is not uncommon and should be sought before any procedure that involves C1. Wedge-shaped vertebrae, bifid vertebrae, or a combination of these also can occur. Klippel–Feil syndrome consists of the classic triad of a short neck, low posterior hairline, and severe restriction of motion of the neck from fusion of the cervical vertebrae.[134,160] Congenital fusion of the cervical spine may predispose a child to injury from trauma by concentrating stresses in the remaining mobile segments.

Hensinger et al.[133] reported congenital anomalies of the odontoid, including aplasia (complete absence), hypoplasia (partial absence in which there is a stubby piece at the base of the odontoid located above the C1 articulation), and os odontoideum. Os odontoideum consists of a separate ossicle of the odontoid with no connection to the body of C2. The cause may be traumatic. These anomalies also may predispose a child to injury or instability.

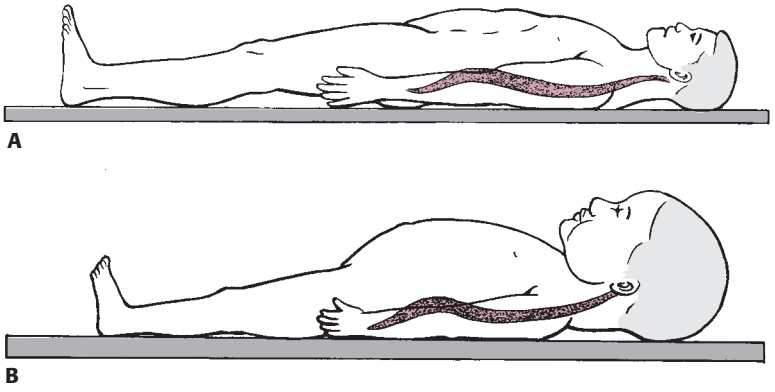

FIGURE 23-13 **A:** Adult immobilized on a standard backboard. **B:** Young child on a standard backboard. The relatively large head forces the neck into a kyphotic position. (From Herzenberg JE, Hensinger RN, Dedrick DK, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg Am.* 1989;71:15–22, with permission.)

Treatment Options For Cervical Spine Injuries

Initial Management of Patients with Suspected Cervical Spine Injury

The initial management of a child with a suspected cervical spine injury is paramount to avoiding further injury to the cervical spine and spinal cord. The initial management of any child suspected of having a cervical spine injury starts with immobilization in the field. Extraction from an automobile or transport to the hospital may cause damage to the spinal cord in a child with an unstable cervical spine injury if care is not taken to properly immobilize the neck. The immobilization device should allow access to the patient's oropharynx and anterior neck if intubation or tracheostomy becomes necessary. The device should allow splintage of the head and neck to the thorax to minimize further movement.

The use of backboards in pediatric trauma patients deserves special attention because of the anatomic differences between children and adults. Compared to adults, children have a disproportionately larger head with respect to the body. This anatomic relationship causes a child's cervical spine to be placed in flexion if immobilization is done on a standard backboard. Herzenberg et al.[136] reported 10 children under the age of 7 years whose cervical spines had anterior angulation or translation on radiograph when they were placed on a standard backboard. The use of a backboard with a recess so that the head can be lowered into it to obtain a neutral position of the cervical spine is one way to avoid unnecessary flexion. Another is a split-mattress technique in which the body is supported by two mattresses and the head is supported by one mattress, allowing the cervical spine to assume a neutral position. Children younger than 8 years of age should be immobilized on a backboard using one of these techniques (Figs. 23-13 and 23-14).[57,213]

Cervical collars supplement backboards for immobilization in the trauma setting. While soft collars tend to be more comfortable and cause less soft tissue irritation, rigid collars are preferred for patients with acute injuries because they provide better immobilization. Even rigid collars may allow up to 17 degrees of flexion, 19 degrees of extension, 4 degrees of rotation, and 6 degrees of lateral motion.[63,196] Supplemental sandbags and taping on either side of the head are recommended in all children and have been shown to limit the amount of spinal motion to 3 degrees in any plane.[142]

Further displacement of an unstable cervical injury may occur if resuscitation is required. The placement of pediatric patients on an appropriate board with the neck in a neutral position makes recognition of some fractures difficult because positional reduction may have occurred, especially with

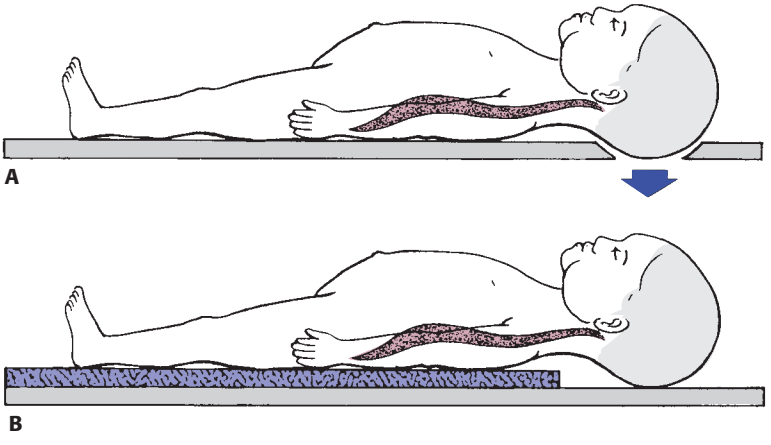

FIGURE 23-14 **A:** Young child on a modified backboard that has a cutout to the recess of the occiput, obtaining better supine cervical alignment. **B:** Young child on modified backboard that has a double-mattress pad to raise the chest, obtaining better supine cervical alignment. (From Herzenberg JE, Hensinger RN, Dedrick DK, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg Am.* 1989;71:15–22, with permission.)

FIGURE 23-15 Clinical photograph of a patient with a cervical spine injury resulting from impact with the shoulder harness of a seatbelt. Note location of skin contusions from the seatbelt.

ligamentous injuries or endplate fractures. An apparently normal lateral radiograph in a patient with altered mental status or multiple injuries does not rule out a cervical spine injury. A study of four patients with unstable cervical spine injuries who had attempted resuscitation in the emergency department showed that axial traction actually increased the deformity.[31] Any manipulation of the cervical spine, even during intubation, must be done with caution and with the assumption that the patient has an unstable cervical spine injury until proven otherwise.

The physical evaluation of any patient with a suspected cervical spine injury should begin with inspection. Head and neck trauma is associated with a high incidence of cervical spine injuries.[4,16] Soft tissue abrasions or shoulder-harness marks on the neck from a seatbelt are clues to an underlying cervical spine injury (Fig. 23-15).[95,106,140] Unconscious patients should be treated as if they have a cervical spine injury until further evaluation proves otherwise. The next step in the evaluation is palpation of the cervical spine for tenderness, muscle spasm, and overall alignment. The most prominent levels should be the spinous processes at C2, C3, and C7. Anterior palpation should focus on the presence of tenderness or swelling. The entire spine should be palpated and thoroughly examined because 20% of patients with cervical spine injuries have other spinal fractures.

A thorough neurologic examination should be done, which can be difficult in pediatric patients. Strength, sensation, reflexes, and proprioception should be documented. In patients who are uncooperative because of age or altered mental status, repeat examinations are important; however, the initial neurovascular examination should be documented even if it entails only gross movements of the extremities. The evaluation of rectal sphincter tone, bulbocavernosus reflex, and perianal sensation are important, especially in obtunded patients and patients with partial or complete neurologic injuries, regardless of age. Patients who are cooperative and awake can be asked to perform supervised flexion, extension, lateral rotation, and lateral tilt. Uncooperative or obtunded patients should not have any manipulation of the neck.

Nonoperative Treatment of Cervical Spine Injury

Immobilization of the cervical spine may continue after the emergency setting if there is an injury that requires treatment. Specific injuries and their treatment are described later in this chapter. Further immobilization of some cervical spine injuries requires a cervical collar. A rigid collar can be used for immobilization if it is an appropriately fitting device with more padding than a standard cervical collar placed in the emergency department. More unstable or significant injuries can be treated with a custom orthosis, a Minerva cast, or a halo device. An advantage of custom devices is the ability to use lightweight thermoplastic materials that can be molded better to each patient's anatomy and can be extended to the

FIGURE 23-16 Custom-made cervicothoracic brace used to treat a C2 fracture that reduced in extension.

thorax (Fig. 23-16). These devices must be properly applied for effective immobilization, and skin breakdown, especially over the chin region, needs to be carefully monitored. Minerva casts tend to provide more immobilization than thermoplastic devices, but their use is not as common and their application requires attention to detail.

A halo device can be used for the treatment of cervical spine injuries even in children as young as 1 year old.[253] The halo can be used as either a ring alone to apply traction or with a vest for definitive immobilization of an unstable cervical spine injury. Prefabricated vests are available in sizes for infants, toddlers, and children, with measurements based on the circumference of the chest at the xiphoid process.

The fabrication of a halo for any patient needs to consider both the size of the ring and the size of the vest. Prefabricated rings and prefabricated vests are available for even the smallest of patients and are based on circumferential measurements at the crown and at the xiphoid process. If the size of the patient or the anatomy of the patient does not fit within these standard sizes, the fabrication of a custom halo may be necessary. Mubarak et al.[203] recommended the following steps in the fabrication of a custom halo for a child: (a) the size and configuration of the head are obtained with the use of the flexible lead wire placed around the head, (b) the halo ring is fabricated by constructing a ring 2 cm larger in diameter than the wire model, (c) a plaster mold of the trunk is obtained for the manufacture of a custom bivalved polypropylene vest, and (d) linear measurements are made to ensure appropriate length of the superstructure.

The placement of pins into an immature skull deserves special attention because of the dangers of inadvertent skull penetration with a pin. CT imaging before halo application aids in determining bone structure and skull thickness. It also aids in determining whether or not cranial suture interdigitation is complete and if the fontanels are closed. The thickness of the skull varies greatly up to 6 years of age and is not similar to that of adults until the age of 16 years.[175] Garfin et al.[97] evaluated the pediatric cranium by CT and determined that the skull is thickest anterolaterally and posterolaterally, making these the optimal sites for pin placement.

The number of pins used for placement of a ring and the insertion torques used in younger children also deserve special mention. The placement of pins at the torque pressures used in adults will lead to penetration during insertion.[175] Pins should be inserted at torques of 2- to 4-in pounds; however, the variability and reliability of pressures found with various torque wrenches during cadaver testing are great, and each pin must be inserted cautiously.[61] The use of 8 to 12 pins inserted at lower torque pressures aids in obtaining a stable ring with less chance of inadvertent penetration (Fig. 23-17). The insertion of each pin perpendicular to the skull also improves the pin–bone interface and the overall strength of the construct.[62] We have had success using halo vests even in children younger than 2 years of age by using multiple pins inserted to finger-tightness rather than relying on torque wrenches.

Technique of Halo Application

A halo can be applied in older children and adolescents with a local anesthetic; however, in most younger children a general anesthetic should be used. The patient is positioned on the operating table in a position that prevents unwanted flexion of the neck and maintains the proper relationship of the head and neck with the trunk. The area of skin in the region of pin insertion is cleaned with antiseptic solution and appropriate areas are shaved as needed for pin placement posteriorly. The ring is placed while an assistant holds the patient's head; it should be placed just below the greatest circumference of the skull, which corresponds to just above the eyebrows anteriorly and 1 cm above the tips of the earlobes laterally. We recommend injection of local anesthetic into the skin and periosteum through the ring holes in which the pins will be placed. The pins are placed with sterile technique.

To optimize pin placement, a few points should be kept in mind. The thickest area of the skull is anterolaterally and posterolaterally, and pins inserted at right angles to the bone have greater force distribution and strength.[62,97] Anterior pins should be placed to avoid the anterior position of the supraorbital and supratrochlear nerves (Fig. 23-18). Placement of the anterior pins too far laterally will lead to penetration of the temporalis muscle, which can lead to pain with mastication and talking, as well as early pin loosening. The optimal position for the anterior pins is in the anterolateral skull, just above the lateral two-thirds of the orbit and just below the greatest circumference of the skull. The posterior pins are best placed posterolaterally directly diagonal from the anterior pins. We also recommend placing the pins to finger-tightness originally and tightening

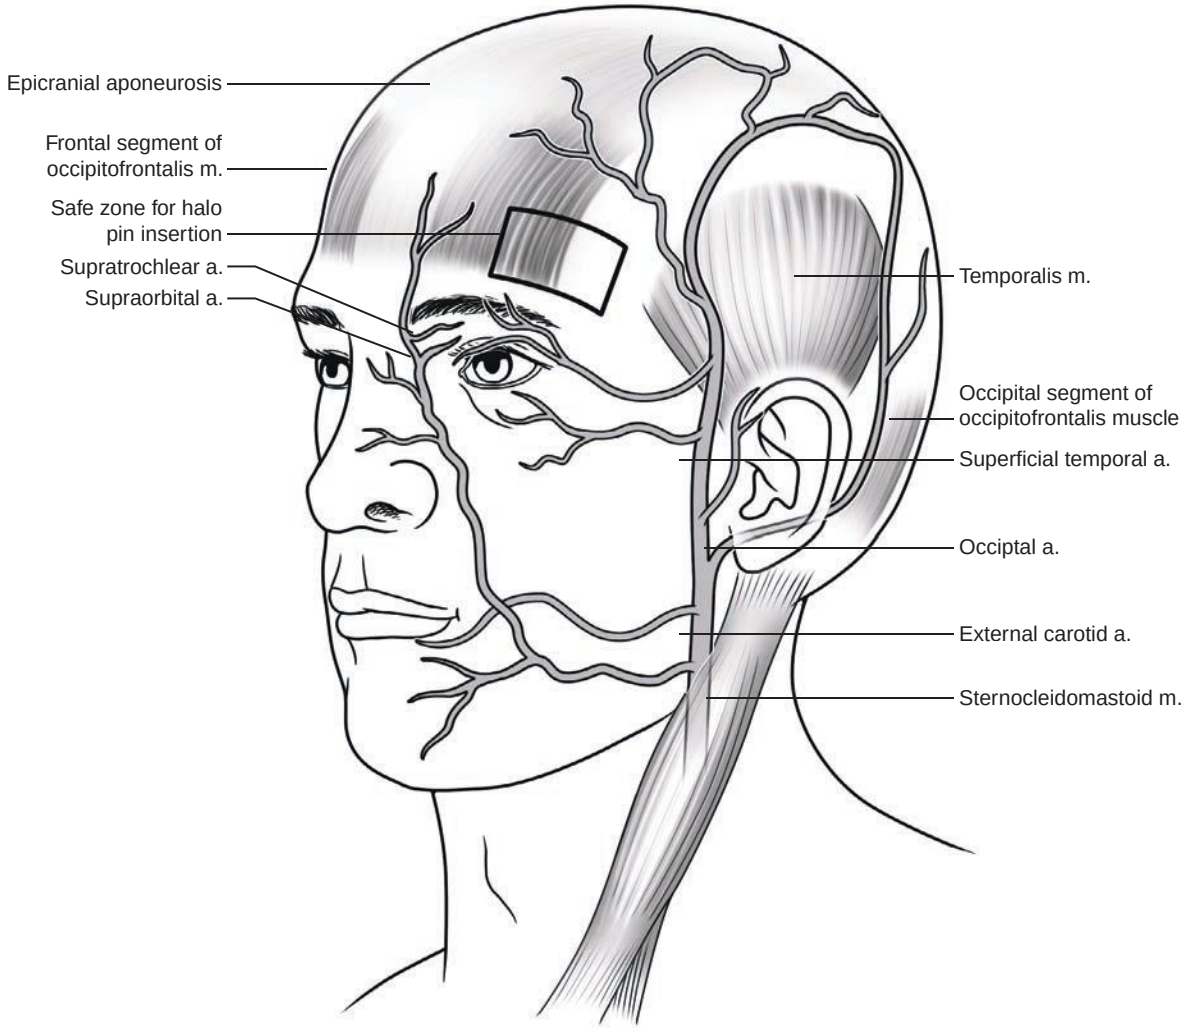

FIGURE 23-17 "Safe Zone" for halo pin insertion. (Adapted from Manson NA, An HS. Halo placement in the pediatric and adult patient. In: Vaccaro AR, Barton EM: *Operative Techniques in Spine Surgery*. Philadelphia, PA: Saunders (2008), p. 13.[185])

two directly opposing pins simultaneously. During placement of the pins, meticulous attention should be paid to the position of the ring to have a circumferential fit on the patient's skull and to avoid any pressure of the ring on the scalp, especially posteriorly.

The number of pins used and the torque pressures applied vary according to the age of the patient. In infants and younger children, we recommend the placement of multiple pins (8 to 12) tightened to finger-tightness or 2- to 4-in pounds to avoid unwanted skull penetration. In older children, six to eight pins are used and tightened to 4-in pounds. In adolescents, four to eight pins can be tightened with a standard torque wrench to 6- to 8-in pounds. Once the pins are tightened, they must be fastened to the ring by the appropriate lock nuts or set screws. The halo vest and superstructure are then applied, with care to maintain the position of the head and neck. Appropriate positioning of the head and neck can be done by adjusting the superstructure (Fig. 23-19).

Daily pin care should consist of hydrogen peroxide/saline cleaning at the pin–skin interface. Retightening of pins at 48 hours should be avoided in infants and children to prevent skull penetration; however, in adolescents, the pins can be retightened at 48 hours with a standard torque wrench. Local erythema or drainage may occur about the pins and can be managed with oral antibiotics and continued pin site care. If significant loosening occurs or the infection is more serious, the pin or pins should be removed. Occasionally, a dural puncture occurs during pin insertion or during the course of treatment. This necessitates pin removal and prophylactic antibiotics until the tear heals, usually at 4 to 5 days.

Outcomes

The complication rate related to the use of a halo in one series of patients was 68%; however, all patients were able to wear the halo until fracture healing occurred or arthrodesis was achieved.[56] The most common complications in this series were superficial

FIGURE 23-18 Child immobilized in a halo for C1 to C2 rotary subluxation. Note the position of the anterior pins, as well as the placement of the posterior pins at 180 degrees opposite the anterior pins.

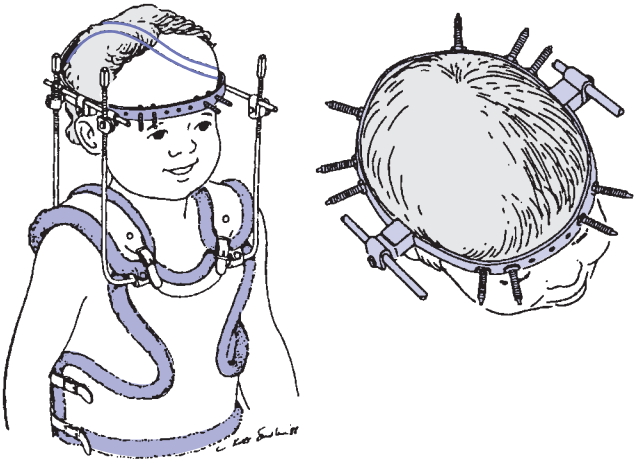

FIGURE 23-19 (*Left*) Custom halo vest and superstructure. (*Right*) In the multiple-pin, low-torque technique, 10 pins are used for an infant halo ring attachment. Usually, four pins are placed anteriorly, avoiding the temporal region, and the remaining six pins are placed in the occipital area. (From Mubarak SJ, Camp JF, Fuletich W, et al. Halo application in the infant. *J Pediatr Orthop.* 1989;9:612–613, with permission.)

pin track infection and pin loosening. Other complications that occur less frequently include dural penetration, supraorbital nerve injury, unsightly pin scars, and deep infection.[23,71] Prefabricated halo vests are used in adults and are easily fitted to older adolescents. Because of the age and size ranges of children, however, a custom vest or even a cast vest may be needed. Improper fitting of a vest may allow unwanted movement of the neck despite the halo, and any size mismatch requires a custom vest or cast vest (see Fig. 23-19).

Nonoperative Treatment of Spinal Cord Injury

If an acute spinal cord injury is determined by examination, the administration of methylprednisolone within the first 8 hours after injury has been shown to improve the chances of neurologic recovery.[33–36] Methylprednisolone in the treatment of acute spinal cord injuries has been shown to improve motor and sensory recovery when evaluated 6 weeks and 6 months after injury[35]; however, this positive effect on neurologic recovery is limited to those treated within the first 8 hours of injury. The initial loading dose of methylprednisolone is 30 mg/kg body weight. If the loading dose is given within 3 hours after injury, then a maintenance infusion of 5.4 mg/kg is given for 24 hours after injury. If the loading dose is given between 3 and 8 hours after injury, then a maintenance infusion of 5.4 mg/kg is given for 48 hours after injury. Methylprednisolone decreases edema, has an anti-inflammatory effect, and protects the cell membranes from scavenging oxygen-free radicals.[33–36]

Once spinal cord injury is diagnosed, routine care includes prophylaxis for stress ulcers, routine skin care to prevent pressure sores, and initial Foley catheterization followed by intermittent catheterization and a bowel training program.

Outcomes

In several series,[33–36] there was a slight increase in the incidence of wound infections but no significant increase in gastrointestinal bleeding. All of these studies involved patients 13 years or older, so no documentation of the efficacy in young children exists. A combination of methylprednisolone and GM1-ganglioside (GM1) is being studied for its possible beneficial effect on an injured spinal cord.[99–102] GM1 is a complex acid-like lipid found at high levels in the cell membrane of the central nervous system that is thought to have a neuroprotective and neurofunctional restorative potential. Early studies have shown that patients given both drugs had improved recovery over those who had received just methylprednisolone. Spinal cord injury remains the most devastating complication after cervical spine fractures. The outcome after a spinal cord injury has been shown to be better in children than in adults and varying and unpredictable improvement in function may occur.[225] The role of steroids in minimizing the inflammatory cascade and limiting neuronal injury has been well received after the results of the National Acute Spinal Cord Injury Studies (NASCIS) were published.[33–36] Recently, the results of the studies have been called into question, and the evidence remains confusing to the physician taking care of patients with spinal cord injuries. There

currently are no randomized clinical trials that have been performed in children with regard to pharmacologic measures to be taken after a spinal cord injury.[226] With that being said, many clinicians continue administer steroids to children in the acute setting of a spinal cord injury given the potentially devastating effects of such an injury. The original recommendations to be followed were: methylprednisolone sodium succinate in a dose regimen of bolus 30 mg/kg over 15 minutes, with maintenance infusion of 5.4 mg/kg per hour infused for 23 hours. No clear evidence exists for the administration of steroids after spinal cord injury; however, a recent review on the subject reveals that many physicians continue to practice this in the face of an injury because of the perceived risks of litigation.[113] The potential side effects of steroids, namely pulmonary complications and wound complications, should be weighed against both the paucity of evidence regarding their therapeutic value and the institutional protocols that may be in place for spinal cord injury patients.

With incomplete lesions, children have a better chance than adults for useful recovery. Hadley et al.[115] noted that 89% of pediatric patients with incomplete spinal cord lesions improved, whereas only 20% of patients with complete injuries had evidence of significant recovery. Laminectomy has not been shown to be beneficial and can actually be harmful[270,320] because it increases instability in the cervical spine; for example, it can cause a swan neck deformity or progressive kyphotic deformity.[188,274] The risk of spinal deformity after spinal cord injury has been investigated by several researchers.[21,25,47,85,158,188] Mayfield et al.[188] found that patients who had a spinal cord injury before their growth spurt all developed spinal deformities, 80% of which were progressive. Ninety-three percent developed scoliosis, 57% kyphosis, and 18% lordosis. Sixty-one percent of these patients required spinal arthrodesis for stabilization of their curves. Orthotic management usually is unsuccessful, but in some patients it delays the age at which arthrodesis is necessary. Lower extremity deformities also may occur, such as subluxations and dislocations about the hip. Pelvic obliquity can be a significant problem and may result in pressure sores and difficulty in seating in a wheelchair.

Nonoperative Treatment of Neonatal Injury

Treatment of neonatal cervical spine injuries is nonoperative and should consist of careful realignment and positioning of the child on a bed with neck support or a custom cervical thoracic orthosis. Healing of bony injuries usually is rapid and complete.[281]

Operative Treatment of Cervical Spine Injury

Indications and contraindications are discussed with specific techniques later in the chapter.

Surgical Procedure(s)

Specific procedures are discussed later the chapter.

Preoperative Planning. The patient with an unstable cervical spine injury must be intubated and properly positioned to avoid further injury.

Stabilization. The injured cervical spine should be immobilized during transport. As discussed early in this chapter, in patients younger than 8 years of age the use of a backboard with and occipital recess or having the trunk elevated approximately 2.5 cm is recommended. This will allow the cervical spine to remain in neutral alignment due to the relative large head size compared with the trunk size in these younger patients. Soft cervical collars provide no significant stability to the cervical spine. Properly fitting cervical collars offer better support. The addition of sandbags and tape immobilization offers even more support.

Airway Management. In a patient with an unstable cervical spine, manipulation during intubation may injure the spinal cord. Axial traction, in particular, has been shown to result in increased distraction during intubation compared with either no immobilization or manual stabilization and is not recommended.[172] Manual in-line stabilization (MILS) is the most widely accepted technique for immobilization during intubation. This technique consists of grasping the mastoid processes with the fingertips with no traction being applied and then cupping the occiput in the palm of the hands.[104,183] Studies have confirmed the clinical safety of orotracheal intubation by direct laryngoscopy with MILS in patients with cervical spine injury.[256,267]

Several methods for intubation have been described for the patient with an unstable cervical spine. Awake intubation that is sometimes performed in adult patients is not feasible in the pediatric patient. Direct laryngoscopy with MILS is the method most often used. Fiberoptic intubation with MILS is a popular alternative. This causes minimal cervical movement and facilitates improved visualization of the vocal cords during intubation. However the time to intubation with the fiberoptic technique is twice as long compared with direct laryngoscopy. The GlideScope videolaryngoscopy (Verathon, Bothell, WA) provides an indirect view of the glottis on a screen and has the potential for reduced motion. Nasotracheal intubation can be performed fiberoptically or without direct visualization. This technique is contraindicated in patient with basilar skull fractures or craniofacial trauma, which often is the case in pediatric cervical spine trauma.

Spinal Cord Monitoring. Spinal cord monitoring is usually used during surgical stabilization of the unstable cervical spine. Motor potential and SSEP are used for monitoring (Table 23-2).

Positioning. The two primary techniques for prone positioning of patients with cervical spine injuries are manual turning using the log-roll technique or use of a spinal positioning table. Cadaver models have shown that turning using a spinal positioning table and a cervical collar results in the least amount of motion and is the preferred technique. If a spinal positioning

TABLE 23-2 Cervical Spine Injury

Preoperative Planning Checklist

- Appropriate stabilization and immobilization
- Airway management and intubation
- Spinal cord monitoring

table is not available, however, the log-roll technique with a cervical collar can be used. Once the patient is positioned, Gardner-Wells tongs or a halo are applied and attached to a Mayfield headrest attachment. Care must be taken when using these devices, because the head is in a fixed position and the torso is relatively free. Distraction and translation at the fracture site can occur, and fluoroscopy is recommended to verify proper alignment of the cervical spine when the patient is prone.

Surgical Approaches. The two most common approaches for surgical treatment of the unstable pediatric cervical spine are the posterior approach and anterior approach.[265] The posterior approach is the most commonly used and is most familiar to most orthopedic surgeon.[289]

Posterior Approach. This approach has been well described and can extend from the base of the occiput to the upper thoracic spine.

Technique. An incision is made in the midline from the suboccipital area down to C3 and can extend distally to C7 or T1 The dissection is extended deep within the relatively avascular intermuscular septum (also known as the ligamentum nuchae) and the cervical musculature is released from the spinous process of C2 and C3. The inferior suboccipital region, the entire posterior arch of C1, and the posterior elements of the C2 to C3 are exposed in a subperiosteal fashion. Bipolar cautery should be used judiciously and hemostatic products incorporated as needed to control bleeding from the perivertebral artery venous plexus, particularly at the C1 to C2 interlaminar space. Dissection at C1 should not go more than 1.5 cm lateral to the midline due to the vertebral artery being 2 cm from the midline in adults and sometimes closer in small children (Table 23-3).

Postoperative Care. Postoperative care depends on the type of procedure performed (see specific techniques later in the chapter).

Potential Pitfalls and Preventative Measures

(1) Autofusion of all exposed vertebrae

(2) Vertebral artery injury with lateral dissection at C1

(3) Lordosis in posterior-only fusion

Anterior Approach. The anterior exposure is performed with the patient supine through a lateral retropharyngeal approach. The lateral retropharyngeal approach described by Whitesides and Kelly is an extension of the Henry approach to the vertebral artery. The sternocleidomastoid muscle is everted and retracted posteriorly, and the remainder of the dissection follows a plane posterior to the carotid sheath.

Technique. A longitudinal incision is made along the anterior margin of the sternocleidomastoid muscle. At the superior end of the muscle, the incision is carried posteriorly across the base of the temporal bone. The muscle is divided at its mastoid origin. The splenius capitis muscle is partially divided at its insertion in the same area. At the superior pole of the incision is the external jugular vein, which crosses the anterior margin of the sternocleidomastoid; this vein should be divided and ligated. Branches of the auricular nerve also may be encountered and may require division. The sternocleidomastoid muscle is everted and the spinal accessory nerve is identified as it approaches and passes into the muscle. The vascular structures that accompany the nerve are divided and ligated. The approach posterior to the carotid sheath and anterior to the sternocleidomastoid muscle is developed (Fig. 23-20). The transverse processes of all the exposed cervical vertebrae are palpable in this interval. Using sharp and blunt dissection, the plane between the alar and prevertebral fascia are developed along the anterior aspect of the transverse processes of the vertebral bodies. The dissection plane is anterior to the longus colli and capitis muscles and the overlying sympathetic trunk and superior cervical ganglion. (An alternative approach is to elevate the longus colli and capitis muscles from their bony insertion on the transverse processes, and retract the muscles anteriorly; however, this approach may disrupt the sympathetic rami communicantes and cause Horner syndrome.) When the vertebral level is identified, a longitudinal incision to bone is made through the anterior longitudinal ligament. The ligament and soft tissues are dissected subperiosteally to expose the vertebral bodies. Instrumentation and fusion may be performed as needed. The wound is irrigated and closed in layers over a suction drain in the retropharyngeal space (Table 23-4).

Postoperative Care. The patient should be monitored closely for postoperative edema and airway obstruction. The patient is immobilized in a cervicothoracic brace or halo vest or halo cast.

Anterior Approach. deAndrade and Macnab described an approach to the upper cervical spine that is an extension of

TABLE 23-3 Posterior Approach to Cervical Spine

Surgical Steps

- Incision: Midline from suboccipital area to C3
- Dissect deep to ligamentum nuchae
- Release cervical musculature
- Expose inferior suboccipital region, posterior arch of C1 and posterior elements of C2–C3 congenital fusion mass

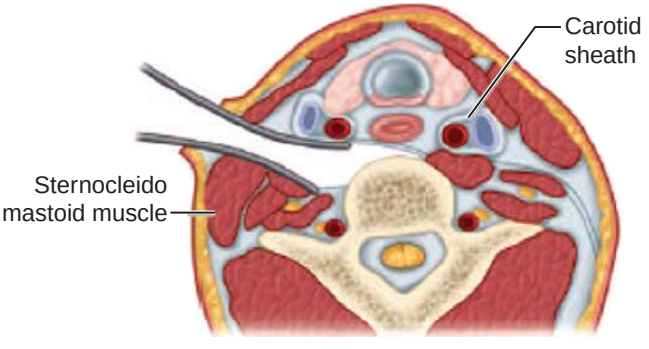

FIGURE 23-20 Anterior approach to the cervical spine (From Canale ST, and Beaty JH, Campbell's operative orthopaedics. 12th ed. Philadelphia, PA: Elsevier/Mosby; 2013.)

TABLE 23-4 Anterior Approach to Cervical Spine

Surgical Steps

- Incise along anterior margin of sternocleidomastoid muscle and carry posteriorly across base of temporal bone
- Divide muscles and nerve and ligate external jugular vein
- Identify spinal accessory nerve and divide and ligate the vascular structures accompanying the nerve
- Develop plane between alar and prevertebral fascia anterior to longus colli and capitis muscles
- Identify vertebral level and make incision through anterior longitudinal ligament
- For fusion place corticocancellous strips in trough made in vertebral bodies
- Irrigate and close wound in layers

the approach described by Robinson and Southwick and Bailey and Badgley. This approach is anterior to the sternocleidomastoid muscle, but the dissection is anterior to the carotid sheath rather than posterior. This approach carries an increased risk of injury to the superior laryngeal nerve.

Potential Pitfalls and Preventive Measures

(1) Recurrent laryngeal nerve

(3) Progressive kyphosis

Occiput-C1 Injuries

Introduction to Occipital Condylar Fracture

Occipital condylar fractures are rare, and their diagnosis requires a high index of suspicion.[198,209]

This fracture was described by Bell in 1817 after a postmortem examination of a patient who fell backward off a wall, and upon being discharged from the hospital turned his head to bid farewell and died immediately because of the instability of his neck injury. The use of CT scan as a diagnostic tool in patients with cranial cervical trauma has led to increased recognition of this injury. The reported incidence of occipital condylar fractures in pediatric patients is not known, as most reported cases are in adult patients.[151] Hanson et al.[121] estimated an incidence of 1 to 20 per 1000 patients. Nobel and Smoker reported an incidence of 1% after CT examination of head and neck in trauma patients.[209]

Assessment of Occipital Condylar Fracture

Mechanisms of Injury for Occipital Condylar Fracture

Fracture may be caused by axial loading with a component of ipsilateral flexion, by an extension of a basilar skull fracture, or by extreme rotation or lateral bending causing avulsion fracture of the inferomedial portion of the condyle that is attached to the alar ligament.

Associated Injuries with and Signs and Symptoms of Occipital Condylar Fracture

Most patients with occipital condylar fractures have associated head injuries.[198] Reports of associated cranial nerve deficits vary from 31% to 53% of patients with occipital condylar fractures.[10,121,296] Damage to the hypoglossal nerve can occur as the nerve passes through the hypoglossal canal that is located above the middle third of the occipital condyle. The function of the hypoglossal nerve can be assessed by asking the patient to protrude the tongue. It will deviate to the paralyzed side.[56] When cranial nerve deficits are noted, the presentation is acute in two-thirds of patient and delayed in one-third of the patients. Delayed cranial nerve palsies may be the result of migration of the fractured bony fragments or compression from proliferation of bone and fibrous tissue during the healing process. Vascular injuries involving the posteroinferior cerebellar artery and carotid arteries also have been reported with occipital condylar fracture.[54,149,152,164,173,177]

The clinical presentation is variable. Pain and tenderness in the posterior occipitocervical region or torticollis may be the only complaints, whereas others may have significant neurologic deficits.

Imaging and Other Diagnostic Studies for Occipital Condylar Fracture

Plain radiographs often do not clearly show occipital condylar fractures, and CT with multiplanar reconstruction usually is necessary to establish the diagnosis.[17,51]

The presence of a retropharyngeal hematoma on a lateral radiograph of the cervical spine may be the only clue to a fracture of the occipital condyle. Tuli et al.[296] recommended that a CT scan be obtained in the following circumstances: presence of lower cranial nerve deficits, associated head injury or basal skull fracture, or persistent neck pain despite normal radiographs.

Classification of Occipital Condylar Fracture

Anderson and Montesano[10] described three types of occipital condylar fractures (Table 23-5 and Fig. 23-21): type I, impaction fracture; type II, basilar skull fracture extending into the condyle; and type III, avulsion fractures. An avulsion fracture is the only type of occipital condylar fracture that is unstable. Type I injuries are the result of axial compression with a component of ipsilateral flexion. Type II injuries are basilar skull fractures that extend to involve the occipital condyle and usually are caused by a direct blow. Type III injuries are avulsion fractures of the inferomedial portion of the condyle that is attached to the alar ligament. Types I and II occipital condylar fractures usually are stable. Type III or avulsion fractures can be stable or unstable.[6]

Tuli et al.[296] also classified occipital condylar fractures based on displacement and stability of the occiput/C1 to C2 complex (Table 23-6). In their classification, type 1 fractures are nondisplaced and type 2 are displaced. They further subdivided type 2 fractures into type 2A, displaced but stable, and type 2B, displaced and unstable.

TABLE 23-5 Anderson and Montesano Classification of Occipital Condylar Fractures

Type	Description	Biomechanics
I	Impaction	Results from axial loading; ipsilateral alar ligament may be compromised, but stability is maintained by contralateral alar ligament and tectorial membrane.
II	Skull base extension	Extends from occipital bone via condyle to enter foramen magnum; stability is maintained by intact alar ligaments and tectorial membrane.
III	Avulsion	Mediated via alar ligament tension; associated disruption of tectorial membrane and contralateral alar ligament may cause instability.

Treatment Options for Occipital Condylar Fracture

Nonoperative Treatment of Occipital Condylar Fracture

Most occipital condylar fractures are stable and can be treated with a cervical orthosis or halo immobilization. Anderson and Montesano Type I and II are stable fractures and can be treated with a cervical orthosis. Tuli type 1 and type 2A are stable and can be treated with a cervical orthosis (Table 23-7).

Operative Treatment of Occipital Condylar Fracture

The decision for surgery is based on cranial cervical instability. Bilateral occipital condylar fractures usually are unstable and require occipital cervical fusion.[121] Type III may be unstable and require occipital cervical fusion. Type 2B will need an occipital cervical fusion.

Surgical Procedure

See pp. 865–868 for occipital cervical fusion techniques.

Atlantooccipital Instability

Atlantooccipital dislocation was once thought to be a rare fatal injury found only at the time of autopsy (Fig. 23-22).[16,30,33,43,273] This injury is now being recognized more often, and children are surviving.[71,78,82,223,280] Bulas et al.[44] reported 11 atlantooccipital dislocations in 1,600 pediatric trauma patients (a 0.7% prevalence) seen over a 5-year period; six children died with severe neurologic deficits, but five patients survived with minimal or no neurologic sequela. This increase in the survival rate may be due to increased awareness and improved emergency care with resuscitation and spinal immobilization by emergency personnel.

Assessment of Atlantooccipital Instability

Mechanisms of Injury for Atlantooccipital Instability

Atlantooccipital dislocation occurs in sudden acceleration and deceleration accidents, such as motor vehicle or pedestrian–vehicle accidents. The head is thrown forward, and this can cause sudden craniovertebral separation.

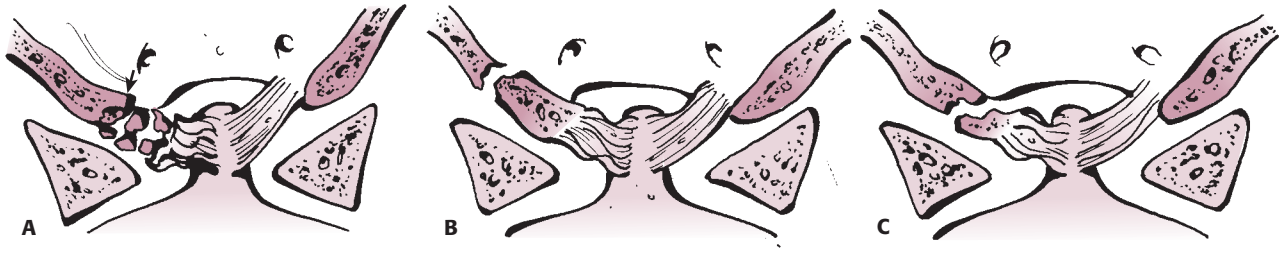

FIGURE 23-21 Classification of occipital condylar fractures according to Anderson and Monsanto.[9] **A:** Type I fractures can occur with axial loading. **B:** Type II fractures are extensions of basilar cranial fractures. **C:** Type III fractures can result from an avulsion of the condyle during rotation, lateral bending, or a combination of mechanisms. (From Hadley MN. Occipital condyle fractures. *Neurosurgery*. 2002;50(Suppl):S114–S119, with permission.)[114]

TABLE 23-7 Occipital Condylar Fracture

Nonoperative Treatment

Indications	Relative Contraindications
Stable Anderson and Montesano type I and II occipital condylar fracture	Anderson and Montesano Type III fracture
Tuli type 1 and type 2A	Tuli type 2B fracture Cranial cervical instability

The atlantooccipital joint is a condylar joint that has little inherent bony stability. Stability is provided by the ligaments about the joint. The primary stabilizers are the paired alar ligaments, the articular capsule, and the tectorial membrane (a continuation of the posterior longitudinal ligament and the major stabilizer of the atlantooccipital joint). In children, this articulation is not as well formed as in adults and it is less cup-shaped. Therefore, there is less resistance to translational forces.[16,27,30,43,44,273] Sectioning of the tectorial membrane in biomechanical cadaver studies have resulted in instability from the occiput to C2.[126,149]

Associated Injuries with and Signs and Symptoms of Atlantooccipital Instability

Diagnosis may be difficult because atlantooccipital dislocation is a ligamentous injury. Spontaneous reduction after initial immobilization may occur and up to 60% may be missed on initial examination.[149,283,286] Although patients with this injury have a history of trauma, some may have no neurologic findings. Others, however, may have symptoms such as cranial nerve injury, vomiting, headache, torticollis, or motor or sensory deficits.[43,49,58,123,138,223] Brain stem symptoms, such as ataxia and vertigo, may be caused by vertebrobasilar vascular insufficiency. Closed head injury and facial trauma are frequently associated with atlantooccipital instability. The high association of closed head injures that may mask other physical findings. Unexplained weakness or difficulty in weaning off a ventilator after a closed head injury may be a sign of this injury.

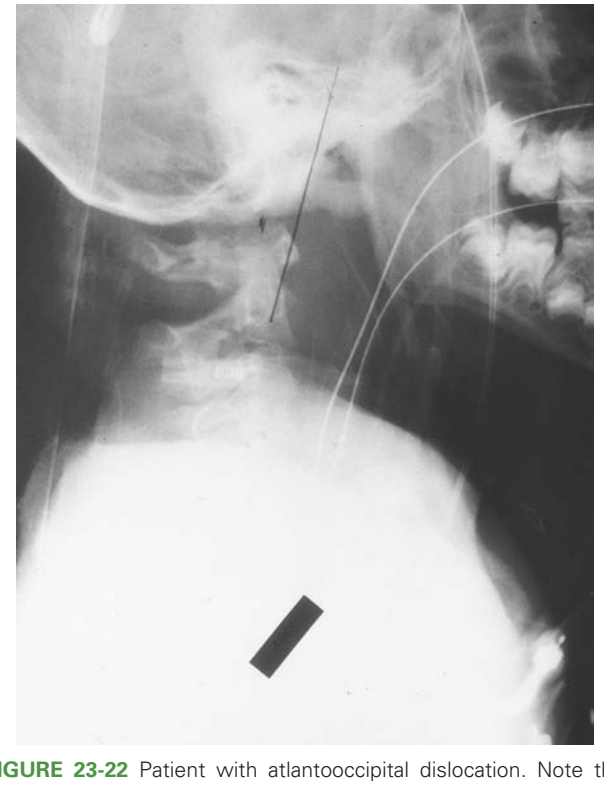

FIGURE 23-22 Patient with atlantooccipital dislocation. Note the forward displacement of the Wackenheim line and the significant anterior soft tissue swelling.

Imaging and Other Diagnostic Studies for Atlantooccipital Instability

The treating physician must have a high index of suspicion in children with closed head injuries or associated facial trauma and must be aware of the radiographic findings associated with atlantooccipital dislocation. A significant amount of anterior soft tissue swelling usually can be seen on a lateral cervical spine radiograph. This increased anterior soft tissue swelling should be a warning sign that an atlantooccipital dislocation may have occurred.

Radiographic findings that aid in the diagnosis of atlantooccipital dislocation are the Wackenheim line, Powers ratio, dens–basion interval, and occipital condylar distance. The Wackenheim line is drawn along the clivus and should intersect tangentially the tip of the odontoid. A shift anterior or posterior of this line represents either an anterior or posterior displacement of the occiput on the atlas (Fig. 23-23). This line is probably the most helpful because it is reproducible and easy to identify on a lateral radiograph. The Powers ratio (see Fig. 23-1) is determined by drawing a line from the basion to the posterior arch of the atlas (BC) and a second line from the opisthion to the anterior arch of the atlas (OA). The length of line BC is divided by the length of the line OA, producing the Powers ratio. A ratio of more than 1.0 is diagnostic of anterior atlantooccipital dislocation. A ratio of less than 0.7 is diagnostic of posterior atlantooccipital dislocation. Values between 1.0 and 0.7 are considered normal.[156] The Powers ratio has the advantage of not being affected by magnification of the radiograph, but the landmarks may be difficult to define. Another radiographic measurement is the dens–basion interval. The distance is measured between the apex of the dens and the tip of the clivus (basion). If the interval measures more than 1.2 cm, then disruption of the atlantooccipital joint has occurred.[44,235] Kaufman et al.[153] described an occipital condylar facet distance of more than 5 mm from the occipital condyle to the C1 facet as indicative of atlantooccipital injury. They recommended measuring this distance from five reference points along the occipital condyle and the C1 facet (Fig. 23-24). Harris et al.[125,126] described the basion–axial interval. A posterior axial line (PAL) is drawn tangential to the posterior wall of the C2 vertebra. A line parallel to the PAL is drawn through the basion. Normal values for children are from 0 to 12 mm. Sun et al.[286] proposed

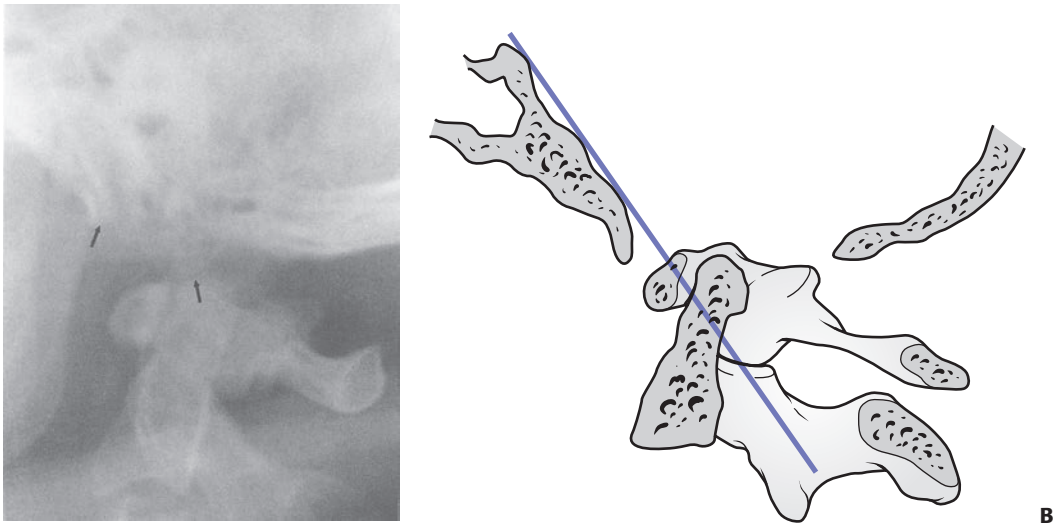

FIGURE 23-23 Craniovertebral dislocation. **A:** Lateral view shows extensive soft tissue swelling. The distance between the basion and the dens is 2.4 cm (*arrows*) (normal is 1 cm). **B:** Line drawing shows the abnormal relationship between the occiput and the upper cervical spine. (From El-Khoury GY, Kathol MH. Radiographic evaluation of cervical trauma. *Semin Spine Surg.* 1991;3:3–23, with permission.)[80]

using an interspinous ratio that was sensitive and specific in detecting tectorial membrane injuries. The interspinous distance between C1 and C2 and between C2 and C3 are determined on lateral radiographs or CT scans. The ratio C1 to C2:C2 to C3 of more than 2.5 was indicative of injury to the tectorial membrane.[149,218,286]

MRI is useful in diagnosing atlantooccipital dislocation by showing soft tissue edema around the tectorial membranes and lateral masses and ligament injury or disruption.[45] Steinmetz et al.[283] and Sun et al.[286] suggested that the disruption of the tectorial membrane is the critical threshold for instability of the occipitoatlantal joint. Disruption of the tectorial membrane can best be identified by MRI.

Classification of Atlantooccipital Instability

Atlantooccipital dislocation is classified radiographically into three types: longitudinal distraction with axial occipital separation, rotational injury, and anterior or posterior occipital displacement with respect to the atlas.[294]

Treatment Options for Atlantooccipital Instability

Nonoperative Treatment of Atlantooccipital Instability

Because atlantooccipital dislocation is a ligamentous injury, nonoperative treatment usually is unsuccessful. Although

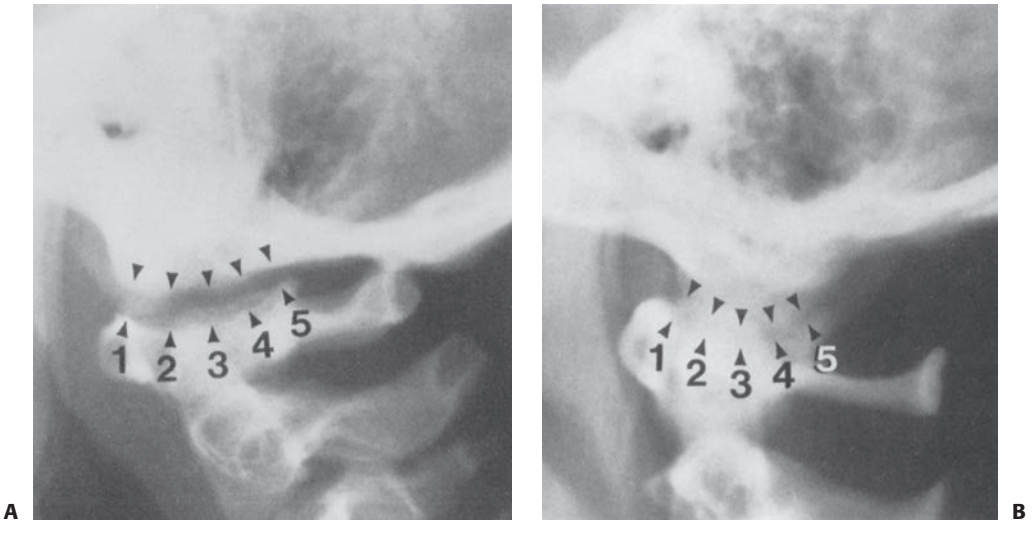

FIGURE 23-24 Atlantooccipital joint measurement points 1 through 5 demonstrated on a normal cross-table lateral skull radiograph in an 8-year-old **(A)** and a 14-year-old **(B).** (From Kaufman RA, Carroll CD, Buncher CR. Atlantooccipital junction: standards for measurement in normal children. *AJNR Am J Neuroradiol.* 1987; 8:995–999, with permission.)

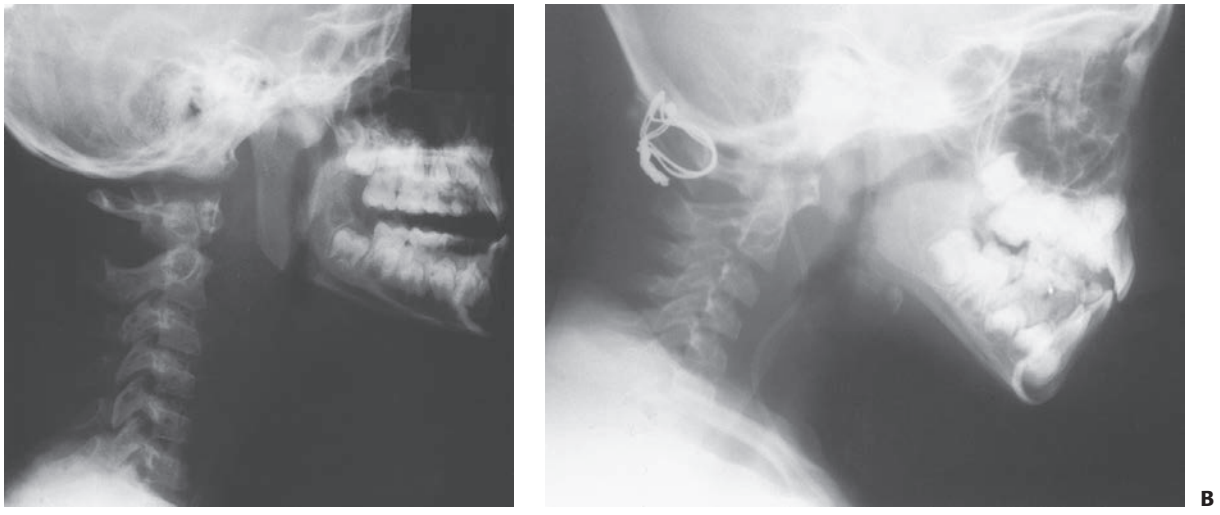

FIGURE 23-25 **A:** Lateral radiograph of a patient with atlantooccipital dislocation. Note the increase in the facet condylar distance. **B:** Lateral radiograph after occipital C1 arthrodesis.

Farley et al.[84] reported successful stabilization in a halo, Georgopoulos et al.[103] found persistent atlantooccipital instability after halo immobilization. Immobilization in a halo should be used with caution: if the vest or cast portion is not fitted properly, displacement can increase (Fig. 23-25) because the head is fixed in the halo but movement occurs because of inadequate immobilization of the trunk in the brace or cast. Traction should be avoided because it can cause distraction of the skull from the atlas (Table 23-8).

Operative Treatment of Atlantooccipital Instability

Surgical stabilization is the recommended treatment.[137] Posterior arthrodesis can be performed in situ, with wire fixation or fixation with a contoured Luque rod and wires or contoured rod and screw fixation.[13,86,109,122,128,130,193,247,249] If the C1 to C2 articulation is stable, arthrodesis may be only from the occiput to C1 so that C1 to C2 motion is preserved.[279,316] Stability of the C1 to C2 articulation often is questionable, and arthrodesis may need to be extended to C2.[150] Most researchers also have expressed reservations about the chance of obtaining fusion in the narrow atlantooccipital interval and have recommended arthrodesis from the occiput to C2.[15,149]

For a patient who presents very late with an unreduced dislocation, an in situ arthrodesis is recommended. DiBenedetto and Lee[67] recommended arthrodesis in situ with a suboccipital craniectomy to relieve posterior impingement.

TABLE 23-8 Atlantooccipital Instability

Nonoperative Treatment	
Indications	**Relative Contraindications**
Nonoperative treatment is usually unsuccessful	

Instability at the atlantooccipital joint is increased in patients with Down syndrome as well as in those with a high cervical arthrodesis below the axis. These patients may be at risk of developing chronic instability patterns and are at higher risk of having instability after trauma.

Several methods of obtaining an occiput to C2 arthrodesis are available to the treating surgeon. The decision of which technique is used usually is based on stability and anatomy of the upper cervical spine of the patient. Because of the inherent instability associated with traumatic injuries to the upper cervical spine, internal fixation is preferred. Instrumentation with rods and screws may not always be possible because of the patient's size and anatomy. When instrumentation cannot be used, the surgeon must be aware of fusion and other stabilization techniques that may rely on stability obtained from the bone graft or wires and cables. These techniques will usually need to be supplemented with external immobilization such as a halo vest or cast or a Minerva cast. Acute hydrocephalus can occur after this injury or in the early postoperative period because of changes in cerebrospinal fluid flow at the cranial-cervical junction.

Surgical Procedures for Occiput-C1 Injuires

Surgical Procedure: Occiput to C2 Arthrodesis Without Internal Fixation

In younger children in whom the posterior elements are absent at C1 or separation is extensive in the bifid part of C1 posteriorly, posterior cervical arthrodesis from the occiput to C2 with iliac crest bone graft may be performed using a periosteal flap from the occiput to provide an osteogenic tissue layer for the bone graft (Fig. 23-26).[163]

Preoperative Planning

See p. 859 for preoperative planning for cervical spine injury.

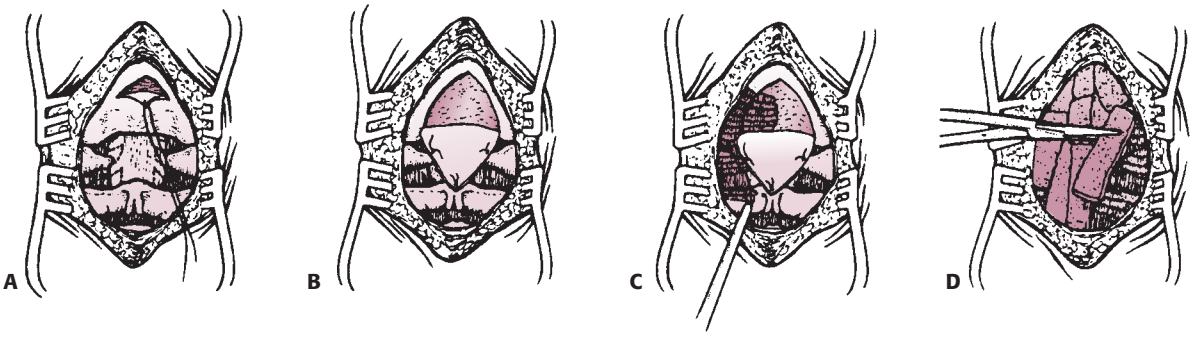

FIGURE 23-26 Technique of occipitocervical arthrodesis used when the posterior arch of C1 is absent. **A:** Exposure of the occiput, atlas, and axis. **B:** Reflection of periosteal flap to cover defect in atlas. **C:** Decortication of exposed vertebral elements. **D:** Placement of autogenous cancellous iliac bone grafts. (From Koop SE, Winter RB, Lonstein JE. The surgical treatment of instability of the upper part of the cervical spine in children and adolescents. *J Bone Joint Surg Am.* 1984;66:403, with permission.)

Positioning

See p. 859 for positioning in cervical spine injury. The patient is placed in a prone position using Gardner-Wells tongs or a halo ring attached to a Mayfield headrest. A radiograph is obtained to evaluate the position of the head and cervical spine in the prone position. The radiograph also aids in identifying landmarks and levels; although once the skin incision is made, the occiput and spinous processes can be palpated.

Surgical Approach

See p. 860 for posterior approach.

Technique

A straight posterior incision is made from the occiput to about C3, with care not to expose below C2 to avoid extension of the fusion to lower levels. An epinephrine and lidocaine solution is injected into the cutaneous and subcutaneous tissues to help control local skin and subcutaneous bleeding. The incision is deepened in the midline to the spinous processes of C2. Once identified, the level of the posterior elements of C1 or the dura is more easily found. After C2 is identified, subperiosteal dissection is carried proximally. Extraperiosteal dissection is used to approach the occiput (see Fig. 23-26A). The dura is not completely exposed; if possible, any fat or ligamentous tissue present is left intact. The interspinous ligaments also should be left intact.

The occipital periosteum is mobilized by making a triangular incision directly on the posterior skull, with the apex posteriorly and the broad base over the foramen magnum region. A flap of 3 or 4 cm at the base can be created. With subperiosteal elevation, the periosteum can be reflected from the occiput to the spinous processes of C2 (see Fig. 23-26B). The apex of the flap is sutured to the spinous process of C2 and is attached laterally to any posterior elements that are present at C1 or other lateral soft tissues. After the periosteum is secured to the bone and any rudimentary C1 ring is exposed subperiosteally, a power burr is used to decorticate the occiput and any exposed portions of C1 and C2 (see Fig. 23-26C).

Iliac crest bone graft is harvested, and struts of iliac bone are placed across the area on the periosteal flap (see Fig. 23-26D). No internal fixation is used other than sutures to secure the periosteum. The wound is closed in a routine fashion, and a body jacket or cast is applied and attached to the halo (Table 23-9).

Postoperative Care

The halo cast is worn until radiographs show adequate posterior arthrodesis, usually in 8 to 12 weeks.

Surgical Procedure: Occiput to C2 Arthrodesis with Triple-Wire Fixation

In patients in whom the posterior elements of C1 and C2 are intact, a triple wire technique, as described by Wertheim and Bohlman,[311] can be used (Fig. 23-27). The wires are passed through the outer table of the skull at the occipital protuberance. Because the transverse and superior sagittal sinuses are cephalad to the protuberance, they are not endangered by wire passage.

Preoperative Planning

See p. 859 for preoperative planning in cervical spine injury.

Positioning

For positioning see p. 859. The patient is placed prone, and a lateral radiograph is obtained to document proper alignment. The subcutaneous tissues are injected with an epinephrine solution (1:500,000).

TABLE 23-9 Occiput to C2 Arthrodesis Without Internal Fixation

Surgical Steps

- Make incision from occiput to C3
- Identify C2
- Dissect subperiosteally proximally and extraperiosteally to approach occiput
- Mobilize occipital periosteum and reflect from occiput to spinous processes of C2
- Secure periosteum to bone
- Decorticate occiput and exposed portions of C1 and C2
- Harvest iliac crest bone graft and place across periosteal flap
- No internal fixation is used
- Close wound and apply body jacket or cast attached to halo

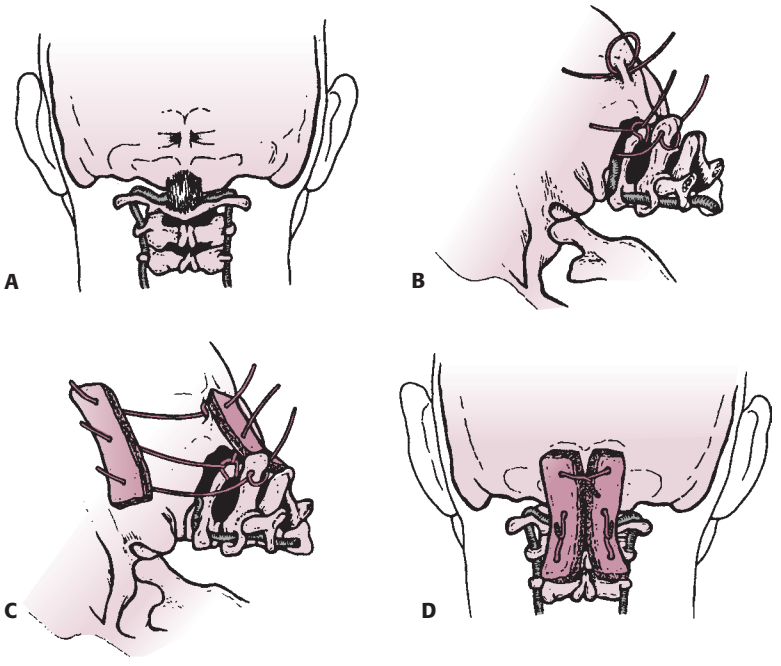

FIGURE 23-27 Technique of occipitocervical arthrodesis used in older adolescents with intact posterior elements of C1 and C2. **A:** A burr is used to create a ridge in the external occipital protuberance, and then a hole is made in the ridge. **B:** Wires are passed through the outer table of the occiput, under the arch of the atlas, and through the spinous process of the axis. **C:** Corticocancellous bone grafts are placed on the wires. **D:** Wires are tightened to secure grafts in place. (From Wertheim SB, Bohlman HH. Occipitocervical fusion: indications, technique, and long-term results. *J Bone Joint Surg Am.* 1987;69: 833, with permission.)[311]

Surgical Approach

See p. 860 for posterior approach.

Technique

A midline incision is made extending from the external occipital protuberance to the spine of the third cervical vertebra. The paraspinous muscles are sharply dissected subperiosteally with a scalpel, and a periosteal elevator is used to expose the occiput and cervical laminae, with special care to stay in the midline to avoid the paramedian venous plexus.

At a point 2 cm above the rim of the foramen magnum, a high-speed diamond burr is used to create a trough on either side of the protuberance, making a ridge in the center (see Fig. 23-27A). A towel clip is used to make a hole in this ridge through only the outer table of bone. A 20-gauge wire is looped through the hole and around the ridge; then another 20-gauge wire is looped around the arch of the atlas. A third wire is passed through a hole drilled in the base of the spinous process of the axis and around this structure, giving three separate wires to secure the bone grafts on each side of the spine (see Fig. 23-27B).

A thick, slightly curved graft of corticocancellous bone of premeasured length and width is removed from the posterior iliac crest. The graft is divided horizontally into two pieces, and three holes are drilled into each graft (see Fig. 23-27C). The occiput is decorticated and the grafts are anchored in place with the wires on both sides of the spine (see Fig. 23-27D). Additional cancellous bone is packed around and between the two grafts. The wound is closed in layers over suction drains (Table 23-10).

Postoperative Care

Either a rigid cervical orthosis or a halo cast is worn for 6 to 12 weeks, followed by a soft collar that is worn for an additional 6 weeks.

Surgical Procedure: Occipitocervical Arthrodesis

Preoperative Planning

See p. 859 for preoperative planning in cervical spine injury.

Positioning

See p. 859 for positioning in cervical spine injury. A halo ring is applied initially with the patient supine. The patient is carefully placed in the prone position, the halo is secured to the operating table with a halo positioning device, and the alignment of the occiput and the cervical spine is confirmed with a lateral radiograph.

Surgical Approach

See p. 860 for posterior approach.

Technique

The midline is exposed from the occiput to the second or third cervical vertebra. Particular care is taken to limit the lateral

TABLE 23-10 Occiput to C2 Arthrodesis with Triple-Wire Fixation

Surgical Steps

- Expose occiput and cervical laminae avoiding the paramedian venous plexus
- Create trough on either side of occipital protuberance and make a hole in the outer table of bone of the ridge created
- Pass three wires to secure bone graft
- Harvest bone graft from iliac crest and divide into two pieces
- Drill three holes in each graft
- Decorticate occiput and anchor grafts with the wires and pack with cancellous bone
- Close wound in layers

dissection to avoid damaging the vertebral arteries.[87] Four holes, aligned transversely, with two on each side of the midline, are made with a high-speed drill through both cortices of the occiput, leaving a 1-cm osseous bridge between the two holes of each pair. The holes are placed caudal to the transverse sinuses. A trough is fashioned into the base of the occiput to accept the cephalad end of the bone graft. A corticocancellous graft is obtained from the iliac crest and is shaped into a rectangle, with a notch created in the inferior base to fit around the spinous process of the second or third cervical vertebra. The caudal extent of the intended arthrodesis (the second or third cervical vertebra) is determined by the presence or absence of a previous laminectomy, congenital anomalies, or the level of the instability. On each side, a looped 16- or 18-gauge Luque wire is passed through the burr holes and looped on itself. Wisconsin button wires (Zimmer, Warsaw, IN) are passed through the base of the spinous process of either the second or the third cervical vertebra. The wire that is going into the left arm of the graft is passed through the spinous process from right to left. The graft is placed into the occipital trough superiorly and about the spinous process of the vertebra that is to be at the caudal level of the arthrodesis (the second or third cervical vertebrae). The graft is precisely contoured so that it fits securely into the occipital trough and around the inferior spinous process before the wires are tightened. The wires are subsequently crossed, twisted, and cut. An intraoperative radiograph is made at this point to assess the position of the graft and the wires as well as the alignment of the occiput and the cephalad-cervical vertebrae. Extension of the cervical spine can be controlled by positioning of the head with the halo frame, by adjustment of the size and shape of the graft, and to a lesser extent by appropriate tightening of the wires (Fig. 23-28 and Table 23-11).

Surgical Procedure: Atlantooccipital Arthrodesis

Although most patients with atlantooccipital dislocations are treated with fusion from the occiput to C2 or lower, Sponseller and Cass[279] described occiput–C1 fusion in two children with atlantooccipital arthrodesis who had complete or near-complete neurologic preservation. Their rationale was that rotation would be preserved by sparing the C1 to C2 articulation from fusion and that less stress would be concentrated on the lower cervical spine by fusing one level instead of two. In both of their patients, stable fusion was obtained and neurologic status was maintained.

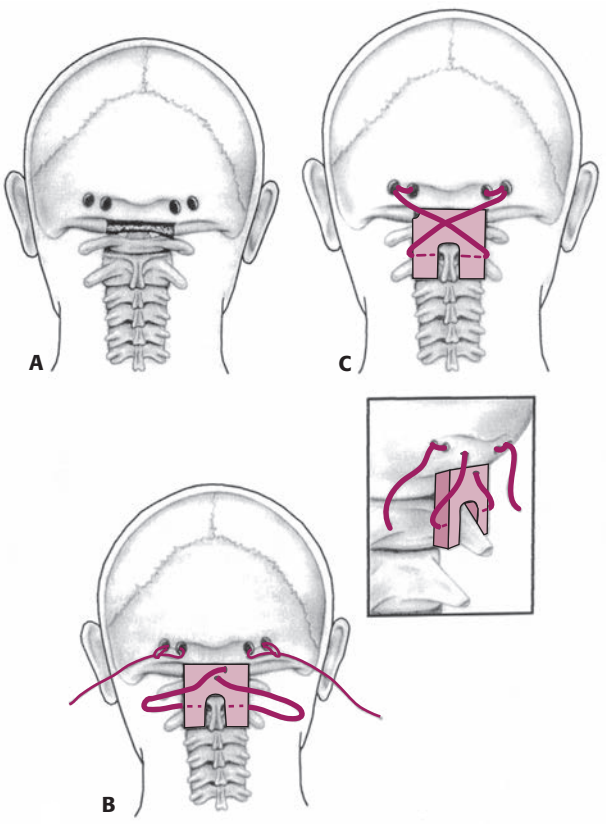

FIGURE 23-28 Occipitocervical arthrodesis. **A:** Four burr holes are placed into the occiput in transverse alignment, with two on each side of the midline, leaving a 1-cm osseous bridge between the two holes of each pair. A trough is fashioned into the base of the occiput. **B:** Sixteen- or 18-gauge Luque wires are passed through the burr holes and looped on themselves. Wisconsin button wires are passed through the base of the spinous process of either the second or third cervical vertebra. The graft is positioned into the occipital trough and spinous process of the cervical vertebra at the caudal extent of the arthrodesis. The graft is locked into place by the precise contouring of the bone. **C:** The wires are crossed, twisted, and cut. The extension of the cervical spine can be controlled by positioning of the head with the halo frame, by adjustment of the size and shape of the bone graft, and to a lesser extent by tightening of the wires. (From Dormans JP, Drummond DS, Sutton LN, et al. Occipitocervical arthrodesis in children. *J Bone Joint Surg Am.* 1995;77:1234–1240, with permission.)[72]

TABLE 23-11 Occipitocervical Arthrodesis

Surgical Steps

- Expose midline from occiput to second or third cervical vertebra
- Create four transverse holes, two on each side of midline of occiput
- Create trough into base of occiput to accept bone graft
- Shape bone graft from iliac crest into rectangle
- Determine caudal extent of arthrodesis
- Pass wires
- Place precisely contoured graft into occipital trough and spinous process at caudal level of arthrodesis
- Cross, twist, and cut wires
- Assess position of graft and alignment

Preoperative Planning

See p. 859 for preoperative planning in cervical spine injury. Before surgery, radiographs and CT scans should be reviewed to be sure a bifid or hypoplastic C1 arch is not present. A halo ring is applied before positioning the patient.

Positioning

See p. 859 for positioning in cervical spine injury. The patient is placed prone, the halo ring is secured to the operating table with a halo positioning device, and the alignment of the occiput

and the cervical spine is confirmed with a lateral radiograph, using a halo ring and attachment.

Surgical Approach

See p. 860 for posterior approach.

Technique

The base of the skull to the ring of C1 is exposed, and the periosteum of the skull is elevated so that it forms a flap from the foramen magnum located posteriorly–superiorly.

The ring of C1 is carefully exposed, with care taken not to dissect more than 1 cm to either side of the midline to protect the vertebral arteries. Care also is taken not to expose any portion of C2 to prevent bridging of the fusion. The dissection of C1 should be done gently. A trough for the iliac crest bone graft is made in the occiput at a level directly cranial to the ring of C1. This trough is unicortical only and extends the width of the exposed portion of C1. Superior to this, two holes are drilled through the occiput as close to the trough as possible to avoid an anteriorly translating vector on the skull when tightening it down to C1. One 22-gauge wire is passed through the holes and another is placed around the ring of C1. The periosteal flap is turned down to bridge the occiput–C1 interval. A small, rectangular, bicortical, iliac crest bone graft approximately 1.5 cm wide and 1 cm high is shaped to fit the trough in the occiput; the graft is contoured to fit the individual patient's occiput–C1 interval. The inferior surface of the bone graft is contoured to fit snugly around the ring of C1 to keep it from migrating anteriorly into the epidural space. Two holes are drilled directly above the distal end of the graft, and the wire around C1 is passed through these holes, forming two distal strands; the wire passed through the occiput forms two proximal strands. These are twisted together and sequentially tightened to apply slight compression to the bone graft. This keeps the graft in the occipital trough and prevents migration into the canal by the occiput. Additional cancellous bone is added to any available space (Table 23-12).

Postoperative Care

The halo vest is kept in place for 6 to 8 weeks in a young child and for as long as 12 weeks in an older child or adolescent. Union is confirmed by a lateral radiograph of the posterior occiput–C1 interval and by flexion–extension lateral views. A rigid cervical collar is used for an additional 2 to 4 weeks to protect the fusion and support the patient's cervical muscles while motion is regained.

Surgical Procedure: Occipitocervical Arthrodesis with Contoured Rod and Segmental Wire

Occipitocervical arthrodesis using a contoured rod and segmental wire has the advantage of achieving immediate stability of the occipitocervical junction (Fig. 23-29), which allows the patient to be immobilized in a cervical collar after surgery, avoiding the need for halo immobilization.

Preoperative Planning

See p. 859 for preoperative planning in cervical spine injury.

TABLE 23-12 Atlantooccipital Arthrodesis

Surgical Steps

- Expose base of skull to ring of C1 and elevate periosteum to create flap
- Create unicortical trough in occiput at level directly cranial to ring of C1
- Drill two holes through occiput close to trough
- Pass wires
- Bridge occiput-C1 interval with periosteal flap
- Shape iliac crest bone graft to fit in trough and place graft in occiput-C1 interval
- Drill two more holes above distal end of graft and pass wires
- Should form two strands and wire through occiput forms two strands
- Twist wires together and tighten
- Add additional cancellous bone to any available space

Positioning

See p. 859 for positioning in cervical spine injury.

Surgical Approach.

See p. 860 for posterior approach to the cervical spine.

Technique

The base of the occiput and the spinous processes of the upper cervical vertebrae are approached through a longitudinal midline incision, which extends deep within the relatively avascular intermuscular septum. The entire field is exposed subperiosteally.

A template of the intended shape of the stainless steel rod is made with the appropriate length of Luque wire. Two burr holes are made on each side, about 2 cm lateral to the midline and 2.5 cm above the foramen magnum. Care should be taken to avoid the transverse and sigmoid sinus when making these burr holes. At least 10 mm of intact cortical bone should be left between the burr holes to ensure solid fixation. Luque wires or Songer cables are passed in an extradural plane through the two burr holes on each side of the midline. The wires or cables are passed sublaminar in the upper cervical spine. The rod is bent to match the template; this usually will have a head–neck angle of about 135 degrees and slight cervical lordosis. A Bend Meister (Sofamor/Danek, Memphis, TN) may be helpful in bending the rod. The wires or cables are secured to the rod. The spine and occiput are decorticated, and autogenous cancellous bone grafting is performed (Table 23-13).

Surgical Procedure: Plate and Rod Fixation Occiput-C2

This technique uses a contoured occipital plate that attaches to a rod for fixation.

Preoperative Planning

See p. 859 for preoperative planning in cervical spine injury.

Positioning

See p. 859 for positioning in cervical spine injury.

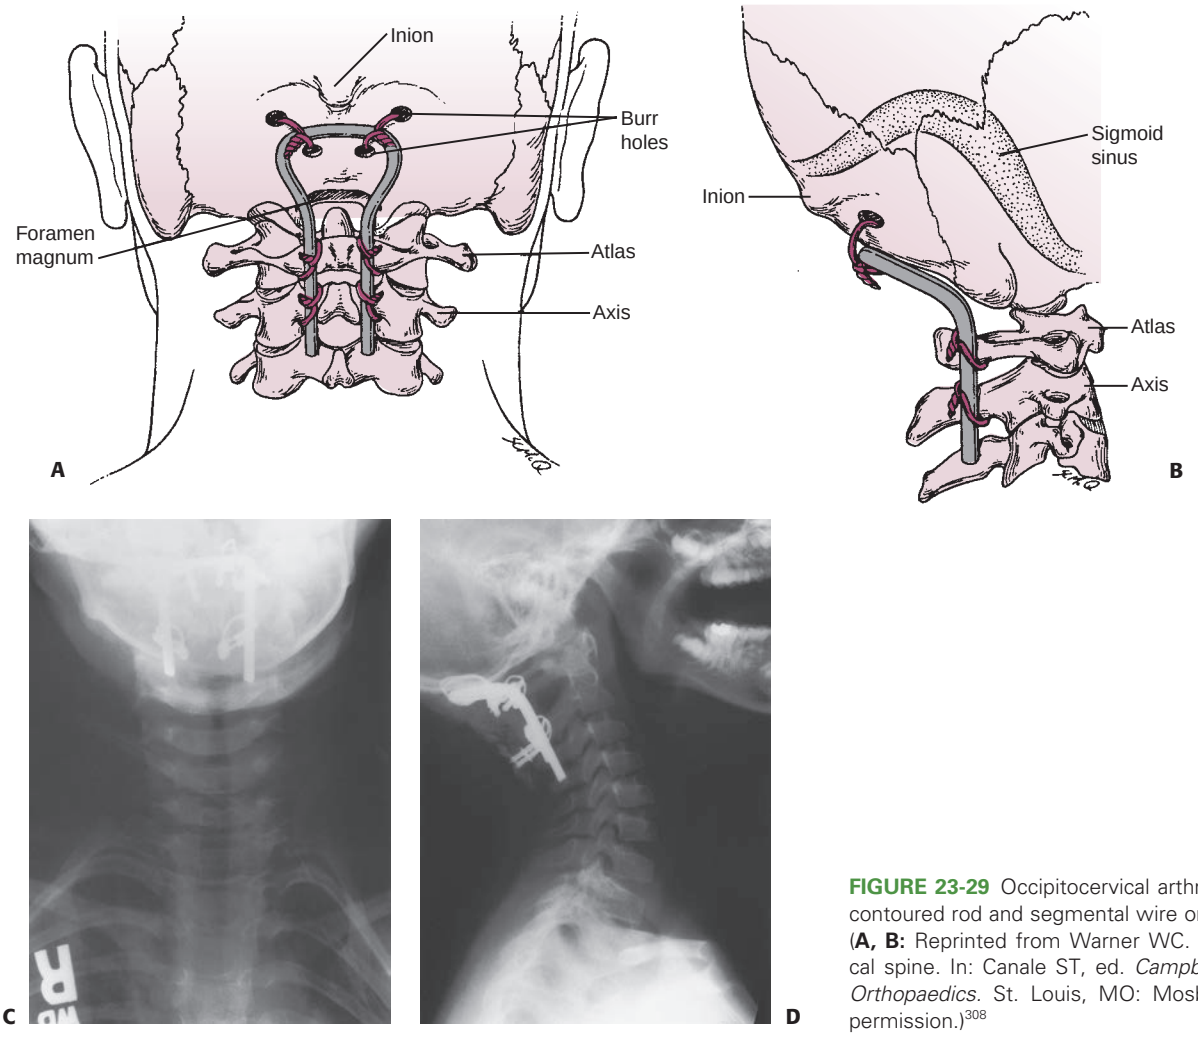

FIGURE 23-29 Occipitocervical arthrodesis using a contoured rod and segmental wire or cable fixation. (**A, B:** Reprinted from Warner WC. Pediatric cervical spine. In: Canale ST, ed. *Campbell's Operative Orthopaedics*. St. Louis, MO: Mosby, 1998, with permission.)[308]

Surgical Approach

See p. 860 for posterior approach.

Technique

Screw fixation is used in the occiput, and, if the anatomy allows, screw fixation may be used at C1 and C2. The occipital plate is positioned in the midline (occipital keel) between the external occipital protuberance and the posterior border of the foramen magnum. The plate is contoured for an anatomic fit against the occiput. Avoid repeated bending of the plate because this may compromise its integrity. It may be necessary to contour the bone of the occiput to allow for an optimal fit of the plate. With an appropriate-size drill bit and guide that match the screw diameter, a hole is drilled into the occiput to the desired predetermined depth. Drilling must be done through the occipital plate to ensure proper drilling depth. Each hole should be completely tapped. The appropriate size occipital screw is inserted and provisionally tightened. The rest of the screws are then inserted and hand-tightened.

If the anatomy allows, a C1 lateral mass screw and a C2 pedicle screw can be placed. If the anatomy does not allow placement of screws, then sublaminar wires or cables may be used for fixation at C1 and C2. The rods are bent to approximately 130 to 135 degrees to allow attachment to the occipital plate. The rods are placed into the implants and stabilized by tightening the set screws. If cables or sublaminar wires are used, these are tightened to secure the rods to the cervical spine. Final tightening of the occipital plate set screws is performed, and all connections of the final construct are checked before wound closure (Table 23-14).

TABLE 23-13 Occipitocervical Arthrodesis with Contoured Rod and Segmental Wire

Surgical Steps

- Expose base of occiput to spinous process of upper cervical vertebrae
- Create a template of intended shape of rod
- Make two burr holes on each side 2 cm lateral from midline and 2.5 cm above foramen magnum
- Pass wires or Songer cables
- Bend rod to match template
- Secure wires or cables to rod
- Decorticate spine and occiput and place autogenous cancellous bone graft

TABLE 23-14 Plate and Rod Fixation Occiput to C2

Surgical Steps

- Expose the occiput and spinous processes of the upper cervical vertebrae
- Position plate in midline of occiput
- Contour plate but avoid repeated bending—may be necessary to contour bone
- Drill holes in occiput and tap
- Insert screws and provisionally tighten
- Place C1 lateral mass screw and C2 pedicle screw or sublaminar cable or wire
- Bend rod to allow attachment to occipital plate
- Place rods into implants and tighten
- Perform final tightening of occipital plate set screws
- Check all connections

Postoperative Care

The cervical spine is immobilized in an orthosis for 8 to 12 weeks.

Pitfalls and Preventative Measures of Surgical Treatment of Atlantooccipital Instability

It is important to remember that acute hydrocephalus can occur after this injury or in the early postoperative period because of changes in cerebrospinal fluid flow at the cranial cervical junction. See p. 860 for further pitfalls with the posterior approach.

C1-C2 Injuries

Fractures of the Atlas

A fracture of the ring of C1 (Jefferson fracture) is a rare injury and accounts for less than 5% of all cervical spine fractures in children.[12,28]

Assessment of Fractures of the Atlas

Mechanisms of Injury of Fractures of the Atlas

This fracture is caused by an axial load applied to the head.[20,29,147,150,186,245,293] The force is transmitted through the occipital condyles to the lateral masses of C1, causing a disruption in the ring of C1, usually in two places, with fractures occurring in both the anterior and posterior rings. In children, an isolated single fracture of the ring can occur with the remaining fracture hinging on a synchondrosis.[24] This is an important distinction in children because fractures often occur through a normal synchondrosis. In addition, there can be plastic deformation of the ring with no evidence of a fracture.[18,150,242,292] This distinction can be seen on plain radiographs and CT scan, with fractures appearing through what appears to be normal physes. As the lateral masses separate, the transverse ligament may be ruptured or avulsed, resulting in C1 and C2 instability.[195] If the two lateral masses are widened more than 7 mm beyond the borders of the axis on an anteroposterior radiograph, then an injury to the transverse ligament is presumed.

Associated Injuries with and Signs and Symptoms of Fractures of the Atlas

Other cervical spine fractures may be present with an atlas fracture, and MRI should be carefully scrutinized to identify other fractures.[189]

The classic signs of an atlas fracture in a child are neck pain, cervical muscle spasm, decreased range of motion, and head tilt.[150]

Imaging and other Diagnostic Studies of Fractures of the Atlas

Injury to the transverse ligament may be from a rupture of the ligament or an avulsion of the ligament attachment to C1. Jefferson fractures may be evident on plain radiographs, but CT scans are superior at showing this injury (Fig. 23-30). CT scans also can be used to follow the progress of healing. MRI is useful in determining the integrity of the transverse atlantal ligament (TAL) and detecting fractures through the normal synchondroses of the atlas. With a fracture through a synchondrosis, associated edema and hemorrhage are seen on MRI.[165]

Classification of Fractures of the Atlas

Treatment algorithms for Jefferson fractures are based on the integrity of the TAL. These fractures are considered potentially unstable if the TAL is disrupted. Dickman[68] classified these unstable fractures into Type I, an intrasubstance tear of the TAL and Type II, an avulsion fracture of the insertion of the TAL. According to Spence et al.,[277] a loss of structural properties of the TAL can occur when the combined overhang of the lateral masses of the atlas extends more than 7 mm beyond the lateral masses of the axis.

Treatment Options for Fractures of the Atlas

Nonoperative Treatment of Fractures of the Atlas

Most Atlas fractures are stable fractures and treatment consists of immobilization in an orthosis (rigid collar or sternal occipital mandibular immobilizer), Minerva cast, or halo brace. The extent of this immobilization is debatable and should consider the patient's age and cooperation.[165] Immobilization usually is for 8 weeks but is based on documented healing by CT imaging and no instability on flexion and extension views. If there is excessive widening (7 mm), halo traction followed by halo brace or cast immobilization is recommended. Stability of C1 to C2 must be documented on flexion and extension lateral radiographs once the fracture is healed (Table 23-15).

Operative Treatment of Fractures of the Atlas

Surgery rarely is necessary to stabilize these fractures but may be indicated if there is a documented intrasubstance tear of the transverse atlantal ligament (Fig. 23-31).

Odontoid (Atlantoaxial) Fracture

Odontoid fracture is a relatively common fracture of the cervical spine in children,[87] occurring at an average age of

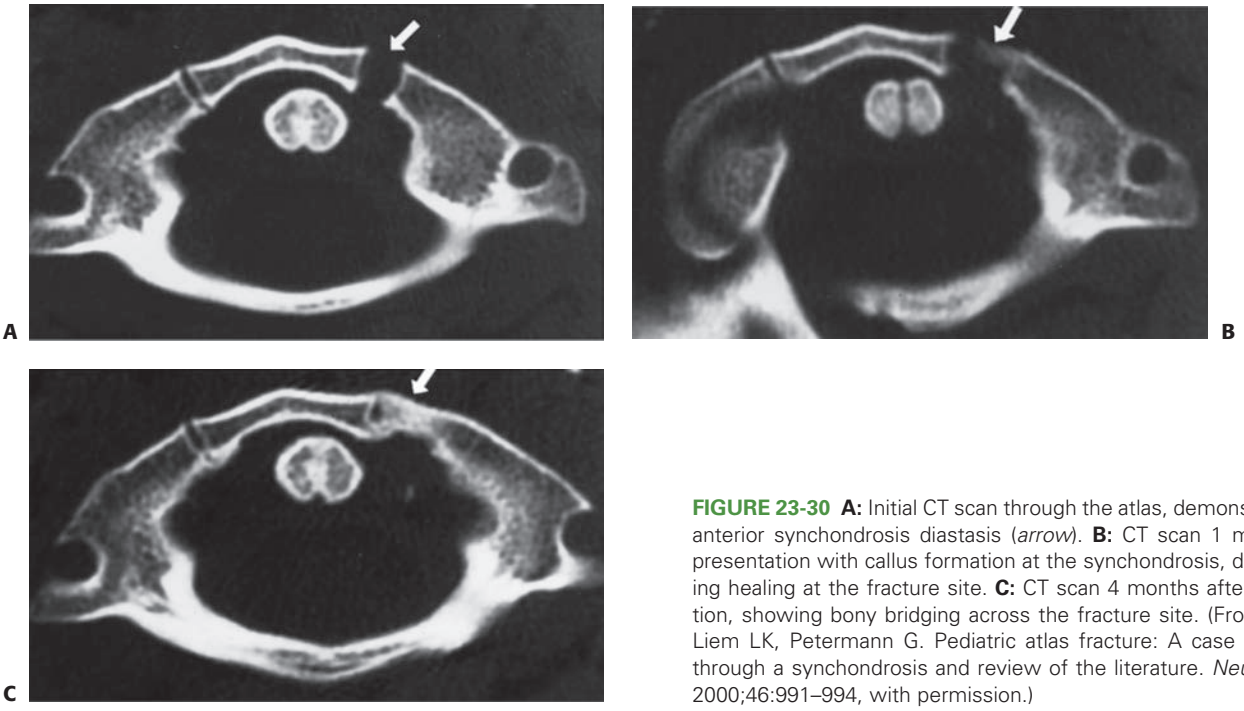

FIGURE 23-30 **A:** Initial CT scan through the atlas, demonstrating left anterior synchondrosis diastasis (*arrow*). **B:** CT scan 1 month after presentation with callus formation at the synchondrosis, demonstrating healing at the fracture site. **C:** CT scan 4 months after presentation, showing bony bridging across the fracture site. (From Judd D, Liem LK, Petermann G. Pediatric atlas fracture: A case of fracture through a synchondrosis and review of the literature. *Neurosurgery*. 2000;46:991–994, with permission.)

4 years.[72,112,264] This fracture accounts for approximately 10% of all cervical spine fractures and dislocations in children. The unique feature of odontoid fractures in children is that the fracture most commonly occurs through the synchondrosis of C2 distally at the base of the odontoid. This synchondrosis is a cartilage line at the base of the odontoid and looks like a physeal or Salter–Harris type I injury. Most odontoid injuries are anteriorly displaced and usually have an intact anterior periosteal sleeve that provides some stability to the fracture when immobilized in extension and allows excellent healing of the fracture.[12,246,257,268] Growth disturbances are uncommon after this type of fracture. This synchondrosis normally closes at about 3 to 6 years of age and adds little to the longitudinal growth of C2.

Assessment of Odontoid Fracture

Mechanism Injury of Odontoid Fracture

A fracture of the odontoid usually is associated with head trauma from a motor vehicle accident or a fall from a height, although it also can occur after trivial head trauma.[261] Odent et al.[214] reported that 8 of 15 odontoid fractures in children were the result of motor vehicle accidents, with the child fastened in a forward-facing seat. The sudden deceleration of the body as it is strapped into the car seat while the head continues to travel forward causes this fracture.

TABLE 23-15 Fractures of the Atlas

Nonoperative Treatment

Indications	Relative Contraindications
Stable atlas fracture	Intrasubstance tear of transverse atlantal ligament

Associated Injuries with and Signs and Symptoms of Odontoid Fracture

Head and facial trauma may be associated with odontoid fracture. Radiographs should be obtained in any child complaining of neck pain. Clinically, children with odontoid fractures complain of neck pain and resist attempts to extend the neck.

Imaging and Other Diagnostic Studies for Odontoid Fracture

Most often, the diagnosis is made by viewing the plain radiographs. Anteroposterior views usually appear normal, and the

FIGURE 23-31 CT scan of an atlas fracture.

diagnosis must be made from lateral views because displacement of the odontoid usually occurs anteriorly. Plain radiographs sometimes can be misleading when the fracture occurs through the synchondrosis and has spontaneously reduced. When this occurs, the fracture has the appearance of a nondisplaced Salter–Harris type I fracture. CT scans with three-dimensional reconstruction views may be needed to fully delineate the injury.[269] MRI also may be useful to diagnose nondisplaced fractures by detecting edema around the injured area, indicating that a fracture may have occurred. Flexion and extension views to demonstrate instability may be obtained if a nondisplaced fracture is suspected. These studies should be done only in a cooperative child and under the direct supervision of the treating physician.

Classification of Odontoid Fracture

Odontoid fractures have been classified in adults by location.[8] Type I (<5%) occurs at the tip of dens at the insertion of alar ligament that connects the dens to the occiput. Type II (>60%) is a fracture at the base of the dens at its attachment to the body of C2. Type III (30%) does not actually involve the dens but is subdentate through the body of C2. Other fractures include a rare longitudinal fracture through dens and body of C2. This classification is useful in older children and adolescents after the C2 synchondrosis has fused. Prior to this most odontoid fractures in children occur through the synchondrosis

Outcome Measures for Odontoid Fracture

Odontoid fractures in children generally heal uneventfully and rarely have complications. Neurologic deficits rarely have been reported after this injury.[214,284] Odent et al.[214] described neurologic injuries in 8 of 15 patients, although most were stretch injuries to the spinal cord at the cervical thoracic junction and not at the level of the odontoid fracture.

TABLE 23-16 Odontoid Fracture

Nonoperative Treatment

Indications	Relative Contraindications
Reducible odontoid fracture	Irreducible fracture
	Grossly unstable fracture

From Warner WC Jr: Pediatric cervical spine. In: Canale ST, Beaty JH, eds. *Campbell's Operative Orthopaedics*, 12th ed., Philadelphia, PA: Elsevier; 2013.

Treatment Options for Odontoid Fracture

Nonoperative Treatment of Odontoid Fracture

Treatment of odontoid fractures is by closed reduction (usually extension or slight hyperextension of the neck), although complete reduction of the translation is not necessary. At least 50% apposition should be obtained to provide adequate cervical alignment, and then the patient should be immobilized in a Minerva or halo cast or custom orthosis. This fracture will heal in about 6 to 8 weeks. After bony healing, stability should be documented by flexion–extension lateral radiographs. Once the Minerva cast or halo is removed, a cervical collar is worn for 1 to 2 weeks. If an adequate reduction cannot be obtained by recumbency and hyperextension, then a head halter or halo traction is needed (Table 23-16).

Operative Treatment of Odontoid Fracture

Rarely, manipulation under general anesthesia is needed for irreducible fractures (Fig. 23-32). Surgery with internal fixation

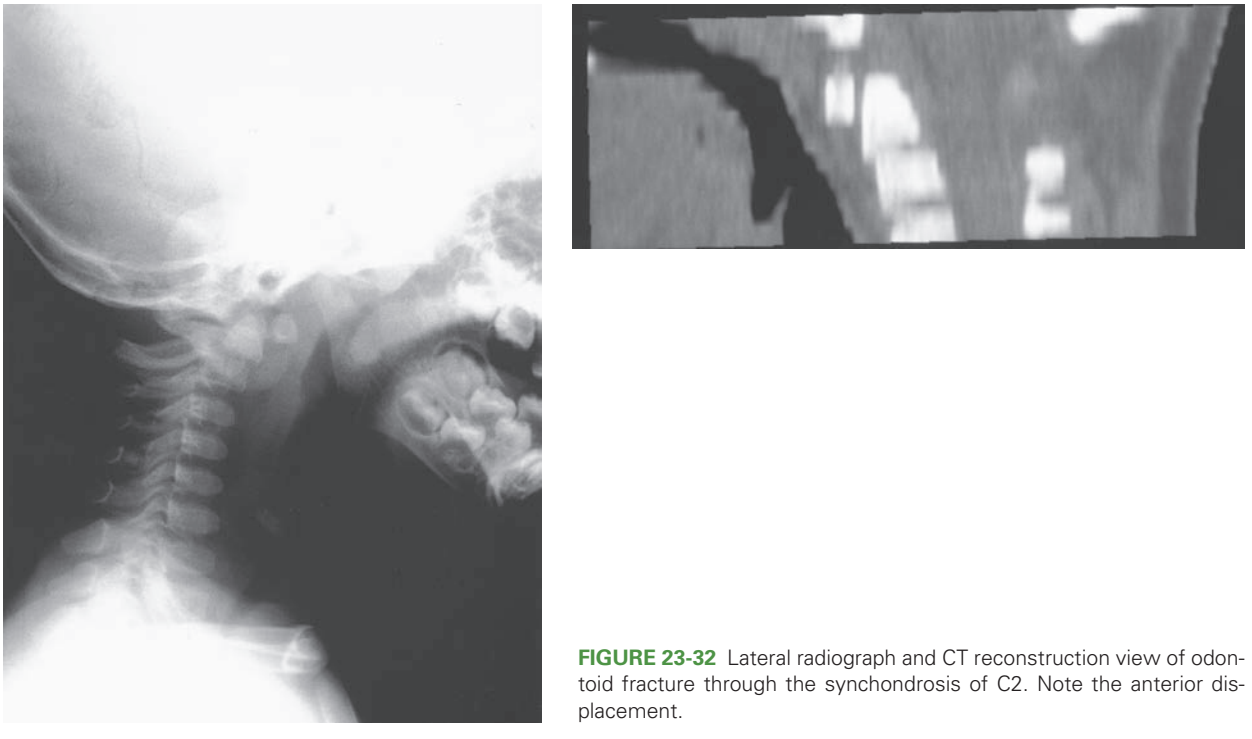

FIGURE 23-32 Lateral radiograph and CT reconstruction view of odontoid fracture through the synchondrosis of C2. Note the anterior displacement.

rarely is needed due to the good results that are achieved with conservative treatment in children.[110,236,259,266,297] In a grossly unstable fracture, a posterior C1 to C2 fusion and instrumentation may be needed (see pp. 877–881; and Table 23-17 for various fusion techniques).[305]

Os Odontoideum

Os odontoideum consists of a round ossicle that is separated from the axis by a transverse gap, which leaves the apical segment without support.

TABLE 23-17 Posterior Fusion Techniques

Atlantoaxial Fusion

GALLIE[96]

Advantage: One wire passed beneath lamina of C1

Disadvantage: Wire may cause unstable C1 vertebra to displace posteriorly and fuse in dislocated position

BROOKS AND JENKINS[42]

Advantage: Greater resistance to rotational movement, lateral bending, and extension

Disadvantage: Requires sublaminar wires at C1 and C2

HARMS AND MELCHER[124]

Advantage: Individual placement of polyaxial screws simplifies technique and involves less risk to C1–C2 facet joint and vertebral artery

Disadvantage: Possible irritation of the C2 ganglion from instrumentation

MAGERL AND SEEMAN[181]

Advantage: Significant improvement in fusion rates over traditional posterior wire stabilization and bone grafting techniques

Disadvantage: Technically demanding and must be combined with Gallie or Brooks fusion for maximum stability

Occipitocervical Fusion

CONE AND TURNER; WILLARD AND NICHOLSON; ROGERS

Required when other bony anomalies occur at occipitocervical junction

WERTHEIM AND BOHLMAN[311]

Wires passed through outer table of skull at occipital protuberance instead of through inner and outer tables near foramen magnum

Lessens risk of danger to superior sagittal and transverse sinuses (which are cephalad to occipital protuberance)

KOOP, WINTER, LONSTEIN[163]

No internal fixation used

Autogenous corticocancellous iliac bone graft

DORMANS ET AL.[72]

Stable fixation is achieved by exact fit of autogenous iliac-crest bone graft and fixation of the spinous process with button wire and fixation of the occiput with wires through burr holes

Can be used in high-risk patients (Downs syndrome) with increased stabilization and shorter immobilization time

CONTOURED ROD, SCREW OR CONTOURED PLATE FIXATION

Has the advantage of achieving immediate stability of the occipitocervical junction

From Warner WC Jr: Pediatric cervical spine. In: Canale ST, Beaty JH, eds. *Campbell's Operative Orthopaedics,* 12th ed., Philadelphia, PA: Elsevier; 2013.[309]

Assessment of Os Odontoideum

Mechanisms of Injury for Os Odontoideum

Fielding et al.[87–91] suggested that this was an unrecognized fracture at the base of the odontoid. Some studies have documented normal radiographs of the dens with abnormal radiographs after trivial trauma. This can be explained by a distraction force being applied by the alar ligaments, which pulls the tip of the fractured odontoid away from the base and produces a nonunion.[127,143,167,244,260,285,301] Other authors believe this to be of congenital origin because of its association with other congenital anomalies and syndromes.[107,270,319] Sankar et al.[254] reported that six of their 16 patients had associated congenital anomalies in the cervical spine and only eight of the 16 reported any previous trauma.[14]

Associated Injuries with and Signs and Symptoms of Os Odontoideum

Cerebellar infarctions due to vertebrobasilar artery insufficiency caused by an unstable os odontoideum were described by Sasaki et al.[255] The presentation of an os odontoideum can be variable. Signs and symptoms can range from a minor to a frank compressive myelopathy or vertebral artery compression. Presenting symptoms may be neck pain, torticollis, or headaches caused by local irritation of the atlantoaxial joint. Neurologic symptoms can be transient or episodic after trauma to complete myelopathy caused by cord compression.[74] Symptoms may consist of weakness and loss of balance with upper motor neuron signs, although upper motor neuron signs may be completely absent. Proprioceptive and sphincter dysfunctions also are common.

Imaging and Other Diagnostic Studies of Os Odontoideum

Os odontoideum usually can be diagnosed on routine cervical spine radiographs, which include an open-mouth odontoid view (Fig. 23-33). Lateral flexion and extension views should be obtained to determine if any instability is present. With os odontoideum, there is a space between the body of the axis and a bony ossicle. The free ossicle of the os odontoideum usually is half the size of a normal odontoid and is oval or round, with smooth sclerotic borders. The space differs from that of an acute fracture in which the space is thin and irregular instead of wide and smooth. The amount of instability should be documented on lateral flexion and extension plain radiographs that allow measurement of both the anterior and posterior displacement of the atlas on the axis. Because the ossicle is fixed to the anterior arch of C1 and moves with the anterior arch of C1 both in flexion and extension, measurement of the relationship of C1 to the free ossicle is of little value because they move as a unit. A more meaningful measurement is made by projecting lines superiorly from the body of the axis to a line projected inferiorly from the posterior border of the anterior arch of the atlas. This gives more information as to the stability of C1 to C2. Another measurement that is very helpful is space available for the cord, which is the distance from the back of the dens to the anterior border of the posterior arch of C1.

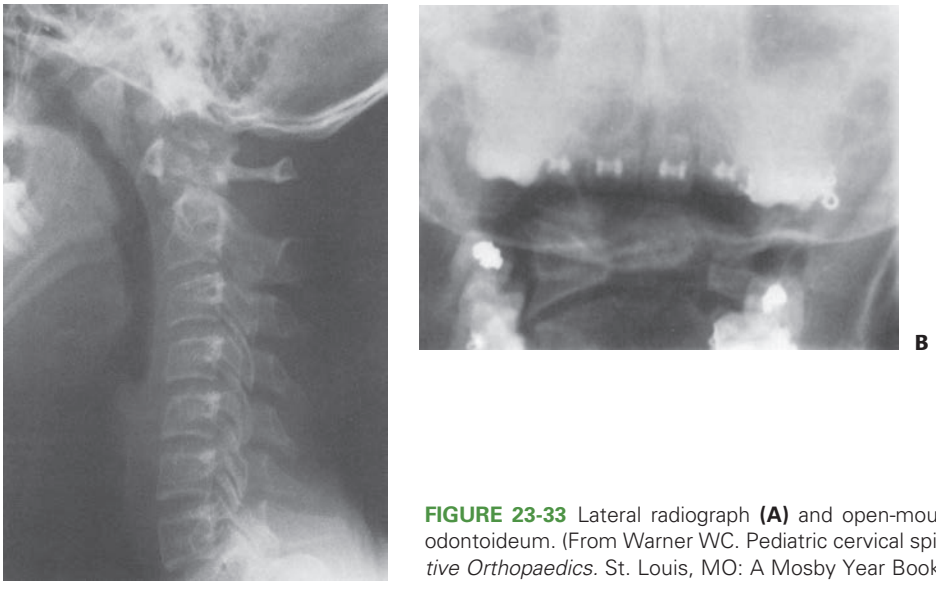

FIGURE 23-33 Lateral radiograph **(A)** and open-mouth odontoid radiograph **(B)** showing os odontoideum. (From Warner WC. Pediatric cervical spine. In: Canale ST, ed. *Campbell's Operative Orthopaedics*. St. Louis, MO: A Mosby Year Book, 1998:2817, with permission.)

Watanabe, Toyama, and Fujimura described two radiographic measurements that correlate with neurologic signs and symptoms.[310] They found that if there is a sagittal plane rotation angle of more than 20 degrees or an instability index of more than 40%, a patient is likely to have neurologic signs and symptoms. The instability index is measured from lateral flexion and extension radiographs. Minimal and maximal distances are measured from the posterior border of the C2 body to the posterior arc of the atlas. The instability index is calculated by the following equation:

$$\text{Instability index} = \text{maximum distance} - \text{minimum distance} + \text{maximum distance} \times 100(\%)$$

The sagittal plane rotation angle is measured by the change in the atlantoaxial angle between flexion and extension. MRI can be useful in identifying reactive retrodental lesions that can occur with chronic instability. This reactive tissue is not seen on routine radiographs but can be responsible for a decrease in the space available for the spinal cord and compressive myelopathy.

Classification of Os Odontoideum

Os odontoideum is radiographically classified as either orthotopic (in which the ossicle may appear free and in a relatively anatomic position) or dystopic (in which the ossicle may be fixed to the clivus or to the anterior ring of the atlas). See above discussion on radiographic findings.

Outcomes Measures for Os Odontoideum

The prognosis of os odontoideum depends on the clinical presentation. The prognosis is good if only mechanical symptoms (torticollis or neck pain) or transient neurologic symptoms exist. It is poor if neurologic deficits slowly progress.

Treatment Options for Os Odontoideum

Nonoperative Treatment of Os Odontoideum

There is little role for nonoperative treatment because of the potential instability of this injury.

Operative Treatment of Os Odontoideum

Absolute indications for surgical stabilization include: evidence of spinal instability, neurologic involvement, or intractable pain.[303] A general guideline for significant instability may include a posterior ADI of less than 13 mm, sagittal plane rotation angle >20 degrees, and instability index of more than 40%, and C1 to C2 translation of more than 5 mm. Due to the abnormal anatomy and potential instability the treating surgeon may still recommend instrumentation and fusion.

Surgical Procedure: Posterior Arthrodesis of C1 to C2

Preoperative Planning. See p. 859 for preoperative planning in cervical spine injury. Before arthrodesis is attempted, the integrity of the arch of C1 must be documented by CT scan. Incomplete development of the posterior arch of C1 is uncommon but has been reported to occur with increased frequency in patients with os odontoideum. This may necessitate an occiput to C2 arthrodesis for stability.

Positioning. See p. 859 for positioning in cervical spine surgery.

Surgical Approaches. See for posterior approach to the cervical spine.

Technique. See pp. 866–868 for C1 to C2 arthrodesis. If a C1 to C2 arthrodesis is done, one must be careful not to over reduce the odontoid and cause posterior translation. Care also must be taken in positioning the neck at the time of arthrodesis and when tightening the wires if a Gallie or Brooks arthrodesis is performed to prevent posterior translation (Figs. 23-34 to 23-36).

FIGURE 23-34 Posterior translation of atlas after C1 to C2 posterior arthrodesis.

Potential Pitfalls and Preventative Measures. See p. 860 for potential pitfalls with the posterior approach.

Treatment-Specific Outcomes. Brockmeyer et al.[41] and Wang et al.[306] both reported good results with transarticular screw fixation and fusion in the treatment of children with os odontoideum (see Fig. 23-35). Wang et al.[306] reported the use of this technique in children as young as 3 years of age. This technique may be preferred depending on the patient's anatomy and the surgeon's experience. Harms and Melcher.[124] and Brecknell and Malham[37] reported that a high-riding vertebral artery may make transarticular screw placement impossible in about 20% of patients.

Traumatic Transverse Ligamentous Disruption

The transverse ligament is the primary stabilizer of an intact odontoid against forward displacement. Secondary stabilizers consist of the apical and alar ligaments, which arise from the tip of the odontoid and pass to the base of the skull. These also stabilize the atlantooccipital joint indirectly.[111] The normal distance from the anterior cortex of the dens to the posterior cortex of the anterior ring of C1 is 3 mm in adults and 4.5 mm in children. In children, if the distance is more than 4.5 mm, disruption of the transverse ligament is presumed. The spinal canal at C1 is large compared with other cervical segments and accommodates a large degree of rotation and some degree of pathologic displacement without compromising the spinal cord. Steel[282] expressed this as a rule of thirds: the spinal canal at C1 is occupied equally by the spinal cord, odontoid, and a free space, which provides a buffer zone to prevent neurologic injury. Steel[282] found that anterior displacement of the atlas that exceeds a distance equal to the width of the odontoid may place the spinal cord at risk.

Acute rupture of the transverse ligament is rare and reportedly occurs in fewer than 10% of pediatric cervical spine injuries.[178,191] However, avulsion of the attachment of the transverse ligament to C1 may occur instead of rupture of the transverse ligament.

Assessment of Transverse Ligamentous Disruption

Mechanisms of Injury for Traumatic Transverse Ligamentous Disruption

This injury may occur from a fall with a blow to the back of the head or other associated upper cervical spine trauma.

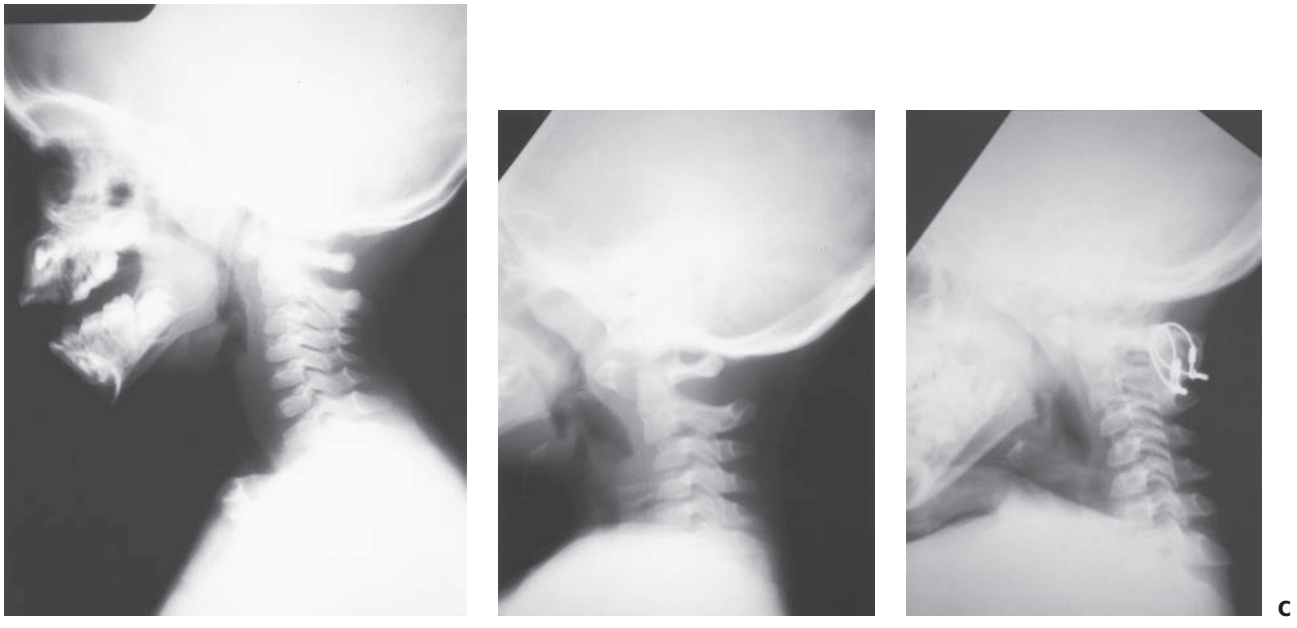

FIGURE 23-35 **A:** Lateral radiograph of traumatic C1 to C2 instability. **B:** Note the increase in the atlanto–dens interval. **C:** Lateral radiograph after C1 to C2 posterior arthrodesis.

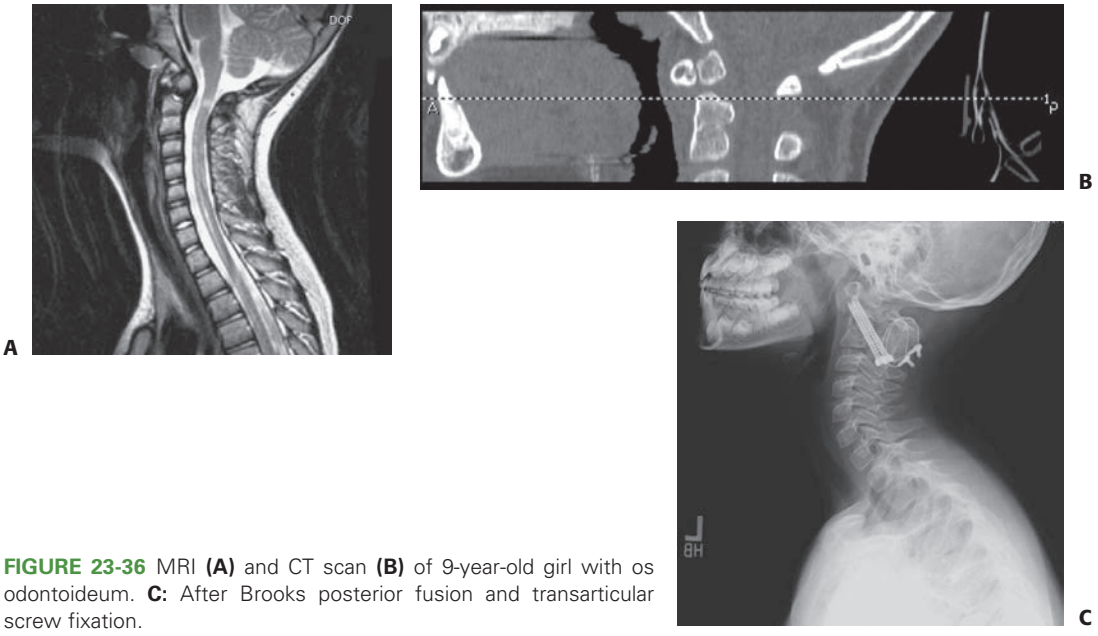

FIGURE 23-36 MRI **(A)** and CT scan **(B)** of 9-year-old girl with os odontoideum. **C:** After Brooks posterior fusion and transarticular screw fixation.

Associated Injuries with and Signs and Symptoms of Traumatic Transverse Ligamentous Disruption

A patient with disruption of the transverse ligament usually has a history of cervical spine trauma and complains of neck pain, often with notable muscle spasms.

Imaging and Other Diagnostic Studies for Traumatic Transverse Ligamentous Disruption

Diagnosis is confirmed on lateral radiographs that show an increased ADI. An active flexion view may be required to show instability in cooperative patients with unexplained neck pain or neurologic findings. CT scans are useful to demonstrate avulsion of the transverse ligament from its origins to the bony ring of C1. MRI is also useful in determining the integrity of the transverse atlantal ligament.

Treatment Options for Traumatic Transverse Ligamentous Disruption

Nonoperative Treatment of Traumatic Transverse Ligamentous Disruption

Nonoperative treatment is not effective for ligamentous disruption. Nondisplaced avulsion injuries with a significant fragment may be treated nonoperatively to allow for bone healing. Stability and bone healing must be documented at the end of the nonoperative period.

Operative Treatment of Traumatic Transverse Ligamentous Disruption

For acute injuries, reduction in extension is recommended, followed by surgical stabilization of C1 and C2. Depending on what type of instrumentation is feasible, immobilization for 8 to 12 weeks in a Minerva cast, a halo brace, or a cervical orthosis may be needed. Flexion and extension views should be obtained after stabilization to document stability.

Surgical Procedures for C1-C2 Injuries

Surgical Procedure: Atlantoaxial Arthrodesis (Brooks and Jenkins)

Depending on the anatomy and size of the patient, wire or cables may be used to stabilized C1 and C2. If anatomy allows for placement of screws in C1 and C2 then a screw and rod construct can be used that will allow for more stable fixation.

Preoperative Planning. See p. 859 for preoperative planning in cervical spine injury.

Positioning. See p. 859 for positioning in cervical spine injury. The patient is placed prone using Gardner-Wells tongs or a halo ring attached to a Mayfield headrest.[42]

Surgical Approach. See p. 860 for posterior approach.

Technique. A lateral cervical spine radiograph is obtained to ensure proper alignment before surgery. The skin is prepared and draped in a sterile fashion and a solution of epinephrine (1:500,000) is injected intradermally to aid hemostasis. C1 and C2 are exposed through a midline incision.

With an aneurysm needle, a Mersiline suture is passed from cephalad to caudad on each side of the midline under the arch of the atlas and then beneath the lamina of C2. These serve as guides to introduce two doubled 20-gauge wires or Songer cables. Another technique is to pass the sublaminar wires or cables subperiosteally around the ring of C1 and lamina of C2. The periosteum can be easily elevated with a periosteal elevator and allows for some protection of the spinal cord when passing the wires or cables, since they do not pass directly into the epidural space with this technique.

TABLE 23-18 Atlantoaxial Arthrodesis (Brooks and Jenkins)

Surgical Steps

- Expose C1 and C2 through a midline incision
- Pass sublaminar wires or cables
- Harvest two full-thickness bone grafts from the iliac crest
- Bevel grafts to fit in the interval between arch of atlas and lamina of axis
- Create notches in upper and lower cortical surfaces to hold wires or cables
- Tighten wires or cables
- Close wound in layers

The size of the wire used may vary depending on the size and age of the patient. Two full-thickness bone grafts, approximately 1.25 × 3.5 cm, are harvested from the iliac crest and beveled so that the apex of the graft fits in the interval between the arch of the atlas and the lamina of the axis. Notches are fashioned in the upper and lower cortical surfaces to hold the circumferential wires or cables and prevent them from slipping. The doubled wires or cables are tightened over the graft. The wound is irrigated and closed in layers over suction drains (Table 23-18 and Fig. 23-37).

Postoperative Care. A halo cast or vest is used for postoperative immobilization for 6 to 8 weeks in a young child and for as long as 12 weeks in an older child or adolescent.

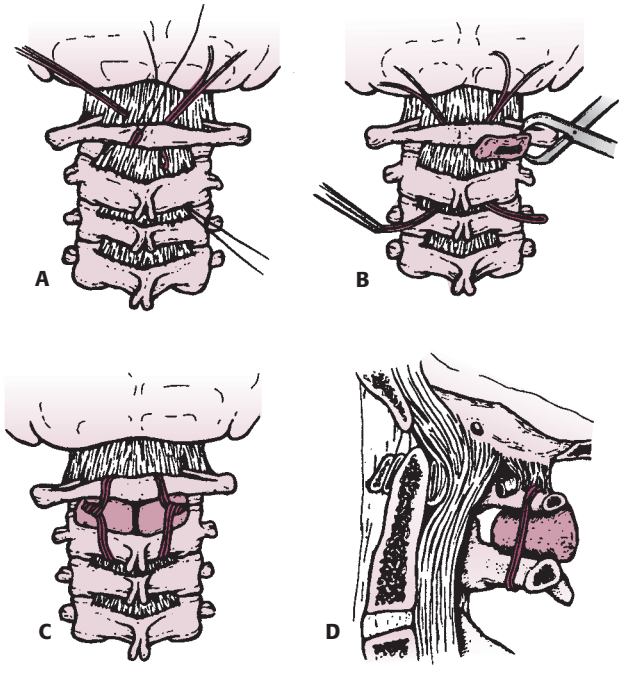

FIGURE 23-37 Technique of atlantoaxial arthrodesis (Brooks-Jenkins). **A:** Wires are inserted under the atlas and axis. **B:** Full-thickness bone grafts from the iliac crest are placed between the arch of the atlas and the lamina of the axis. **C, D:** The wires are tightened over the graft and twisted on each side. (Adapted from Brooks AL, Jenkins EB. Atlantoaxial arthrodesis by the wedge compression method. *J Bone Joint Surg Am.* 1978;60:279, with permission.)

Potential Pitfalls and Preventative Measures. See p. 860 for potential pitfalls with the posterior approach.

Surgical Procedure: Atlantoaxial Arthrodesis (Gallie)

Preoperative Planning. See p. 859 for preoperative planning in cervical spine injury.

Positioning. See p. 859 for positioning in cervical spine injury. The patient is placed prone using Gardner-Wells tongs or a halo ring attached to a Mayfield headrest.[96]

Surgical Approach. See p. 860 for posterior approach.

Technique. A lateral cervical spine radiograph is obtained to ensure proper alignment before surgery. The skin is prepared and draped in a sterile fashion, and a solution of epinephrine (1:500,000) is injected intradermally to aid hemostasis.

A midline incision is made from the lower occiput to the level of the lower end of the fusion, extending deeply within the relatively avascular midline structures, the intermuscular septum, or ligamentum nuchae. Care should be taken not to expose any more than the area to be fused to decrease the chance of spontaneous extension of the fusion.

By subperiosteal dissection, the posterior arch of the atlas and the lamina of C2 are exposed. The muscular and ligamentous attachments from C2 are removed with a curet. Care should be taken to dissect laterally along the atlas to prevent injury to the vertebral arteries and vertebral venous plexus that lie on the superior aspect of the ring of C1, less than 2 cm lateral to the midline. The upper surface of C1 is exposed no farther laterally than 1.5 cm from the midline in adults and 1 cm in children. Decortication of C1 and C2 generally is not necessary. From below, a wire loop of appropriate size is passed upward under the arch of the atlas either directly or with the aid of a Mersiline suture. The Mersiline suture can be passed with an aneurysm needle. The free ends of the wire are passed through the loop, grasping the arch of C1 in the loop.

A corticocancellous graft is taken from the iliac crest and placed against the lamina of C2 and the arch of C1 beneath the wire. One end of the wire is passed through the spinous process of C2, and the wire is twisted on itself to secure the graft in place. The wound is irrigated and closed in layers with suction drainage tubes (Table 23-19 and Fig. 23-38).

Postoperative Care. A halo cast or vest is used for postoperative immobilization for 6 to 8 weeks in a young child and for as long as 12 weeks in an older child or adolescent.

TABLE 23-19 Atlantoaxial Arthrodesis (Gallie)

Surgical Steps

- Expose the posterior arch of the atlas and lamina of C2
- Pass a wire loop under arch of atlas
- Harvest corticocancellous bone graft from iliac crest
- Place graft against lamina of C2 and arch of C1 beneath wire
- Pass wire through spinous process of C2 and twist wire on itself to secure graft
- Irrigate wound and close in layers

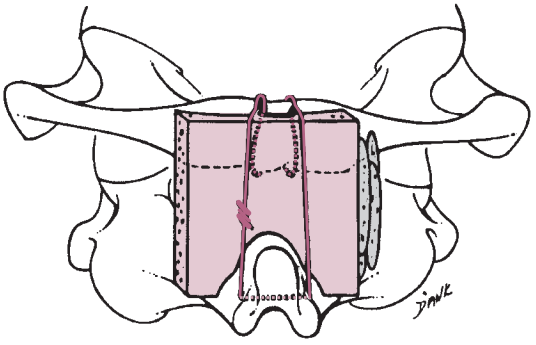

FIGURE 23-38 Wires are passed under the lamina of the atlas and through the spine of the axis and tied over the graft. This method is used most frequently. (From Fielding JW, Hawkins RJ, Ratzan SA. Spine fusion for atlanto-axial instability. *J Bone Joint Surg Am.* 1976;58:400, with permission.)

Potential Pitfalls and Preventative Measures. See p. 860 for potential pitfalls with the posterior approach.

Surgical Procedure: Atlantoaxial Arthrodesis with Posterior C1 to C2 Transarticular Screw Fixation

Posterior C1 to C2 transarticular screw fixation can be used to stabilize the atlantoaxial joint. This technique has the advantage of being biomechanically superior to posterior wiring techniques,[131] and postoperative halo vest immobilization usually is not required. The disadvantages of this technique are potential injury to the vertebral artery, its technical difficulty, and the requirement for sublaminar wire and fusion (Brooks or Gallie technique).

Preoperative Planning. See p. 859 for preoperative planning for cervical spine injury. Preoperative imaging should include plain radiographs, CT scan, MRI, and MRA of the cervical spine. Supervised dynamic lateral flexion and extension views must determine the reducibility of the atlantoaxial joint.[192] If an anatomic reduction cannot be obtained, transarticular screws cannot be safely used. MRA can delineate the course of the vertebral artery through the foramen transversarium and its relationship to the surrounding bony architecture. Approximately 20% of patients show anatomic variations in the path of the vertebral artery and osseous anatomy that would preclude transarticular screw placement.[1,37,124]

Positioning. See p. 859 for positioning in cervical spine injury.

Surgical Approach. See p. 860 for posterior approach.

Technique. The patient is placed prone with the head held in a Mayfield skull clamp or with a halo ring attached to the Mayfield attachment. Under fluoroscopic guidance, proper alignment of the atlantoaxial joint is confirmed. The spine is prepared and draped from the occiput to the upper thoracic spine. The upper thoracic spine must be included in the surgical field to allow percutaneous placement of the transarticular screw. Percutaneous screw placement may be necessary because of the cephalad orientation of the C1 to C2 transarticular screw.

A midline posterior cervical exposure is made from C1 to C3.

The C2 inferior facet is used as the landmark for screw entry: the entry point is 2 mm lateral to the medial edge and 2 mm above the inferior border of the C2 facet (Fig. 23-39A). The drill trajectory is angled medially 5 to 10 degrees. On the lateral fluoroscopic radiograph, the drill trajectory is adjusted toward the posterior cortex of the anterior arch of C1. Percutaneous placement of the C1 to C2 facet screws may be necessary if the intraoperative atlantoaxial alignment precludes drilling or placement of screws through the operative incision. After tapping, a 3.5-mm lag screw is placed across the C1 to C2 joint (Fig. 23-39B). Another screw is then placed in exactly the same way on the other side. After placement of the C1 to C2 transarticular screw, a bone graft is harvested from the posterior iliac crest. A traditional posterior C1 to C2 fusion

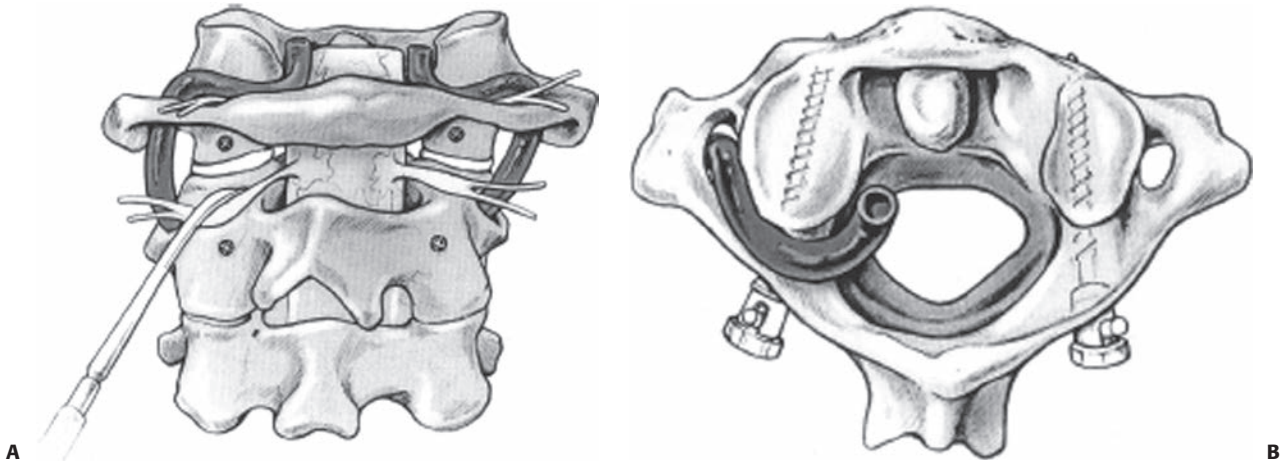

FIGURE 23-39 Posterior C1 to C2 transarticular screw fixation. **A:** Location of entry points in C1 and C2 for screw placement. **B:** Polyaxial screws placed bicortically into the lateral mass. FIGURE 23-40 Position of vertebral arteries and position of screws across atlantoaxial joint. (From Menezes AH. Surgical approaches to the craniocervical junction. In: Weinstein SL, ed. *Pediatric Spine Surgery*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2001.)

is done using either the Gallie or the Brooks technique (Fig. 23-40 and Table 23-20).

Postoperative Care. The patient is immobilized in a hard cervical collar only; no halo or Minerva cast is used postoperatively.

Potential Pitfalls and Preventative Measures. The disadvantages of this technique are potential injury to the vertebral artery, its technical difficulty, and the requirement for sublaminar wire and fusion (Brooks or Gallie technique). See p. 860 for potential pitfalls with the posterior approach.

Surgical Procedure: Atlantoaxial Arthrodesis with Posterior C1 to C2 Polyaxial Screw and Rod Fixation

Harms and Melcher[124] described a technique of atlantoaxial stabilization using fixation of the C1 lateral mass and the C2 pedicle with polyaxial screws and rods (Fig. 23-41). This technique has the advantages of minimizing the risk of vertebral artery injury, does not require the use of sublaminar wires, and does not require an intact posterior arch of C1.

TABLE 23-20 Atlantoaxial Arthrodesis with Posterior C1–C2 Transarticular Screw Fixation

Surgical Steps

- Expose the spine from C1 to C3
- Using C2 inferior facet as landmark, entry point for drill is 2 mm lateral to medial edge and 2 m above inferior border of C2 facet
- Tap hole and place 3.5-mm lag screw across C1–C2 joint on both sides
- Harvest bone graft from posterior iliac crest
- Perform C1–C2 fusion using either Brooks or Gallie technique

Preoperative Planning. See p. 859 for preoperative planning for cervical spine injury.

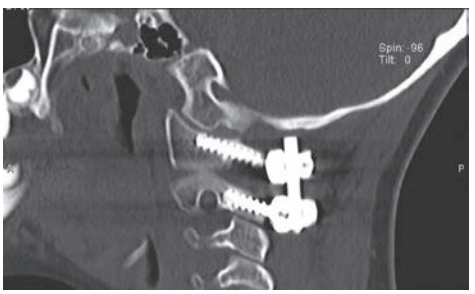
Positioning. See p. 859 for positioning in cervical spine injury.

Surgical Approach. See p. 860 for posterior approach to the cervical spine.

Technique. The patient is placed prone with the head held in a Mayfield skull clamp or with a halo ring attached to the Mayfield attachment. Under fluoroscopic guidance, proper alignment of the atlantoaxial joint is confirmed. The cervical spine is exposed from the occiput to C3.

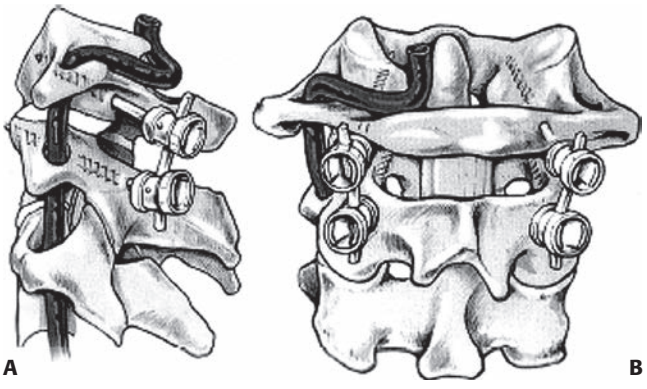
The C1 to C2 complex is exposed to the lateral border of the C1 to C2 articulation. The C1 to C2 joint is exposed and opened by dissection over the superior surface of the C2 pars interarticularis. The dorsal root ganglion of C2 is retracted in a caudal direction to expose the entry point for the C1 screw. This entry point is at the midpoint of the C1 lateral mass at its junction with the posterior arch of C1. A 2-mm high-speed burr is used to mark the starting point for the drill. The drill bit is directed in a straight to slightly convergent trajectory in the anteroposterior plane and parallel to the posterior arch of C1 in the sagittal plane. After determining the appropriate screw length, the drill hole is tapped and a 3.5-mm polyaxial

A



B

FIGURE 23-41 Radiograph **(A)** and MRI **(B)** after fixation with polyaxial screws and rods.



A B

FIGURE 23-42 Lateral **(A)** and posterior **(B)** views after C1 to C2 fixation by the polyaxial screw and rod technique. (From Harms J, Melcher RP. Posterior C1 to C2 fusion with polyaxial screw and rod fixation. *Spine.* 2001;26:2467–2471, with permission.)

screw is inserted. A number 4 Penfield elevator is used to define the medial border of the C2 isthmus or pedicle. The starting point for the C2 pedicle screw is in the superior and medial quadrant of the C2 lateral mass. A C2 pedicle pilot hole is drilled with a 2-mm drill in a 20- to 30-degree convergent and cephalad trajectory, using the superior and medial surface of the C2 pedicle as a guide. The hole is tapped, and a 3.5-mm polyaxial screw of appropriate length is inserted. Fixation of the rods to the polyaxial screws is obtained with locking nuts (Fig. 23-42). C1 and C2 are decorticated posteriorly and cancellous bone from the posterior iliac crest is used for bone graft (Table 23-21).

Postoperative Care. Rigid cervical collar immobilization is used postoperatively.

Potential Pitfalls and Preventative Measures. Disadvantages of this technique are the anatomic limitations of the C1 lateral mass, which may prevent the use of a 3.5-mm screw, and the potential risk of irritation or injury of the C2 ganglion. See p. 860 for potential pitfalls with posterior approach.[145]

TABLE 23-21 Atlantoaxial Arthrodesis with Posterior C1–C2 Polyaxial Screw and Rod Fixation

Surgical Steps

- Expose the spine from the occiput to C3
- Expose entry point for C1 screw
- Direct drill bit to midpoint of C1 lateral mass
- Tap drill hole and insert 3.5-mm polyaxial screw
- Drill pilot hole for C2 pedicle screw in superior and medial quadrant of C2 lateral mass
- Tap drill hole and insert a 3.5-mm polyaxial screw into CT
- Fix rods to polyaxial screws with locking nuts
- Decorticate C1 and C2 and insert cancellous bone from posterior iliac crest

C1-C2 Injuries Associated with Other Conditions

Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Although acute atlantoaxial instability in children is rare, chronic atlantoaxial instability occurs in certain conditions such as juvenile rheumatoid arthritis, Reiter syndrome, Down syndrome, and Larsen syndrome. Bone dysplasia—such as Morquio polysaccharidosis, spondyloepiphyseal dysplasia, and Kniest syndrome—also may be associated with atlantoaxial instability, as well as os odontoideum, Klippel–Feil syndrome, and occipitalization of the atlas.[48,65,120,132,161,166,197] Certain cranial facial malformations have high incidences of associated anomalies of the cervical spine, such as Apert syndrome, hemifacial microsomy, and Goldenhar syndrome.[272] Treatment recommendations are individualized based on the natural history of the disorder and future risk to the patient. Minimal trauma may result in significant instability and neurologic compromise in patients with these conditions. There has been considerable interest in the incidence and treatment of atlantoaxial instability in children with Down syndrome.[5,64,237,238,276,299,317]

Assessment of Atlantoaxial Instability Associated with Congenital Anomalies and Other Conditions

Mechanisms of Injury for Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Generalized ligamentous laxity caused by the underlying collagen defect can result in atlantoaxial and atlantooccipital instability in children with Down syndrome. Pizzutillo and Herman[233] made a distinction between cervical instability and hypermobility in Down syndrome patients. Instability implies pathologic motion that jeopardizes neurologic integrity. Hypermobility refers to increased excursions that occur in the cervical spine of patients with Down syndrome compared with normal controls but do not result in loss of structural integrity of the anatomical restraints that protect neural tissues. [318]

Atlantoaxial instability has been reported to occur in 10 to 20% of children with Down syndrome.[277] Atlantooccipital instability may also occur in patients with Down syndrome. Despite reports of atlantoaxial and atlantooccipital instability in Down syndrome patients, the exact natural history related to this instability is unknown. Differentiating between hypermobility and clinically significant instability in these patients may be difficult.

Associated Injuries with and Signs and Symptoms of Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Cervical instability usually is discovered on routine screening examination or cervical radiographs obtained for other reasons.

Neurologic symptoms are present in 1% to 2.6% of patients with cervical instability. Progressive instability leading to neurologic symptoms is most common in boys older than 10.5 years of age. Involvement of the pyramidal tract usually results in gait abnormalities, hyperreflexia, and motor weakness. Other neurologic symptoms include neck pain, occipital headaches, and torticollis. Detailed neurologic examination often is difficult in patients with Down syndrome, and somatosensory-evoked potentials may be beneficial in documenting neurologic involvement.

Imaging and Other Diagnostic Studies for Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Radiographic examination should include anteroposterior, flexion and extension lateral, and odontoid views. CT scans in flexion and extension or cineradiography in flexion and extension may be needed to evaluate the occipitoatlantal joint and the atlantoaxial joint for instability. MRI may help to demonstrate spinal cord signal changes in suspected instability and neurologic compromise in patients in whom it is often difficult to obtain a detailed neurologic examination. Radiographic evidence of atlantooccipital instability is not as well defined as that for atlantoaxial instability, but measurements described by Wackenheim (see Fig. 23-2), Wiesel and Rothman (Fig. 23-43), Powers (See Fig. 23-1), and Tredwell et al.[295] are helpful. A Powers ratio of more than 1.0 is indicative of abnormal anterior translation of the occiput, and a ratio of less than 0.55 indicates posterior translation. However, some studies have reported the poor reliability and reproducibility of these measurements in Down syndrome. CT scans in flexion and extension or cineradiography may be needed to give better detail and information about possible atlantooccipital instability. An ADI of 4.5 to 5 mm indicates instability in normal pediatric patients. An increased ADI in patients with Down syndrome has not been directly correlated with an increase in neurologic compromise. This suggests that radiographs of the cervical spine in Down syndrome must be evaluated by standards specific to that population and not by standards for general pediatric patients because this may result in overdiagnosis of a pathologic process. Neurologic compromise occurs with a similar incidence in individuals with Down syndrome who have a normal ADI and those with an ADI from 4 to 10 mm. In Down syndrome, an ADI of less than 4.5 mm is normal; an ADI of 4.5 to 10 mm is considered hypermobile but not unstable unless there are neurologic findings; and an ADI of more than 10 mm is considered unstable; the patient is at risk for neurologic compromise because of the decrease in the space available for the spinal cord.

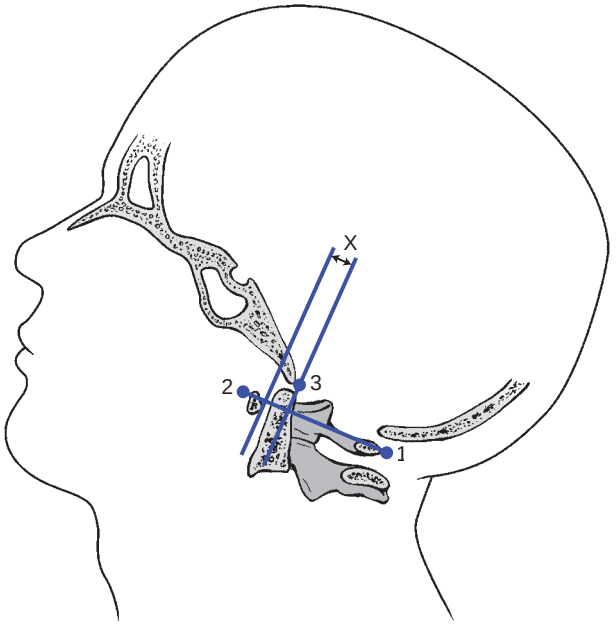


FIGURE 23-43 Atlantooccipital instability measurement according to Wiesel and Rothman. Lines are drawn on flexion and extension lateral radiographs. Translation should be no more than 1 mm. Atlantal line joins points 1 and 2. Line drawn perpendicular to atlantal line at posterior margin of anterior arch of atlas. Point 3 is basion. Distance from point 3 to perpendicular line is measured in flexion and extension. Differences represent anteroposterior translation. (Adapted from Warner WC Jr. Pediatric cervical spine. In: Canale ST, Beaty JH, eds. *Campbell's Operative Orthopaedics,* 12th edition, Philadelphia, PA: Elsevier, 2013.)

Classification of Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

See p. 873 for discussion on atlantoaxial injuries.

Treatment Options for Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Nonoperative Treatment of Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

Hypermobility of the occipitoatlantal junction has been observed in more than 60% of patients with Down syndrome, but this usually is not associated with neurologic risk. If hypermobility of this joint is documented but the patient is neurologically normal, then high-risk activities should be restricted. When the ADI is less than 4.5 mm, no restriction of activities is necessary. In those who have an ADI of 4.5 to 10 mm, with no neurologic symptoms, high-risk activities also are restricted (Table 23-22).

TABLE 23-22 Atlantoaxial Instability Associated with Down Syndrome

Nonoperative Treatment

Indications	Relative Contraindications
ADI 4.5–10 mm with no neurologic symptoms	Hypermobility Neurologic deficit Abnormal MRI signal change in spinal cord ADI more than 10 mm

Operative Treatment of Atlantoaxial Instability Associated with Congenital Anomalies and Syndromes

If there is hypermobility and a neurologic deficit or an abnormal signal change in the spinal cord on MRI, then an occiput to C2 or C3 fusion is recommended. If there is a neurologic deficit or spinal cord changes on MRI, a C1 to C2 fusion is indicated (See pp. 877–881). If the ADI is 10 mm or more, posterior fusion and wiring are recommended (See pp. 866–867).

Surgical Procedure

See pp. 877–881 for surgical procedures. Before fusion and passage of the wire, the unstable C1 to C2 joint should be reduced by traction. If reduction cannot be obtained, an in situ fusion reduces the risk of neurologic compromise, which may occur if intraoperative reduction is performed and the wires are passed through a narrowed space available for the spinal cord.

Postoperative Care. Postoperative immobilization in a halo cast or halo vest should be continued for as long as possible because graft resorption 6 months after fusion has been reported. More stable fixation may decrease this complication. C1 to C2 transarticular screw fixation or occiput to C2 instrumentation with plates and rods can be used successfully.

Potential Pitfalls and Preventative Measures. See p. 860 for potential pitfalls with posterior approach.

Treatment-Specific Outcomes. Complications are relatively common after cervical fusions in children with Down syndrome. Segal et al.[263] reported frequent graft resorption after 10 posterior fusions and suggested as causes inadequate inflammatory response and collagen defects. Msall et al.[202] reported the frequent development of instability above and below C1 to C2 fusion in patients with Down syndrome.

Atlanto-Rotatory Subluxation

Atlantoaxial rotatory subluxation is a common cause of childhood torticollis. This condition is known by several names, such as rotatory dislocation, rotatory displacement, rotatory subluxation, and rotatory fixation. Atlantoaxial rotatory subluxation probably is the most accepted term used, except for long-standing cases (3 months), which are called rotatory fixation.

A significant amount of motion occurs at the atlantoaxial joint; half of the rotation of the cervical spine occurs there. Through this range of motion at the C1 to C2 articulation, some children develop atlantoaxial rotatory subluxation. Differential diagnoses include torticollis caused by ophthalmologic problems, sternocleidomastoid tightness from muscular torticollis, brain stem or posterior fossa tumors or abnormalities, congenital vertebral anomalies, and infections of the vertebral column.

Assessment of Atlanto-Rotatory Subluxation

Mechanisms of Injury for Atlanto-Rotatory Subluxation

The two most common causes are trauma and infection; the most common cause is an upper respiratory infection (Grisel syndrome).[312] Subluxation also can occur after a retropharyngeal abscess, tonsillectomy, pharyngoplasty, or trivial trauma. There is free blood flow between the veins and lymphatics draining the pharynx and the periodontoid plexus.[228] Any inflammation of these structures can lead to attenuation of the synovial capsule or transverse ligament or both, with resulting instability. Another potential etiologic factor is the shape of the superior facets of the axis in children. Kawabe et al.[154] showed that the facets are smaller and more steeply inclined in children than in adults. A meniscus-like synovial fold was found between C1 and C2 that could prohibit reduction after displacement has occurred. Although atlantoaxial rotatory subluxation is most commonly seen from inflammatory syndromes, it also can occur after trauma.

Associated Injuries with and Signs and Symptoms of Atlanto-Rotatory Subluxation

If the cause is traumatic, other spine and head injuries may be associated. Clavicular fracture associated with atlanto-rotatory subluxation also has been described.[206]

Clinical findings include neck pain, headache, and a cock-robin position of rotating to one side, as well as lateral flexion to the other (Fig. 23-44). When rotatory subluxation is acute, the child resists attempts to move the head and has pain with any attempts at correction. Usually, the child is able to make the deformity worse but cannot correct it. Associated muscle spasms of the sternocleidomastoid muscle occur predominantly on the side of the long sternocleidomastoid muscle in an attempt to correct the deformity. If the deformity becomes fixed, the pain subsides but the torticollis and the decreased range of motion will persist.[89] If rotatory fixation has been present for a long time in a small child, plagiocephaly is sometimes

FIGURE 23-44 Child with rotary subluxation of C1 on C2. Note the direction of head tilt and rotation of the neck.

noted. Neurologic abnormalities are extremely rare, although a few cases have been reported.

Imaging and Other Diagnostic Studies for Atlanto-Rotatory Subluxation

Adequate radiographs may be difficult to obtain because of the associated torticollis and difficulty in positioning the head and neck. Anteroposterior and open-mouth odontoid views should be taken with the shoulders flat and the head in as neutral a position as possible.[182] Lateral masses that have rotated forward appear wider and closer to the midline, whereas the opposite lateral mass appears narrower and farther away from the midline on this view. One of the facet joints may be obscured because of apparent overlapping. The distance between the lateral mass and the dens also will be asymmetric. On the lateral view, the lateral facet appears anterior and usually appears wedge-shaped instead of the normal oval shape. The posterior arches of the atlas may fail to superimpose because of head tilt, giving the appearance of fusion of C1 to the occiput (occipitalization). Flexion and extension lateral views are recommended to exclude C1 to C2 instability.

Cineradiography has been used for the evaluation of atlantoaxial rotatory subluxation.[87,91,137] This technique is limited in the acute stage because pain restricts the motion necessary for a satisfactory study. With atlantoaxial rotatory fixation, cineradiography may be helpful in confirming the diagnosis by showing that the atlas and axis are rotating as a unit. However, this technique requires high radiation exposure and generally has been replaced by CT imaging.[12,73,91,98,234] CT should be performed with the head and body positioned as close to neutral as possible. This will show a superimposition of C1 on C2 in a rotated position and will allow the degree and amount of malrotation to be quantified. Some researchers have recommended dynamic CT scans taken with the patient looking to the right and the left to diagnose rotatory fixation.[232] McGuire et al.[192] classified findings on dynamic CT scans into three stages: stage 0, torticollis but a normal dynamic CT scan; stage 1, limitation of motion with less than 15 degrees difference between C1 and C2, but with C1 crossing the midline; and stage 2, fixed with C1 not crossing the midline. Duration of treatment and intensity of treatment were greater the higher the stage. Three-dimensional CT scans also are helpful in identifying rotatory subluxation.[257] Ishii et al.[144] reported the use of the lateral inclination angle to grade the severity of subluxation: grade 1, no lateral inclination; grade 2, less than 20 degrees; and grade 3, more 20 degrees (Fig. 23-45). They also noted adaptive changes in the superior facet joint of C2 in grade 3 subluxations and reported that grade 3 subluxations were more commonly irreducible. MRI demonstrates more soft tissue detail, such as associated spinal cord compression, integrity of the transverse atlantal ligament and underlying vertebral or soft tissue infections (Fig. 23-46).[248]

Classification of Atlanto-Rotatory Subluxation

Fielding and Hawkins[89] classified atlantoaxial rotatory displacements into four types based on the direction and degree of rotation and translation (Fig. 23-47). Type 1 is a unilateral facet subluxation with an intact transverse ligament. This is the most common and benign type. Type 2 is a unilateral facet subluxation with anterior displacement of 3 to 5 mm. The unilateral anterior displacement of one of the lateral masses may indicate an incompetent transverse ligament with potential instability. Type 3 is bilateral anterior facet displacement with more than 5 mm of anterior displacement. This type is associated with deficiencies of the transverse and secondary ligaments, which can result in significant narrowing of the space available for the cord at the atlantoaxial level. Type 4 is an unusual type in which the atlas is displaced posteriorly. This usually is associated with a deficient dens. Although types 3 and 4 are rare, neurologic involvement may be present. Both types must be managed with great care.

Treatment Options for Atlanto-Rotatory Subluxation

Nonoperative Treatment of Atlanto-Rotatory Subluxation

Treatment depends on the duration of the symptoms.[232] Many patients probably never receive medical treatment because symptoms may be mild and the subluxation may reduce spontaneously over a few days before medical attention is sought. If rotatory subluxation has been present for a week or less, a soft collar, anti-inflammatory medication, and an exercise program are indicated. If this fails to produce improvement and the symptoms persist for more than a week, head halter traction should be initiated. This can be done either at home or in

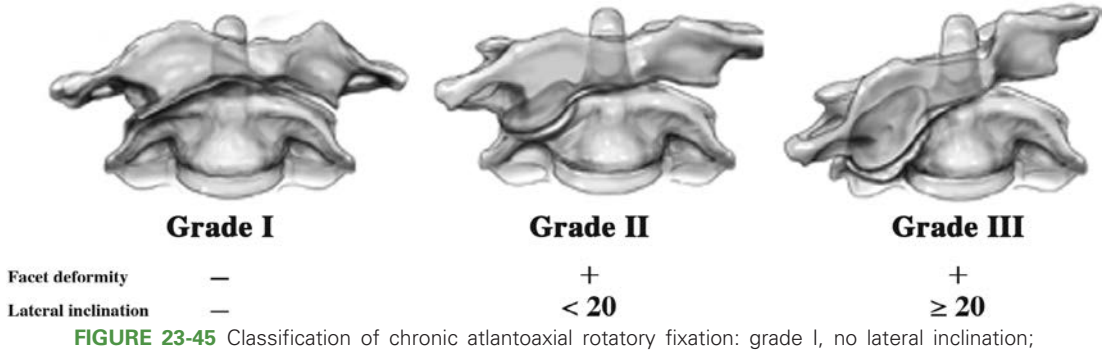

FIGURE 23-45 Classification of chronic atlantoaxial rotatory fixation: grade I, no lateral inclination; grade II, 20 degrees; grade III, 20 degrees. (From Ishii K, Chiba K, Maruiwa H, et al. Pathognomonic radiological signs for predicting prognosis in patients with chronic atlantoaxial rotatory fixation. *J Neurosurg Spine.* 2006; 5:385–391, with permission.)

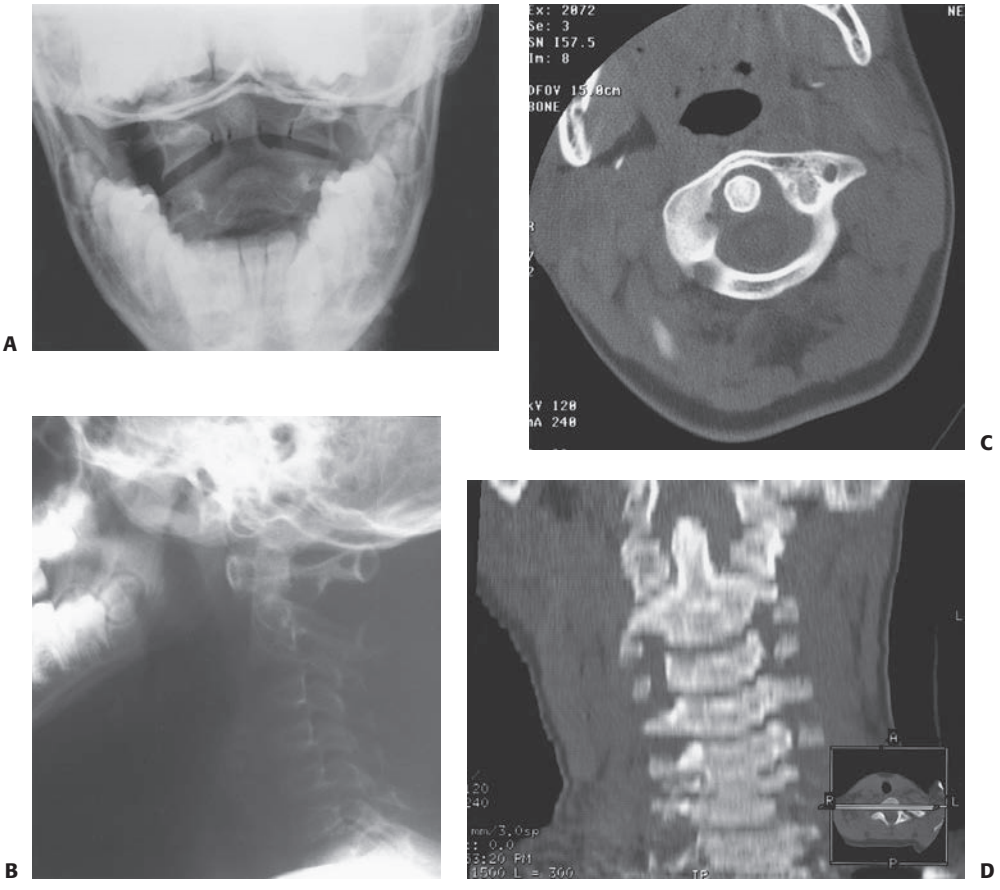

FIGURE 23-46 A, B: Odontoid view and lateral cervical spine radiograph of rotary subluxation of C1 on C2. **C:** Note the asymmetry on the open-mouth odontoid view. **D:** CT and CT reconstruction documenting rotary subluxation.

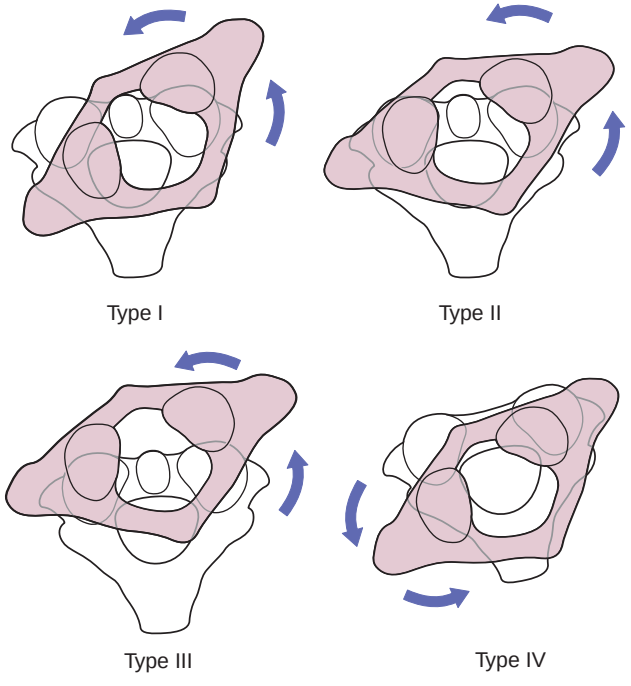

FIGURE 23-47 Classification of rotary displacement. (From Fielding JW, Hawkins RJ. Atlantoaxial rotary fixation. *J Bone Joint Surg Am.* 1977;59: 37, with permission.)

the hospital, depending on the social situation and the severity of symptoms. Muscle relaxants and analgesics also may be needed. Phillips and Hensinger[232] found that if rotatory subluxation was present for less than 1 month, head halter traction and bed rest were usually sufficient to relieve symptoms. If the subluxation has been present for longer than a month, successful reduction is not very likely.[49] However, halo traction can still be used to try to reduce the subluxation. The halo allows increased traction weight to be applied without interfering with opening of the jaw or causing skin pressure on the mandible. While the traction is being applied, active rotation to the right and left should be encouraged. Once the atlantoaxial rotatory subluxation has been reduced, motion has been restored, and the reduction is documented by CT scan, the patient is maintained in a halo vest for 6 weeks (Table 23-23).

Operative Treatment of Atlanto-Rotatory Subluxation

If reduction cannot be maintained, posterior atlantoaxial arthrodesis is recommended.[217] Even though internal rotation and alignment of the atlas and axis may not be restored, successful fusion should result in the appearance of normal head alignment by relieving the muscle spasms that occurred in response to the malrotation. Posterior arthrodesis also is recommended if any signs of instability or neurologic deficits secondary to the subluxation are present, if the deformity has been present for more than 3 months, or if conservative treatment of 6 weeks of immobilization has failed.

TABLE 23-23 Atlanto-Rotatory Subluxation

Nonoperative Treatment

Indications	Relative Contraindications
Reducible subluxation	Irreducible subluxation Instability Neurological deficits

Surgical Procedure

Posterior atlantoaxial arthrodesis (See pp. 877–881).

C2-C3 Injuries

Hangman's Fracture

Bilateral spondylolisthesis of C2, or Hangman's fractures, also may occur in children.[234] This injury probably occurs more frequently in this age group because of the disproportionately large head, poor muscle control, and hypermobility. The possibility of child abuse also must be considered.[159,241,300]

Assessment of Hangman's Fracture

Mechanism of Injury for Hangman's Fracture

The mechanism of injury is forced hyperextension and axial loading. Most reports of this injury have been in children under the age of 2 years.[83,94,139,159,227,234,243,251]

Associated Injuries with and Signs and Symptoms of Hangman's Fracture

Facial and head injuries may be associated. Patients present with neck pain and resist any movement of the head and neck. There should be a positive history of trauma (Fig. 23-48).

Imaging and Other Diagnostic Studies for Hangman's Fracture

Radiographs reveal a lucency anterior to the pedicles of the axis, usually with some forward subluxation of C2 on C3. One must be sure this is a fracture and not a persistent synchondrosis of the axis.[187,210,275,300,315] Differentiating a persistent synchondrosis from a fracture may be difficult. Several radiographic findings can help distinguish congenital spondylolysis from a Hangman's fracture. With congenital spondylolysis, there should be a symmetrical osseous gap with smooth, clearly defined cortical margins; no prevertebral soft tissue swelling should be observed; and there should be no signs of instability. Often, small foci of ossification are seen in the defect. CT scans show the defect to be at the level of the neurocentral chondrosis. MRI does not show any edema or soft tissue swelling that typically is present with a fracture.[199,300]

Classification of Hangman's Fracture

The classification by Effendi et al.,[77] which was modified by Levine[176] and later by Müller,[204] is based on the severity of associated soft tissue injuries. Type I is a bilateral pars fracture with less than 3 mm of anterior C2 to C3 subluxation with intact C2 to C3 discoligamentous complex. It is considered stable. Type II fracture is associated with a discoligamentous injury at C2 to C3 with displacement of the pars fracture and anterior translation of the C2 body. Type IIB is distraction across C2 to C3 disc and flexion angulation of C2–body and dens. Müller subclassified type II fractures as flexion, extension, and listhesis. Type III is a fracture of the pars interarticularis with C2 to C3 facet dislocations. This classification is for adult patients and may not be completely applicable to pediatric patients.[176,213]

FIGURE 23-48 Lateral radiograph of patient with traumatic C2 spondylolisthesis (Hangman's fracture).

Treatment Options for Hangman's Fracture

Nonoperative Treatment of Hangman's Fracture

Treatment of stable Hangman's fractures should be with immobilization in a Minerva cast, halo, or cervical orthosis for 8 to 12 weeks. Pizzutillo et al.[234] reported that four of five patients healed with immobilization (Table 23-24).

Operative Treatment of Hangman's Fracture

If union does not occur or there is documented instability, a posterior or anterior arthrodesis can be done to stabilize this fracture. Posterior or anterior arthrodesis may be necessary (pp. 877–881).

TABLE 23-24 Hangman's Fracture

Nonoperative Treatment

Indications	Relative Contraindications
Stable fracture	Nonunion Documented instability

Subaxial (C3-C7) Injuries

Fractures and dislocations involving C3 to C7 are rare in children and infants.[92,148,190,271] and usually occur in teenagers or older children. Lower cervical spine injuries in children as opposed to those in adults can occur through the cartilaginous endplate.[67] The endplate may break completely through the cartilaginous portion (Salter–Harris type I) or may exit through the bony edge (Salter–Harris type II). Usually, the inferior endplate fractures because of the protective effect of the uncinate processes of the superior endplate.[16,307]

Depending on the size and anatomy of the patient, adult posterior instrumentation techniques with screw and rods usually can be used in subaxial spine fractures.[146] Occasionally, wire fixation may be needed for posterior stabilization of subaxial spine fractures. Posterior instrumentation techniques that are used in the adult spine (plate or rods and lateral mass screws) can be used in the pediatric cervical spine. Before these techniques are used, the size of the lateral masses must be evaluated to ensure that there is adequate room to place these screws.

Posterior Ligamentous Disruptions

Assessment of Posterior Ligamentous Disruptions

Mechanism of Injury for Posterior Ligamentous Disruption

Posterior ligamentous disruption can occur with a flexion or distraction injury to the cervical spine.

Associated Injuries with and Signs and Symptoms of Posterior Ligamentous Disruption

Intervertebral disc disruption, facet fracture, and other ligamentous disruptions may be associated with this injury. The patient usually has point tenderness at the injury site and complains of neck pain.

Imaging and Other Diagnostic Studies for Posterior Ligamentous Disruption

Initial radiographs may be normal except for loss of normal cervical lordosis. This may be a normal finding in young children but should be evaluated for possible ligamentous injury in an adolescent. Widening of the posterior interspinous distance is suggestive of this injury. Guidelines for instability in children have not been fully developed. Instability in adults has been defined as angulation between adjacent vertebrae in the sagittal plane of 11 degrees more than the adjacent normal segment or translation in the sagittal plane of 3.5 mm or more.[167,168,237,238] Brockmeyer[39] has suggested that more than 7 degrees of kyphotic angulation between adjacent vertebral bodies in the pediatric spine implies an unstable ligamentous injury.[200,201] MRI may be helpful in documenting ligamentous damage.

Reproduced with permission from Patel JC, Dailey A, Brodke DS, et al. Subaxial cervical spine trauma classification: The Subaxial Injury Classification system and case examples. *Neurosurg Focus.* 2008;25:E8.

Classification of Posterior Ligamentous Disruption

The Subaxial Injury Classification (SLIC) and Severity score identifies three major injury characteristics to describe subaxial cervical injuries: injury morphology, discoligamentous complex integrity, and neurologic status (Table 23-25).[229]

Treatment Options for Posterior Ligamentous Disruption

Nonoperative Treatment of Posterior Ligamentous Disruption

Posterior ligamentous injuries if stable should be protected with an extension orthosis, and patients should be followed closely for the development of instability (Table 23-26).

TABLE 23-26 Posterior Ligamentous Disruption

Nonoperative Treatment

Indications	Relative Contraindications
Stable posterior ligamentous disruption	Instability

Operative Treatment of Posterior Ligamentous Disruption

If signs of instability are present, then a posterior arthrodesis should be performed (See pp. 891–894).

Compression Fracture

Compression fractures are stable injuries and heal in children in 3 to 6 weeks.

Assessment of compression fracture

Mechanisms of Injury for Compression Fracture

Compression fractures, the most common fractures of the subaxial spine in children, are caused by flexion and axial loading that result in loss of vertebral body height.

Associated Injuries with and Signs and Symptoms of Compression Fracture

Associated injuries can include anterior teardrop, laminar, and spinous process fractures. Pain and neurologic symptoms may be present.

Imaging and Other Diagnostic Studies for Compression Fracture

These injuries can be detected on a lateral radiograph. Because the vertebral disks in children are more resilient than the vertebral bodies, the bone is more likely to be injured. Many compression fractures may be overlooked because of the normal wedge shape of the vertebral bodies in young children. Flexion and extension films to confirm stability should be obtained 2 to 4 weeks after injury. In children under 8 years of age, the vertebral body may reconstitute itself with growth, although Schwarz et al.[262] reported that kyphosis of more than 20 degrees may not correct with growth.

Classification of Compression Fracture

See Table 23-25 for subaxial cervical spine injury classification.

Treatment Options for Compression Fracture

Nonoperative Treatment of Compression Fracture

Immobilization in a cervical collar is recommended for 3 to 6 weeks.

Operative Treatment of Compression Fracture

Operative treatment is not usually necessary.

Unilateral and Bilateral Facet Dislocations

Unilateral facet dislocations and bilateral facet dislocations are the second most common injuries in the subaxial spine in children. Most occur in adolescents and are similar to adult injuries.

Assessment of Unilateral and Bilateral Facet Dislocations

Mechanisms of Injury for Unilateral and Bilateral Facet Injury Dislocations

Facet dislocations can occur from a range of injury mechanisms that include hyperflexion, hyperextension, and/or axial rotation injuries from motor vehicle accidents, diving accidents, and falls.

Associated Injuries with and Signs and Symptoms of Unilateral and Bilateral Facet Dislocations

Cervical spine ligamentous injuries are often associated with bilateral dislocations as well as disc herniations. Bilateral facet dislocation has a high risk of cord damage.

Unilateral facet dislocation may have minimal localized pain or no symptoms; however, pain and neurologic symptoms are frequent in bilateral dislocations.

Imaging and Other Diagnostic Studies for Unilateral and Bilateral Facet Dislocations

The diagnosis usually can be made on anteroposterior and lateral radiographs. In children, the so-called perched facet is a true dislocation. The cartilaginous components are overlapped and locked. On the radiograph, the facet appears perched because the overlapped cartilage cannot be seen.

Classification of Unilateral and Bilateral Facet Dislocations

See Table 23-25 for subaxial spine injury classification.

Treatment Options for Unilateral and Bilateral Facet Dislocations

Nonoperative Treatment of Unilateral and Bilateral Facet Dislocations

Unilateral facet dislocation is treated with traction and reduction.

Operative Treatment of Unilateral and Bilateral Facet Dislocations

Indications/Contraindications

If reduction cannot be easily obtained, open reduction and arthrodesis are indicated. Complete bilateral facet dislocation, although rare, is more unstable and has a higher incidence of neurologic deficit (Fig. 23-49). In a patient with bilateral jumped facets and motor-complete spinal cord injury, and emergent reduction followed by immediate MRI to evaluate for an epidural hematoma or herniated disk should be done. In a patient who is neurologically intact or has a motor-incomplete lesion with jumped facets, an urgent MRI is obtained to evaluate for a herniated disk or hematoma in the canal. In the absence of such a lesion, a closed reduction is obtained by traction. After reduction, treatment may consist of either an anterior or posterior instrumentation and arthrodesis (pp. 891–894).

Burst Fracture

Although rare, burst fractures can occur in children.

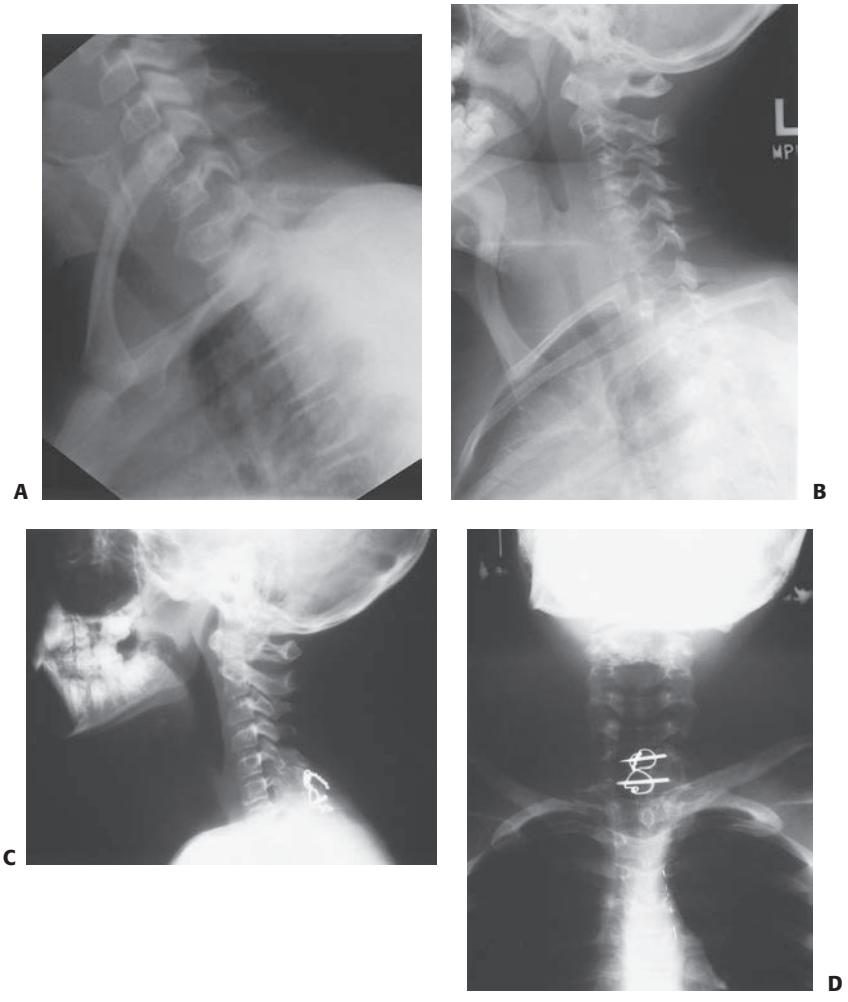

FIGURE 23-49 **A, B:** Lateral radiograph of a patient with the so-called perched facets, demonstrating a facet dislocation. **C, D:** Lateral and anteroposterior radiographs after reduction and posterior arthrodesis.

Assessment of Burst Fracture

Mechanisms of Injury for Burst Fracture

These injuries are caused by an axial load after high-energy trauma.

Associated Injuries with and Signs and Symptoms of Burst Fracture

Patients may present with pain, deformity, and neurologic symptoms.

Imaging and Other Diagnostic Studies for Burst Fracture

Radiographic evaluation should consist of anteroposterior and lateral views. CT scans aid in detecting any spinal canal compromise from retropulsed fracture fragments and occult laminar fractures. The posterior aspect of the vertebral body can displace posteriorly, causing canal compromise and neurologic deficit. Loss of body height may be noted on radiographs.

Classification of Burst Fracture

See Table 23-25 for classification of subaxial injuries. Treatment decisions are based on the severity of deformity, canal compromise, degree of vertebral body height loss, and degree of neurologic deficit.

Treatment Options for Burst Fracture

Nonoperative Treatment of Burst Fracture

If no neurologic deficit or significant canal compromise is present, treatment consists of traction followed by halo immobilization (Table 23-27).

Operative Treatment of Burst Fracture

Anterior arthrodesis rarely is recommended in pediatric patients, except in a patient with a burst fracture and significant canal compromise.[264] Anterior arthrodesis destroys the anterior growth potential; as posterior growth continues, a kyphotic deformity may occur (Fig. 23-50). In older children and adolescents, anterior instrumentation can be used for stabilization (Fig. 23-51). Anterior instrumentation can be used for

TABLE 23-27 Burst Fracture

stabilization in older children and adolescents when there is significant canal compromise (p. 895).

Spondylolysis and Spondylolisthesis

Spondylolysis and spondylolisthesis of C2 to C6 have been reported.

Assessment of Spondylolysis and Spondylolisthesis

Mechanisms of Injury for Spondylolysis and Spondylolisthesis

These injuries can occur from either a hyperextension or flexion axial loading injury.

Associated Injuries with and Signs and Symptoms of Spondylolysis and Spondylolisthesis

Associated anterosuperior avulsion or compression fractures of the vertebral body may occur. Patients may present with shoulder or localized neck pain.

Imaging and Other Diagnostic Studies for Spondylolysis and Spondylolisthesis

The diagnosis usually is made on plain radiographs that show a fracture line through the pedicles. Oblique views may be necessary to better identify the fracture line. CT imaging and MRI may be useful in differentiating an acute fracture from a normal synchondrosis.

Classification of Spondylolysis and Spondylolisthesis

See Table 23-5 for SLIC.

TABLE 23-28 Spondylolysis and Spondylolisthesis

Nonoperative Treatment

Indications	Relative Contraindications
Stable spondylolysis and spondylolisthesis	Instability Nonunion

Treatment Options for Spondylolysis and Spondylolisthesis

Nonoperative Treatment of Spondylolysis and Spondylolisthesis

Treatment consists of immobilization in a cervical orthosis or halo brace (Table 23-28).

Operative Treatment of Spondylolysis and Spondylolisthesis

Surgical stabilization is recommended only for truly unstable fractures or nonunions. Neurologic involvement is rare.

Surgical Procedure for Subaxial Injuries

Posterior Arthrodesis (Fig. 23-52)

Preoperative Planning. See p. 859 for preoperative planning.

Positioning. See p. 859 for position for cervical spine injury. The patient is placed prone using a Mayfield headrest or Gardner-Wells tongs or a halo ring attached to a Mayfield headrest.

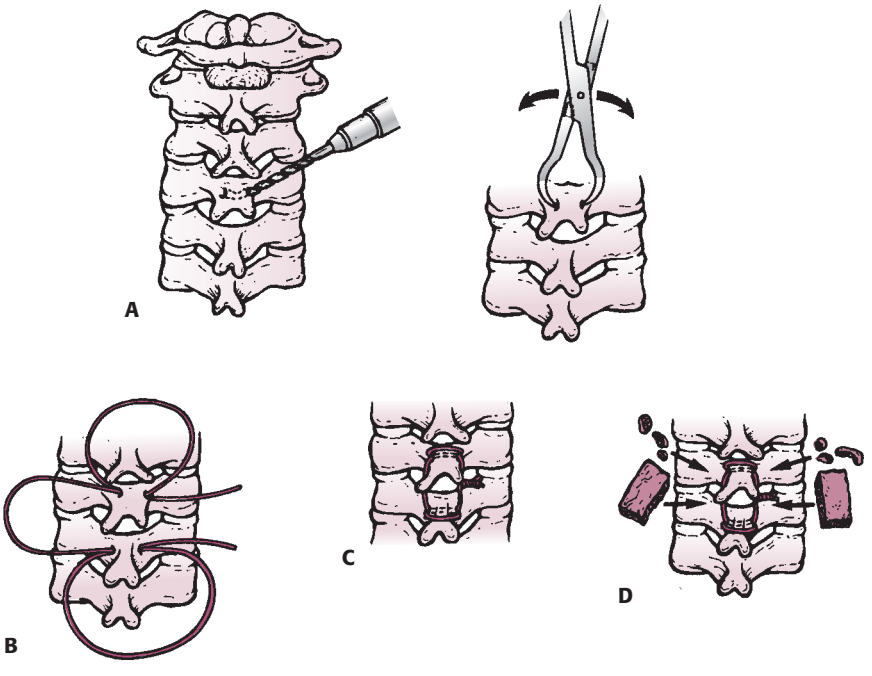

FIGURE 23-52 Technique of posterior arthrodesis in subaxial spine levels C3 to C7. **A:** A hole is made in the spinous process of the vertebrae to be fused. **B:** An 18-gauge wire is passed through both holes and around the spinous processes. **C:** The wire is tightened. **D:** Corticocancellous bone grafts are placed. (From Murphy MJ, Southwick WO. Posterior approaches and fusions. In: Cervical Spine Research Society. *The Cervical Spine.* Philadelphia, PA: JB Lippincott, 1983:506–507, with permission.)[205]

Surgical Approach. See p. 860 for posterior approach to the cervical spine.

Technique. Radiographs are obtained to confirm adequate alignment of the vertebrae and to localize the vertebrae to be exposed. Extension of the fusion mass can occur when extra vertebrae or spinous processes are exposed in the cervical spine. A midline incision is made over the chosen spinous processes, and the spinous process and lamina are exposed subperiosteally to the facet joints.

If the spinous process is large enough, a hole is made in the base of the spinous process with a towel clip or Lewin clamp. An 18-gauge wire is passed through this hole, looped over the spinous process, and passed through the hole again. A similar hole is made in the base of the spinous process of the inferior vertebra to be fused, and the wire is passed through this vertebra. The wire is then passed through this hole, looped under the inferior aspect of the spinous process, and then passed back through the same hole. The wire is tightened and corticocancellous bone grafts are placed along the exposed lamina and spinous processes. The wound is closed in layers. If the spinous process is too small to pass wires, then an in situ arthrodesis can be performed and external immobilization used.

Hall et al.[117] used a 16-gauge wire and threaded Kirschner wires. The threaded Kirschner wires are passed through the bases of the spinous processes of the vertebrae to be fused. This is followed by a figure-of-eight wiring with a 16-gauge wire (Fig. 23-53). After tightening the wire about the Kirschner wires, strips of corticocancellous and cancellous bone are packed over the posterior arches of the vertebrae to be fused (Table 23-29).

Surgical Procedure: Posterior Arthrodesis with Lateral Mass Screw Fixation

Several techniques of lateral mass screw fixation for the lower cervical spine have been described. They differ primarily in the entry points for the screws and in the trajectory of screw placement, which yield different exit points.[180,249]

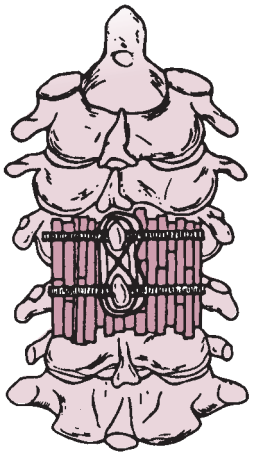

FIGURE 23-53 Alternative fixation method for posterior arthrodesis of C3 to C7. A 16-gauge wire is placed in a figure-of-eight pattern around two threaded Kirschner wires passed through the bases of the spinous processes of the vertebrae to be fused. (From Hall JE, Simmons ED, Danylchuk K, et al. Instability of the cervical spine and neurological involvement in Klippel–Feil syndrome: A case report. *J Bone Joint Surg Am.* 1990; 72:460, with permission.)[118]

TABLE 23-29 Posterior Arthrodesis for Subaxial Injuries

Surgical Steps

- Expose the chosen spinous processes with a midline incision
- Make a hole in the base of the spinous process and in spinous process of inferior vertebra to be fused
- Pass wire and tighten
- Place corticocancellous bone graft
- Close wound in layers

Preoperative Planning. See p. 859 for preoperative planning.

Positioning. See p. 859 for position for cervical spine injury. The patient is placed prone using a Mayfield headrest or Gardner-Wells tongs or a halo ring attached to a Mayfield headrest.

Surgical Approach. See p. 860 for posterior approach to the cervical spine.

Technique (Roy-Camille).[250] The entry point for the screw is at the center of the rectangular posterior face of the lateral mass or can be measured 5 mm medial to the lateral edge and midway between the facet joints (Fig. 23-54A). The drill is directed perpendicular to the posterior wall of the vertebral body with a 10-degree lateral angle (Fig. 23-54B). This trajectory establishes an exit point slightly lateral to the vertebral artery and below the exiting nerve root. The lateral mass depth from C3 to C6 ranges from 6 to 14 mm in men (average 8.7 mm) and 6 to 11 mm in women (average 7.9 mm). An adjustable drill guide set to a depth of 10 to 12 mm is used to prevent penetration beyond the anterior cortex. The depth can be gradually and safely increased if local anatomy permits. If the additional 20% of pullout strength with bicortical fixation is desired, the exit point should be at the junction of the lateral mass and the transverse process. Lateral fluoroscopic imaging makes it easier to choose the optimal trajectory and avoid penetration of the subjacent facet joint (Fig. 23-54C), which is especially important at the caudal level of fixation because this joint should be included in the fusion (Table 23-30).

Technique (Magerl). The entry point for the screw is 1 mm medial and rostral (proximal) to the center point of the posterior surface of the lateral mass (Fig. 23-55A). It is oriented at a 45- to 60-degree rostral angle, parallel to the adjacent facet

TABLE 23-30 Posterior Arthrodesis with Lateral Mass Screw Fixation (Roy-Camille)

Surgical Steps

- Place entry point for screw at center of rectangular posterior face of lateral mass
- Drill perpendicular to posterior wall to a safe depth
- Exit point should be at junction of lateral mass and transverse process for additional pullout strength

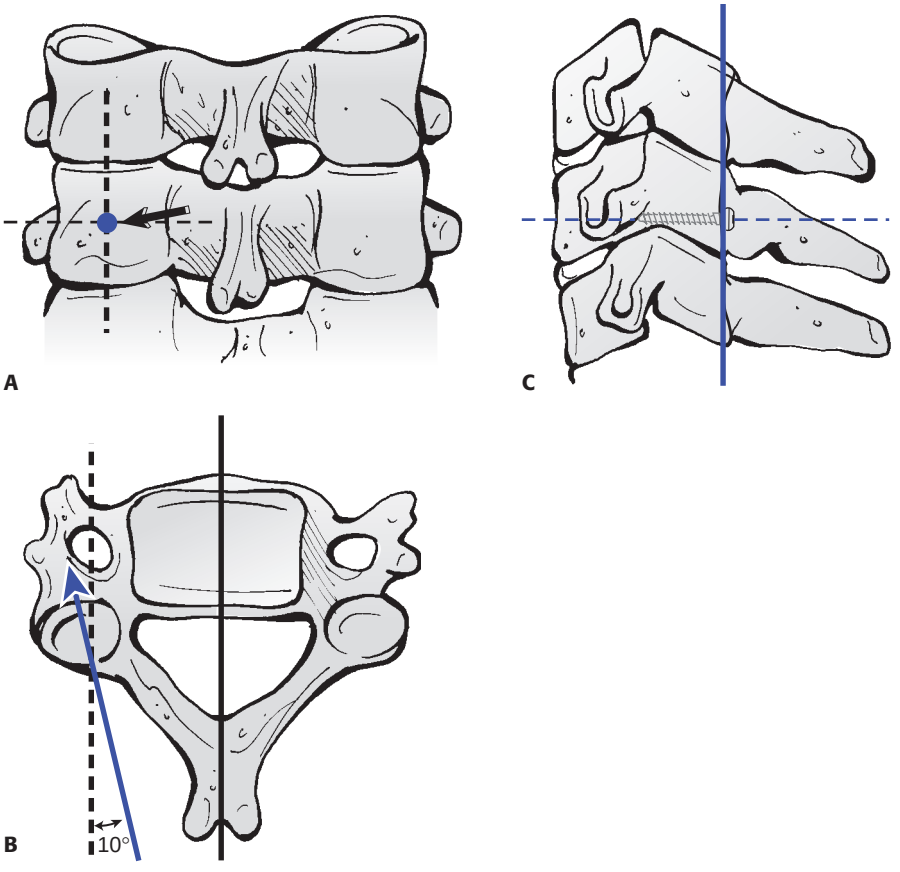

FIGURE 23-54 Roy-Camille technique of lateral mass screw insertion. **A:** Entry point for screw insertion. **B:** Drill is directed perpendicular to posterior wall of vertebral body with a 10-degree lateral angle. **C:** Final screw position. (From Heller JG, Jeffords P. Internal fixation of the cervical spine. Posterior instrumentation of the lower cervical spine. In: Frymoyer JW, Wiesel SW, eds. *The Adult and Pediatric Spine*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2004, with permission.)

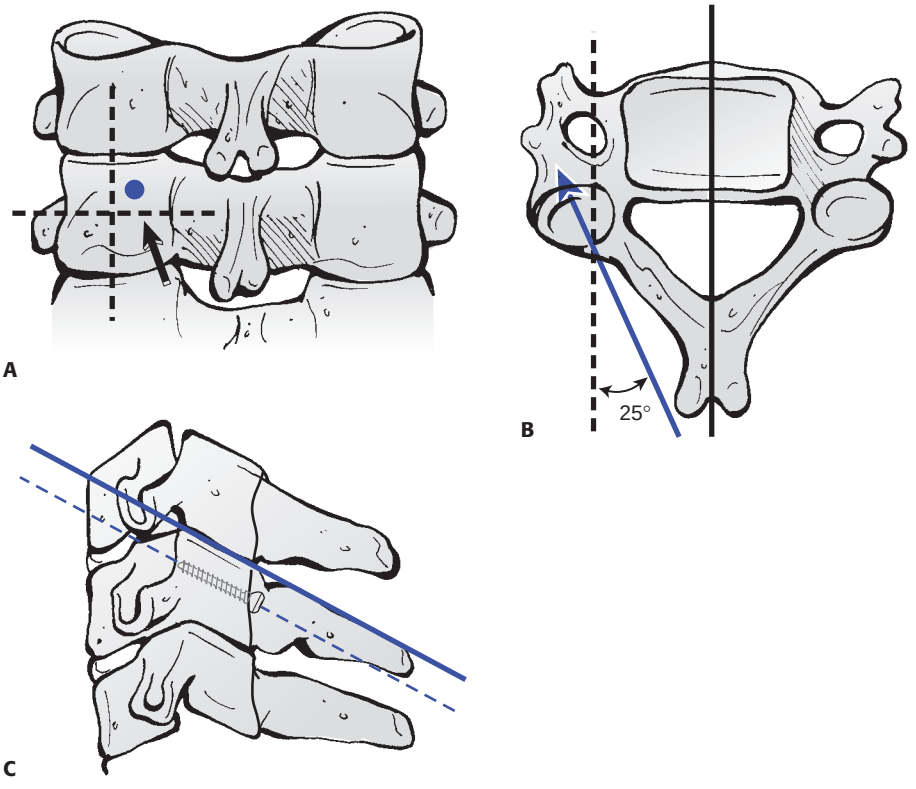

FIGURE 23-55 Magerl technique of lateral mass screw insertion. **A:** Entry point for screw insertion. **B:** Drill is directed at a 25-degree lateral angle. **C:** Final screw position. (From Heller JG, Jeffords P. Internal fixation of the cervical spine. Posterior instrumentation of the lower cervical spine. In: Frymoyer JW, Wiesel SW, eds. *The Adult and Pediatric Spine*. 3rd ed. Philadelphia, PA: Lippincott C Williams & Wilkins, 2004, with permission.)

TABLE 23-31 Posterior Arthrodesis with Lateral Mass Screw Fixation (Magerl)

Surgical Steps

- Place entry point for screw 1 mm medial and rostral to center point of posterior surface of lateral mass
- Drill at a 45- to 60-degree rostral angle parallel to adjacent fact joint articular surface and 25-degree lateral angle
- Depth of penetration is approximately 18 mm

joint articular surface, and at a 25-degree lateral angle (Fig. 23-55B). This trajectory establishes an exit point lateral to the vertebral artery and above the exiting nerve root while engaging the lateral portion of the ventral cortex of the superior articular facet (Fig. 23-55C). The proper trajectory for this technique is more difficult to achieve that in the Roy-Camille technique. The prominence of the thorax can impede proper alignment of the drill and guide, risking injury to the nerve root if the second cortex is penetrated. The depth of penetration at this angle is approximately 18 mm, compared to 14 mm with the Roy-Camille technique, which has some implications for purchase strength and mode of screw failure (Table 23-31).

Surgical Procedure: Crossed Translaminar Screw Fixation of C2

Crossed translaminar screws may be used for posterior fixation if the lateral masses are not adequate for screw fixation. This has been described for fixation at C2 but can also be used in the lower cervical spine.

Preoperative Planning. See p. 859 for preoperative planning.

Positioning. See p. 859 for position for cervical spine injury. The patient is placed prone with the head maintained in the neutral position in a Mayfield head holder.

Surgical Approach. See p. 860 for posterior approach to the cervical spine.

Technique. The posterior arch of C1 and the spinous process, laminae, and medial–lateral masses of C2 are exposed. A high-speed drill is used to open a small cortical window at the junction of the C2 spinous process and the lamina on the left, close to the rostral margin of the C2 lamina (Fig. 23-56). With a hand drill, the contralateral (right) lamina is carefully drilled along its length, with the drill visually aligned along the angle of the exposed contralateral laminar surface. A small ball probe is used to palpate the length of the drill hole and verify that no cortical breakthrough into the spinal canal has occurred. A 4-mm diameter polyaxial screw is inserted along the same trajectory. In the final position, the screw head remains at the junction of the spinous process and lamina on the left, with the length of the screw within the right lamina. Next, a small cortical window is made at the junction of the spinous process and lamina of C2 on the right, close to the caudal aspect of the lamina. Using the same technique, a 4-mm diameter screw is placed into the left lamina, with the screw head remaining on the right side of the spinous process (Fig. 23-57). Appropriate rods are then placed into the screw heads and attached to C1 screws or lateral mass screws below C2 (Fig. 23-58 and Table 23-32).[53,174]

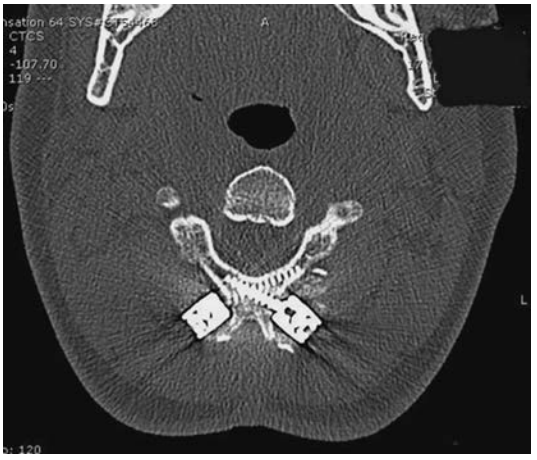

FIGURE 23-57 CT shows placement of screws.

Potential Pitfalls and Preventative Measures. See p. 860 for potential pitfalls with posterior approaches.

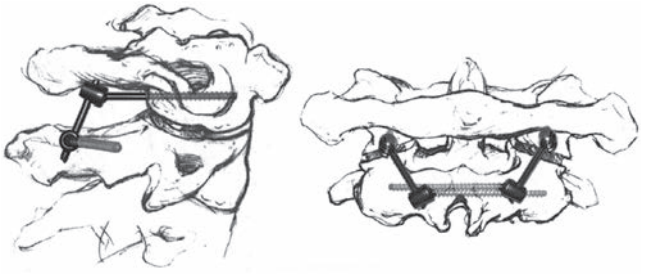

FIGURE 23-58 Lateral (*left*) and anteroposterior (*right*) views of completed C1 to C2 fixation with C1 lateral mass screws connected to C2 laminar screws (*lateral view*). (From Leonard JR, Wright NM. Pediatric atlantoaxial fixation with bilateral, crossing C2 translaminar screws. Technical note. *J Neurosurg Pediatr.* 2006;104:59–63, with permission.)

Anterior Arthrodesis

In older pediatric patients and adolescents, adult anterior instrumentation and fusion techniques may be used. Anatomy of the vertebral body should be evaluated preoperatively to determine if anterior plates and screws may be used.[22]

Author's Preferred Treatment for Cervical Spine Injury

Occipital Condyle Fracture

Most occipital condyle fractures can be treated nonoperatively with an orthosis. A rigid occipital mandibular orthosis or cervical collar is the preferred method of immobilization. In the rare case that surgical stabilization is needed **(type III),** fusion from the occiput to C2 with a Luque rod and wire instrumentation or an occipital plate with screw fixation are recommended.

Atlantooccipital Instability.

Atlantooccipital dislocation is an unstable ligamentous injury. The author recommends operative treatment in the vast majority of patients. Fusion with instrumentation of the occiput to C2 is the preferred treatment. Instrumentation will depend on the size of the patient and the anatomy of the upper cervical spine. In small children in whom placement of screws will be difficult, contoured Luque rods and cables will give adequate stabilization. This provides immediate stabilization, and the patient can be mobilized in a cervical collar. If the patient's anatomy allows, an occipital plate and C1 and C2 screw fixation can be used; this rod and screw fixation provides more secure fixation than Luque rods and cables. These injuries usually are in younger patients, and screw and plate instrumentation may not be possible. Instrumentation to C2 is preferred over ending instrumentation at C1. There are usually significant soft tissue injuries and associated injuries. Extending the fusion and instrumentation to C2 gives better fixation and more surface area for fusion but is at the expense of increased loss of motion of the upper cervical spine postoperatively.

TABLE 23-32 Crossed Translaminar Screw Fixation of C2

Surgical Steps

- Open a small cortical window at C2 spinous process and lamina on left
- Drill right lamina and insert a 4-mm polyaxial screw
- Make a small cortical window at junction of spinous and lamina of C2 on right
- Drill left lamina and insert a 4-mm polyaxial screw
- Place rods into screw heads and attach to C1 screws or lateral mass screws

Fractures of the Atlas

Most pediatric patient with an atlas fracture may be treated nonoperatively. Minimally displaced fractures or greenstick type fractures through the synchondrosis often can be treated in a rigid collar. If there is significant displacement on plain radiographs (>7 mm overhand) or on CT scan, then a short period of traction followed by halo immobilization is recommended.

Odontoid Fracture

Most odontoid fractures can be treated nonoperatively in an extension Minerva cast or halo cast or brace. If the patient cannot be managed nonoperatively, then a C1 to C2 fusion is the authors' preferred method. In older children, the Harms C1, C2 instrumentation is used. If the anatomy does not allow for screw fixation, then a Brooks-type fusion is performed, and patient is immobilized in a halo.

Atlantoaxial Instability

Atlantoaxial instability from rupture of the transverse ligament is rare in children.

When an avulsion fracture of the transverse ligament occurs and is nondisplaced, nonoperative treatment may be considered in this special situation. Most injuries to the transverse ligament are unstable. The authors' preferred method of stabilization is with the Harms C1, C2 screw and rod technique and posterior fusion. Transarticular screw fixation is another acceptable stabilization method but is more difficult in a small child because of anatomical consideration. If the anatomy does not allow for safe placement of screws, then Brooks instrumentation and fusion are recommended. This will require halo or Minerva cast immobilization postoperatively.

Subaxial Injuries

Most subaxial injuries occur in older children and adult instrumentation and fusion techniques are appropriate. In unstable subaxial injuries, such as facet fracture dislocations, lateral mass screw and rod fixation usually can be performed in children. Anterior instrumentation and fusion may need to be performed in burst type fractures or fracture-dislocation with disc herniation.

24 THORACOLUMBAR SPINE FRACTURES

Peter O. Newton and Scott J. Luhmann

Introduction to Thoracolumbar Spine Fractures

Fractures of the thoracic and lumbar spine in pediatric patients are relatively uncommon compared with those in adult patients.[33,68] Although cervical spine injuries outnumber thoracic and lumbar spinal column injuries, fractures of the thoracolumbar region are certainly not rare. The mechanisms of injury vary with age,[16,69] whereas the classification of these injury patterns follow adult spine fracture guidelines. These fractures can be broadly grouped as compression, burst, flexion–distraction, and fracture-dislocations. The treatment principles are based on the mechanism of injury and the "stability" of the fracture.

Clarifying the stability of any given fracture can be challenging, and controversy remains as to how to establish which fractures require surgical stabilization. The status of the neurologic system is an important variable in treatment.[3,24] In addition, other associated injuries are common,[5] particularly with flexion–distraction "lap belt" injuries.[31,36,47,51,65] Understanding the mechanism of injury, the neurologic status and associated injuries will allow logical decision making about the treatment approach to a pediatric patient with thoracolumbar spinal injury.

The goals of treatment for all spinal injuries are to maximize the potential for recovery of spinal cord function if a spinal cord injury (SCI) was present and/or to provide skeletal stability to the spinal column to protect against future SCI. These two goals may be analyzed separately when both instability and SCI exist. Optimizing return of any lost spinal cord function is paramount, and the potential for recovery of spinal cord function in general is greater in children than in adults.[24,83]

Assessment of Thoracolumbar Spine Fractures

Mechanisms of Injury of Thoracolumbar Spine Fractures

One of the most important aspects of treating thoracolumbar spinal fractures is understanding the mechanism of injury. In general, the mechanism of injury correlates with the age of the patient.[16] Spine trauma, just like appendicular trauma, should generate concern for nonaccidental injury in infants and young children.[12,18,42] Levin et al.[48] reported on seven unstable thoracolumbar spinal fractures in abused children.

Motor vehicle accidents may be the most common cause of spinal column injury in all age groups.[5] The type of seat belt restraint has clear implications in the mechanism of force transfer to the spine, with the lap belt a common cause of both intra-abdominal and spinal injuries.[31,47,65,70,76] The lap belt has been long known to create hyperflexion of the trunk over the belt with the spine pinching the intra-abdominal organs anteriorly. The point of flexion is anterior to the spine leading to anterior compression combined with posterior column distraction (Fig. 24-1). Addition of a shoulder strap or child seat with a full frontal harness limits flexion with frontal impact accidents and protects the spine (and other parts of the body) from injury.

Falls from a height generally result in axial loading of the spine, which may result in a "burst" fracture or wedge compression fracture, depending on the degree of flexion of the trunk at the time of impact. These fracture patterns are possible with any mechanism associated with axial compression and can occur with motor vehicle accidents and sporting injuries.[16] Compression of the vertebra with the trunk flexed creates the greatest forces in the anterior aspect of the vertebra, leading more commonly to anterior column wedging. This is in contrast to the trunk in an extended position, which loads the vertebral body more symmetrically. Fractures in this case often collapse with radial expansion or "bursting." Displacement of the posterior vertebral body fragments into the spinal canal may cause injury or compression of the neurologic elements (spinal cord or cauda equina).[34]

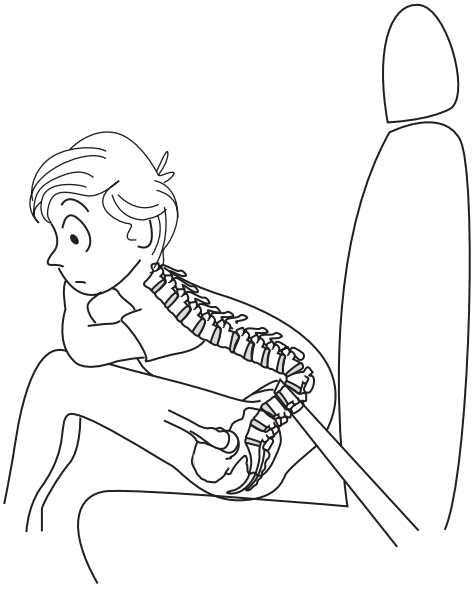

FIGURE 24-1 A lap belt used for a child can create a point of rotation about which the spine is flexed with an abrupt stop. This is a common mechanism for creating both intra-abdominal and flexion–distraction spinal injuries.

If the magnitude of injury sustained seems out of proportion to the force applied, the possibility of an insufficiency fracture due to weak bone should be considered. Osteoporotic insufficiency fractures, common in the elderly, are rare in children; however, several disease states may predispose children to these fractures. Chronic corticosteroid use associated with the management of many pediatric rheumatologic and cancerous diseases often leads to osteoporosis and increased risk of compression fractures.[80] In addition, primary lesions of the bone, such as Langerhans histiocytosis, often affects thoracic vertebrae.[4,25] Other tumors and infections warrant consideration when nontraumatic compression fractures are identified.[54,67]

Associated Injuries with Thoracolumbar Spine Fractures

Just as the mechanism of injury should raise suspicion of a particular injury (e.g., lap belt injury and flexion–distraction lumbar fracture pattern), so should the presence of one injury raise suspicion of a concomitant associated injury. First, any spinal fracture should be considered a significant risk factor for a spinal fracture at another level.[50] The traumatic force required to create one fracture is often enough to result in one or more additional fractures at other locations. Similarly, a cervical injury is frequently associated with closed head injury and vice versa.

The lap belt mechanism of injury is well known to create flexion–distraction injuries of the spine, but also is associated with intra-abdominal injury.[65] Compressed between the seat belt and the spinal column, the aorta, intestinal viscera, and abdominal wall musculature are at risk for laceration. Abdominal injuries are present in almost 50% of pediatric patients with Chance fractures.[56] Ecchymosis on the anterior abdomen is suggestive of intra-abdominal injury that warrants further evaluation with laparoscopy, laparotomy, or additional imaging by computed tomography (CT).[5,76] A high index of suspicion is required, because missed injuries may be life-threatening.[47]

Associated injury to the spinal cord has obvious significance and may be present with many fracture patterns. Disruption of the stability of the spinal column or bony intrusion into the spinal canal may result in compromise of neurologic function. All patients with a known spinal column fracture or dislocation warrant a careful neurologic examination. Overall, most pediatric patients with thoracolumbar fractures are neurologically intact (85%), and less commonly present with SCIs (incomplete in 5% and complete in 10%).[20] Similarly, patients with a traumatic neurologic deficit require a careful evaluation of the spinal column integrity. There are, however, a subset of patients who present with SCI without

radiographic abnormality.[57,58] This scenario has been termed SCIWORA, a phenomenon much more common in children than adults. It is thought that the flexibility of the immature spine allows spinal column segmental displacements great enough to lead to SCI without mechanically disrupting the bony and/or ligamentous elements.[57] Although these injuries may not be visible on plain radiographs, nearly all will have some evidence of soft tissue injury of the spine on more sensitive magnetic resonance imaging (MRI) studies.[29] The term SCIWORA is less relevant in the era of routine MRI, which is now obtained in all patients with possible SCI[39] and some have suggested a new acronym SCIWONA (SCI without neuroimaging abnormality).[79,90]

Signs and Symptoms of Thoracolumbar Spine Fractures

Careful evaluation of a patient with a potential traumatic spinal injury begins as with any serious trauma victim. The ABCs of resuscitation (airway, breathing, circulation) are performed while maintaining cervical and thoracolumbar spinal precautions. The frequency of spinal injuries in the setting of major trauma (motor vehicle accident, fall, etc.) is particularly high. After stabilizing the cardiorespiratory systems, symptoms of pain, numbness, and tingling should be sought if the patient is old enough and alert enough to cooperate. Pain in the back is often not appreciated when other distracting injuries exist and the patient is immobilized on a backboard. Examination of the back must not be forgotten and is performed by logrolling the patient. Visual inspection, along with palpation, should seek areas of swelling, deformity, ecchymosis, and/or tenderness that may provide a clue to the presence of an injury. In trauma patients, thoracolumbar fractures are more common in older children and adolescents, and there is a low mortality rate and infrequent need for operative stabilization.[71] Clinically the ability to diagnosis a thoracolumbar spine fracture in pediatric trauma patients has been demonstrated to have good sensitivity and average specificity.[37] Hence routine screening radiographs of any patients suspected of having a thoracolumbar spine injury should be performed, to minimize the likelihood of missing an injury.

Neurologic examination provides information on the integrity of the spinal cord. The age of the patient may limit the thoroughness of this assessment, but some indication of sensory and motor function should be sought. In cases of spinal cord deficit, a detailed examination of the strength of each muscle group, sensory levels, and rectal tone will need to be serially compared over time and the quality of the documentation cannot be overemphasized. The prognosis for recovery is significantly better if the SCI is incomplete.[13,32,83] The status of the neurologic function over time may lead to important treatment decisions regarding the necessity and timing of surgical intervention. A progressive neurologic deficit warrants immediate surgical attention, whereas an improving status may suggest a less urgent approach. Overall, the physical examination has a sensitivity of 87% in identifying thoracolumbar fractures.[71]

Imaging and Other Diagnostic Studies for Thoracolumbar Spine Fractures

Following a careful clinical examination of all patients with a suspected spinal injury, plain radiographs are usually valuable. An alert, cooperative patient without pain or tenderness in the back can be cleared without radiographs. However, any patient with a significant mechanism or associated injury (motor vehicle accident, fall from greater than 10 ft, major long-bone fracture, cervical or head injury) requires thoracolumbar spine radiographs if they have spinal tenderness, are obtunded, or have a distracting injury. Initial films should include supine anteroposterior (AP) and lateral views of the thoracic and lumbar spine. In addition, because of the strong association between cervical spine fractures and thoracolumbar spine fractures after blunt vehicular trauma, routine imaging of the complete spine when a cervical fracture is identified is indicated.[87]

Plain radiographs often show relatively subtle findings that should be sought in all cases. On AP radiographs, soft tissue shadows may be widened by paravertebral hematoma. The bony anatomy is viewed to evaluate for loss of height of the vertebral body as compared with adjacent levels. Similar comparisons can be made with regard to interpedicular distance and interspinous spacing.[10] Lateral radiographs give important information about the sagittal plane: Anterior vertebral wedging or collapse or posterior element distraction or fracture. Careful scrutiny of the plain radiographs is always prudent; however, the CT scan will nearly always be used to clarify any suspected fractures. Antevil et al.[1] reported the sensitivity of plain radiographs to be 70% (14 of 20 patients) for spine trauma, whereas the sensitivity was 100% for CT scanning (34 of 34 patients).

CT is now a standard component of the evaluation of many trauma patients. Multidetector scanners allow rapid assessment with axial, coronal, and sagittal images for patients with plain radiographic abnormalities. The axial images are best for evaluating the integrity of the spinal canal in cases of a burst fracture, whereas the sagittal views will demonstrate vertebral body compression as well as posterior element distraction or fracture. In addition, major dislocations easily seen on plain radiographs will be better understood with regard to the space left in the spinal canal for the neurologic elements. The amount of spinal canal compromise has been correlated with the probability of neurologic deficit.[55]

MRI is the modality of choice for evaluating the discs, spinal cord, and posterior ligamentous structures.[39,46,77] Although more difficult to obtain in a multiply injured patient, this study is mandatory in patients with a neurologic deficit to assess the potential cause of cord dysfunction. The MRI is able to distinguish areas of spinal cord hemorrhage and edema. Assessment of the posterior ligamentous complex (PLC) is critical in differentiating stable and unstable burst fractures, as well as compression fractures and flexion–distraction injuries. Although subject to overinterpretation, MRI has been shown to modify the diagnosis made by plain radiographs and CT and correlates very well with intraoperative findings of the structural integrity of the posterior soft tissues.[46,62]

Classification of Thoracolumbar Spine Fractures

There are several methods of classifying thoracolumbar fractures: Holdsworth—two column, Denis—three column,[17] McCormack—load sharing,[53] Gertzbein—comprehensive,[27] Thoracolumbar Injury Classification and Severity Score,[61] each with purported advantages. Designed primarily with the adult spine fracture patterns in mind, the Denis classification translates well for the categorization of most pediatric thoracolumbar injuries.[44] Based on theories of stability related to the three-column biomechanical concept of the spine (anterior, middle, posterior columns), the Denis classification in its simplest form includes compression, burst, flexion–distraction, and fracture-dislocations (Fig. 24-2).

Compression fractures are the most common thoracolumbar spine fracture pattern.[11,35] The vertebral body loses height anteriorly compared with the posterior wall. The anterior aspect of the vertebral body is involved, but the posterior wall of the vertebral body is by definition intact. Axial load with flexion is the common mechanism. Depending on the degree and direction of flexion, the wedging may vary between the coronal and sagittal planes (Fig. 24-3). The percentage of lost height defines the severity of compression fractures, which rarely have an associated neurologic deficit. However, the fractures are often associated with similar or occasionally more severe fractures at adjacent or distant levels. Contiguous compression fractures, each of a modest degree, together may result in a substantial kyphotic deformity. Because the cause of these injuries, such as a fall, is fairly common, it is at times necessary to determine if a wedged vertebra seen radiographically represents an acute compression fracture, sequelae of Scheuermann kyphosis, or a remote injury. Clinical examination can localize pain to the site of the fracture in acute injuries; however, MRI or bone scanning can confirm acute fracture based on signal changes and increased isotope uptake.

Burst fractures likely represent a more severe form of compression fracture that extends posteriorly in the vertebral body to include the posterior wall (middle column). Axial compression is the primary mechanism, although posterior ligamentous injury and/or posterior element fractures may also occur. Laminar fractures have been known to entrap the dural contents. The fractures are most common in the lower thoracic and upper lumbar levels. Associated neurologic injury is related to the severity of injury (greater injury index scores correlate with greater frequency of SCI[49]) and the degree of spinal canal encroachment by retropulsed bony fragments.[34] SCI at the thoracolumbar junction may result in conus medullaris syndrome or cauda equina syndrome. Careful examination of the perineal area is required to identify these spinal lesions.

Flexion–distraction injuries are especially relevant to the pediatric population because this classic lap belt injury is more frequent in backseat passengers, particularly when a shoulder strap is lacking. Motor vehicle accidents are the primary cause of this injury. The lap belt, which restrains the pelvis in adults, may ride up onto the abdomen in children. Chance, and later Smith, described how with a frontal impact, the weight of the torso is driven forward, flexing over the restraining belt. With the axis of rotation in front of the spine, distractive forces are placed on the posterior elements, with variable degrees of anterior vertebral compression. This three-column injury is generally unstable. The disruption of the posterior elements may occur entirely through the bony (Chance) or ligamentous (Smith) elements, although many times the fracture propagates through both soft and hard tissues.

The injury is most obvious on lateral radiographs; however, if no fracture exists, widening of the intraspinous distance may be the only finding on an AP radiograph. Standard transverse plain CT imaging may also miss this injury because the plane of injury lies within the plane of imaging. One classic finding in ligamentous flexion–distraction injuries is the "empty facet" sign. When the inferior articular process of the superior vertebra is no longer in contact with the superior articular process of the inferior vertebra, the facet appears empty in the transverse CT image.[26] Sagittal reconstructions are most revealing and MRI will provide information about the integrity of the PLC. Identification of a purely intravertebral flexion–distraction fracture is important, because this may alter the treatment in patients with these injuries compared to those with severe ligamentous injury.

Fracture-dislocations of the spinal column result from complex severe loading mechanisms. These are by definition unstable injuries with a component of shearing and/or rotational displacement. A special note in the pediatric population is the documentation of this injury pattern in young patients exposed to nonaccidental trauma.[18,42]

Injury patterns specific to the pediatric population that do not fit the Denis classification include apophyseal avulsion fractures and SCIWORA. Apophyseal injuries, typically of the lumbar spine, occur in adolescents as a result of trauma. The mechanism is thought to be related to flexion with a portion of the posterior corner of the vertebral body (ring apophysis) fracturing and displacing posteriorly into the spinal canal. Symptoms may mimic disc herniation, although the offending structure is bone and cartilage rather than disc material (Fig. 24-4).[19,21]

The concept of SCIWORA was popularized by Pang and Wilberger[58] who described their experience at the University of Pittsburgh. They noted a series of patients presenting with traumatic SCIs that were not evident on plain radiographs or tomograms. Several mechanisms to explain these findings have been proposed, including spinal cord stretch and vascular disruption/infarction. MRI studies have confirmed patterns of both cord edema and hemorrhage in such cases.[29] Important additional facts about SCIWORA include the finding that some patients had a delayed onset of their neurologic deficits. Transient neurologic symptoms were persistent in many who later developed a lasting deficit. In addition, the younger patients (less than 8 years old) had more severe neurologic involvement.[7,57,58]

Outcome Measures for Thoracolumbar Spine Fractures

SCIs in children have remarkable potential for recovery. In a study from a major metropolitan trauma center, complete SCIs were associated with fatal injuries in one-third and no neurologic recovery in another third, whereas most of the remaining

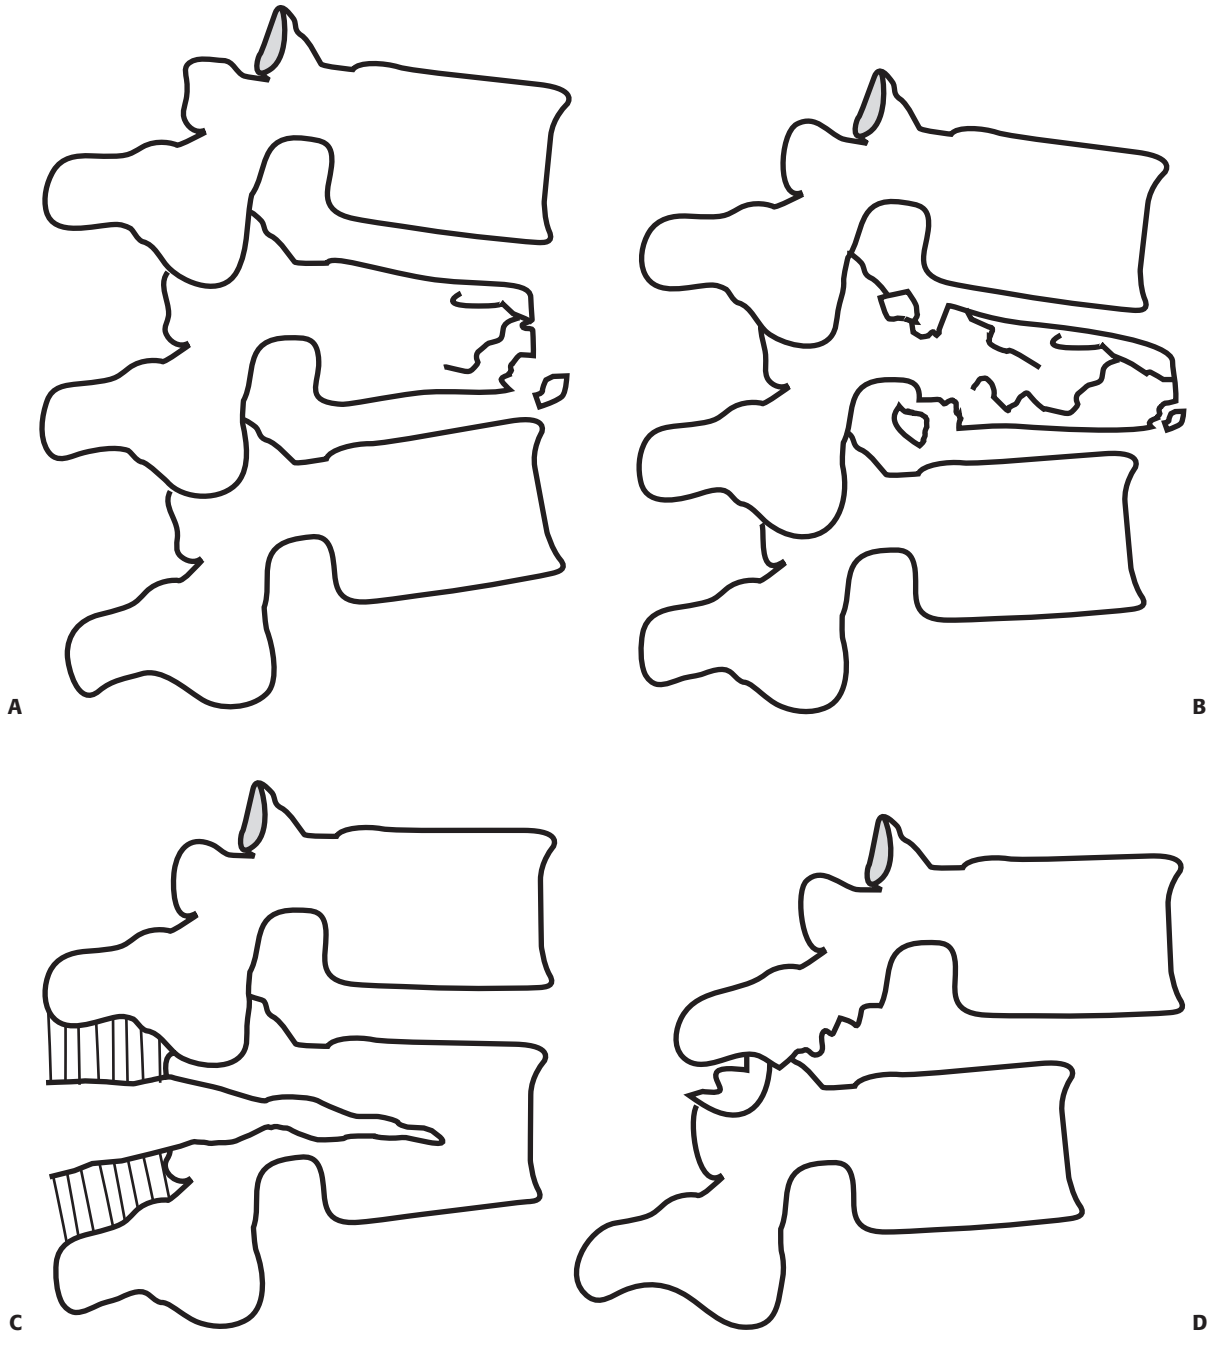

FIGURE 24-2 Denis classification of thoracolumbar fractures. **A:** Compression fracture: This injury results in mild wedging of the vertebra primarily involving the anterior aspects of the vertebral body. The posterior vertebral height and posterior cortex remain intact. **B:** Burst fracture: A burst fracture involves both the anterior and middle columns with loss of height throughout the vertebral body. There may be substantial retropulsion of the posterior aspect of the vertebra into the spinal canal. In addition, posterior vertebral fractures and/or ligamentous injury may occur. **C:** Flexion–distraction injuries: This fracture, which occurs commonly with a seat belt injury mechanism, results in posterior distraction with disruption of the ligaments and bony elements of the posterior column, commonly extending into the anterior columns with or without compression of the most anterior aspects of the vertebra. **D:** Fracture-dislocation: These complex injuries involve marked translation of one vertebra on another with frequently associated SCI as a result of translations through the spinal canal.

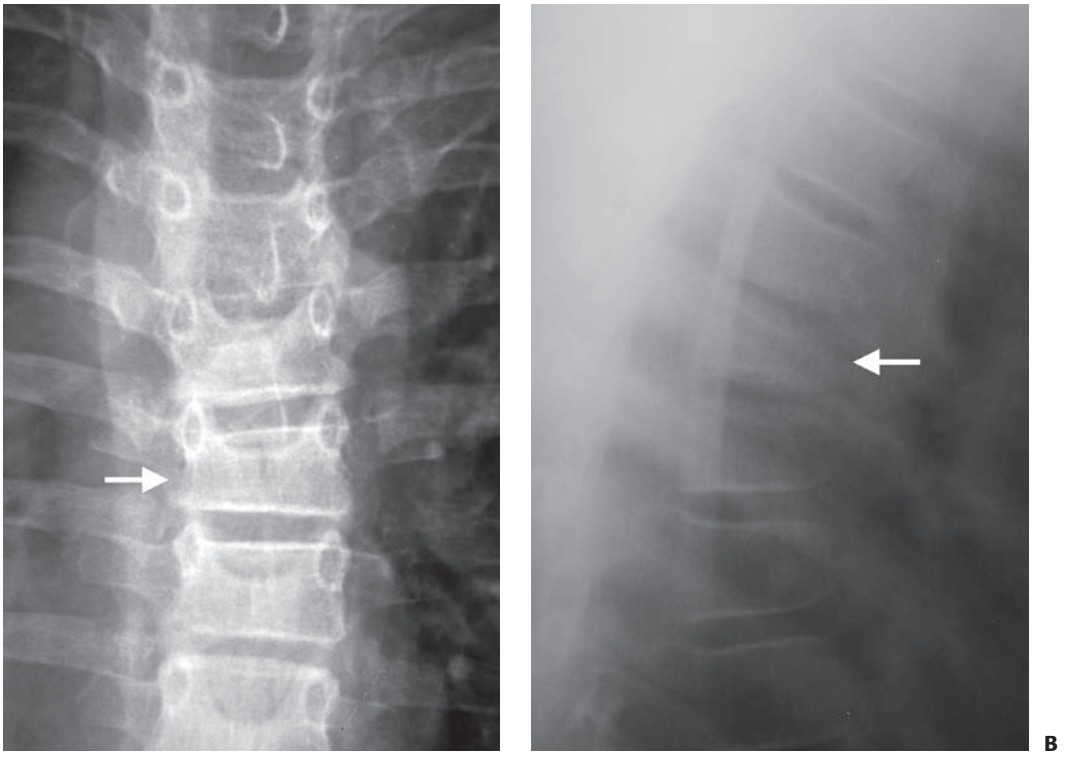

FIGURE 24-3 Compression fractures. **A:** This PA view demonstrates wedging in the coronal plane. **B:** The more commonly recognized compression fractures involve wedging primarily in the sagittal plane with loss of anterior vertebral height.

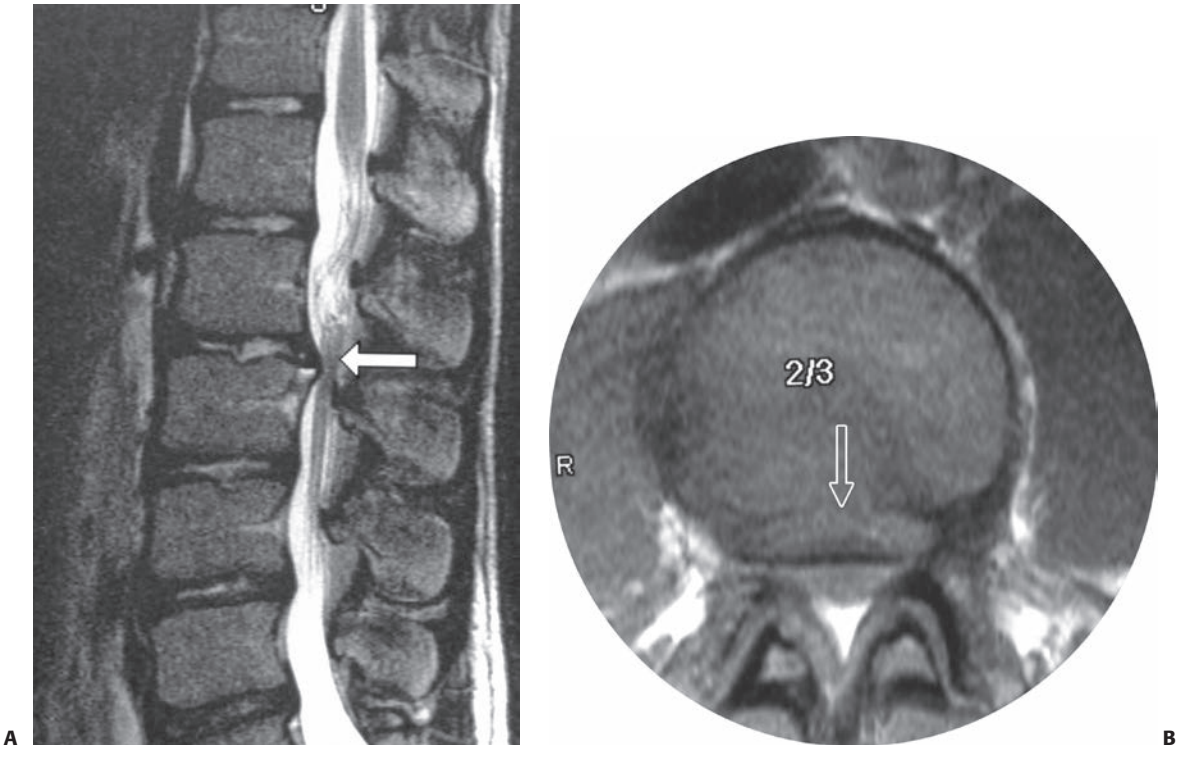

FIGURE 24-4 Ring apophyseal avulsion injuries. **A:** This lateral MRI image demonstrates displacement of the ring apophysis, which functionally acts as a disc herniation. This, however, represents largely a bony and cartilaginous fragment, which results in neural element compression. **B:** Transverse image demonstrating canal stenosis associated with this injury.

one-third of patients made improvements that ultimately allowed functional ambulation. Less surprisingly, nearly all patients with incomplete SCI made some improvement over time as well.[83] This ability to recover, even from complete injuries, has led some to suggest more aggressive attempts at spinal cord decompression in the early course of treatment,[23,59] whereas others have suggested a period of "spinal cord rest" with observation.[49] In adults, early fracture fixation has been shown to be beneficial, minimizing respiratory morbidity and decreasing days in the intensive care setting and length of hospital stay.[6] There is certainly no controlled series of pediatric patients treated by both approaches to support either hypothesis. The data do, however, suggest a more optimistic view regarding the potential recovery of traumatic SCIs in children compared with adults.

Spinal column structural integrity should be assessed in all cases of injury because the functional capacity of the vertebral elements to protect the spinal cord will continue to be required. This evaluation may be performed with functional radiographs, such as flexion–extension views (much more common in the cervical spine) or with an MRI evaluation of associated soft tissue injuries that may coexist with more obvious bony fractures. Several methods of estimating spinal column stability have been proposed including the three-column concept of Denis.[17] Based on division into anterior, middle, and posterior columns, injuries to two and certainly three of these sagittal columns may be associated with an unstable injury pattern. Plain radiography with a CT scan is appropriate for evaluating the bony elements. An MRI is often required to elucidate the nature of the disc and ligamentous injuries.[30,39,78] MRI is extremely sensitive and, given the brightness of edema fluid on T2 images, may be overinterpreted. A study correlating MRI and intraoperative surgical findings, however, demonstrated high levels of both sensitivity and specificity in the MRI evaluation of posterior soft tissue injuries (Fig. 24-5).[46]

The ultimate treatment goal is a stable spinal column. This often requires surgical treatment in unstable fracture patterns. In contrast, most stable injuries can be managed nonoperatively. There are particular exceptions to these generalizations, of course. At times the associated SCI or a substantial associated deformity may alter the treatment approach to an otherwise mechanically stable injury. The presence of a complete SCI in a child younger than 10 years is also a determinant that may affect treatment strategies. The incidence of paralytic spinal deformity (scoliosis) is nearly 100% in such cases, and a long instrumented fusion will likely be required at some point.[45,60] Depending on the fracture pattern and age of the patient, it may be prudent to include much of the thoracic and lumbar spine in the initial instrumented fusion.[52] However, in the patient without neurologic deficit, there is evidence that the use of posterior stabilization of thoracolumbar fractures using nonfusion methods followed by removal of metal implants within an appropriate period appears to be a safe, viable option.[41]

FIGURE 24-5 This sagittal MRI demonstrates marked increased signal in the posterior ligamentous complex. Anteriorly a loss of height at the vertebra can be seen, suggesting a three-column spinal injury.

Pathoanatomy and Applied Anatomy Relating to Thoracolumbar Spine Fractures

The thoracic and lumbar spine links the upper and lower extremities through the torso. The 12 thoracic and 5 lumbar vertebrae are joined by intravertebral discs and strong ligaments, both anteriorly and posteriorly. The bony architecture of the vertebrae varies, with the smaller thoracic vertebrae having a more shingled overlapping configuration compared to the lumbar segments. The thoracic facets are oriented in the coronal plane whereas those in the lumbar spine lie nearly in the sagittal plane (Fig. 24-6).

Mobility is less in the thoracic spine owing both to the adjacent and linked rib cage, as well as the smaller intervertebral discs. The ribs make an important connection between the vertebra with each rib head articulating across a given disc's space. This is in contrast to the relatively mobile lumbar segments, which have thick intravertebral discs that permit substantial flexion–extension, lateral bending, and axial rotation motion. The junction between the stiffer thoracic spine and more flexible lumbar spine is a region of frequent injury because of this transition between these two regions, which have differing inherent regional stability.

Ligamentous components include the anterior and posterior longitudinal ligaments, facet capsules, ligamentum flavum, and interspinous and supraspinous ligaments. Together, these structures limit the motion between vertebrae to protect the neurologic elements. The anterior longitudinal ligament is rarely disrupted in flexion injuries but may be rendered incompetent by extension loading or a severe fracture-dislocation. On

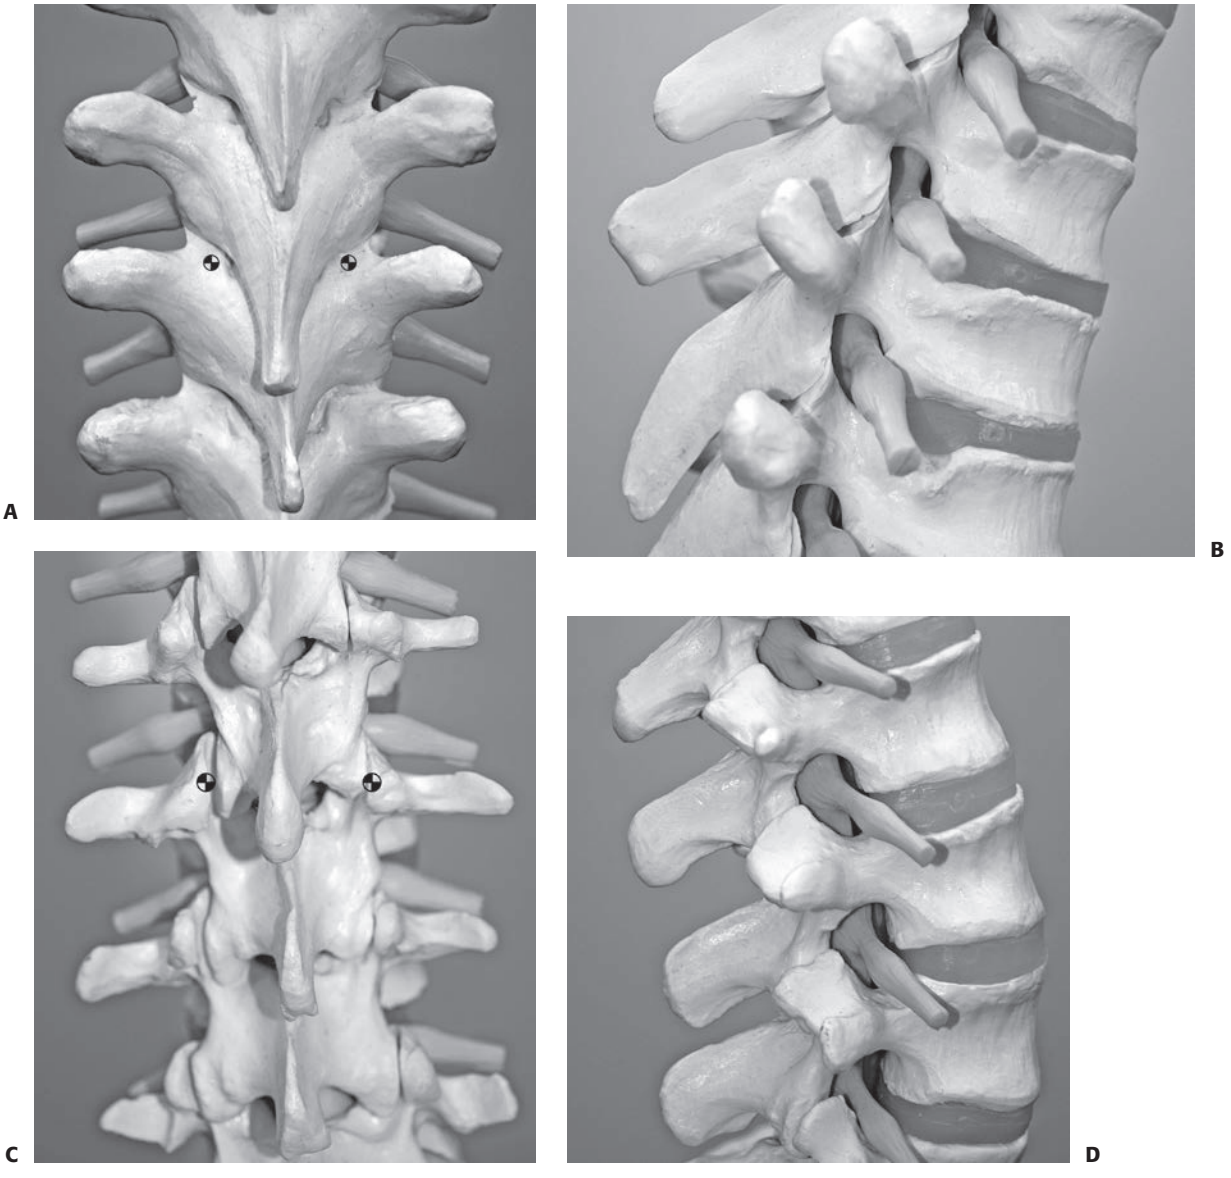

FIGURE 24-6 **A, B:** Thoracic spine posterior and lateral views demonstrating the overlapping lamina and spinous processes present in this region. The circles mark the location of the thoracic pedicles, which may be important in surgical reconstruction. **C, D:** Lumbar spine posterior and lateral projections demonstrating the differences in lumbar spine anatomy. Again, the circles mark locations of the lumbar pedicles relative to the facets and transverse processes.

the contrary, flexion is the primary mechanism of injury to the posterior ligaments—supraspinous and interspinous, facet capsule, and ligamentum flavum. The healing capacity of the completely torn PLC is limited, whereas bony fractures are more likely to heal with resultant stability.

The neural anatomy varies over the length of the thoracolumbar spine as well. The space within the canal is largest in the lumbar spine. The spinal cord traverses the entirety of the thoracic spine and typically terminates as the conus medullaris at the L1 or L2 level. The cauda equina occupies the dural tube below this level, and injuries below L1 are generally less likely to lead to permanent neurologic deficit. This is not to say that compression at this level cannot be serious, and careful examination of the perineum for sensation as well as rectal tone is important in the evaluation of potential conus medullaris and cauda equina syndromes.

Thoracolumbar Spine Fracture Treatment Options: Compression Fractures

Nonoperative Treatment of Compression Fractures

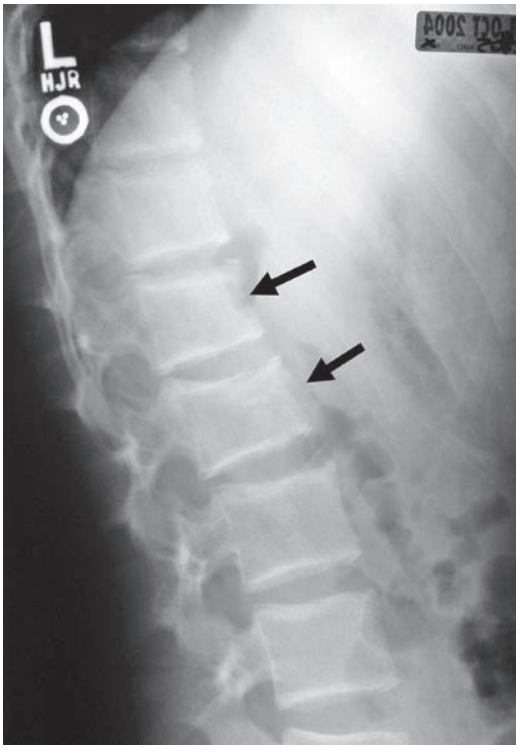
Indications/Contraindications

These are nearly always stable injuries, although examination of the posterior soft tissues is required to rule out any more

severe flexion–distraction injury. If there is concern for a higher energy injury a CT scan is required to rule out a burst fracture (Fig. 24-7). Indications for nonoperative treatment are intact posterior soft tissues and kyphosis less than 40 degrees. The presence of disrupted posterior soft tissues implies the injury is more significant, such as a burst fracture, which most likely will require operative intervention.

Techniques

An isolated fracture without neurologic involvement is the most common thoracolumbar fracture pattern and can nearly always be treated with immobilization with a thoracolumbosacral orthosis (TLSO). Molding into slight hyperextension at the fracture site will limit flexion, provides pain relief, and reduces further loading of the fracture.



A

B

C

FIGURE 24-7 **A:** This lateral radiograph demonstrates two upper lumbar vertebrae with slight loss of height suggestive of compression fractures. **B, C:** The CT images confirm an intact posterior vertebral body wall. This injury, therefore, represents a compression fracture rather than a burst fracture injury.

Outcomes

Most fractures heal in 4 to 6 weeks without significant additional collapse; however, radiographs in the first several weeks should be obtained to follow the sagittal alignment. Long-term studies have suggested modest remodeling capacity of compression fractures occurring in childhood.[38,63] Asymmetric growth at the endplates seems to allow some correction in the wedged alignment over time in the skeletally immature patient. Long-term results of compression fractures have been generally favorable, although fractures of the endplates are associated with later disc degeneration.[40]

Osteoporosis of a variety of etiologies may affect children and adolescents to a degree that predisposes them to insufficiency fractures that are most often compression fractures (Fig. 24-8).

FIGURE 24-8 **A:** Lateral radiograph demonstrating what appears to be a routine compression fracture. The patient did not have a significant history of trauma; however, pain was present and a bone scan was obtained to further evaluate this site. **B:** The bone scan demonstrated markedly increased uptake, confirming an acute process and prompting additional study. **C:** An MRI was obtained, which demonstrated loss of height and a lesion within the anterior aspect of the vertebral body, which was later confirmed to be an infectious process.

Multiple-level fractures are more frequent in this setting, and problematic kyphosis may develop. Differentiating new from old fractures can be difficult if serial radiographs are not available. A TLSO for a period of time longer than typically used for simple compression fracture healing may be necessary to prevent progressive kyphosis, though treating the primary cause of the osteopenia is critical to maintaining normal alignment in such cases. An endocrinologic evaluation and assessment of bone density by dual-energy x-ray absorptiometry are advised.

Operative Treatment of Compression Fractures

Indications/Contraindications

If the kyphosis associated with a fracture markedly alters local sagittal alignment by 30 to 40 degrees of additional relative kyphosis than would be anticipated for that region of the spine, surgical treatment may be considered. This is most frequent in multiple adjacent compression fractures that together create unacceptable focal region of relative kyphosis.

Surgical Procedures

The preferred surgical treatment of such fractures is generally a posterior compression instrumentation construct that spans one or two levels above and below the affected vertebrae. Anterior surgical treatment is rarely required. The intact posterior vertebral wall provides a fulcrum to achieve kyphosis correction. The method of posterior fixation may be either hooks or pedicle screws. A posterior fusion over the instrumented segments ensures a lasting stable correction. Cadaver studies and clinical studies on the use of balloon vertebroplasty with calcium phosphate cement in adult patients are encouraging, as this technique may be a potentially viable option to treat compression fractures with significant angulation.[43,81,82]

Thoracolumbar Spine Fracture Treatment Options: Burst Fractures

Nonoperative Treatment of Burst Fractures

Axial compression injuries that are more severe and extend into the posterior wall of the vertebral body are labeled as burst fractures. The treatment and classification of this fracture pattern are controversial areas of spinal trauma management. There are clearly some burst fractures that can be easily managed nonoperatively in a brace and others that collapse further, resulting in increased deformity unless surgically stabilized. Defining the characteristics of stable and unstable burst fractures has been attempted by several authors.[17,27,53] An additional compounding variable in the treatment algorithm is SCI, which is more frequent with burst fractures than with compression fractures.

Indications/Contraindications

Assuming an intact neurologic system, defining stable and unstable burst fractures has been attempted based on the degree of comminution, loss of vertebral height, kyphotic wedging, and integrity of the PLC. A load-sharing classification system assigns points based on comminution, fragment apposition, and kyphosis.[53] Although the Denis classification suggests that all burst fractures are unstable because of the involvement of at least two columns, it is clear that in many cases the addition of a third-column injury (PLC) is required to result in a truly unstable condition. Vertebral body translation of greater than 3.5 mm has been demonstrated to predict PLC injury.[64] Some advocate differentiating stable and unstable burst fractures solely on the integrity of the PLC.[74,88]

Techniques

When a burst fracture is deemed stable, it must be done so on a presumptive basis. Treatment is then based on an extension molded cast or TLSO with the goal of allowing an upright position and ambulation.[75] Frequent radiographic and neurologic follow-up is necessary to identify early failures. Depending on the age of the patient and severity of the fracture, immobilization is suggested for a duration of 2 to 4 months.

Outcomes

Studies of immature patients treated for burst fractures are uncommon,[44] yet much of the adult literature provides valuable information about the outcomes to expect following nonoperative treatment. Most of these fractures in adults heal with little change in kyphosis and function and minimal, if any, residual pain.[28,85] It is reasonable to expect adolescent patients to heal at least as well and probably even faster. Wood et al.[88] compared operative and nonoperative treatment in a prospective randomized study of patients with burst fractures who were neurologically intact with a normal PLC. The radiologic and functional outcomes were not substantially different, and these authors concluded that nonoperative treatment should be considered when the PLC and neurologic function are intact.[88] Functional outcome does not appear to correlate with the degree of spinal kyphosis, although long-term studies of scoliosis treatment do suggest that an alteration of sagittal alignment may be detrimental (flat back syndrome) in the long term.

Operative Treatment of Burst Fractures

Indications/Contraindications

Fractures with three-column involvement, neurologic deficit, concomitant musculoskeletal injury, and thoracic/abdominal injury precluding the use of a brace have all been reported as indications for surgical management of burst fractures. Contraindications mainly center on medical conditions (coexisting or new) which make surgical intervention too risky.

Surgical Procedure

Even some fractures with PLC disruption have been successfully treated nonoperatively[15]; however, these three-column injuries are often operatively stabilized. When surgical treatment is selected, either an anterior or posterior approach can be used, although this also remains controversial. Anterior stabilization generally involves discectomy and strut grafting that spans the fractured vertebra. Stabilization with a plate or dual-rod system is appropriate. Posterior options include pedicle screw fixation one or two levels above and below the fractured

vertebra. Advances in the application of posterior instrumentation for thoracolumbar fractures have demonstrated encouraging, early outcomes with fracture stabilization without fusion and in minimally invasive surgical techniques.[84,86]

The decision to proceed anteriorly or posteriorly for the surgical treatment of a burst fracture is largely dictated by surgeon preference and, to some degree, the features of the fracture. Posterior approaches are familiar to all surgeons and can easily be extended over many levels. In addition, a transforaminal lumbar interbody fusion (TLIF) can be performed if anterior interbody support is deemed beneficial to construct stability. Decompression of the spinal cord can be achieved by indirect or direct methods. Restoration of the sagittal alignment frequently leads to spontaneous repositioning of the posteriorly displaced vertebral body fracture fragments. If additional reduction of posterior wall fragments is required, direct fracture reduction can be accomplished with a posterolateral or transpedicular decompression.[23] This also allows additional anterior column bone grafting that may add structural integrity and speed fracture healing.

The anterior approach allows direct canal decompression through a corpectomy of the fractured vertebra. Structural strut grafting restores the integrity of the anterior column. With this graft, a load-sharing anterior plate or rod system completes the reconstruction. This approach deals most directly with the pathology, which in burst fractures lies within the anterior and middle vertebral columns (Fig. 24-9). Proponents of the anterior approach cite better biomechanical stabilization of the unstable spine, better correction of segmental kyphosis, and less loss of correction postoperatively.[72,73,89] In adults, a combined anterior and posterior approach may provide the best stability and sagittal alignment, especially in very unstable injuries. However, the increased morbidity with this approach is likely not necessary routinely in the pediatric/adolescent patient population.[66]

Thoracolumbar Spine Fracture Treatment Options: Flexion–Distraction Injuries (Chance Fractures)

Nonoperative Treatment of Chance Fractures

Indications/Contraindications

The treatment of flexion–distraction injuries is dictated by the particular injury pattern and the associated abdominal injuries. In general, these fractures are reduced by an extension moment that can be maintained with either a cast or internal fixation. A hyperextension cast is ideal for younger patients (less than approximately 10 years) with a primary bony injury pattern and no significant intra-abdominal injuries. As described above, the posterior disruption may pass through ligaments or joint capsules in a purely soft tissue plane of injury or traverse an entirely bony path. The distinction is important, because bony fractures have the potential for primary bony union, whereas the severe ligamentous injuries are less likely to heal with lasting stability without surgical intervention.

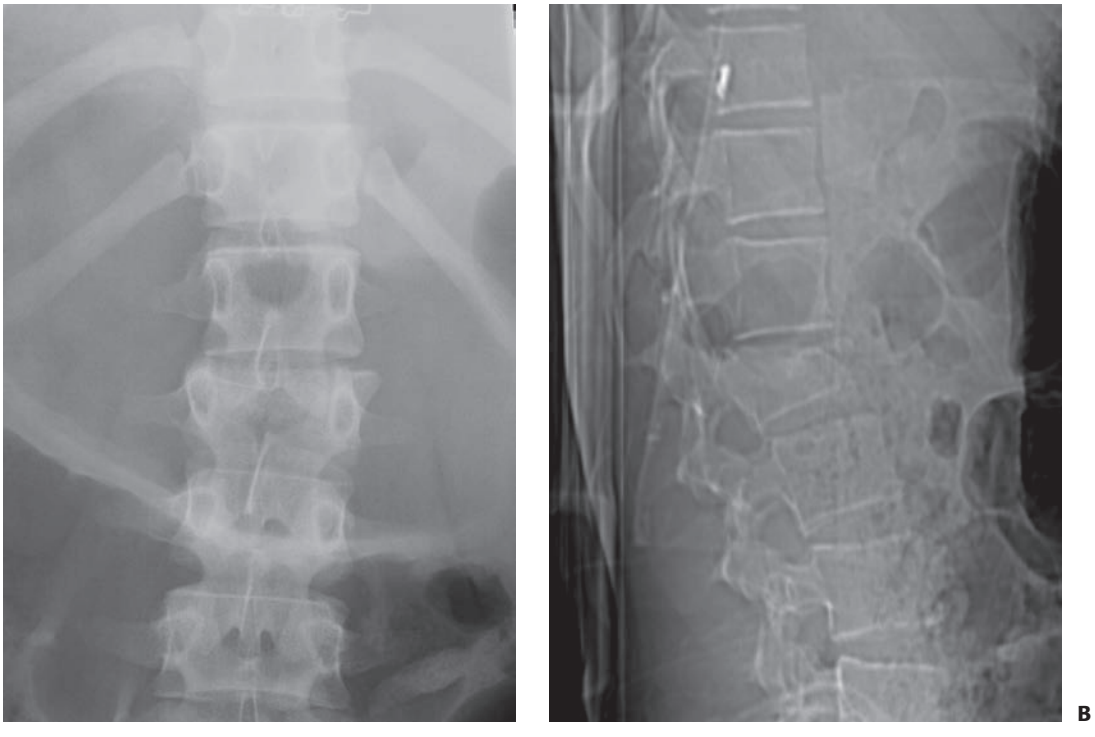


FIGURE 24-9 Burst fracture. **A:** This teenage patient presented with loss of vertebral body height associated with a motorcycle accident after jumping more than 20 ft. His neurologic examination was intact. **B:** CT scan confirmed a burst fracture component with very little retropulsion into the spinal canal.

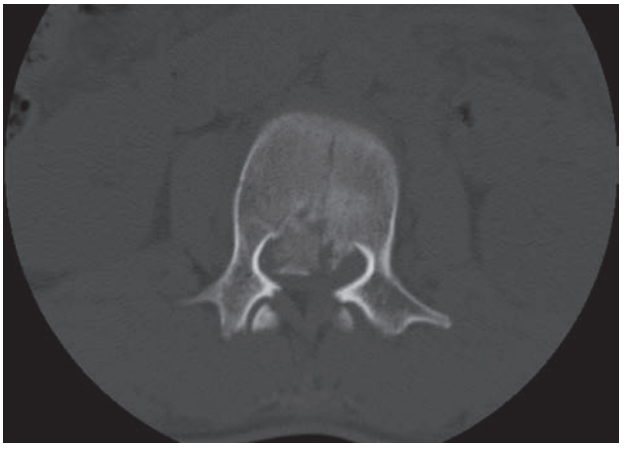
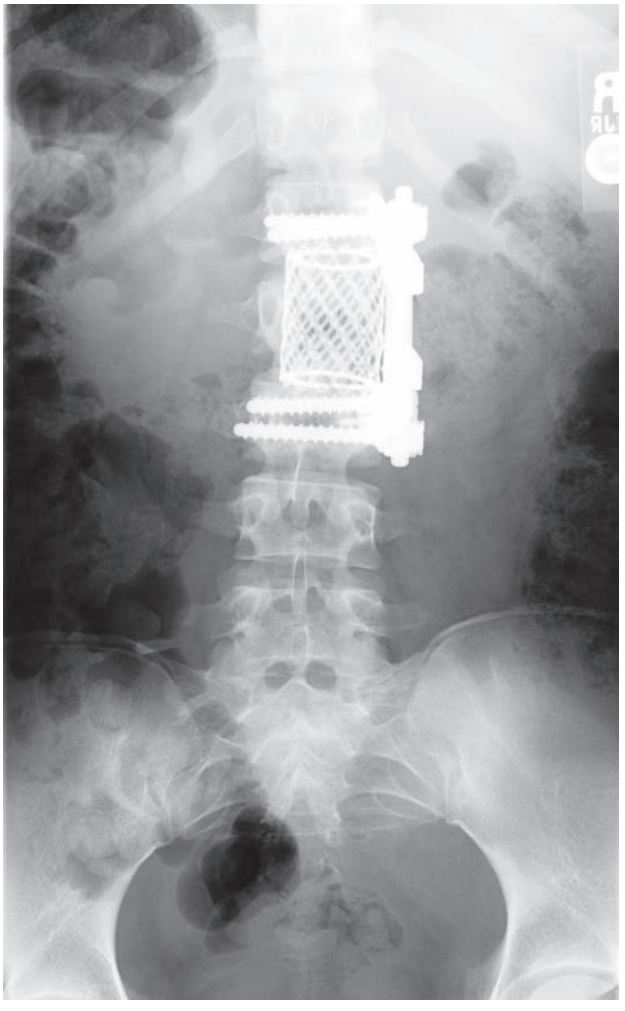


C

D



E

F

FIGURE 24-9 (*continued*) This appeared to be a stable injury and was initially managed with an orthosis. There was poor compliance with the orthosis and further collapse **(C, D).** Given the lack of compliance and progressive kyphosis, the patient underwent anterior reconstruction with an iliac crest strut graft and plating **(E, F).**

Technique

Hyperextension cast or TLSO as detailed for compression and burst fractures.

Outcomes

Nonoperative treatment has been demonstrated to be effective in selected patients. The most frequent problem with the nonoperative approach has been progression of the kyphotic deformity.[2]

Operative Treatment of Chance Fractures

Indications/Contraindications

The greater the degree of ligamentous/facet disruption, the more likely the need for stabilization with an arthrodesis of the injured motion segment. In addition, the greater the degree of injury kyphosis the more likely posttraumatic kyphosis will become a problem.[2]

Surgical Procedure

Options for internal fixation include posterior wiring in young children (supplemented with a cast) and segmental fixation in a primarily compressive mode (Fig. 24-10). This approach can decrease the injury kyphosis and maintain this alignment during the healing process. Operative treatment has been demonstrated to have a good clinical outcome in 84% of pediatric patients, compared to 45% in the nonoperative group (NS).[2]

Thoracolumbar Spine Fracture Treatment Options: Fracture-Dislocations

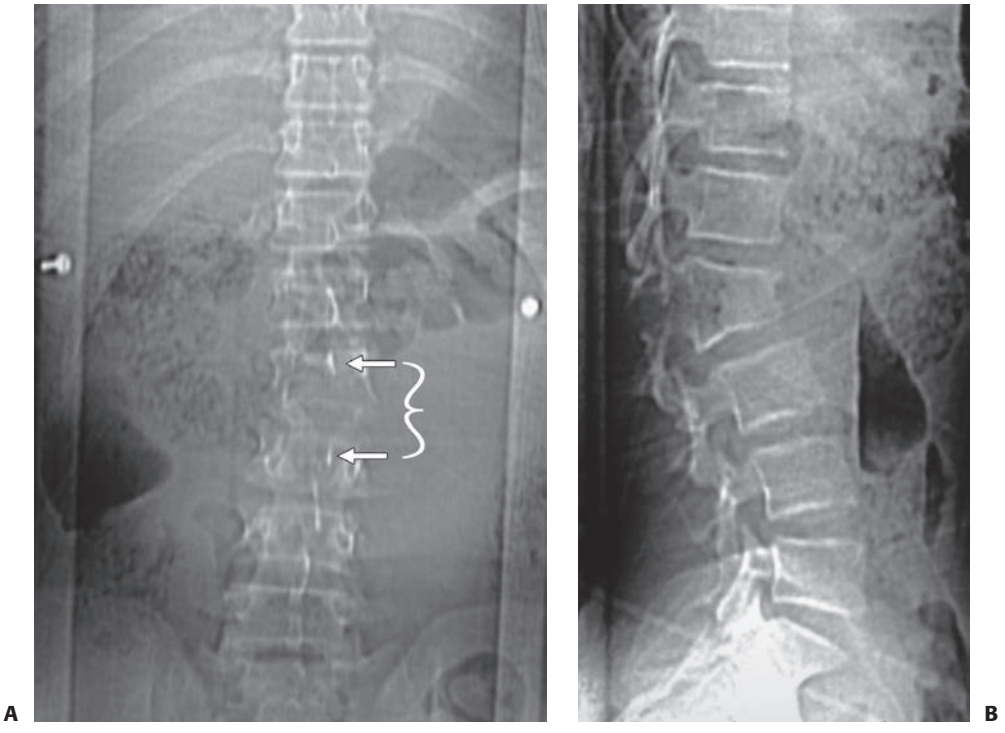
Operative Treatment of Fracture-Dislocations

Indications/Contraindications

These highly unstable injuries nearly always require surgical stabilization. When the spinal cord function remains intact, instrumented fusion gives the greatest chance for maintaining cord function. On the other hand, if a complete SCI has occurred, internal fixation will aid in the rehabilitation process, allowing early transfers and upright sitting.

Surgical Procedure

The typical procedure is a posterior instrumented fusion which extends at least two levels above and below the level of injury to ensure restoration of alignment and stability. In cases of SCI below the age of 10 years, a longer fusion may be considered to reduce the incidence and severity of subsequent paralytic scoliosis. Those injured after the adolescent growth spurt are at low risk for late deformity if the fracture is well aligned at the time of initial fixation (Fig. 24-11).



A **B**

FIGURE 24-10 Flexion–distraction injury. **A, B:** Plain radiographs of a restrained backseat passenger who was involved in a motor vehicle accident. The wedging of L2 with posterior distraction is visible on the lateral radiograph. The intraspinous widening is noted on the AP radiograph as well (*arrows*).

FIGURE 24-10 (*continued*) **C:** Sagittal CT images confirm the injury pattern. **D:** Lateral radiographs following reconstruction with posterior spinal instrumentation.

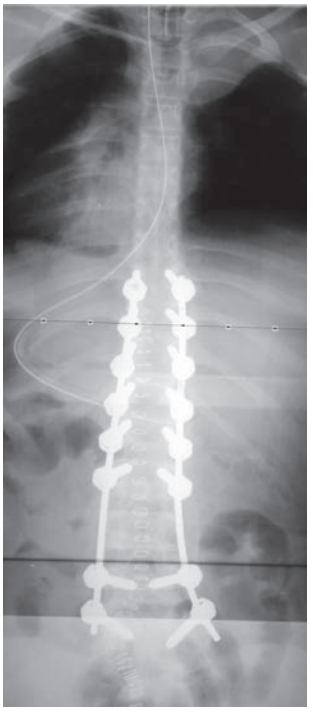
D



A

B

FIGURE 24-11 **A, B:** AP and lateral radiographs demonstrating reconstruction after a lower thoracic level complete SCI associated with fracture-dislocation in the lumbar spine combined with a burst fracture in the lower thoracic spine. Given the complete paraplegia present, a relatively long instrumentation construct was selected to provide a stable foundation in this skeletally immature patient. Four years postoperatively, the patient has no evidence of progressive spinal deformity; however, there is certainly some risk remaining of developing pelvic obliquity and upper thoracic deformity given the paraplegia.

Author's Preferred Treatment for Thoracolumbar Spine Fractures

Compression Fractures

Nearly all are managed nonoperatively in an off-the-shelf TLSO brace. Occasionally, a fracture is too proximal for such an orthosis and an extension to the chin/occiput is required. For fractures proximal to T6, a Minerva brace is used. These fractures typically heal within 4 to 6 weeks, when the immobilization can be discontinued. Activities should be limited for an additional 6 weeks. Compression fractures with more than 50% loss of anterior vertebral height are considered for either a closed reduction in an extension molded body cast or surgical correction with posterior instrumentation. The determination of which of these two approaches to choose is based on associated injuries and a discussion with the family. Compression fractures associated with neurologic injury are managed surgically.

Burst Fractures

Our preferred approach to neurologically intact patients with burst fractures is nonoperative approach in light of recent studies. If the neurologic status is normal and the posterior soft tissues are intact, a TLSO or cast is used for 3 months. A cast is used when local kyphosis is more than 20 degrees, and the cast is placed in a hyperextension position in an attempt to restore sagittal alignment. If the posterior soft tissues are disrupted (and the patient is neurologically intact), posterior surgical stabilization is preferred. An anterior decompression can be performed for canal compromise, especially when greater than 50% of spinal canal volume.

Flexion–Distraction Injuries

Our treatment of Chance fractures is based on two findings: Associated abdominal injuries and the presence of a ligamentous component to the fracture. If either exists, surgical treatment is the preferred approach. Casting in extension is appropriate for fractures that transverse an entirely bony plane without intra-abdominal pathology. A thigh is incorporated into the cast for greater control of lumbar lordosis. Surgical treatment is by a posterior approach and includes only the involved vertebrae. Monosegmental pedicle screw fixation is generally preferred.

Fracture-Dislocation

Posterior surgery is the treatment of choice for all fracture-dislocations with or without neurologic injury (Fig. 24-12). The timing of such intervention depends on the associated injuries and the ability of the patient to tolerate surgical intervention;

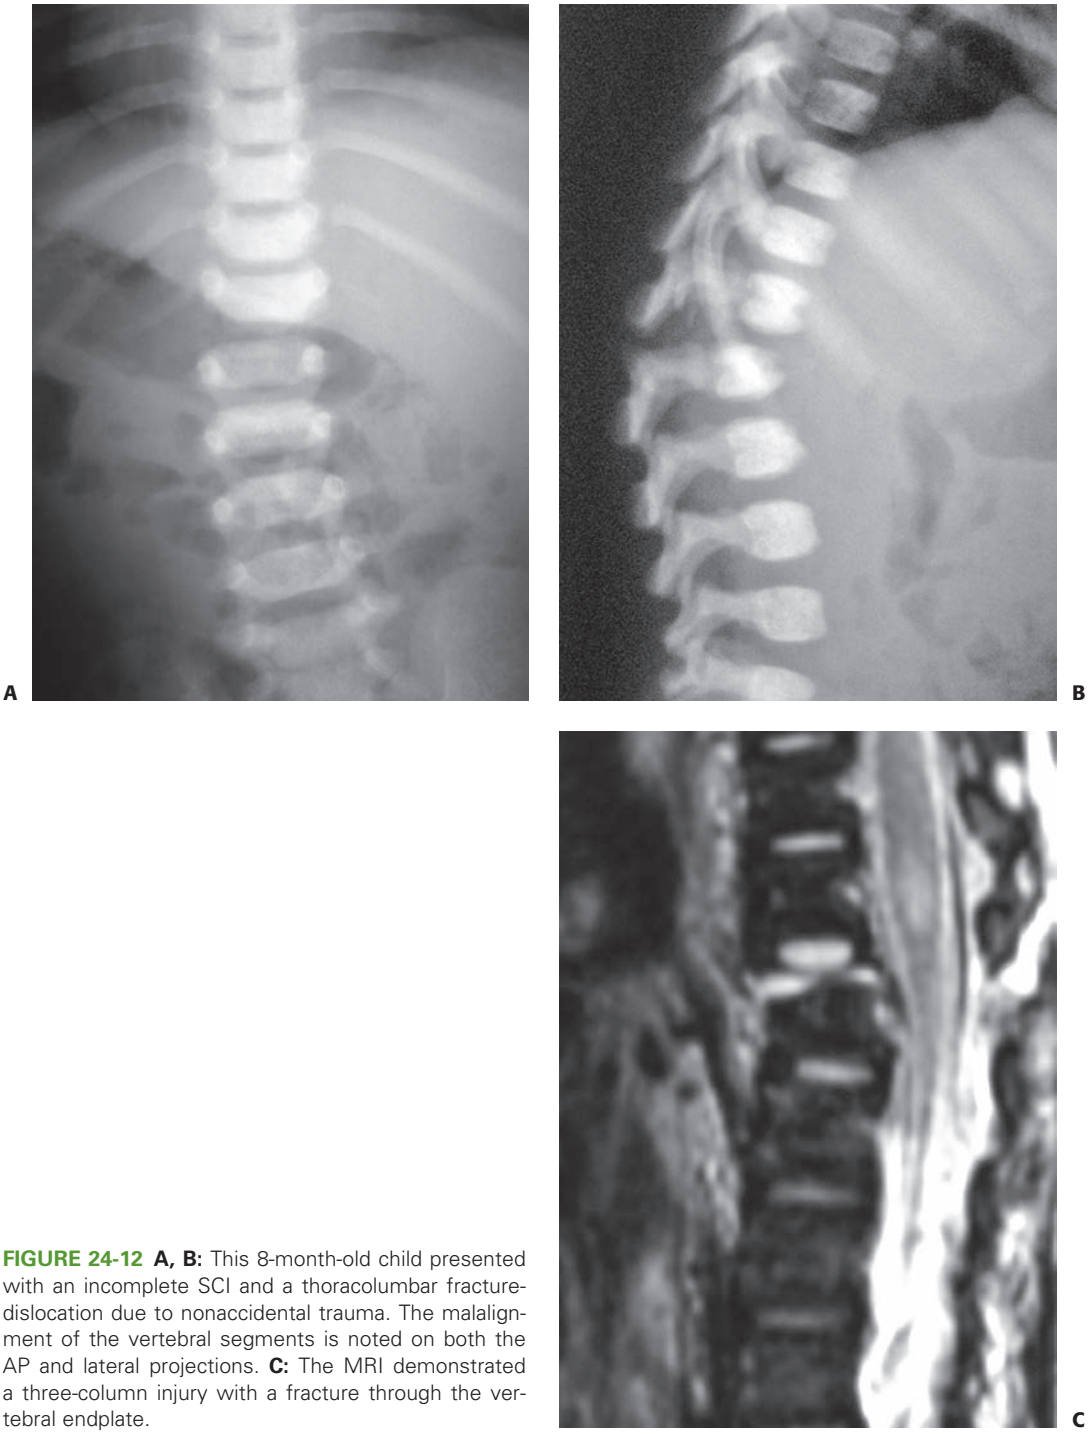


FIGURE 24-12 **A, B:** This 8-month-old child presented with an incomplete SCI and a thoracolumbar fracture-dislocation due to nonaccidental trauma. The malalignment of the vertebral segments is noted on both the AP and lateral projections. **C:** The MRI demonstrated a three-column injury with a fracture through the vertebral endplate.

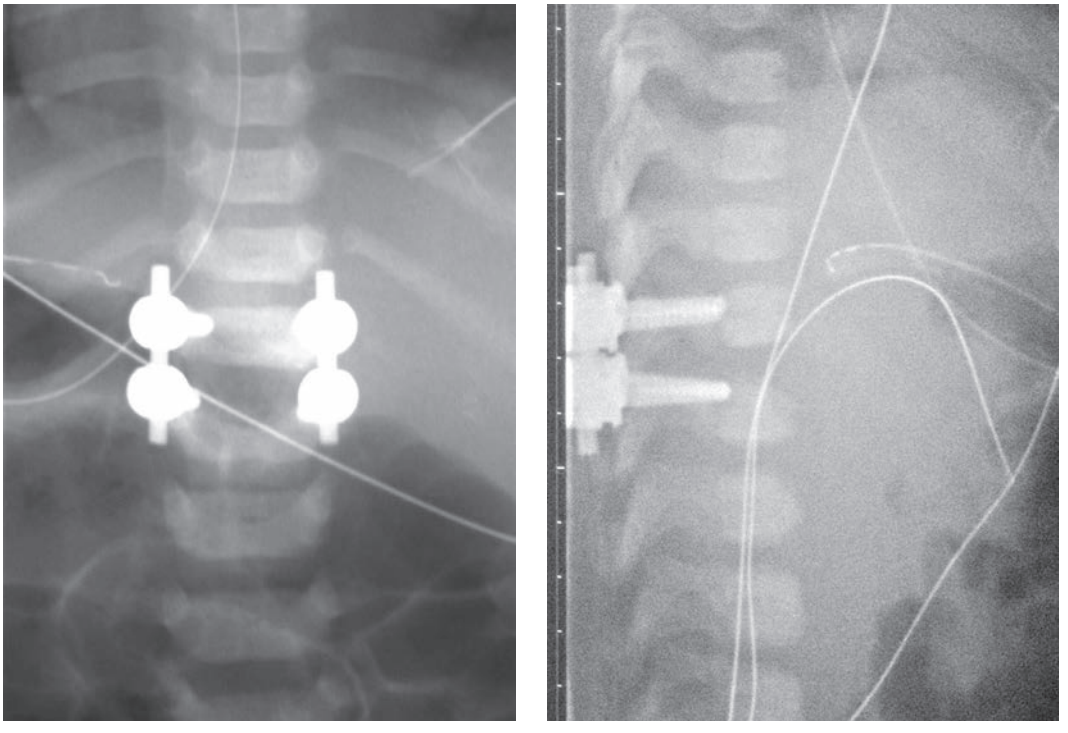

FIGURE 24-12 (*continued*) **D, E:** The patient had an open reduction and instrumentation with pedicle screw fixation using a 3.5-mm cervical system.

however, stabilization as early as possible is preferred. SCI nearly always complicates the management of these injuries, and a deteriorating neurologic examination makes surgical treatment of the spine an emergency that should be treated as quickly as possible.

Steroid Treatment

Despite the controversies, we continue to follow the recommendations of the Third National Acute Spinal Cord Injury Study and prescribe methylprednisolone if it can be given within 8 hours of the time of injury. We are skeptical that this provides significant benefit, but we believe this remains the current medical and legal standard.

Potential Pitfalls and Preventative Measures in Thoracolumbar Spine Fractures

Pitfalls

- Watch for associated injuries, both musculoskeletal and others.
- Do not let MRI/CT findings replace a careful examination of the back.
- Monitor neurologic status carefully because an unrecognized change may limit the ability to intervene early and prevent permanent sequelae.

Preventative Measures

- Do not hesitate to get advanced imaging, especially CT imaging.
- Understand the mechanics of the injury to develop a rational treatment plan.
- Always seek to identify additional levels of spinal injury when one is discovered.
- Document the neurologic examination precisely and repeat it often.

Summary, Controversies, and Future Directions Related to Thoracolumbar Spine Fractures

Several areas of controversy remain with regards to the management of acute SCI associated with thoracolumbar fractures. These include both nonoperative and operative methods of treatment. Investigations into the benefits of steroids in mitigating the effects of the secondary phase of SCI that follows the acute trauma have been mixed, although clinical trials have suggested benefit in specific instances.

SCI that results from direct trauma may acutely disrupt the neural tissue, possibly with compression remaining from fracture fragments or displacement. Once the initial injury occurs, biochemical cascades are set into motion, resulting in further injury of spinal cord tissue. Experimental studies have suggested that steroids administered early in the post injury period could limit these detrimental secondary effects. Based on randomized clinical trials of methylprednisolone administration after acute SCI,[8,9] current recommendations for steroid use are dependent on the timing of administration relative to the occurrence of the injury. If the time lapse is less than 3 hours, a bolus of 30 mg/kg of methylprednisolone is followed by an

hourly infusion of 5.4 mg/kg for 24 hours duration. If the lapse between injury and treatment is 3 to 8 hours, an infusion of the same dose is continued for 48 hours. More importantly, if more than 8 hours have passed following the SCI, no steroids are recommended.[9]

The benefit of steroids with regard to functional levels of recovery has been questioned, and in all studies of high-dose steroid use, there has been an increased complication rate. Infection is the most common with both pneumonia and sepsis occurring. Steroids are known to depress the immune response.[22] These issues have resulted in an inconsistent adoption of the National Acute Spinal Cord Injury Study recommendations.

The timing and necessity of spinal decompression for an SCI also remains debated. Traditional teaching suggests no benefit to decompression when a complete SCI exists. This may be true, but if early decompression of an incomplete SCI is beneficial, and there are experimental data to suggest it is, then it may be impossible to determine early on if the patient has an incomplete injury but remains in spinal shock. Spinal shock may last for 24 hours, leaving an incomplete SCI patient completely unresponsive with regard to spinal cord function. The data to suggest a benefit to early decompression are largely experimental; however, a clinical study also reported a benefit. In a series of 91 pediatric patients, 66 with immediate decompression were compared to 25 with whom decompression was delayed. Improvement of at least one Frankel grade occurred in one-half of the early decompression patients compared to one-quarter of those who had delayed decompression.[59] Early surgery has been documented to shorten the intensive care unit stays and length of hospitalizations, shorten time on mechanical ventilation support, and lower overall complication rates in patients with thoracolumbar spine injuries.[14]

In pediatric patients with SCI, it is difficult to argue against spinal cord decompression if the MRI documents persistent compression in the setting of an SCI. Pediatric patients have a substantial potential for recovery, and reducing pressure on the neural elements may be important in maximizing functional recovery. There is little controversy if spinal cord function is deteriorating in a patient with a known compressive lesion. This is an emergency that warrants decompression by either an anterior or posterior approach. Realignment of the spinal column and removal of fragments from the canal are required. The exact surgical approach depends on the location of offending structures and the nature of the instability.

25 PELVIC AND ACETABULAR FRACTURES

James McCarthy, Martin J. Herman, and Wudbhav N. Sankar

Introduction to Pelvic and Acetabular Fractures

Pelvic and acetabular fractures in children vary from simple apophyseal avulsion and stress fractures to high-energy unstable pelvic ring injuries that are life-threatening. Pelvic and acetabular fractures in the pediatric population are quite uncommon. Pelvic fractures account for less than 1% of all pediatric fractures, but as many as 5% of children admitted to level 1 pediatric trauma centers with blunt trauma have pelvic fractures.[4,10,11,14,25,99] Although published studies focus on pelvic fractures from high-energy mechanisms, most pelvic fractures in children and adolescents occur from low-energy mechanisms and are stable ring injuries or avulsions of secondary ossification centers of the pelvis. Acetabular fractures, especially as isolated pelvic fractures, are rare in the pediatric age group.

Pediatric pelvic and acetabular fractures differ in important ways from adult pelvic fractures. Children in general have greater plasticity of the pelvic bones, increased elasticity of the sacroiliac joints and symphysis pubis, and thicker and stronger periosteum. Therefore, a relatively greater amount of energy can be dissipated before sustaining a pelvic fracture in a child as compared to an adult, and the relative force needed to sustain a pelvic fracture in a child is higher than in an adult.[13,31,83,95] The

presence of the triradiate cartilage is another major difference. This critical physeal area is responsible for acetabular growth and development, acts as a stress riser in the pelvic ring, and is susceptible to permanent damage. These important differences correlate with clinical outcomes. Children have a lower mortality rate associated with these injuries compared to adults and, when mortality occurs, it is more commonly related to associated injuries of the thorax, abdomen, and central nervous systems rather than direct blood loss from the pelvic injury.[4,11,14,25,30,36,51,69,83,94,99]

Most low-energy stable pelvic ring injuries and avulsions are treated through conservative measures. Unstable pelvic ring injuries may be a source of life-threatening hemorrhage in children. Coordinated management of a multidisciplinary trauma team and careful treatment of the associated head and thoracoabdominal injuries, in addition to pelvic ring fracture management, improve outcomes. Although historically most pelvic fractures, including unstable injuries, were treated nonoperatively, experience extrapolated from the care of adults with pelvic fractures has led to a growing movement to treat selected cases surgically in an attempt to decrease long-term disability.[19,41,96] In addition, follow-up after acetabular fractures in children with at least 2 years of growth remaining is critical because damage to the triradiate cartilage may cause a long-term growth abnormality.[41]

Assessment of Pelvic and Acetabular Fractures

Mechanisms of Injury for Pelvic and Acetabular Fractures

Most pediatric pelvic fractures result from motor-vehicle related accidents.[4,11,52,69,83] These injuries are seen most commonly in children who are occupants of motor vehicles involved in collisions or who are struck by motor vehicles while riding a bicycle or other types of wheeled vehicles.[80] Other mechanisms include falls from motorized vehicles, such as all-terrain vehicles or motor bikes, falls from heights, and equestrian accidents.

Sporting activities account for 4% to 11% of pelvic fractures, the majority of which are simple avulsion fractures of the secondary ossification centers of the growing pelvis. Avulsion injuries are the result of forceful contraction of large muscles, typically those which traverse both the hip and knee joints and have their origins on pelvic apophyses. Gymnasts typically sustain acute ischial tuberosity avulsion fractures from the violent pull of hamstring muscles, whereas soccer players more commonly sustain avulsions of the anterior-superior and anterior-inferior iliac apophyses, the result of contraction of the sartorius and rectus femoris muscles, respectively.[70] Iliac apophysitis is most frequently associated with long distance running and is thought to result from repetitive muscle traction injury from the pull of the external oblique muscles of the abdomen.[12]

Much like pelvic ring fractures, acetabular fractures usually result from high-energy injuries, although sporadic cases of low-energy mechanisms from sports have been reported.[19,51] The mechanism of injury of acetabular fractures in children is similar to that in adults: the fracture occurs from a force transmitted through the femoral head to the articular surface of the acetabulum. The position of the leg with respect to the pelvis and the direction of the impact determine the fracture pattern; the magnitude of the force determines the severity of the fracture or fracture-dislocation. For example, forces applied along the axis of the femur with the hip in a flexed position usually result in injury to the posterior aspect of the acetabulum. Fractures of the acetabulum are intimately associated with pelvic fractures. Some acetabular fractures involve only the hip socket. Others represent the exit point of a fracture of the pelvic ring. Pelvic fractures, particularly ramus fractures, may propagate into the triradiate cartilage (Fig. 25-1). Even fracture-dislocations of the sacroiliac joint have been associated with triradiate cartilage injuries.[43,76]

Child abuse is a rare cause of pelvic and acetabular fractures. The diagnosis of a pelvic fracture in infants and very young children, especially those without a reported history of high-energy injury, mandates a thorough investigation by the child protection team and child welfare services.

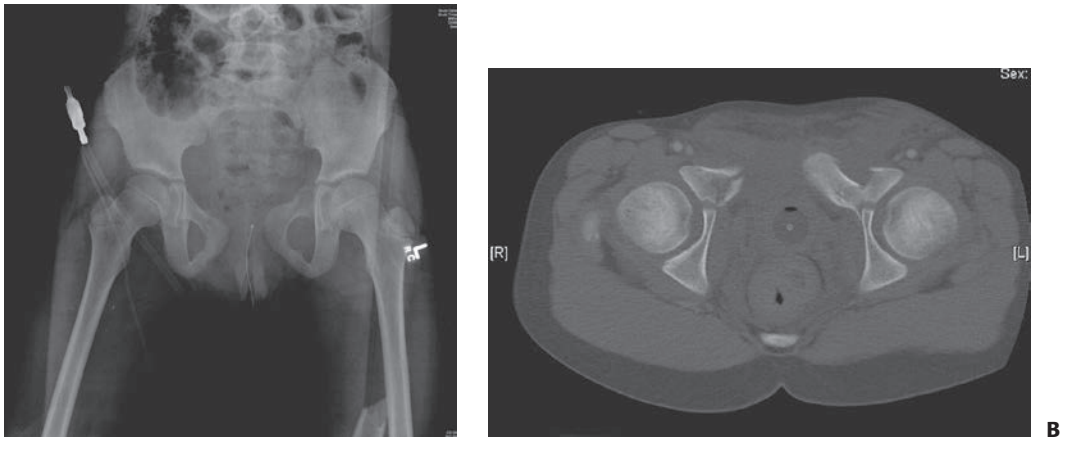

FIGURE 25-1 **A:** Pelvic radiograph showing a pelvic fracture with the left superior rami injury propagating toward the triradiate cartilage. **B:** CT scan showing the rami fractures propagating into the triradiate cartilage.

Associated Injuries with Pelvic and Acetabular Fractures

While death rates in children who sustain pelvic fractures have been reported to be as high as 25%, most series report a mortality rate of 2% to 12% in children.[1,5,12–14] Significant hemorrhage that requires blood transfusion occurs in as many as 30% of patients with pelvic fractures[80] and is most common in patients who sustain anterior and posterior pelvic ring fractures and those with unstable fractures. However, hemorrhage from pelvic fracture–related vascular injury is the cause of death in less than 1% of children as compared to 3.4% of adults who sustain pelvic ring and acetabular fractures.[29,36] One possible explanation for the low rate of hemorrhage relates to the lack of underlying atherosclerotic disease and the increased contractility of children's smaller arterial vessels, both of which result in greater vasoconstriction after injury.[36] In addition, children are injured typically in motor vehicle versus pedestrian accidents and therefore tend to sustain lateral compression forces, as opposed to anterior–posterior forces like adults. Injuries caused by laterally directed forces do not as commonly result in expansion of the pelvic ring or disruption of the sacroiliac joints, generally resulting in less intrapelvic hemorrhage.[30]

Associated injuries, rather than fractures about the pelvis, are more commonly the causes of morbidity and mortality in children and adolescents who are diagnosed with pelvic ring and acetabular fractures. Between 58% and 87% of children who sustain pelvic fractures have at least one associated injury and many have several.[11,20,25,30,69,83] The most common associated injuries are other fractures, particularly of the lower extremities and spine, which are identified in nearly half of children with pelvic fractures.[25,80] In one study of 79 children with pelvic fractures, patients with even one additional fracture demonstrated a significantly increased need for other nonorthopedic procedures.[97] The incidence of associated traumatic brain injuries varies from as little as 9% to nearly 50%[4,11,25,30,52,55,69,83] and clearly is the most important comorbidity that influences outcomes. Associated thoracoabdominal injuries occur at a rate between 14% and 33% in children with pelvic fractures.[4,11,14,25,55,80,83] These injuries are second only to head injuries as the primary cause of death in children with pelvic fractures and should be carefully ruled out in children who sustain serious pelvic ring or acetabular injuries.

Other less common injuries have been reported in children who sustain pelvic fractures. Vaginal and rectal lacerations are seen in 2% to 18% of children with pelvic fractures.[3,67,89] The incidence of these injuries is much higher in open fractures of the pelvis, a rare injury in children.[54] The surgeon must have a high index of suspicion for these types of injuries because early detection, appropriate irrigation and debridement, and repair of lacerations may prevent the development of infection. Genitourinary injuries, most commonly urethral tears and bladder disruptions, are diagnosed in 4% of patients who sustain fractures[25] but hematuria has been noted in up to 50% of children with pelvic fractures.[11,66,89] Peripheral nerve injury occurs in less than of 3% of children. Posterior displacement of the hemipelvis or the iliac wing from severe pelvic ring disruption can cause tension on the lumbosacral plexus and sciatic nerve as they exit the pelvis.[20,67,92] A thorough neurologic examination of the lower extremities, including motor and sensory testing, and assessment of sphincter tone and perianal sensation should be routine in all patients with displaced fractures. Magnetic resonance imaging (MRI) is sometimes helpful to assess the integrity of the lumbosacral plexus. Neurophysiologic studies are indicated in the recovery phase if deficits persist.

Signs and Symptoms of Pelvic and Acetabular Fractures

A full systematic examination of the child with a pelvic or acetabular injury is indicated. The patient will often be first seen in the trauma bay by a multidisciplinary trauma team. Other life-threatening issues may prevent a complete examination immediately, and the patient's mental status may be impaired. Secondary examinations after the patient is stabilized are critical to identify lesser injuries that may not have been as obvious initially.

Evaluation of a child with a suspected pelvic injury should begin with the assessment of the airway, breathing and circulatory status, as with any polytraumatized patient.[95] Careful examination of the head, neck, and spine should be performed to assess for spinal injury and closed head injury. A complete neurovascular examination including peripheral pulses should be part of the initial survey. Documentation of the function of the muscles innervated by the lumbosacral plexus and the skin supplied by its sensory branches is sometimes difficult to fully assess in the acute setting. A secondary survey after stabilization of cardiovascular status and provisional treatment of injuries should include this neurologic evaluation in cooperative patients.

After the primary survey, the evaluation specific to pelvic injuries begins with a complete inspection of the pelvis and perineum to evaluate for lacerations and ecchymosis. The child should be gently log-rolled to facilitate a complete inspection. The Morel-Lavellee lesion (a degloving injury in which the skin and subcutaneous fat is sheared from the underlying muscle, creating a large space where a hematoma can form) may be identified[95] (Fig. 25-2). A careful genitourinary evaluation must be performed because of the intimate relationship between the pelvis, bladder, and urethra. Rectal examination has historically been recommended for children with significantly displaced fractures pelvic or if there is any blood in the perineal area. A more recent study, however, revealed that routine use of this examination for all patients may not be necessary, but should be reserved for patients at higher risk for more significant injury.[78]

Pelvic landmarks including the anterior-superior iliac spine, crest of the ilium, sacroiliac joints, and symphysis pubis should be palpated. Manual manipulation should be performed carefully when needed. The maneuvers are often painful and if performed too vigorously may further displace the fracture or stimulate further intrapelvic bleeding. Pushing posteriorly on the anterior-superior iliac crest produces pain at the fracture site as the pelvic ring is opened. Compressing the pelvic ring

FIGURE 25-2 Clinical photograph of a Morel–Lavellee lesion, the result of an underlying unstable pelvic fracture. This is an internal degloving injury in which the skin and subcutaneous fat are sheared off the underlying muscle. (Reproduced by permission from Samir Mehta, MD.)

by squeezing the right and left iliac wings together also causes pain, and crepitation may be felt if a pelvic fracture is present. Pressure downward on the symphysis pubis and posteriorly on the sacroiliac joints causes pain and possibly motion if there is a disruption. Pain with range of motion of the extremities, especially the hip joint, may indicate articular involvement and other fractures or tendon and ligament injuries.

Avulsion fractures of the pelvis typically result in localized swelling and tenderness at the site of the avulsion fracture. Motion is limited because of guarding, and pain may be mild or marked. In the case of repetitive stress injury, pain and limitation of motion usually are gradually progressive. In patients with ischial avulsions, pain at the ischial tuberosity can be elicited by flexing the hip and extending the knee (straight-leg raising). In this position, as the hip is moved into abduction, the pain increases. Patients may also have pain while sitting or moving on the involved tuberosity.

Imaging and Other Diagnostic Studies for Pelvic and Acetabular Fractures

Following initial stabilization of the child, all multitrauma patients and those with suspected pelvic or acetabular trauma should undergo an anteroposterior (AP) radiograph of the pelvis as part of the initial trauma series. Multiple fractures are often an indication of associated thoracoabdominal or head injuries. Once the primary survey is completed and the patient is stable, region-specific radiographs should be obtained of any area with signs of trauma on secondary assessment.

Additional views, including the inlet and outlet and Judet views are useful for further evaluation of pelvic ring injuries. The inlet view is obtained by directing the x-ray beam caudally at an angle of 60 degrees to the x-ray plate. The inlet view is best for the determination of posterior displacement of a hemipelvis. The outlet view is obtained by directing the x-ray beam in a cephalad direction at an angle of 45 degrees to the x-ray plate. The outlet view best demonstrates superior displacement of the hemipelvis or vertical shifting of the anterior pelvis.[91] Internal and external rotation views (Judet or oblique) are primarily obtained when an acetabular fracture is identified.

A number of studies have tried to identify clinical criteria which would effectively rule out the need for any pelvic radiographs in childhood trauma patients.[32,43,45] In general, children with no lower extremity fractures, a normal examination of the abdomen and pelvis, and who are alert and neurologically intact without pelvic pain regardless of a high-risk mechanism of injury, are unlikely to have sustained a pelvic fracture. The value of these criteria for avoiding radiation to the pelvis is a noble effort but its efficacy has not yet been established and most polytraumatized children do not meet these criteria.

Computer tomography (CT) scanning is considered to be the best modality to evaluate the bony pelvis, especially at the sacroiliac joint, sacrum, and acetabulum. Most authors agree that CT scanning is indicated if there is doubt about the diagnosis on the plain radiographs or if operative intervention is planned. This imaging modality helps better define the type of fracture, the degree of displacement, and can detect retained intra-articular fragments which can prevent concentric reduction (Fig. 25-3).[7,9,27,51,82] This information is crucial for determining the best treatment option and selection of the operative approach.[48] Three-dimensional CT reconstructions can give an excellent view of the overall bony fracture pattern but often underestimate the magnitude of cartilaginous fragments, especially of posterior wall fractures in children.[71] Many trauma centers routinely obtain CT scans of the abdomen and pelvis looking for visceral injury.

MRI currently has minimal role in evaluation of the acute trauma patient, although this practice may evolve with quicker sequencing and better access. MRI is better than CT in delineating soft tissue injuries, and does not emit ionizing radiation. Cartilaginous structures, such as posterior wall fractures associated with hip dislocations, or nonacute fractures, such as occult stress fractures or avulsion fractures, may be diagnosed more readily with MRI.[30,71] An MRI is recommended as an adjunctive imaging study for all pediatric acetabular fractures because MRI discloses the true size of largely cartilaginous posterior wall fragments in children (Fig. 25-4). Radioisotope bone scan is rarely indicated but may be useful for the identification of occult pelvic fractures or other acute injuries in children and adults with head injuries or multiple-system injuries.[34,91]

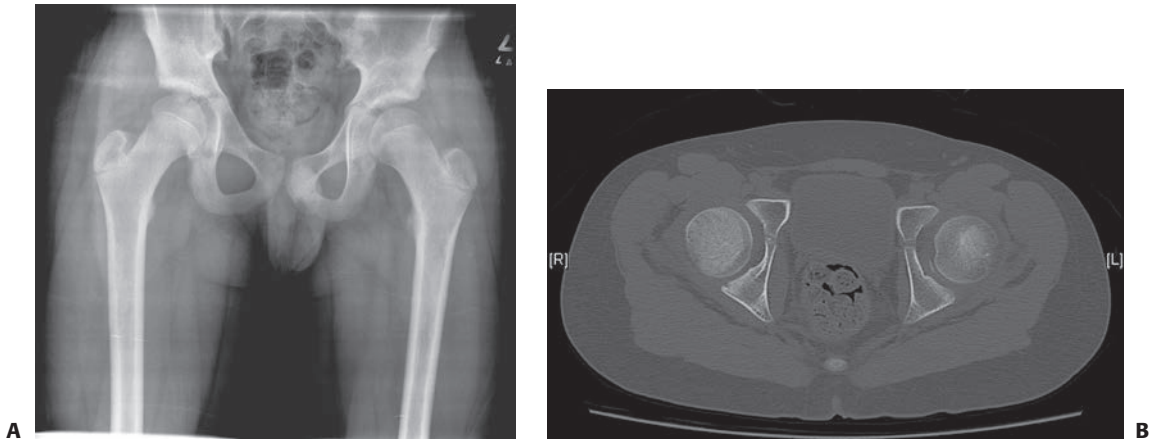

FIGURE 25-3 **A:** Postreduction anteroposterior pelvis radiograph of a 12-year old with the left hip appearing nonconcentric. **B:** CT scan showing a bony fragment from the posterior wall impeding reduction.

In children with avulsions of the pelvis, radiographs will usually show displacement of the affected apophysis. Avulsion injuries affect secondary centers of ossification before the center is fused with the pelvis, primarily in children of ages 11 to 17 years.[18,53,88] Comparison views of the contralateral apophysis should be obtained to ensure that what appears to be an avulsion fracture is not in reality a normal adolescent variant. Radiographs of children with delayed presentations of these injuries may demonstrate callus formation and these findings can occasionally mimic a malignant process.

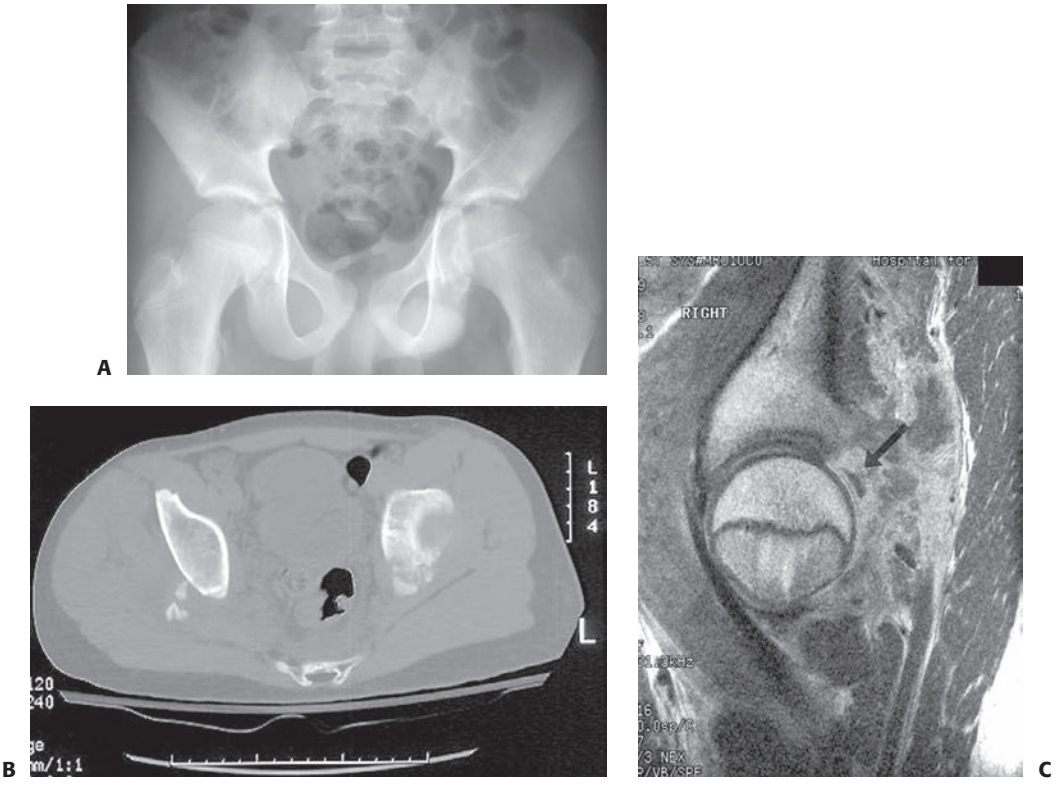

FIGURE 25-4 **A:** Postreduction radiograph of a left hip dislocation in a 12-year-old boy. **B:** CT scan demonstrates small ossified posterior wall fragments. **C:** Sagittal MRI demonstrates 90% posterior wall involvement with intra-articular step-off (*black arrow*). Classification of Pelvic and Acetabular Fractures

Pelvic Fracture Classification

The Torode and Zieg[94] classification based on plain radiographs, and its most recent modification based on radiographs and CT scans,[51] is the most commonly used classification of pediatric pelvic fractures. To create this classification, the authors reviewed 141 children with pelvic fractures and classified the injuries on the basis of the severity of the fractures as well as their associated prognosis. The classification has type I (avulsion fractures), type II (iliac wing fractures), type III (simple ring fractures), and type IV (ring disruptions). The modified scheme is identical to the earlier scheme but additionally divides type III "stable" simple ring injuries into IIIA (anterior only ring fractures) and IIIB (anterior and posterior ring fractures) (Table 25-1 and Fig. 25-5).[51] The morbidity, mortality,

TABLE 25-1 Modified Torode and Zieg Classification of Pelvic Fractures in Children

I. Avulsion fractures
II. Iliac wing fractures
  a. Separation of the iliac apophysis
  b. Fracture of the bony iliac wing
III. Simple anterior ring fractures
IV. Stable anterior and posterior ring fractures
V. Unstable ring disruptions
  a. "Straddle" fractures, characterized by bilateral inferior and superior pubic rami fractures.
  b. Fractures involving the anterior pubic rami or pubic symphysis and the posterior elements (e.g., sacroiliac joint, sacral ala).
  c. Fractures that create an unstable segment between the anterior ring of the pelvis and the acetabulum.

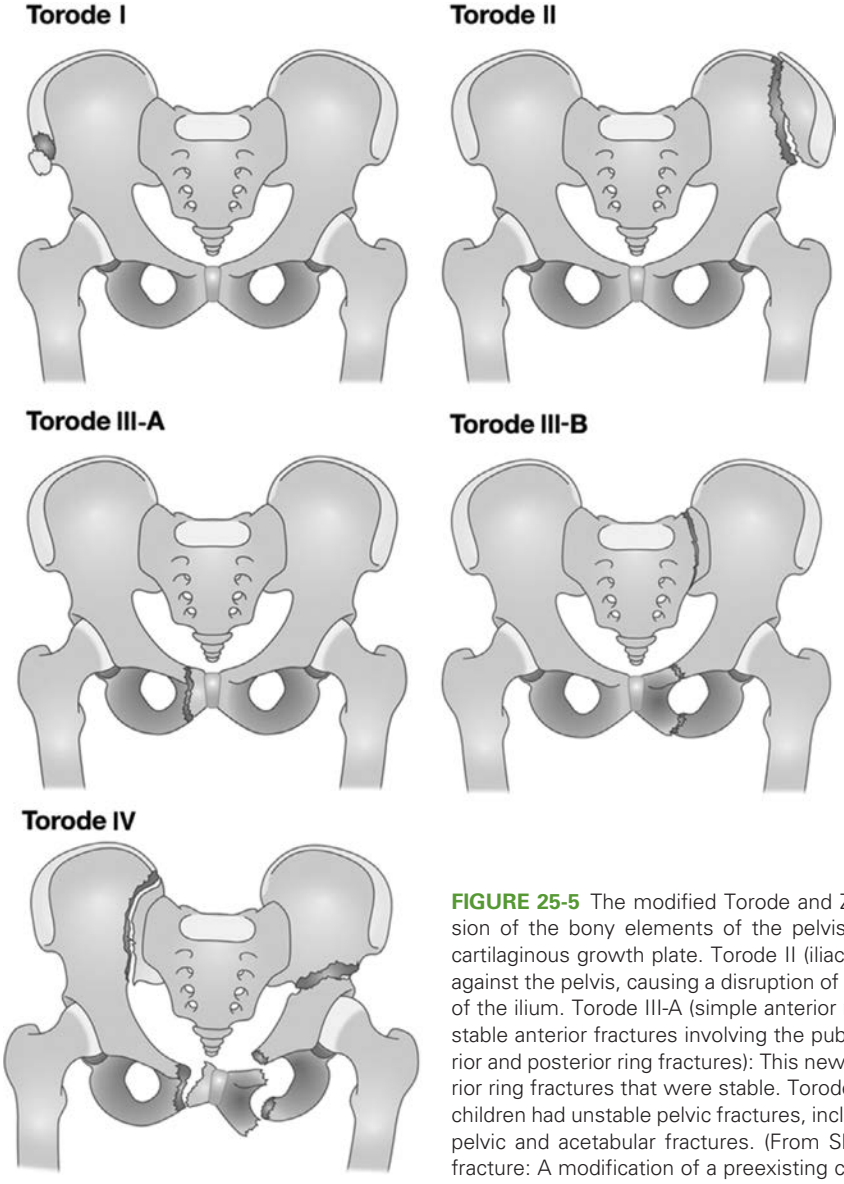

FIGURE 25-5 The modified Torode and Zieg classification. Torode I (avulsion fractures): avulsion of the bony elements of the pelvis, invariably a separation through or adjacent to the cartilaginous growth plate. Torode II (iliac wing fractures): Resulting from a direct lateral force against the pelvis, causing a disruption of the iliac apophysis or an infolding fracture of the wing of the ilium. Torode III-A (simple anterior ring fractures): This group involved only children with stable anterior fractures involving the pubic rami or pubic symphysis. Torode III-B (stable anterior and posterior ring fractures): This new group involved children with both anterior and posterior ring fractures that were stable. Torode IV (unstable ring disruption fractures): This group of children had unstable pelvic fractures, including ring disruptions, hip dislocations, and combined pelvic and acetabular fractures. (From Shore BJ, Palmer CS, Bevin C, et al. Pediatric pelvic fracture: A modification of a preexisting classification. *J Pediatr Orthop.* 2012;32(2):162–168.)

and complications are all greatest in the type IV group with "unstable" ring disruptions. This classification does not include acetabular fractures.

Silber and Flynn[81] reviewed radiographs of 133 children and adolescents with pelvic fractures and classified them into two groups: Immature (Risser 0 and all physes open) and mature (closed triradiate cartilage). They suggested that in the immature group, management should focus on the associated injuries because the pelvic fractures rarely required surgical intervention compared to the group with mature pelvises. Fractures in the mature group were best classified and treated according to adult pelvic fracture classification and management principles.[7,63,91]

Quinby[65] and Rang[47] classified pelvic fractures in children into three categories: (i) Uncomplicated or mild fractures, (ii) fractures with visceral injury requiring surgical exploration, and (iii) fractures with immediate, massive hemorrhage often associated with multiple and severe pelvic fractures. This classification system emphasizes the importance of the associated soft tissue injuries, but does not account for the mechanism of injury or the prognosis of the pelvic fracture itself. Watts[98] classified pediatric pelvic fractures according to the severity of skeletal injury: (a) Avulsion, caused by violent muscular contraction across the unfused apophysis; (b) fractures of the pelvic ring (secondary to crushing injuries), stable and unstable; and (c) acetabular fracture associated with hip dislocation.

Adult Pelvic Fracture Classifications

Pennal et al.[60] classified adult pelvic fractures according to the direction of force producing the injury: (a) AP compression, (b) lateral compression with or without rotation, and (c) vertical shear. This classification was modified and expanded by Tile et al. (Table 25-2).[94] Burgess et al.[7] further modified the Pennal system and incorporated subsets to the lateral compression and AP compression groups to quantify the amount of force applied to the pelvic ring. They also created a fourth category, combined mechanical injury, to include injuries resulting from combined forces that may not be strictly categorized according to the classification scheme of Pennal.

TABLE 25-2 Tile and Pennal Classification of Pelvic Fractures

A. Stable fractures
  A1. Avulsion fractures
  A2. Undisplaced pelvic ring or iliac wing fractures
  A3. Transverse fractures of the sacrum and coccyx
B. Partially unstable fractures
  B1. Open-book fractures
  B2. Lateral compression injuries (includes triradiate injury)
  B3. Bilateral type B injuries
C. Unstable fractures of the pelvic ring
  C1. Unilateral fractures
    C1-1. Fractures of the ilium
    C1-2. Dislocation or fracture-dislocation of the sacroiliac joint
    C1-3. Fractures of the sacrum
  C2. Bilateral fractures, one type B and one type C
  C3. Bilateral type C fractures

TABLE 25-3 AO/Association for the Study of Internal Fixation Classification of Pelvic Fractures

A. Stable fractures
B. Rotationally unstable fractures, vertically stable
C. Rotationally and vertically unstable fractures
  C1. Unilateral posterior arch disruption
    C1-1. Iliac fracture
    C1-2. Sacroiliac fracture-dislocation
    C1-3. Sacral fracture
  C2. Bilateral posterior arch disruption, one side vertically unstable
  C3. Bilateral injury, both unstable

The Tile classification has been incorporated into the Orthopaedic Trauma Association/AO classification, which is divided into bone segments, types, and groups (Table 25-3).[63] The Orthopaedic Trauma Association/AO system classifies pelvic fractures on the basis of stability versus instability, and surgical indications are based on the fracture types. Surgery is rarely indicated for type A fractures, whereas anterior and/or posterior surgical stabilization may be indicated for type B and C fractures. Numerous subtypes are included, and further details are described in the chapter on adult pelvic fractures.

In general, the basic classifications, (a) mature or immature pelvis and (b) stable or unstable fracture, are very useful for making treatment decisions. Regardless of the classification system that is used, if there is a break in the anterior and posterior pelvic ring, an extremely misshapen pelvis, a displaced posterior ring injury, or a displaced triradiate fracture, the pelvis is unstable.

Acetabular Fracture Classification

Pediatric Classifications. Bucholz et al.[6] classified pediatric acetabular fractures based on the Salter–Harris classification (Fig. 25-6). Their classification system is used to help determine the prognosis of a triradiate cartilage injury that may result in a deformity of the acetabulum with growth. The anatomy of the triradiate is such that the superior weight-bearing portion of the acetabulum is separated from the inferior third by the superior arms of the triradiate cartilage. These superior arms are usually the ones involved in a fracture. In the Bucholz classification, a type I or II injury occurs from a traumatic force to the ischial ramus, pubic ramus, or proximal femur resulting in a shearing force through the superior arms of the triradiate cartilage. If there is a metaphyseal bone fragment, this is a type II fracture. A type V injury is a crush injury to the physis.[6,45,98] Watts[98] described four types of acetabular fractures in children: (i) Small fragments that most often occur with dislocation of the hip, (ii) linear fractures that occur in association with pelvic fractures without displacement and usually are stable, (iii) linear

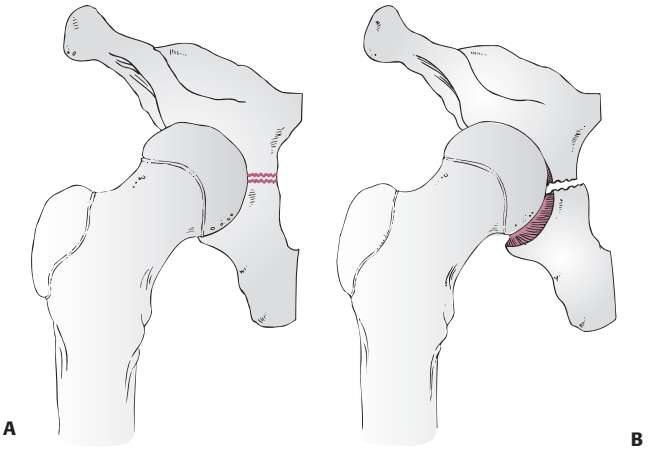

FIGURE 25-6 Types of triradiate cartilage fractures. **A:** Normal triradiate cartilage. **B:** Salter–Harris type I fracture.

fractures with hip joint instability, and (iv) fractures secondary to central fracture-dislocation of the hip.

Adult Acetabular Fractures

Acetabular fractures in children can also be described similarly to those in adults, which are usually classified by the system of Judet et al.[37] and Letournel and Judet.[44] A more comprehensive system is the AO fracture classification, which groups all fractures into A, B, and C types with increasing severity. Type A acetabular fractures involve a single wall or column; type B fractures involve both columns (transverse or T-types) and a portion of the dome remains attached to the intact ilium; and type C fractures involve both columns and separate the dome fragment from the axial skeleton by a fracture through the ilium. Both of these classification systems are discussed in more detail in Rockwood and Green's, Fractures in Adults, Chapter 36, Volume 2.[68]

Outcome Measures for Pelvic and Acetabular Fractures

Outcome data has been assessed by several functional assessments. A national multicenter study is currently tracking outcomes using the WeeFim functional assessment.[58] Other measures used to evaluate the quality of life in trauma patients include the Child Health Questionnaire (CHQ), the Functional Independence Measure, the Impact of Family Scale,[76] and the Health Related Quality of Life (HRQOL) scale.[75] Preliminary results demonstrate that 6-month functional scores after injury approach baseline levels,[58] despite the increased patient and family stress encountered.

Pathoanatomy and Applied Anatomy Relating to Pelvic and Acetabular Fractures

Pelvic and Acetabular Development

The pelvis of a child arises from three primary ossification centers: The ilium, ischium, and pubis. The three centers meet at the triradiate cartilage and fuse at approximately 12 to 14 years of age (Fig. 25-7).[59] The pubis and ischium fuse inferiorly at

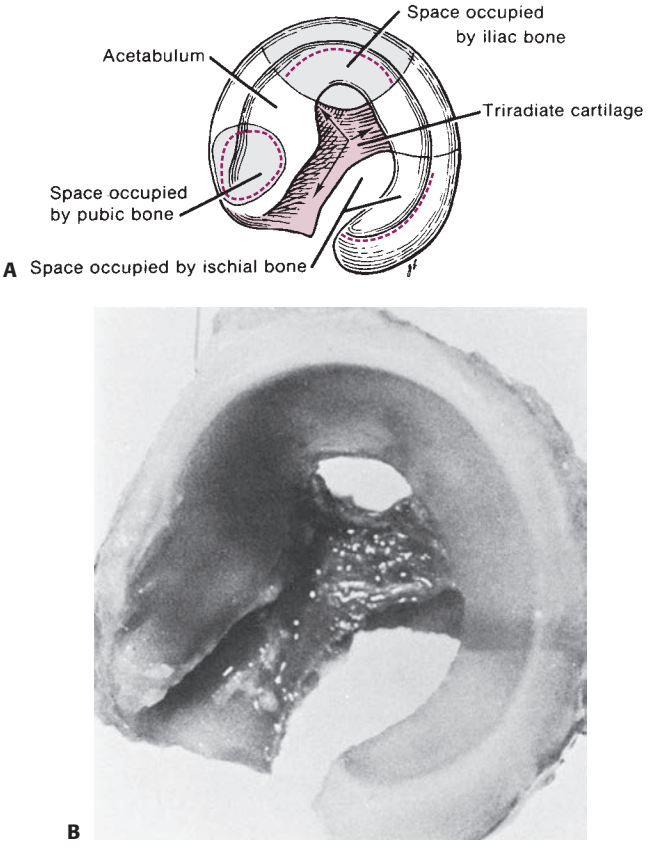

FIGURE 25-7 A: Triradiate-acetabular cartilage complex viewed from the lateral side, showing the sites occupied by the iliac, ischial, and pubic bones. **B:** Normal acetabular cartilage complex of a 1-day-old infant. The ilium, ischium, and pubis have been removed with a curette. The lateral view shows the cup-shaped acetabulum. (From Ponseti IV. Growth and development of the acetabulum in the normal child. Anatomical, histological, and roentgenographic studies. *J Bone Joint Surg Am.* 1978;60(5):575–585, with permission.)

the pubic ramus at 6 or 7 years of age. Occasionally, at approximately the time of fusion of the ischium to the pubis, an asymptomatic lucent area is noted on radiographs in the midportion of the inferior pubic ramus, termed the ischiopubic synchondrosis. It is often bilateral, fuses completely in most children, and may be confused with an acute or stress fracture of the pelvis.

Secondary centers of ossification arise in the iliac crest, ischium, anterior-inferior iliac spine, pubic tubercle, angle of the pubis, ischial spine, and the lateral wing of the sacrum. Secondary ossification of the iliac crest is first seen at age 13 to 15 years and fuses to the ilium by age 15 to 17 years. The secondary ossification center of the ischium is first seen at 15 to 17 years and fuses at 19 years of age, although in some young adults it may fuse as late as 25 years of age. A center of ossification appears at the anterior-inferior iliac spine at approximately 14 years, fusing at 16 years of age.[59,98] Knowledge about the location, age of appearance, and fusion of the secondary centers are important in differentiating these centers from fractures and avulsion injuries.

The acetabulum contains the shared physes of the ilium, ischium, and pubis that merge to become the triradiate

cartilage. Interstitial growth in the triradiate part of the cartilage complex causes the acetabulum to expand during growth and causes the pubis, ischium, and ilium to enlarge as well. The concavity of the acetabulum develops in response to the presence of a spherical head. The depth of the acetabulum increases during development as the result of interstitial growth in the acetabular cartilage, appositional growth of the periphery of this cartilage, and periosteal new bone formation at the acetabular margin.[64] The triradiate cartilage of the acetabulum closes at approximately 12 years of age in girls and 14 years of age in boys.[95] At puberty, three secondary centers of ossification appear in the hyaline cartilage surrounding the acetabular cavity. The os acetabuli, which is the epiphysis of the pubis, forms the anterior wall of the acetabulum. The epiphysis of the ilium, the acetabular epiphysis[64,98] forms a large part of the superior wall of the acetabulum. The small secondary center of the ischium is rarely seen. The os acetabuli, the largest part, starts to develop at approximately 8 years of age and expands to form the major portion of the anterior wall of the acetabulum; it unites with the pubis at approximately 18 years of age. The acetabular epiphysis develops in the iliac acetabular cartilage at approximately 8 years and fuses with the ilium at 18 years of age, forming a substantial part of the superior acetabular joint surface (Fig. 25-8). The secondary center of the ischium, the smallest of the three, develops in the ninth year, unites with the acetabulum at 17 years, and contributes very little to acetabular development. These secondary centers are sometimes confused with avulsion fractures or loose bodies in the hip joint.

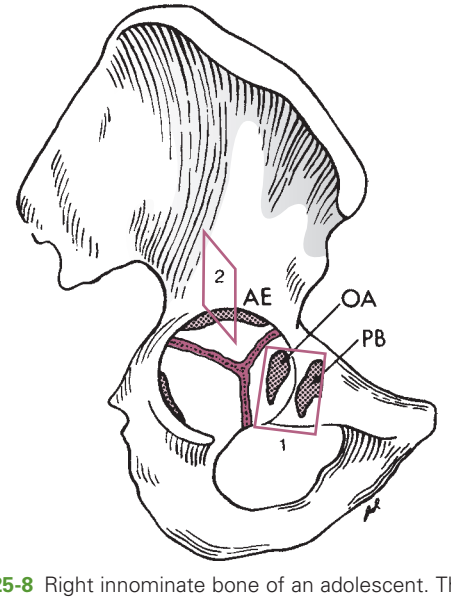

FIGURE 25-8 Right innominate bone of an adolescent. The os acetabuli (OA) is shown within the acetabular cartilage adjoining the pubic bone (PB); the acetabular epiphysis (AE), within the acetabular cartilage adjoining the iliac bone; and another small epiphysis (not labeled), within the acetabular cartilage adjoining the ischium (**left**). (From Ponseti IV. Growth and development of the acetabulum in the normal child. Anatomical, histological, and roentgenographic studies. *J Bone Joint Surg Am.* 1978;60(5):575–585, with permission.)

TABLE 25-4 Characteristics of the Pediatric Pelvis That Distinguish it from the Adult Pelvis

1. Greater bone plasticity and ligament elasticity that permits more bone deformation and greater mobility of the SI joints and symphysis pubis with trauma.
2. Thick periosteum, structural cartilage components, including the triradiate cartilage that also permit more mobility of the ring but are susceptible to growth disturbance.
3. The presence of bone–cartilage apophyses toward the end of skeletal growth that are susceptible to avulsion fractures from violent contraction of attached muscles.

Child Versus Adult Pelvis

As mentioned previously, there are important anatomic differences between the pelvis of a child and that of an adult (Table 25-4). Because of some of these differences, the pediatric pelvis is better able to absorb energy without significant displacement. Minimally displaced fractures and single breaks of the ring are frequently seen in pediatric pelvic fractures, a finding opposed to the traditional concept of a mandatory "double break" in the ring seen in adult fractures.[47,59] More importantly, a child may sustain a higher energy injury than suspected from the bony injury, making it crucial that the surgeon be aware that even minor pelvic fractures may be associated with other potentially serious injuries.

Treatment Options for Stable Pelvic Fractures

Avulsion Fractures (Torode and Zieg Type I)

Nonoperative Treatment

Of the 268 pelvic avulsion fractures reported in the four largest series,[18,21,70,88] 50% were ischial avulsions, 23% were avulsions of the anterior-superior iliac spine, 22% were avulsions of the anterior-inferior iliac spine, and 2% were avulsion of the iliac apophysis. Athletes who participate in jumping sports also sustain avulsions of the lesser trochanter from traction by the iliopsoas muscle, injuries that are often reported with pelvic apophyseal avulsion fractures (although more accurately a femur fracture) (Fig. 25-9). Most pelvic avulsion fractures in children heal satisfactorily with nonoperative management including rest, partial weight bearing on crutches for 2 or more weeks, and extremity positioning to minimize muscle stretch. Typically children resume normal activities by 6 to 8 weeks. Two small series of adolescents with pelvic avulsion fractures treated conservatively concluded that nonsurgical treatment was successful in all patients, and all patients returned to preinjury activity levels.[18,53] In another series, only 3 of 198 competitive adolescent athletes with pelvic avulsion fractures were treated operatively.[70]

Others, however, have suggested that nonoperative treatment is associated with a higher incidence of functional disability and inability to return to competitive athletic activity.[88] In one long-term follow-up study of 12 patients with ischial

FIGURE 25-9 Avulsion fracture of the lesser trochanter.

avulsions, 8 reported significant reduction in athletic ability and 5 had persistent local symptoms.[73] Thus, some controversy exists surrounding the acute management of displaced ischial avulsion fractures. Although many have satisfactory outcomes without surgery, indications for surgical management are not clear nor is the best operative technique established. Most agree that excision of the ischial apophysis is indicated in the setting of chronic pain and disability. Some authors, however, recommend open reduction and internal fixation of those rare acute ischial avulsion fragments displaced more than 1 to 2 cm (Fig. 25-10).[46] Operative treatment of the other types of avulsion fractures is rarely indicated.

Operative Treatment

Indications/Contraindications. Most avulsion fractures may be successfully treated nonsurgically. Significant displacement greater than 1 to 2 cm, persistent pain, or bony prominence that interferes with sitting are all relative indications for surgery.

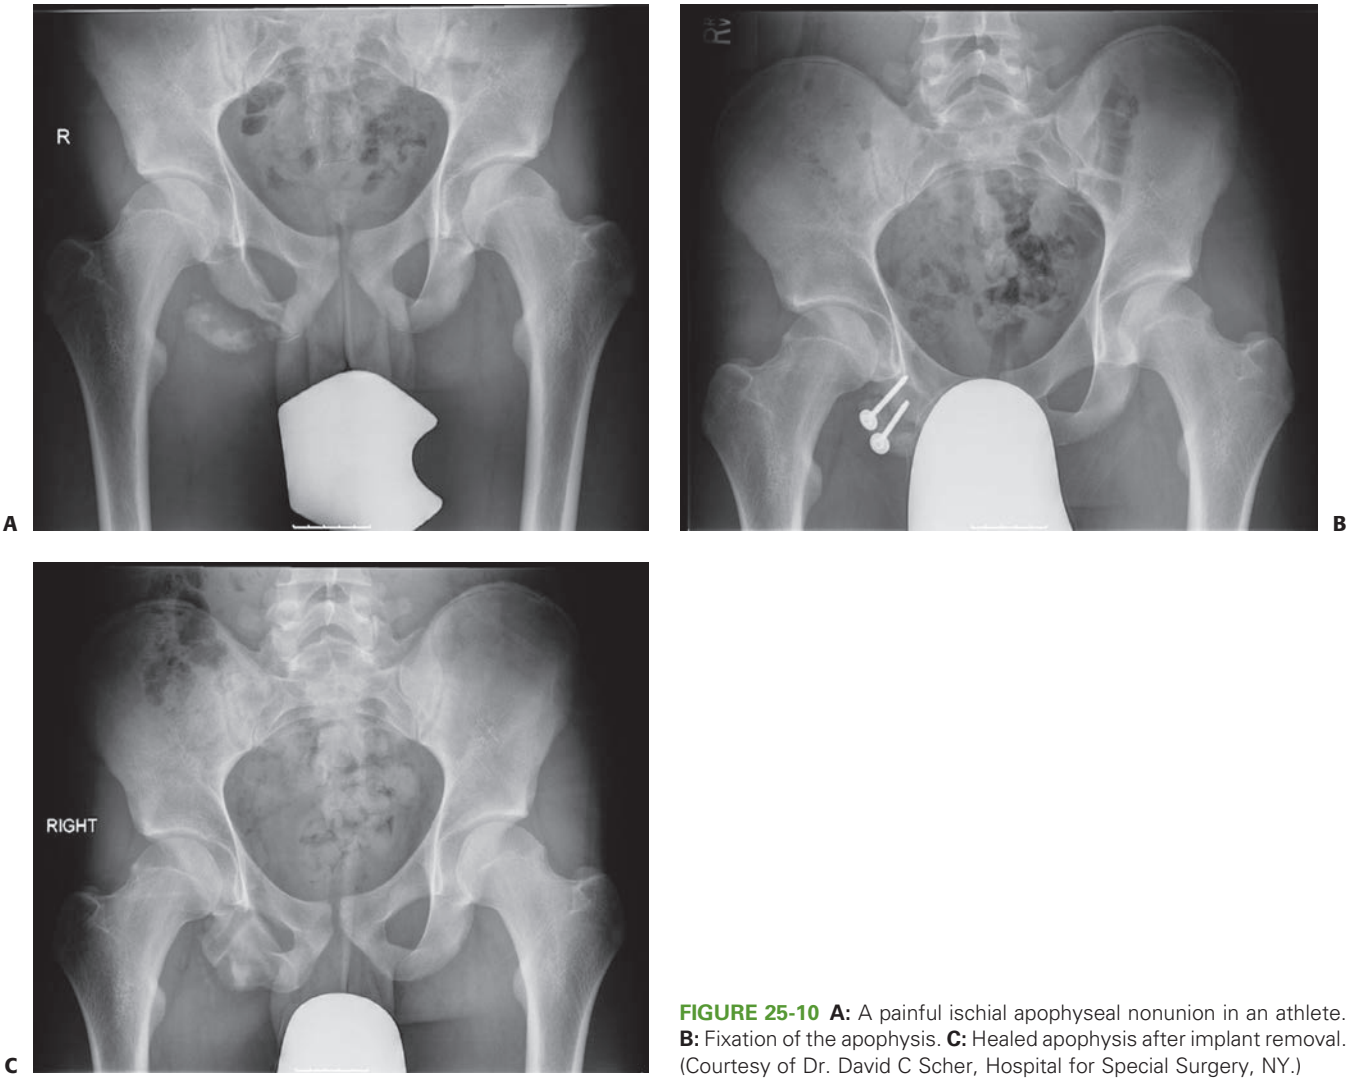

FIGURE 25-10 **A:** A painful ischial apophyseal nonunion in an athlete. **B:** Fixation of the apophysis. **C:** Healed apophysis after implant removal. (Courtesy of Dr. David C Scher, Hospital for Special Surgery, NY.)

Ischial Avulsion Fracture

Preoperative planning checklist includes:

1. C-arm
2. Fluoroscopic table such as a Jackson table
3. Screw set including 4.5- to 6.5-mm screws with washers
4. Cables, wires, and/or suture anchors available as a back up

Positioning: prone surgical approach for open reduction and internal fixation of an ischial avulsion fracture.

After appropriate anesthesia, the patient should be placed in a prone position with the hip and knee slightly flexed. An approximately 7- to 10-cm incision is made along the gluteal crease. The inferior edge of the gluteus maximus is identified and elevated. The plane between gluteus maximus and the hamstring muscles is then developed as the gluteus maximus is traced proximally. The bony fragment with the hamstrings attached is identified. Radiographs or C-arm can be used to identify this more clearly if needed. The fragment may be reduced more easily with the hip extended and the knee slightly flexed. After reduction, the fragment is stabilized with cancellous screws, with or without washers. If necessary, additional fixation with suture anchors, cables, or wires may be needed to ensure stability.

Postoperative Care

After surgery, the patient is permitted to sit up with the hips and knees slightly flexed to decrease stress on the hamstrings. Initially made nonweight bearing, patients may progress to full weight bearing in 3 to 6 weeks. At 12 weeks postoperatively, the patient may resume full activities.

Isolated Iliac Wing Fractures (Torode and Zeig Type II)

Direct trauma may fracture the wing of the ilium, but isolated iliac wing fractures are relatively rare, with a reported incidence of 5% to 14% in children with fractures of the pelvis.[66,69,80] However, iliac wing fractures often occur in conjunction with other fractures of the pelvis, and thus the overall incidence of iliac wing fractures is significantly higher than the incidence of isolated iliac wing fractures.

The patient with an iliac wing fracture typically presents with pain that is located over the wing of the ilium. On examination, motion at the fracture site may be noted. A painful Trendelenburg gait may be present because of spasm of the hip abductor muscles. A fracture of the wing of the ilium may be overlooked on an underexposed radiograph of the pelvis where the ilium is poorly seen as a large area of radiolucency. Displacement of the fracture usually occurs laterally, but it may occur medially or proximally. Severe displacement is rare because the iliac wing is tethered by the abdominal muscles and the hip abductors.

Treatment of an iliac wing fracture is mostly dictated by the associated injuries. Symptomatic treatment is all that is necessary for most iliac wing fractures and typically includes pain management and partial weight bearing on crutches until the symptoms are completely resolved. Regardless of comminution or displacement, these fractures usually unite without complications or sequelae (Fig. 25-11). Open reduction with screws or plating is rarely indicated except for large fragments with severe displacement.

FIGURE 25-11 Stable fracture of the iliac wing.

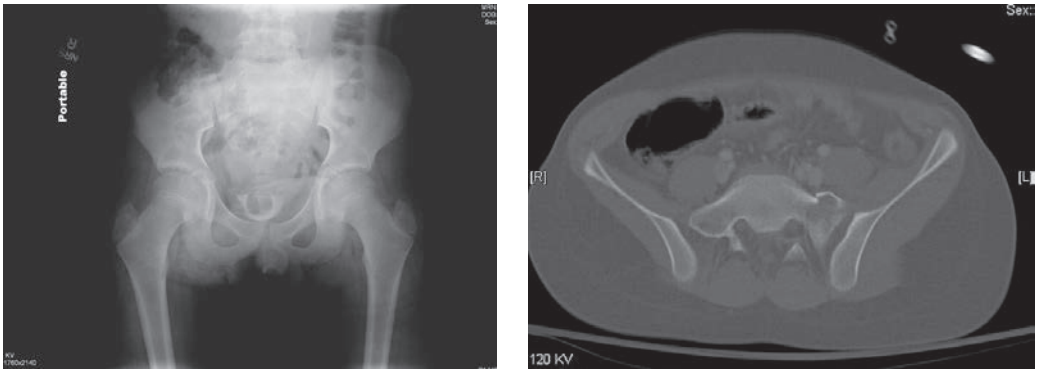
Other Stable Fractures

Fractures of the Sacrum

Sacral fractures constitute a small fraction of pelvic fractures reported in children. Rieger and Brug[69] reported two sacral fractures and seven sacroiliac fracture-dislocations in their 54 patients. Sacral fractures are probably more common than reported, but because they are obscured by the bony pelvis and the soft tissue shadows of the abdominal viscera, and because they are rarely displaced, they may be overlooked. Nine of 166 patients (5.4%) with pelvic fractures in the series by Silber et al.[83] had associated sacral fractures, none with nerve root involvement. There are two general types of sacral injuries. Spinal-type injuries may present as crush injury with vertical foreshortening of the sacrum or horizontal fractures across the sacrum. These fractures may be significant because they may damage the sacral nerves, resulting in the loss of bowel and bladder function. Alar-type injuries are generally vertical fractures through the ala or foramina. These fractures are significant in that they may represent the posterior break of the double ring fracture.

The presence of sacral fractures may be suggested clinically. Pain and swelling may be present, usually over the sacrum. Because digital rectal examination in pediatric trauma patients has a high false-negative rate, its usefulness is questionable and is not routinely performed in all centers.[79] When the examination is performed in patients with sacral fractures, fracture fragments, rectal tears, and urethral disruptions may sometimes be identified.

Sacral fractures are difficult to see on plain radiographs. The fracture can be oblique, but most are transverse with minimal displacement and occur through a sacral foramen, which is the weakest part of the body of the sacrum. Minimal offset of the foramen or offset of the lateral edge of the body of the sacrum is an indication of sacral fracture. Lateral views are



A B

FIGURE 25-12 **A:** An example of an anterior–posterior pelvic radiograph where the sacral fracture is not well visualized. **B:** CT scan of the patient showing the sacral fracture.

helpful only if there is anterior displacement, which is rare. A 35-degree caudal view of the pelvis may reveal a fracture of the body of the sacrum. CT and MRI scans are best in the identification of sacral fractures missed on plain radiographic images.[24,27,77] In one study comparing radiographs with CT scans in a consecutive series of 103 pediatric trauma patients with pelvic radiographs and pelvic CT scans, only three sacral fractures were identified with plain radiographs whereas nine sacral fractures were identified with CT (Fig. 25-12).[27] Sacral fractures are generally managed expectantly and treated symptomatically. In rare cases, pinched sacral nerve roots may need to be decompressed.

Fractures of the Coccyx

Many children fall on the tailbone and have subsequent pain. The possibility of fracture must be entertained. Because the coccyx is made up of multiple small segments, is obscured by soft tissue, and naturally has a crook in it, it is difficult to determine on radiographs whether a coccygeal fracture has occurred, especially in a child. These fractures rarely have associated injuries. Clinically, patients describe immediate, severe pain in the area of the coccyx. Pain on defecation may be present as well as pain on rectal examination. Because radiographic identification is difficult, the diagnosis should be made clinically by digital rectal examination. Exquisite pain may be elicited, and an abnormal mobility of the coccygeal fragments may be noted. Acute symptoms may abate in 1 to 2 weeks, but may be remarkably persistent. The differential diagnosis is between fracture and coccydynia. Lateral radiographs of the coccyx with the hips flexed maximally may reveal a fracture (Fig. 25-13). Apex posterior angulation of the coccyx is a normal variant, and should not be falsely interpreted as a fracture or dislocation. CT and MRI scanning may be helpful in differentiating between physeal plates and fracture lines.[13] Treatment is symptomatic only and consists of activity restriction and a pressure-relieving cushion for sitting with an expectation of resolution in 4 to 6 weeks for acute fractures. In our experience, however, some patients have chronic pain that persists for several months, probably better described by the diagnosis "coccydynia." Symptomatic treatments, injections, and coccygectomy are some management options with good results in adolescents.[26]

Stress Fractures of the Pubis or Ischium

Stress fractures are rare in small children, but they do occur in adolescents and young adults from chronic, repetitive stress to a bony area or during the last trimester of pregnancy. Stress fractures of the pubis are likewise uncommon, but a small series of stress fractures, primarily in the inferior pubic rami, has been reported. Chronic symptoms and pain increased by stress may be noted in the inferior pubic area. Radiographs may show no evidence of fracture for as long as 4 to 6 weeks, and then only faint callus formation may be visible; however, MRI or a technetium bone scan may reveal increased uptake early.[34] Treatment should consist of avoiding the stressful activity and limited weight bearing for 4 to 6 weeks.

The ischiopubic synchondrosis usually closes between 4 and 8 years of age.[40] The radiographic appearance of the

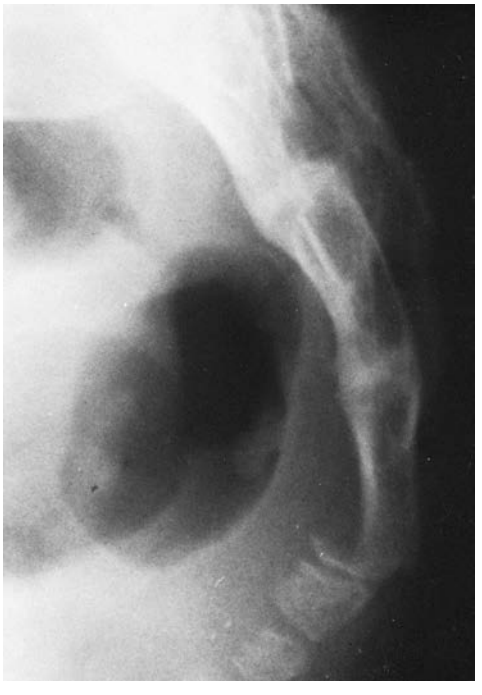


FIGURE 25-13 Lateral radiograph with the hips maximally flexed reveals a displaced coccygeal fracture in a 14-year-old boy.

FIGURE 25-14 Radiograph of the pelvis of a 9-year-old child. Although the differentiation could not be made between a fracture and fusion of the right ischiopubic ossification at the time of radiograph, the patient was asymptomatic and the mass was considered a variant of normal development.

synchondrosis at the ischiopubic junction may be misinterpreted as a fracture. Caffey and Ross[8,42] noted that bilateral fusion of the ischiopubic synchondrosis is complete in 6% of children at 4 years of age and in 83% of children at 12 years of age. The presence of the synchondrosis itself is common and usually asymptomatic. Bilateral swelling of the synchondrosis was also noted in 47% of children at age 7 years. Irregular ossification and clinical swelling at the ischiopubic synchondrosis has been called ischiopubic osteochondritis or van Neck disease. If this syndrome is noted in a child older than 10 years of age, it should be treated as a repetitive stress injury (Fig. 25-14).

Treatment Options for Unstable Pelvic and Acetabular Fractures

Simple Ring Fractures (Torode and Zieg Type III A and B)

Based on the original classification scheme, simple ring injuries constitute up to 56% of all pelvic fractures in children,[46,50,63,77] with the majority resulting from motor vehicles striking pedestrians.[81] Many of these reported injuries were breaks in the anterior pelvic ring and were single ramus fractures—most commonly fractures of the superior ramus (Fig. 25-15).[46] In evaluating the usefulness of the classification subsequent to the original description and with the increased use of CT scans to define these injuries, it became apparent that not all stable pelvic ring injuries are the same with regard to fracture pattern, mechanism, associated injuries, or prognosis. To reflect important differences among the types of simple ring injuries, Shore et al., working with Torode from the original classification, modified the Torode and Zeig scheme. In the modified classification, type III stable or simple ring fractures are subdivided into types IIIa and IIIb. Type IIIa fractures are defined as simple anterior ring fractures and type IIIb fractures are stable anterior and posterior ring fractures. This distinction is critical because type IIIb injuries are associated with an increased need for blood transfusions, an increased length of hospital stay, more frequent admissions to the ICU, and more associated injuries compared to type IIIa fractures.

Nonsurgical Treatment

Patients with these injuries typically present with pain and tenderness about the pubic rami. Weight bearing is difficult or impossible secondary to pain and hip range of motion is often limited because of muscle guarding around the hip. The pelvic ring is grossly stable to rocking and compression but, for patients with type IIIb injuries, tenderness along the sacrum and sacroiliac joints may be elicited with palpation. Pelvic inlet and outlet radiographic views, or more commonly a CT scan, are used to distinguish type IIIa from type IIIb fractures.

Most stable ring fractures require no surgical intervention for management of the pelvic ring injury because, by definition, the pelvic ring is stable. For patients with type IIIb fractures, monitoring of cardiovascular status and blood loss, and management of associated injuries are priorities compared to pelvic fracture management. Most patients with type III fractures, however, require only symptomatic treatment. Pain control and mobilization out of bed with nonweight bearing or protected weight bearing, as dictated but the status of associated injuries when present, is important for the initial 1 to 2 weeks after

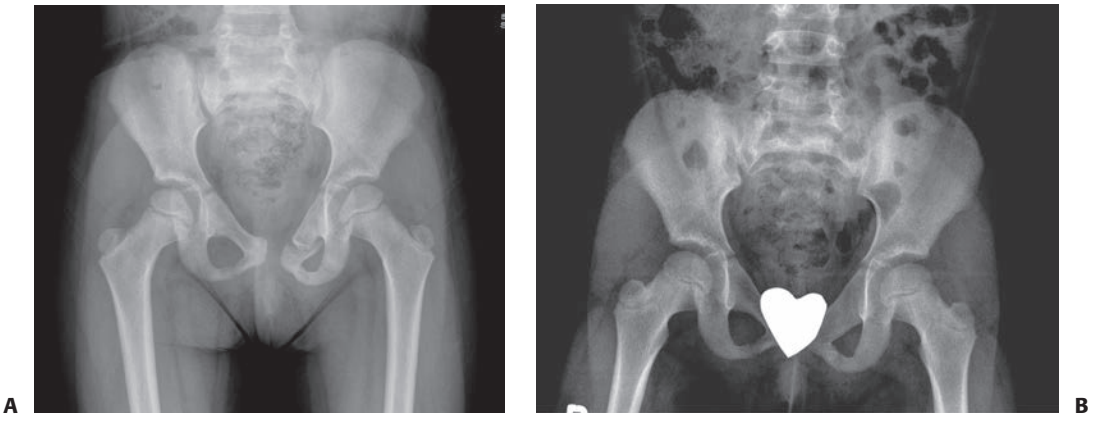

FIGURE 25-15 **A:** Stable superior pubic ramus fracture. The patient was allowed full weight bearing as tolerated. **B:** Radiographs show complete fracture union and remodeling.

injury. After pelvic ring healing has progressed and the pain has diminished, progressive weight bearing is permitted. Most children with type III pelvic fractures return to full activities within 6 to 8 weeks of the initial injury, unless associated comorbidities influence recovery.

Special Situations

Fractures of the Two Ipsilateral Rami

Fractures of the ipsilateral superior and inferior pubic rami comprised 18% of pediatric pelvic fractures in one series of 120 pediatric pelvic fractures.[11] Although these fractures are generally stable, they may be associated with injuries of the abdominal viscera, especially the genitourinary system (e.g., bladder rupture).[17] A careful examination of the perineum, rectal examination, and a cystourethrogram may be indicated to fully assess these injuries. Because these fractures typically unite without surgical treatment, most are treated nonsurgically except when severe displacement has occurred.

Fractures of the Body of the Ischium

Fracture of the body of the ischium near the acetabulum is extremely rare in children. The fracture occurs from external force to the ischium, most commonly in a fall from a considerable height. The fracture usually is minimally displaced and management consists of symptomatic treatment and progressive weight bearing (Fig. 25-16).

Widening of the Symphysis Pubis

Isolated injuries to the symphysis pubis are rare because these typically occur in association with disruption of the posterior ring at or near the sacroiliac joint most commonly. Although significant force appears to be necessary to disrupt or fracture the symphysis pubis, isolated disruption of the symphysis pubis can occur.[98] Clinically, exquisite pain is present anteriorly at the symphysis. The lower extremities may lie externally rotated when the patient is supine. Motion of the hips in flexion, abduction, external rotation, and extension is restricted and painful (FABER sign). Pain associated with a pubic diastasis is often improved by side-lying compared to supine positioning.[98]

Radiographs and CT imaging may reveal subluxation or widening of the symphysis or in the bone of the anterior ring just adjacent to it, and vertical or anterior–posterior offset of the two sides of the symphysis.[90] Although some elasticity of the pubic symphysis is normal in children and adolescents, diastasis greater than or equal to 2.5 cm or rotational deformity greater than 15 degrees suggests significant instability and is an indication for reduction.[23] Because of the normal variation of the width of the symphysis in children, the extent of traumatic separation may be difficult to evaluate. Watts[98] suggested obtaining radiographs with and without lateral compression of the pelvis to detect abnormalities, with greater than 1 cm of difference in the width of the symphysis pubis between the two views indicating a symphyseal separation. Imaging must also be carefully scrutinized to detect sacroiliac joint disruptions and triradiate cartilage fractures, both of which may occur in association with symphysis pubis separation (Fig. 25-17).[59]

Treatment of an isolated injury of the symphysis pubis with less than 2 cm of diastasis is generally symptomatic, similar to that described above for other stable pelvic ring injuries. Wider diastasis is best treated with closed reduction and external fixation (2) or open reduction and plating of the symphysis through an anterior Pfannenstiel incision (Fig. 25-18).

Isolated Fractures Near or Through the Sacroiliac Joint

Isolated posterior ring disruptions near or through the sacroiliac joint are rare in children. More commonly, posterior disruptions of the pelvic ring occur in conjunction with disruption of the anterior pelvis. Sacroiliac dislocations differ from those in adults in important ways. In children, disruptions tend to be incomplete because the anterior sacroiliac ligaments rarely tear through the entire ligament complex. In addition, the sacroiliac joint injury may separate, not through the joint, but instead through the physis of the ilium adjacent to the joint.[59] This fracture, through the relatively weak physeal cartilage, technically leaves the sacroiliac joint intact.[15]

Derangement of the sacroiliac joint should be suspected after high-velocity trauma with impact to the posterior pelvis. In patients with these injuries, the FABER sign is typically markedly positive on the ipsilateral side.[15,18] Associated vascular and neurologic injuries may occur. Lumbosacral nerve root avulsions have been described in children with this fracture.[15] Radiographs, particularly inlet and outlet pelvic views, and axial CT imaging, reveal subtle asymmetry of the iliac wings or the clear spaces that demarcate the sacroiliac joints. Offset of the distal articular surface is an indication of sacroiliac joint disruption (Fig. 25-19).

Symptomatic treatment and limited weight bearing on crutches are sufficient treatments for most isolated subluxations

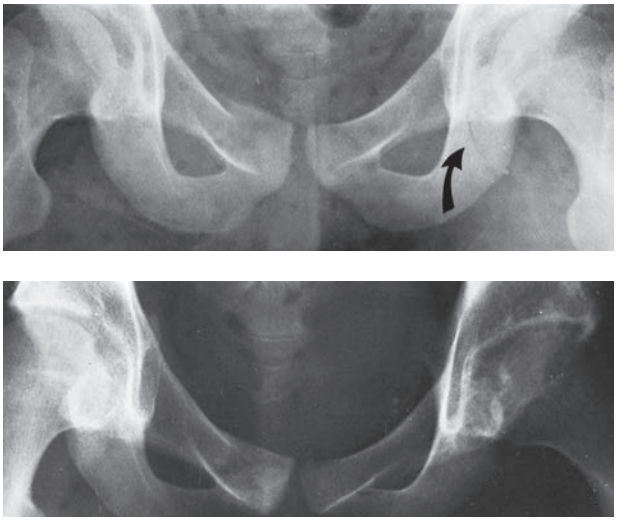

FIGURE 25-16 **A:** Nondisplaced fracture (*curved arrow*) through left ischium and contralateral pubic ramus fracture. **B:** Follow-up radiograph shows mild displacement and incongruity of the acetabulum and complete healing of the superior pubic ramus fracture. Either displacement of the fracture fragments or premature closure of the triradiate cartilage could have contributed to the incongruity of the femoral head in the acetabulum.

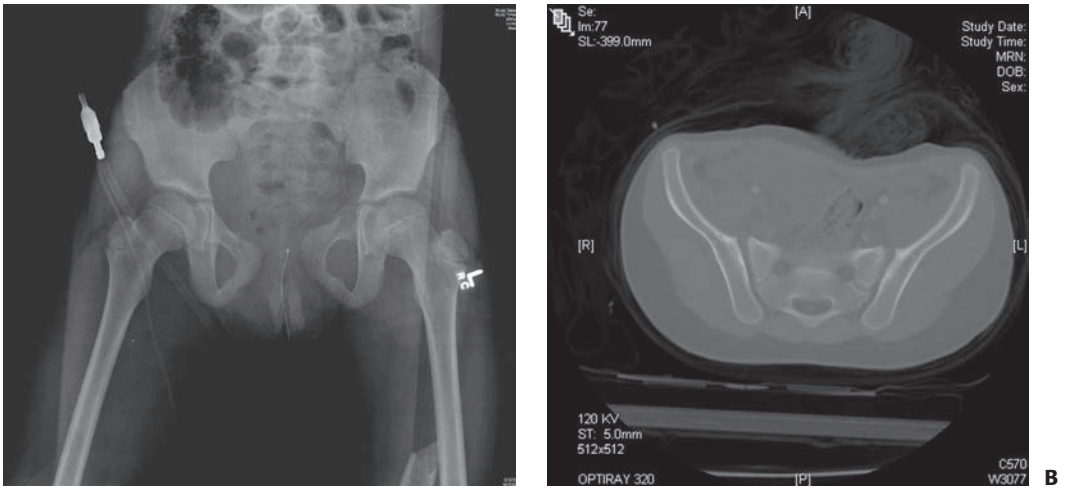

FIGURE 25-17 **A:** Fracture adjacent to the symphysis pubis with symphysis pubis separation. **B:** CT scan showing no posterior instability.

FIGURE 25-18 Radiograph of the pelvis after plating of the pubic symphysis that also includes acetabular fixation.

or fractures involving the sacroiliac joint. In one report,[31] isolated sacroiliac joint dislocations were treated in 18 children, 10 of whom had extensive degloving injuries of the posterior pelvis. While 10 patients were treated with nonsurgical treatment, 8 required surgery. The majority of these patients underwent open reduction and plate fixation. Based on this report, outcomes for this injury are not uniformly good, with nearly all patients experiencing complications such as chronic pain and incomplete recovery of nerve root injuries.

Ring Disruption: Unstable Fracture Patterns (Torode and Zieg Type IV)

Unstable pelvic fractures in children and adolescents constitute a small percentage of all pelvic fractures in pediatric patients. In one series of pelvic ring fractures, type IV injuries represented 10% of all pelvic fractures seen.[80] Most of these injuries result from high-velocity trauma, such as motor vehicle collisions and pedestrians being struck by motor vehicles. Children older than 12 years of age and those with closed triradiate

C

FIGURE 25-19 (*continued*) **C:** CT scan showing no anterior ring injury.

cartilages[80,81] are more likely to sustain these types of fractures compared to younger patients and those with open triradiate cartilages about the pelvis. Blood transfusions, intensive care unit lengths of stay, and surgical interventions, among other parameters, are generally increased in patients with type IV fractures compared to other types of pelvic fractures, as is the incidence of death.

Type IV fractures are typically divided into three subcategories:

1. Double anterior ring disruptions. This injury subtype includes bilateral pubic rami fractures (the straddle or floating injury) and disruptions of the pubis with an associated second break in the anterior ring.
2. Anterior and posterior pelvic ring (double ring) disruptions with instability and displacement, including vertical displacement (Malgaigne type). The anterior disruptions may be rami fractures or symphysis pubis disruption. Posterior ring injuries include fractures of the sacrum or ilium and disruptions through or adjacent to the sacroiliac joints.
3. Multiple crushing injuries that produce at least two severely comminuted fractures located at any site in the pelvic ring.

Bilateral Fractures of the Inferior and Superior Pubic Rami

Bilateral fractures of the inferior and superior pubic rami may occur in a fall while straddling a hard object, by lateral compression of the pelvis, or by sudden impact while riding a motorized cycle. The floating fragment usually is displaced superiorly, pulled in this direction by the rectus abdominis muscles.[98] As with ipsilateral superior and inferior pubic rami fractures, which may occur by similar mechanisms, bladder, or urethral disruptions[59] are commonly associated injuries that must be ruled out in patients with this type of pelvic fracture.

Radiographically, an inlet view or CT scan most accurately determines the amount of true displacement. Bilateral fractures of the inferior and superior pubic rami (straddle fractures) or disruption of the symphysis pubis with unilateral fractures of the rami are two fracture patterns that result in a floating anterior segment of the pelvic ring. Although this floating anterior arch is inherently unstable (Fig. 25-20) the posterior ring is usually not disrupted except, in some cases, by stable fractures of the sacrum or ilium.

FIGURE 25-20 Example of a straddle fracture.

Treatment

Because in most cases the posterior ring is intact and the anterior fractures are not displaced, treatment is similar to that described for type IIIb injuries. After associated injuries have been diagnosed and managed appropriately, treatment initially includes bed rest and pain control. Skeletal traction is unnecessary, and a pelvic sling is contraindicated because of the possibility that compression will cause medial displacement of the ilium.[59,98] Protected weight bearing with progression to full weight bearing and unrestricted activities is then permitted as pain improves. In children, pelvic ring healing occurs reliably in 6 to 8 weeks for most injuries. Bone remodeling can be expected over the ensuing months. Surgical treatment of the superior ramus with screw fixation or plating techniques are rarely necessary to treat children but may be indicated in adolescents, especially for those with significant displacement.

Anterior and Posterior Ring Disruptions

Double breaks in the pelvic ring, in which fractures occur both anterior and posterior to the acetabulum, (Fig. 25-21) result in instability of the pelvis. These injuries result from a variety of mechanisms. In one report,[83] AP compression forces were suspected to be the mechanism of injury, although the exact forces were not readily defined in all patients. Other possible causes of injury are severe direct lateral compressive forces, indirect forces transmitted proximally along the femoral shaft with the hip fixed in extension and abduction, and combined mechanisms of injury in which the pelvis is subject to multiple forces from different directions.

These unstable fractures are often accompanied by retroperitoneal and intraperitoneal bleeding and are most likely to be associated with severe, life-threatening hemorrhage. Concomitant abdominal injury occurs with an incidence of 35% to 60% in patients with these unstable pelvic fractures compared to 11% to 18% of patients with stable pelvic fractures.[4,96]

FIGURE 25-21 An unstable pelvis fracture with fractures in both the anterior and posterior ring of the pelvis. The left hemipelvis is displaced and rotated.

Aside from the physical signs usually associated with pelvic fractures, leg-length discrepancy and asymmetry of the pelvis may be present. Apparent leg-length discrepancy is seen in patients with vertical or cephalad displacement of the fractured hemipelvis. Internal or external rotation of the unstable hemipelvis may appear as asymmetry of the iliac crests. Inlet and outlet radiographs and CT scan reveal the amount of pelvic displacement.

Treatment

Initial treatment is focused on cardiovascular resuscitation with fluids and blood products, and stabilization of the child's overall condition before treatment of the pelvic fractures.[92] Pelvic binders or sheets, placed circumferentially across the greater trochanters to limit pelvic ring expansion with severe hemorrhage, may be used safely in larger children and adolescents with similar indications and precautions as in adults. Some injuries caused predominantly by lateral compression forces, however, may not be amenable to this because compression may increase the pelvic deformity. Embolization of arterial vessels is also an option for uncontrolled bleeding. Evidence-based literature regarding the use of pelvic binders and embolization in younger children is lacking, however, predominantly because unstable ring injuries that contribute to hemodynamic instability are exceedingly rare. The search for other sites of hemorrhage must be undertaken before attributing hemodynamic instability to the pelvic trauma in these younger children.

Minimally Displaced Fractures

Treatment of the pelvic ring injury varies based on the fracture pattern, degree of displacement and the age and condition of the child. For fractures with minimal displacement regardless of fracture pattern or age, symptomatic treatment that includes pain control, weight-bearing restrictions, and close radiographic follow-up for displacement is satisfactory to achieve healing (Fig. 25-22). Spica casting can be used in the younger child to improve the comfort of the patient and to prevent weight bearing, after cardiovascular parameters and associated injures have been stabilized. In some cases, older children and adolescents with minimally displaced fractures benefit from fixation to lessen pain associated with the fracture and facilitate mobilization. The majority of minimally displaced fractures, however, are treated nonsurgically.

Displaced Fractures

Nonsurgical Treatment. Historically, operative treatment of pelvic fractures in children has not been routinely utilized because of the following: (a) Severe hemorrhage from the pelvic fracture is unusual in children, making operative pelvic stabilization to control bleeding rarely necessary[2,55]; (b) the thick periosteum and ligaments about the pelvis in children limit displacement and stabilize the fracture to some degree, limiting fracture fragment mobility and facilitating healing so that nonsurgical treatment is well tolerated by patients,[66] and prolonged immobilization is not necessary for fracture healing[56]; (c) remodeling may occur in skeletally immature patients,

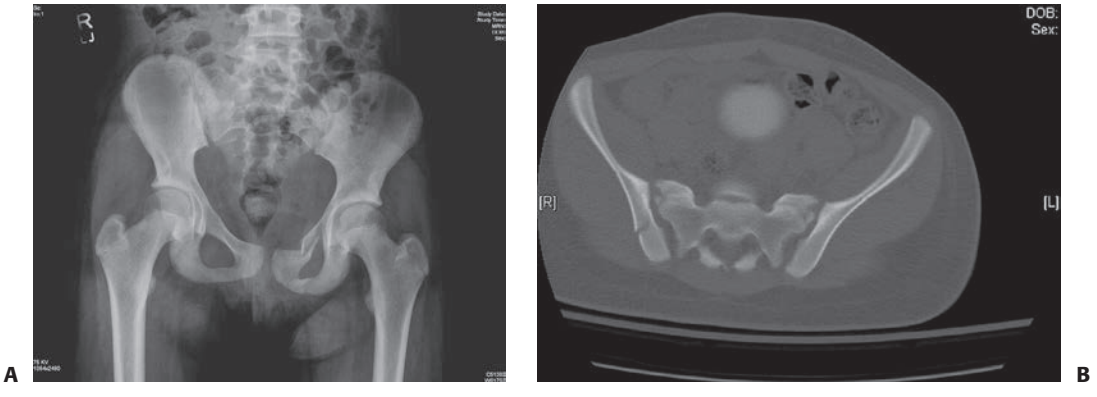

FIGURE 25-22 A potentially unstable pelvic fracture with anterior and posterior injury. **A:** The radiograph shows a left superior and inferior rami fractures. **B:** The CT scan shows a minimally displaced fracture adjacent to the sacroiliac joint. This is also an example where both CT and plan radiographs can be used to evaluate the injury and help decide on displacement and treatment. This patient was treated nonoperatively with follow-up making sure there was no displacement.

reducing the need to achieve anatomic alignment of some fractures; and (d) with few exceptions, long-term morbidity after pelvic fractures is rare in children.[25,38,55]

Techniques. Nonoperative treatment for unstable pelvic fractures includes bedrest and spica cast immobilization, neither of which significantly improves fracture alignment. For children younger than 8 years of age, closed reduction and spica casting may be used for symphyseal disruptions and sacroiliac joint injuries with small degrees of displacement. Skeletal traction is the only nonsurgical treatment that can be used to improve alignment of widely displaced fractures. Unstable fractures with vertical displacement of the hemipelvis may be reduced with this modality. Longitudinal traction is applied through a pin placed in the distal femur with weights similar to those utilized for femoral shaft reduction, typically 5 to 7 lb or one-eighth of body weight depending on the size of the child. Postreduction imaging is used to assess reduction and progression of healing. Traction is applied for a minimum of 2 to 4 weeks to achieve some stability of the injury, after which the child may be placed in a spica or kept on bedrest until further healing allows safe mobilization. Skeletal traction cannot improve alignment of symphyseal "open book" injuries, severe sacroiliac disruptions with widening, or fractures with rotational deformities of the hemipelvis.

Outcomes. Despite the fact that the classic assumptions and observations regarding pelvic fractures are generally correct, the published outcomes of nonsurgical treatments have not been uniformly satisfactory. Nierenberg et al.[56] reported excellent or good results after conservative treatment of 20 unstable pelvic fractures in children, despite radiographic evidence of deformity. These authors concluded that treatment guidelines for unstable pelvic fractures are not the same for children as for adults, and recommended that external or internal fixation should be used only when conservative methods fail.[56] In another study,[50] however, the authors found that a third of 15 skeletally immature patients with unstable fractures treated nonoperatively had chronic pain at follow-up. Similar findings were shown in another large series of unstable pediatric pelvic fractures treated nonsurgically with a mean of 7.4 years follow-up. In this study, about one-fourth of patients had musculoskeletal complaints at follow-up, including leg-length discrepancy, back pain, and sacroiliac ankylosis.[85] In addition, these authors identified important nonorthopedic complications, including 23 patients with genitourinary abnormalities, such as incontinence and erectile dysfunction, and 31 patients with psychiatric diagnoses such as posttraumatic stress disorder and major depression. These authors stressed the importance of minimizing prolonged hospital stays, addressing urologic needs fully, and anticipating the need for mental health support.

Surgical Treatment. Because past results of nonsurgical treatment of unstable fractures have been mixed, surgical treatment of significantly displaced and unstable pediatric pelvic fractures has become the practice standard at many pediatric trauma centers. The development of reliable and safe surgical techniques that may be applied to children and the availability of experienced adult orthopedic trauma personnel may be responsible for the growing trend toward the surgical management of unstable pediatric pelvic fractures.

In addition to the advantages of improved mobilization, anatomic or near-anatomic realignment of pelvic fractures likely improves outcomes. Residual pelvic ring asymmetry, specifically vertical displacement of the hemipelvis and sacroiliac joint malalignment, and acetabular deformity do not reliably remodel after fracture healing and have been associated with poor long-term outcomes such as leg-length discrepancy, back pain, scoliosis, and sacroiliac arthrosis in children.[74,84,87] Pelvic obliquity and asymmetry has also been associated with pelvic floor dysfunction and pain. In one[74] long-term follow-up study of 17 children with unstable pelvic fractures treated nonoperatively, 8 patients had pelvic asymmetry at follow-up. Of these eight patients, five had functional deformities, including scoliosis and leg-length discrepancies that resulted in chronic back pain. In another study, Smith et al.[87] followed 20 patients with open triradiate cartilages who were treated for unstable pelvic fractures for a mean of 6.5 years. Pelvic asymmetry was quantified[41] on an AP pelvis radiograph by measuring the difference in length (in centimeters) between two diagonal lines drawn from the border of the sacroiliac joint to the contralateral triradiate cartilage. Eighteen patients were treated operatively with external fixation, internal fixation, or a combination of both; pelvic asymmetry was less than 1 cm in 10 of 18 patients. At follow-up, the authors noted that pelvic asymmetry did not remodel to any significant degree, even in younger patients. Based on the Short Musculoskeletal Function Assessment (SMFA) questionnaire, patients with 1 cm or less of pelvic asymmetry had significantly less back and sacroiliac pain, and better SMFA outcome scores than those patients with pelvic asymmetry greater than 1 cm. In addition, all patients with greater than 1.1 cm of pelvic asymmetry had three or more of the following: nonstructural scoliosis, lumbar pain, a Trendelenburg sign, or sacroiliac joint tenderness and pain. The authors concluded that fractures associated with at least 1.1 cm of pelvic asymmetry following closed reduction should be treated with open reduction and internal or external fixation to improve alignment and the long-term functional outcome.[87]

Because of concerns for poor outcomes based on prior experience with nonsurgical treatment of unstable pediatric pelvic fractures, Karunaker et al.[39] surgically managed 18 unstable pelvic and acetabular fractures in children younger than 16 years of age using the principles of anatomic realignment and stable fixation routinely applied to adults. All patients healed by 10 weeks after surgery and had recovered full function with minimal residual pain at follow-up. No significant complications occurred, notably no cases of premature triradiate cartilage closure or sacroiliac joint abnormalities. They recommended operative intervention in skeletally immature patients with significant deformity of the pelvis at the time of injury to prevent late morbidities.[39] Others have drawn similar conclusions based on their experience with surgical management of unstable pediatric pelvic disruptions.[57,69,93]

Indications. The exact indications for surgical treatment are not clearly delineated in the literature and are somewhat

controversial. Holden et al.[35] determined, after a review of the literature prior to 2006, that fractures with more than 2 cm of displacement must be reduced and stabilized in children. Others have suggested that pelvic asymmetry greater than or equal to 1.1 cm is an indication for reduction. Silber and Flynn,[81] in one review of 166 children with pelvic fractures, recommended that all patients with closed triradiate cartilages, regardless of age, be treated as adults with anatomic realignment and stable fixation. Anatomic realignment and fixation is recommended by others for all displaced pelvic ring fractures regardless of age.[39,57,69,93]

Preoperative Planning. Surgery for pelvic ring reduction and fixation in children is rare. Ideally complex surgery is performed by an experienced orthopedic traumatologist, in conjunction with a pediatric orthopedic surgeon, utilizing techniques more commonly needed in adults but modified for children. These modifications include implants sized appropriately for children and techniques that preserve, as much as possible, the potential for growth. Perioperative care is best accomplished with a multidisciplinary team that is familiar with pediatric anesthesia and critical care and includes pediatric trauma nursing, child support services, and pediatric rehabilitation.

The timing of surgery is based on the needs of the individual patient. Although uncommon, emergency placement of external or internal fixation may be necessary to achieve cardiovascular stability, such as with an open book pelvis fracture not stabilized by a pelvic binder. Complex surgery, however, represents a "second hit" to the traumatized patient that further incites inflammatory processes and challenges the body's ability to respond to the stress of surgery. Although not directly studied in children, the concept of "Damage Control Orthopedics"[22] favors delaying surgery until concomitant injuries have been managed and after a period of cardiovascular stability. Because of this, pelvic surgery is typically performed in a delayed fashion, typically 7 to 10 days after the initial injury.

Many different surgical strategies and techniques may be utilized to achieve reduction and stability. The surgical team must carefully plan which technique or combination of techniques is best for the individual patient. Stabilization of the anterior ring may be accomplished with external fixation, symphyseal, and/or rami plate fixation, or screw fixation of the rami and anterior column (Fig. 25-23). Options for posterior stabilization include sacroiliac screw fixation and plate fixation (Fig. 25-24A–E). Because these techniques are discussed in detail in the companion to this text, Rockwood and Green's *Fractures in Adults*, this section will discuss only the two most commonly utilized techniques for children, external fixation and sacroiliac screw fixation.

External Fixation. External fixation is used to stabilize an unstable fracture with anterior ring separation or anterior fractures. This technique maintains reduction, decreases pain, facilitates mobilization out of bed, and may be better tolerated by older children than spica casting.[23,41] External fixation, however, may not effectively control the posterior ring[49] for all fracture patterns. Anterior external fixation may be achieved by placing one or two pins in the supra-acetabular bone on each side of the pelvis (Fig. 25-25)[72] or by placing one to two pins into each iliac crest and spanning these pin clusters with an external frame, ideally one that allows access to the abdomen.

Positioning. The child is typically placed supine on a radiolucent operating room table to allow access for the fluoroscopy

FIGURE 25-24 A 6-year-old boy who was struck by a school bus. He had a pneumothorax and a pelvic fracture. AP pelvis **(A)** and initial CT scan **(B)** show an unstable type IV fracture with vertical displacement of the hemipelvis. He was placed in traction during resuscitation **(C)** with realignment of the fracture. After stabilization 6 days after injury, he underwent closed reduction, SI screw fixation, and application of an external fixator. Post-op radiograph **(D)** of the pelvis and CT scan **(E)** show near-anatomic reduction.

FIGURE 25-25 Fixation of an unstable pelvic fracture with external fixation. One or two pins are placed in the iliac wing. The starting point is 1 to 2 cm posterior to the anterior-superior iliac spine. An anterior-to-posterior supra-acetabular pin may also be used.

unit. Before sterile prepping and draping that extends from just above the umbilicus and includes the anterior pelvis and both lower limbs, the ability to obtain AP, inlet, outlet, and oblique views of the pelvis is confirmed.

Approach and Technique. After preparing and draping the patient, manual reduction is attempted, sometimes aided by longitudinal traction applied through an ipsilateral supracondylar femoral traction pin. Once adequate reduction is confirmed by fluoroscopy, external fixation pins are placed through a limited incision at the site of placement. For pins placed into the iliac crest, small transverse stab incisions perpendicular to the crest are made on the ilium approximately 2 cm posterior to the anterior-superior iliac spines. The iliac apophysis is then split at the site of pin placement along the top of the iliac crest. For pins placed above the acetabulum, incisions are made 2 cm superior to the joint and just medial to an imaginary line that extends between the anterior-superior and anterior-inferior iliac spines. Careful muscle splitting is then performed until the periosteum of the anterior supra-acetabular pelvis is visualized.

For iliac screws, the iliac table may be located by carefully placing a spinal needle or Lenke pedicle probe between the inner and outer tables of the iliac crest. Fluoroscopy is utilized to confirm the location within the iliac crest. The appropriately sized drill is then used to make a tract for the screw. Use of minimal force allows the drill to more easily find its path through the cancellous bone between the dense cortical tables. Once the outer cortex is drilled, the half pin is placed into the ilium. For children, pins measuring 4 to 4.5 mm in diameter are selected and placed by hand with a T-handle driver; 5 mm diameter half-pins are used for adolescents and adults. After placement is confirmed by fluoroscopy, the process is repeated. One to three half-pins are placed in each crest based on the size of the child. Supra-acetabular pins can be placed in an open fashion through anterior incisions utilizing similar techniques.

The frame is then built by attaching a small rod to each pin cluster. These small rods are then attached to two longer rods that extend medially and obliquely across the midline of the abdomen. These rods are then clamped together anterior to the pelvis with enough space between the frame and the abdomen to allow for swelling and access for examination or potential surgery. The reduction of the pelvic ring is then assessed and the stability of the construct is confirmed by manual stressing under fluoroscopy.

Postoperative Care. After frame placement, patients may be out of bed to a chair if pelvic ring stability is acceptable and the associated injuries permit mobilization. Half-pin care is typically initiated within 4 to 7 days of surgery and continues until the frame is removed. Care regimens vary but daily cleaning is typically recommended. By 4 to 6 weeks after placement, limited weight bearing is started. Weight bearing in the frame may be possible for some patients but typically for children is not fully instituted until removal of the frame, which is typically done in the operating room 6 to 10 weeks after application.

Symphyseal Plating. Symphyseal plating is a good alternative to anterior ring fixation in some children and adolescents[23] This fixation choice is less bulky then external fixation and can often be performed at the time of other procedures for associated urogenital or abdominal injuries The approach and technique are identical to that utilized for adult symphyseal plating, except that the plate size must be selected appropriately based on the size of the child. The best choice is a rigid plate–screw construct, such a 3.5-mm reconstruction plate, but small and less bulky choices may be indicated for smaller patients.

Sacroiliac Screw Fixation. Posterior ring injuries in children are typically sacroiliac joint disruptions, either from a true joint disruption or from fractures of the ilium that extend into the SI joint, or sacral fractures. Indications for surgical treatment of these injuries are unstable ring injuries with combined anterior and posterior instability and posterior ring fractures with displacement greater than about 1 cm, although, as noted above, the amount of acceptable displacement is controversial. Closed reduction and percutaneous stabilization is an important strategy for pelvic fracture management in children and is the first option when addressing displaced fractures. Open reduction and plate fixation of posterior ring injuries is indicated when closed reduction and screw fixation techniques cannot achieve adequate realignment or stable fixation.

Sacroiliac Reduction and Screw Fixation

Preoperative Planning. Before considering this technique, the CT scan of the pelvis must be carefully scrutinized to determine if the fracture pattern is amenable to closed reduction. Specifically, it is important to determine if comminution or severe displacement may prevent reduction or risk soft tissue or neurovascular entrapment or injury. The CT scan is also necessary to assess the sacral anatomy of the individual patient, which may vary widely, to determine the ideal entry position and safe trajectory. In the pediatric patient, the narrow corridor for safe screw placement makes the procedure difficult.[87] When a concomitant anterior pelvic injury is present, it may be necessary to stabilize it prior to fixation of the posterior injury.

Positioning. Sacroiliac screw fixation may be performed with the patient supine or prone, determined by the coexisting injuries of the patient. More commonly, the patient is positioned supine on the operating table in such a manner as to permit multiple fluoroscopic views of the pelvis and sacrum including AP, inlet, outlet, and lateral views of the pelvis and sacrum. The patient is prepped and sterilely draped about the entire pelvis extending from the umbilicus to the knee or foot of the limb where displacement is most pronounced. A distal femoral traction pin placed in this limb may be useful to obtain longitudinal traction and influence reduction.

Technique. After prepping and draping, the SI joint separation or sacral fracture is manually reduced by applying the appropriate forces—typically compression and longitudinal traction. The reduction is confirmed with AP, inlet, and outlet views. The size of the cannulated screw size should be predetermined based on the CT scan and is typically 7.3 mm for adolescents. In younger children, smaller sizes, such as 6.5 mm and 4.5 mm diameters, can be used. The next step is identifying the starting point for screw entry. Utilizing inlet and outlet pelvic views, the location of the S1 neural foramen is determined and marked to provisionally establish the guide pin entry point. The lateral view is then utilized to identify the optimal location of the starting point in the dorsal/ventral plane. To ensure that a true lateral is obtained, the greater sciatic notches should overlap completely on the image. Based on clinical landmarks, the entry point laterally is typically at the intersection of the long axis of the femur and a vertical line drawn posteriorly from the ASIS.

Returning to the AP outlet view, the guide pin is then inserted just lateral to the S1 neural foramen and directed toward the safe zone, the area between the alar cortex superoanteriorly and the sacral neural foramen posteriorly. Multiple fluoroscopic views, including the inlet, outlet, and lateral views, are used to confirm guide pin placement. Once the ideal pin

E

FIGURE 25-26 (*continued*) **E:** Outlet view showing screw placement in the body of S1.

placement is achieved, it is advanced just to the midline of the sacrum and the position is reconfirmed with the image intensifier. The guide pin is measured for length and the appropriate cannulated screw is selected. A small incision is then made around the guidewire to allow passage of the cannulated drill, a bone washer if preferred, and the screw without damage to the skin. The screw tract is predrilled and the screw is placed. After fixation, the quality and stability of reduction are assessed (Fig. 25-26). If continued rotational instability is determined, a second may be added.

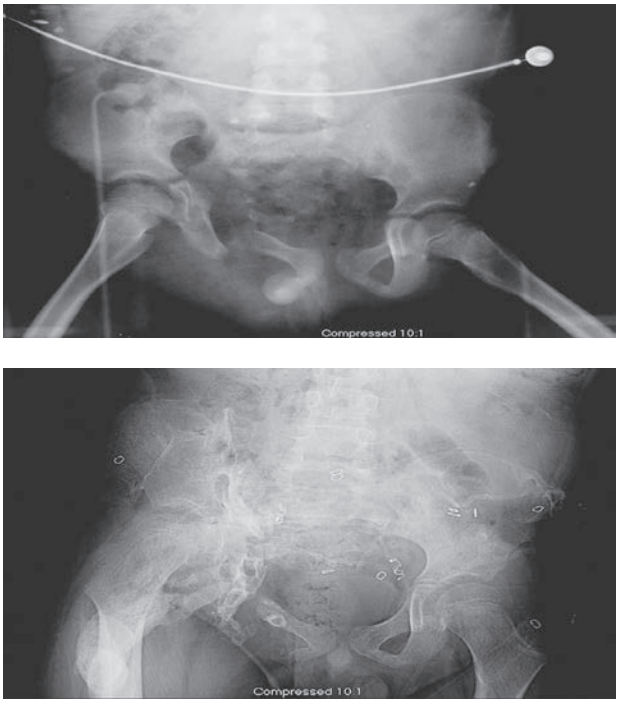
Postoperative Care. If the pelvic ring is stable after fixation, cast immobilization is not necessary. A spica cast may be necessary for younger children or those with inadequate fixation and ring stability. The patient may be out of bed to a chair after surgery. Weight bearing is restricted for a minimum of 6 weeks before gradual progression. Sacroiliac screws are not typically removed in adults. Although the consequences of SI joint fixation in younger children are not fully understood, it is our preference to remove screws after healing in this younger age group.

Open Reduction and Plate Fixation

Like adults, open reduction and plating of SI joint disruptions and fractures of the posterior ring are also sometimes indicated, most commonly when adequate reduction cannot be achieved with closed manipulative techniques, such as with large vertical displacement of the hemipelvis. This technique can be done either through an anterior retroperitoneal approach or via a posterior approach. The choice of implants is based on the size of the patient and the fracture type. Safe and effective plate fixation of unstable pelvic injuries has been reported in toddlers utilizing 3.5-mm plating systems and adult techniques.[86]

Severe Crush Injuries and Open Fractures

Crush injuries of the pelvis and open fractures are relatively rare. In patients with crushing injuries, distortion of the pelvic ring is severe, resulting in multiple breaks in both the anterior and posterior pelvis as well as the acetabulum and triradiate



A

B

FIGURE 25-27 **A:** Open pelvic fracture with severe displacement. **B:** The soft tissue injury precluded pelvic reduction and fixation. This radiograph shows remarkable late deformity.

cartilage. These uncommon injuries are nearly always associated with serious concomitant injuries, particularly thoracoabdominal and genitourinary abnormalities (Fig. 25-27). Neurologic injuries of the lumbosacral plexus and vascular injuries are also common associated findings. Risk of massive hemorrhage is highest for patients who sustain these types of fractures and, in one series, about 20% of children with crushed open pelvic fractures died within hours of admission secondary to uncontrolled hemorrhage.[54] Open fractures are more common than crush injuries, representing 13% of patients[54] with pelvic fractures, the result of motor vehicle trauma and gunshot wounds.

The principles of emergency management are similar to those applied for other unstable pelvic fractures. Surgical stabilization of the pelvic ring may be extremely challenging in the face of multiple fractures sites, comminution, and soft tissue trauma. Lacerations of the vagina and rectum, bladder injuries, and urethral disruptions complicate management and increase the risk of infection. External fixation alone may not be sufficient to manage these complex injuries, making it frequently necessary to perform internal fixation or a combination of these techniques. Stable pelvic fixation, multiple debridements, soft tissue management, and careful surveillance for infection are recommended to improve the chances of successful outcomes.[54]

Treatment Options for Acetabular Fractures

Acetabular fractures constitute only 6% to 17% of pediatric pelvic fractures, making them very uncommon.[25,54,81] However, these injuries carry the potential for significant long-term morbidity.

The goals of treatment for acetabular fractures in children are twofold. The first is to restore a congruent and stable joint with an anatomically reduced articular surface. The second is to preserve alignment of the triradiate cartilage in hopes of ensuring normal growth. Schlickewei et al.[72] noted that there are a variety of injury patterns and limited evidence of outcomes for any specific treatment. Thus, each fracture should be evaluated on an individual basis with the following guidelines: (i) Anatomic reduction will likely result in a good long-term outcome; (ii) MRI is the best tool for identifying closure of the triradiate cartilage; and (iii) patients should be informed about the possibility of growth arrest and secondary associated problems such as joint subluxation or dysplasia.[72]

Nonoperative Treatment of Acetabular Fractures

In general, conservative treatment is indicated for simple, nondisplaced fracture patterns. Short-term bed rest followed by non–weight-bearing ambulation with crutches can be used for nondisplaced or minimally (≤2 mm) displaced fractures, particularly those that do not involve the superior acetabular dome. Because weight-bearing forces must not be transmitted across the fracture, crutch ambulation is appropriate only for older children who can reliably avoid weight bearing on the injured limb. Nonweight bearing usually is continued for 6 to 8 weeks. Radiographs should be obtained frequently in the first few weeks to confirm fracture alignment. For those younger children who cannot comply with nonweight bearing ambulation, spica cast immobilization is preferred.

Skeletal traction is an option for those rare acetabular fractures that can be reduced to ≤2 mm of displacement or those with medical contraindications to surgical treatment. To avoid injury to the physis, the traction pin is usually inserted in the distal femur under anesthesia using fluoroscopic guidance. Follow-up radiographs should confirm fracture reduction and joint congruency, and traction is generally maintained for 4 to 6 weeks until fracture healing is sufficient to allow progressive weight bearing.

There are few studies reporting the outcome of nonoperative treatment of acetabular fractures in children. Heeg et al.,[32] reported on 23 patients with a variety of fracture patterns, with 18 being treated conservatively. The authors reported excellent functional and radiographic results of nonoperative treatment in those who were able to maintain congruent joints.

Operative Treatment of Acetabular Fractures

Indications/Contraindications

The primary indications for operative treatment of pediatric acetabular fractures are either (1) an unstable joint or (2) an incongruent joint, regardless of fracture pattern. Instability usually results from posterior or anterior wall fractures, and when present must be remedied by operative reduction and fixation. Lack of congruency may result from bony fragments and/or soft tissue within the joint or from fracture displacement in the weight-bearing dome. In the former situation, open reduction is necessary to remove the offending agents and avoid premature osteoarthritis and in the latter case, anatomic restoration of the articular surface with stable internal fixation is the operative goal. Gordon et al.,[23] recommended accurate reduction and internal fixation of any displaced acetabular fracture in a child. They noted that the presence of incomplete fractures and plastic deformation may make accurate reduction difficult or impossible; they recommended that incomplete fractures be completed and that osteotomies of the pubis, ilium, or ischium be made if necessary to achieve accurate reduction of the acetabulum.[23] Improved outcomes with early (<24 hours) fixation of acetabular fractures in adults have been reported,[62] and Gordon et al.[23] noted that early fixation (before callus formation) is especially important to prevent malunion in young patients in whom healing is rapid (Fig. 25-28).

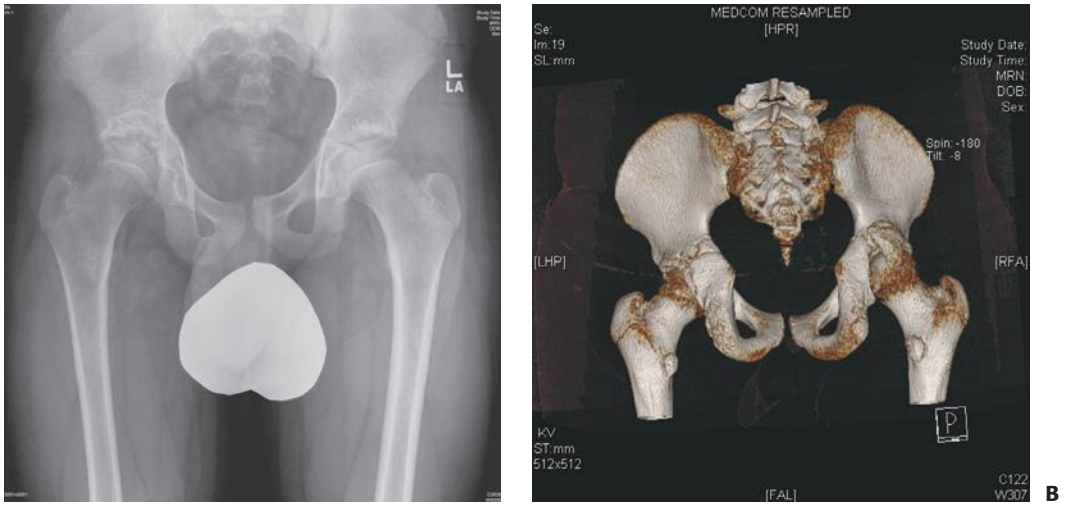


FIGURE 25-28 **A:** Pelvic radiograph of a 12-year old 1 year after an acetabular fracture. The fracture is a malunion with subluxation of the hip joint. **B:** Three-dimensional CT scan showing the malunited fragment.

Another important indication for surgical treatment is malalignment of the triradiate cartilage, which can result in growth arrest and progressive acetabular dysplasia (Fig. 25-29). Linear growth of the acetabulum occurs by interstitial growth in the triradiate part of the cartilage complex, causing the pubis, ischium, and ilium to enlarge. The depth of the acetabulum develops in response to the presence of a spherical femoral head and interstitial growth of the acetabular cartilage.[64,75] Growth derangement of all or part of the triradiate cartilage as a result of poor fracture reduction may result in a dysplastic acetabulum. Since the ilioischial limb of the triradiate contributes the most to acetabular growth, injury to the ilioischial limb of the triradiate cartilage has a greater potential for late acetabular deformity than an anterior iliopubic limb injury.[21]

Preoperative planning checklist would include:

- C-arm
- Fluoroscopic table such as a Jackson table
- Screw set including long 3.5 to 4.5 mm and various sized cannulated screws
- Threaded Kirschner wires
- Plate set including small fragment plates, pelvic reconstruction plates, and smaller "hook" plates
- Pelvic retractors, clamps, and reduction instruments
- Femoral distractor

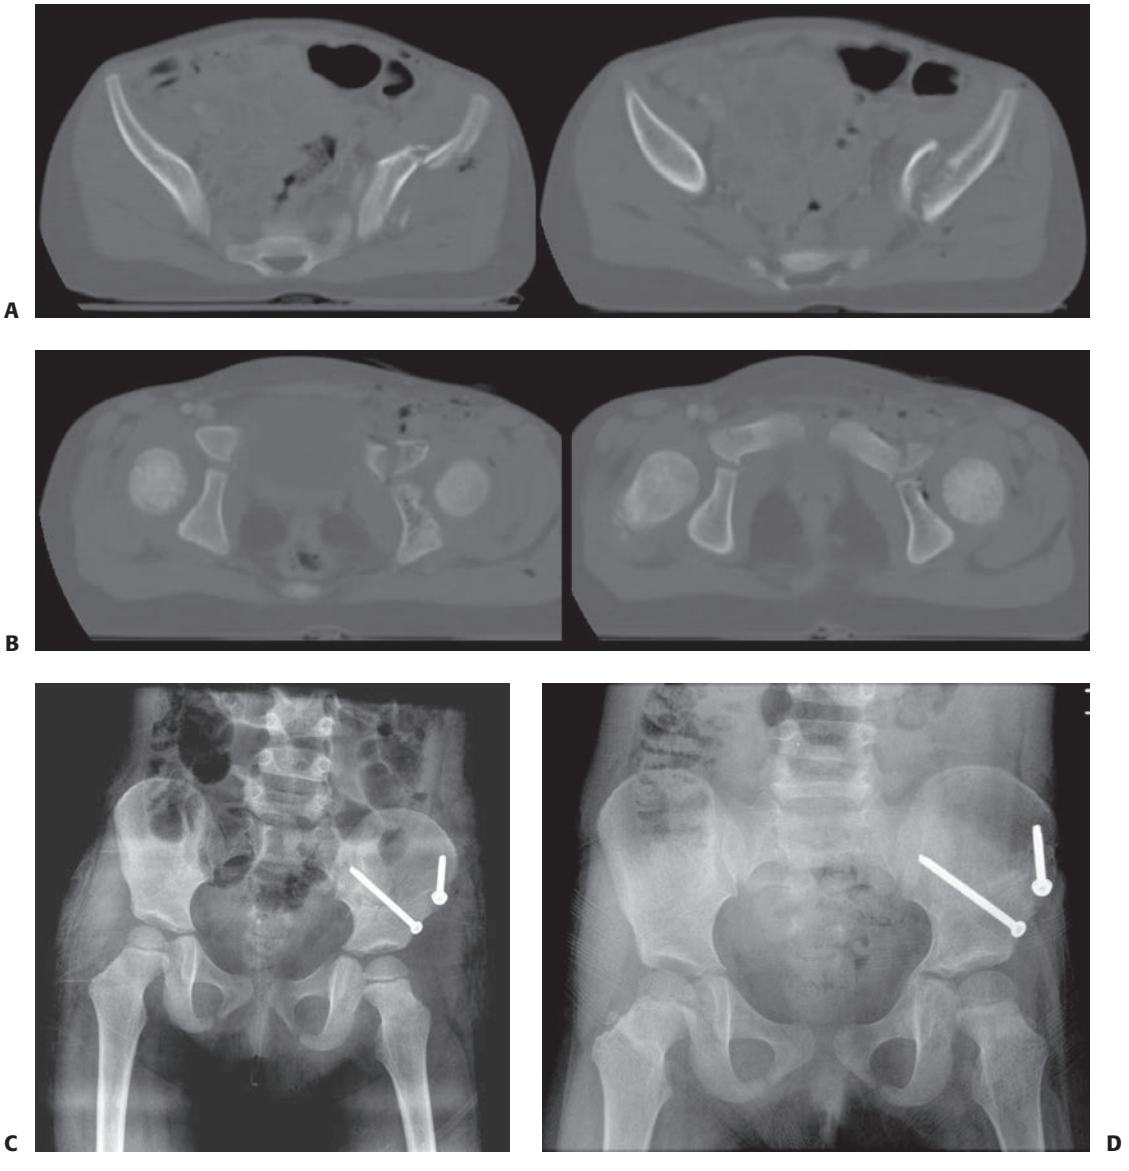

FIGURE 25-29 **A:** CT scan of a 7-year old with a displaced pelvic wing fracture **B:** CT scan showing the fracture propagation into the triradiate cartilage. **C:** Anatomic reduction of the triradiate cartilage with open reduction and internal fixation. **D:** Despite anatomic reduction, medial osseous bar spans the triradiate cartilage at follow-up.

TABLE 25-5 Surgical Exposure for Operative Fixation of Acetabular Fractures

Fracture Type	Exposure
Anterior column or wall	Ilioinguinal
Posterior column or wall	Kocher–Langenbeck
Transverse	Ilioinguinal (or extended lateral)
T-shaped	Ilioinguinal and Kocher–Langenbeck (or extended lateral)
Anterior column and posterior hemitransverse	Ilioinguinal
Both columns	Ilioinguinal (or extended lateral)

From Gordon RG, Karpik K, Hardy S. Techniques of operative reduction and fixation of pediatric and adolescent pelvic fractures. *Oper Tech Orthop.* 1995;5:95–114, with permission.

Positioning and surgical approach

The positioning and approach for ORIF of pediatric acetabular fractures varies according to the pattern of the fracture and the direction of the displacement as determined on the preoperative radiographs and CT scans (Table 25-5).[23] Fractures of the posterior wall and/or posterior column can be approached through a Kocher–Langenbeck approach with the patient either in the lateral decubitus or prone position (Fig. 25-30). Anterior column injuries can be approached through an ilioinguinal approach with the patient placed supine. Some transverse fractures may require an extended iliofemoral approach.[1] The extended lateral approaches, which include the extended iliofemoral and triradiate approaches, should be avoided as much as possible because of the risk of devascularization of the ilium and heterotopic bone formation.[28]

Technique

The operative treatment of pediatric/adolescent acetabular fractures is technically demanding and is best performed by experienced surgeons. Given the rarity of these injuries in children, it may be helpful to consult and/or collaborate with an adult orthopedic traumatologist.[58] The operative surgeon should be familiar with the treatise by Judet et al.[37] on the operative reduction of acetabular fractures and with Letournel and Judet's[44] work before performing this surgery. For smaller children and smaller fragments, Watts[98] recommended threaded Kirschner wires for fixation. In larger children, cannulated screws can provide secure fixation (Figs. 25-31 and 25-32).

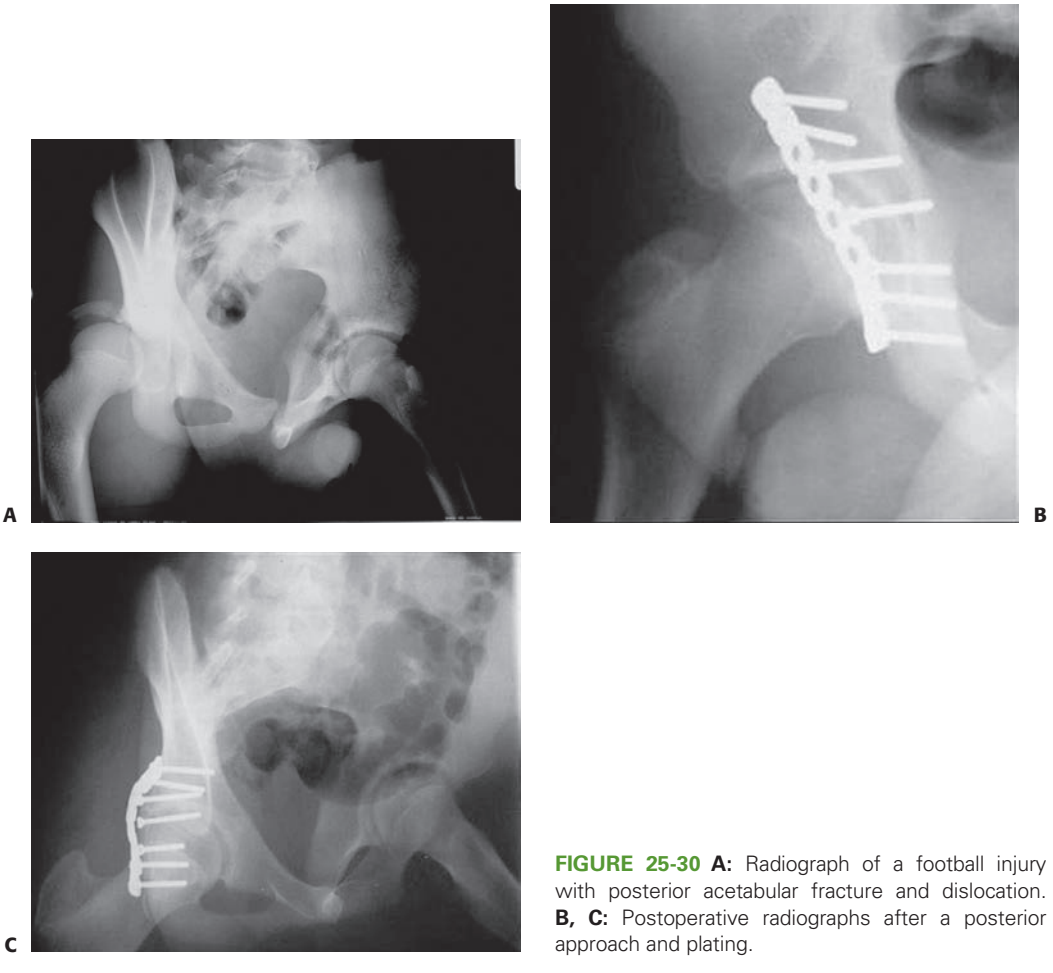

FIGURE 25-30 A: Radiograph of a football injury with posterior acetabular fracture and dislocation. **B, C:** Postoperative radiographs after a posterior approach and plating.

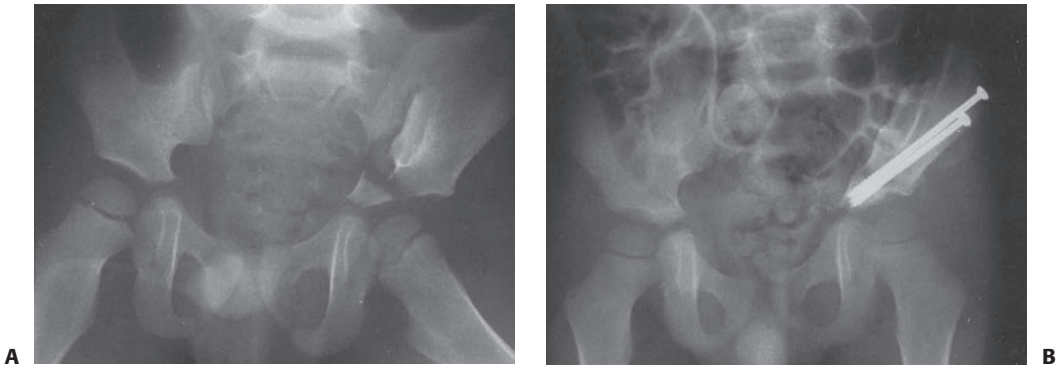

FIGURE 25-31 **A:** Fracture of the wing of the ilium with extension into the dome of the acetabulum in a 3-year-old boy. **B:** After reduction and fixation with two cannulated screws. (From Habacker TA, Heinrich SD, Dehne R. Fracture of the superior pelvic quadrant in a child. *J Pediatr Orthop.* 1995;15(1):69–72, with permission.)

Small-fragment reconstruction plates, appropriately contoured, also can be used. Gordon et al.[23] described the addition of a small (two- or three-hole) "hook plate" for small or comminuted fragments (Fig. 25-33).

Brown et al.[5] described the use of CT image-guided fixation of acetabular fractures in 10 patients, including bilateral posterior wall fractures in a 14-year-old girl. They cite as advantages of image-guided surgery reduced operating time (~20% reduction), less extensive surgical dissection, reduced fluoroscopic time, and compatibility with traditional fixation techniques. Most important, it allows accurate and safe placement of screws and pins for acetabular fixation. This technology is attractive, but anatomic reduction of the joint surface and secure fixation outweigh the benefits of surgical convenience.

Postoperative Care

Small children can be immobilized in a spica cast for 6 weeks after surgery. If radiographs show adequate healing at that time, the cast is removed and free mobility is allowed. In an older child with stable fixation, crutches are used for protected

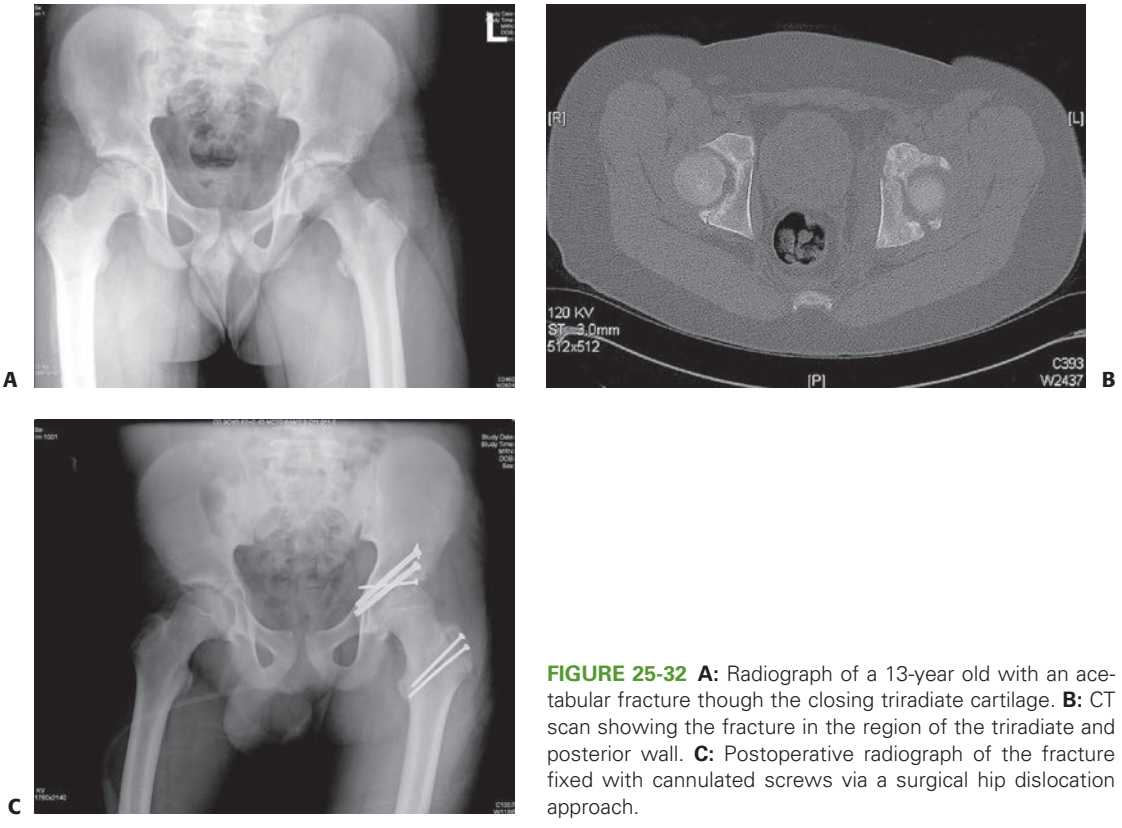

FIGURE 25-32 **A:** Radiograph of a 13-year old with an acetabular fracture though the closing triradiate cartilage. **B:** CT scan showing the fracture in the region of the triradiate and posterior wall. **C:** Postoperative radiograph of the fracture fixed with cannulated screws via a surgical hip dislocation approach.

FIGURE 25-33 **A:** Anterior column plate and additional wall "hook" plate. **B:** Posterior wall buttress plate and hook plate. (From Gordon RG, Karpik K, Hardy S. Techniques of operative reduction and fixation of pediatric and adolescent pelvic fractures. *Oper Tech Orthop.* 1995;5:95–114, with permission.)

weight bearing for 6 to 8 weeks. If radiographs show satisfactory healing, weight bearing is progressed as tolerated. Return to vigorous activities, especially competitive sports is delayed for at least 3 months. For most children, metallic implants should be removed 6 to 18 months after surgery, assuming adequate healing, to facilitate future imaging and operative procedures about the hip.

Pelvic radiographs should be obtained for 2 years after an acetabular fracture looking for a triradiate closure. If the radiographs indicate a physeal bar, CT and MRI can be obtained to confirm the diagnosis.

Potential Pitfalls and Preventive Measures

The potential complications following treatment of an acetabular fracture include avascular necrosis, posttraumatic arthritis, premature closure of the triradiate cartilage, infection, iatrogenic nerve injury, heterotopic ossification, fracture malunion, intra-articular penetration of implants, and venous thromboembolism. Although some of these outcomes may be unavoidable as a result of the initial injury, many can be prevented or at least mitigated by accurate decision making, detailed surgical technique, and appropriate perioperative care (Table 25-6).

TABLE 25-6 Pitfalls of Acetabular Fracture Surgery and Suggestions for Prevention

Pitfalls or Complications	Strategies for Prevention or Treatment
Avascular necrosis of the femoral head	Urgent treatment of fracture-dislocations of the hip
Posttraumatic arthrosis	Anatomic or near-anatomic (≤2 mm) reduction of the articular surface
Iatrogenic sciatic nerve injury (posterior approach)	Consider intraoperative nerve monitoring; careful patient positioning; maintain knee flexion during posterior approach
Iatrogenic LFCN injury (anterior approach)	Careful retraction of LFCN; inform patient about potential for postoperative symptoms
Heterotopic ossification	Minimize stripping of gluteal muscles from outer table of ilium; careful choice of surgical approach; consider prophylaxis with indomethacin
Fracture malunion	Timely and accurate reduction and fixation of fractures
Intra-articular placement of implants	Use of intraoperative fluoroscopy supplemented by intraoperative portable radiographs when necessary. Consider postoperative CT scan to confirm appropriate implant position.
Venous thromboembolism	Early mobilization; mechanical prophylaxis (e.g., compression boots, foot pumps); consider chemoprophylaxis

LFCN, lateral femoral cutaneous nerve.

Author's Preferred Treatment of Pelvic and Acetabular Fractures

We almost always manage low energy pelvic avulsion fractures (Torode and Zieg Type I) conservatively with rest and partial weight bearing on crutches for 2 or more weeks, followed by gradual resumption of normal activities after about 6 weeks. For those rare fractures with significant displacement (>2 cm) or persistent disability, fragment fixation, or excision may be warranted.

For higher-energy pelvic and acetabular fractures, a multispecialty approach is essential, especially at the time of initial presentation. The team should be aware of the large incidence of concomitant injuries to the head, thorax, and abdomen. The urogenital system should be carefully evaluated specifically looking for open fractures. If there is hemodynamic instability, the trauma surgeon, orthopedic surgeon, radiologist, and blood bank should work together to stabilize the patient. The orthopedic surgeon can provide temporary relief with pelvic wrapping, external fixation, or wound packing depending on the treatment of other injuries. If needed, operative fixation can be done in the same session as surgery for associated injuries or it can be timed later when the patient is stabilized.

Definitive treatment is usually conservative for isolated iliac wing fractures (Torode and Zieg Type II), and simple pubis and ischium fractures (Torode and Zieg Type III), and consists of symptomatic treatment and protected weight bearing. For toddlers and younger school-age children, this treatment may include a spica cast for immobilization and comfort. For more involved pelvic and acetabular fractures, treatment is more likely to be conservative in children with an immature pelvis and operative in children with an unstable fracture pattern and a mature pelvis or closed triradiate cartilage.[81] In the younger, immature child with severe displacement, femoral traction on the displaced side of the hemipelvis may be indicated if operative reduction with implants is not technically feasible. There is mounting evidence, however, that unstable pelvic fractures and displaced acetabular fractures in children should be operatively reduced and stabilized using the same principles as in adults. Given the technically demanding nature of these operations, it is important that the surgeon has experience with these procedures and, if necessary, we recommend consultation and collaboration with an adult orthopedic traumatologist.

Torode and Zieg class IV injuries with displacement and/or pelvic ring fractures with displacement of more than 1 cm and anterior and posterior ring fractures should undergo reduction and fixation. Open reduction of the sacroiliac joint or a posterior iliac injury can be performed with a combination of plate and/or screws. The approach can be anterior in the iliac fossa or posterior depending on the fracture characteristics. Sacroiliac screws can be used in the immature pelvis, but the anatomy and size of S1 must be conducive for screw placement. Imaging, including the use of fluoroscopy for placement of the screws, is necessary. With a widened symphysis, anterior external fixation or plating is recommended along with posterior stabilization. Similarly, we advocate open reduction and internal fixation for any pediatric acetabular fracture that is associated with hip instability, incongruity of the joint, or significant displacement of the triradiate cartilage. The surgical approach and technique for fixation is dictated by the fracture pattern.

Complications and Adverse Outcomes Related to Pelvic and Acetabular Fractures

The major adverse outcomes following treatment of pediatric pelvic and acetabular fractures are malunion of the pelvic ring leading to long-term morbidity and premature triradiate closure after acetabular fracture. Because of the rapid healing in young children, loss of reduction and nonunion usually are not problems. Malunion of the pelvis can lead to leg-length discrepancy, sacroiliac joint arthrosis, back pain, lumbar scoliosis, incompetency of the pelvic floor, and distortion of the birth canal. Because of the possibility of dystocia during childbirth, pelvimetry is recommended before pregnancy. Rieger and Brug[69] reported one female patient who Required Caesarean section because of ossification of the symphysis pubis after nonoperative treatment of an open-book fracture. Schwarz et al.[74] reported leg-length discrepancies of 1 to 5 cm in 10 of 17 patients after nonoperative treatment of unstable pelvic fractures; 5 had low back pain at long-term follow-up. McDonald[50] reported that one-third of 15 skeletally immature patients treated nonoperatively with unstable pelvic fractures had residual pain. Heeg and Klassen[31] reviewed 18 children with unstable pelvic fractures and reported that 9 had a leg-length discrepancy greater than 1 cm and 3 had back pain. For those patients with growth remaining, an appropriately timed epiphysiodesis may be used to manage any residual leg length discrepancy. Of course the best way to avoid the negative effects of pelvic malunion is to achieve and maintain an adequate initial reduction.

Acetabular dysplasia secondary to growth arrest of the triradiate cartilage is a concerning complication after trauma to the acetabulum. Premature closure of the triradiate cartilage has an overall incidence of less than 5% (range 0% to 11%) after pediatric acetabular fractures.[32,45,75,95] Heeg[33] reported acetabular deformity and subluxation of the hip in two of three patients with premature fusion of the triradiate cartilage. Peterson and Robertson[61] reported formation of a physeal osseous bar in a 7-year-old boy 2 years after fracture of the lateral portion of the superior ramus at the junction with the triradiate cartilage. After excision of the osseous bridge, the physis remained open. Although the injured physis closed earlier than the contralateral side, there was only a slight increase in the thickness of the acetabular wall and lateral displacement of the femoral head. The authors emphasized that early recognition and treatment are essential before premature closure of the entire physis and development of permanent osseous deformity (Fig. 25-34).[61]

Bucholz et al.[6] noted two main patterns of physeal injury in nine patients with triradiate cartilage injury: A Salter–Harris type I or II injury, which had a favorable prognosis for continued normal acetabular growth, and a crush injury (Salter–Harris V), which had a poor prognosis with premature closure of the triradiate cartilage caused by formation of a medial osseous bridge. In either pattern, the prognosis depended on the child's age at the time of injury. In young children, especially those younger than 10 years of age, acetabular growth

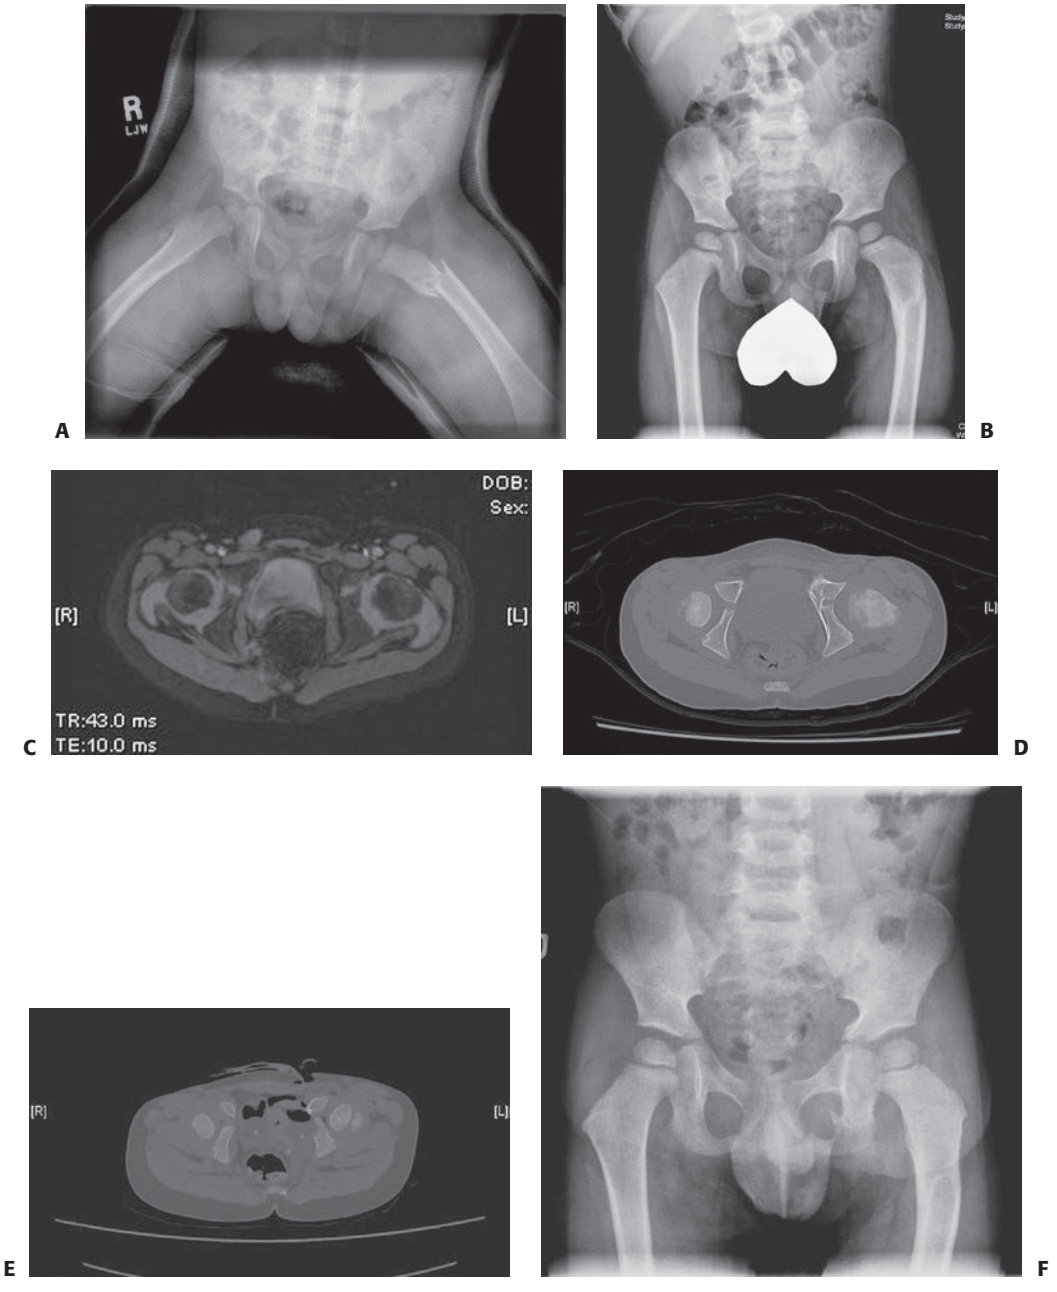

FIGURE 25-34 **A:** Radiograph of a 2-year old with a ramus fracture that involves the triradiate cartilage. **B:** Six months after the injury, there is indication of a physeal bar on the medial aspect of the triradiate cartilage. **C:** MRI confirming the presence of a physeal bar. **D:** CT scan confirming the physeal bar. **E:** CT scan confirming the physeal bar excision. This procedure was performed through an ilioinguinal approach and CT-guided excision. **F:** Radiograph of the pelvis after bar excision.

abnormality was common and resulted in a dysplastic acetabulum. By the time of skeletal maturity, disparate growth increased the incongruity of the hip joint and led to progressive subluxation. Triradiate injuries that occurred after the age of 10, however, generally did not result in significant changes to the acetabulum because of the diminished growth remaining in these patients. As a result, excision of a physeal bar is generally recommended for patients younger than 10 years of age.

The typical dysplastic changes seen after premature closure of the triradiate cartilage differ significantly from developmental dysplasia and include both lateralization of the hip joint and acetabular retroversion.[16,95] In severe cases, subluxation or dislocation can develop. Once present, this posttraumatic dysplasia often requires a complete redirectional acetabular osteotomy to improve femoral head coverage and correct the malorientation of the acetabulum.[6,95]

Summary, Controversies, and Future Directions Related to Pelvic and Acetabular Fractures

Pelvic fractures are less common in the pediatric population, with only a small percentage of patients requiring operative treatment. In children, the overall long-term prognosis is generally more favorable than in adults. Many children, however, have serious associated injuries including head trauma, and thoracoabdominal and genitourinary injuries that contribute to the morbidity for these patients. Massive hemorrhage and death are rarely caused by the pelvic fracture itself and more commonly result from the concomitant injuries associated with unstable fracture patterns, particularly those with vertical displacement of the hemipelvis and double breaks in the pelvic ring (modified Torode and Zeig types IIIb and IV). The goals of emergency treatment are to stabilize the hemodynamic status of the patient and to diagnose and treat serious, life-threatening associated injuries. Unstable pelvic fractures may initially require stabilization with a pelvic binder or external fixator. For most patients with displaced pelvic ring fractures, fracture realignment and stable fixation is utilized to reduce the risk of long-term complications such as leg-length discrepancy, back pain, and sacroiliac joint arthrosis.

The future of pelvic fracture management has to address several important topics. Although much progress has been made regarding the delivery of specialized pediatric trauma care, the development of techniques and the knowledge gained from research at these specialized centers must continually be updated and disseminated to all who provide emergency trauma care for children. This is particularly important with regard to management of unstable pediatric pelvic fractures. Because of their rarity, few surgeons gain a broad experience managing these injuries at children's hospitals where most of these injuries initially present. Collaboration with adult orthopedic traumatologists is, in our opinion, the solution to this problem. Together, principles of treatment and protocols for care can be refined including emergency management strategies, such as the use of embolization for massive bleeding, and the best indications for surgery that are specific for pediatric patients.

From the standpoint of surgical techniques, pelvic fracture management must continue to improve so that procedures that are routinely performed on adults may be safely applied to children. Advances in implant development and the increased availability of intraoperative navigation may improve the outcomes of pelvic fracture surgery for children of all ages with severe injuries. With advances in the care of the pediatric polytrauma patient and technical improvements for pelvic fracture management, the hope is that mortality will be greatly reduced and that the long-term complications may be eliminated or at least made more manageable for patients as they progress into adulthood.

26 FRACTURES AND TRAUMATIC DISLOCATIONS OF THE HIP IN CHILDREN

Ernest L. Sink and Young-Jo Kim

Introduction to Hip Fractures

Hip fractures are very common in adults, but are rare in children, comprising less than 1% of all pediatric fractures.[11,12,98] Pediatric hip fractures typically result from high-energy mechanisms that can result in other extremity, visceral, or head injuries in 30% of patients, unlike low-energy adult hip fractures common in elderly patients (whose fractures are typically associated with osteoporosis). Occasionally, pediatric hip fractures result from minor trauma superimposed upon bone that is weakened by

tumor or metabolic bone disease. These fractures can occur through the physis, but more commonly occur through the femoral neck and the intertrochanteric region.

The presence of the proximal femoral physis presents many important considerations when treating pediatric femoral neck fractures. Injury to the greater trochanter apophysis following an intertrochanteric fracture can lead to coxa valga.[18] Damage to the physis of the femoral neck from fracture, necrosis, or from implant use can result in limb length discrepancies or coxa breva or vara. The surgeon should generally place fixation across the physis in older children with poor bone quality, in adolescents who have little growth potential remaining or if fracture location dictates that adequate fixation must cross the physis. If fixation is not placed across the physis, it may be less stable and the surgeon has to be cognizant how to guide weight-bearing status and provide further immobilization such as a spica cast in younger children. The physis may also be a barrier to any potential interosseous blood supply for the femoral head. Because of this, and the fact that there is little blood supply to the femoral head from the ligamentum teres, an increased risk of necrosis is present following fracture and injury to the important retinacular vessels.

Although they are less common than other pediatric fractures pediatric hip fractures are important because of the high rate of complications and the potential lifetime morbidity that may result from complications. Potential complications from the fracture and its treatment include chondrolysis, osteonecrosis (ON), varus malunion, nonunion, delayed physiolysis, and growth abnormalities leading to length discrepancy or angular deformities.[18] Because the hip is developing in the growing child, deformities can progress and change with age. In addition, review of more recent publications is important because it has been suggested that outcome can be significantly improved if certain treatment principles are consistently followed.[11,38,111]

Assessment of Hip Fractures

Mechanisms of Injury for Hip Fractures

Hip fractures in children can be caused by axial loading, torsion, hyperabduction, or a direct blow to the hip. Almost all hip fractures in children are caused by severe, high-energy trauma.[6,37,105] Except for the physis, the proximal femur in children is extremely strong, and high-energy forces, such as from motor vehicle accidents and high falls, are necessary to cause fracture.[28] If a child suffers a fracture as a result of insignificant trauma, then one should suspect an underlying etiology such as prior injury or surgery,[21] metabolic bone disease, or pathologic lesion of the proximal femur (Fig. 26-1).

Associated Injuries with Hip Fractures

Because these fractures are caused by high-energy trauma, they frequently are accompanied by associated injuries that can affect the patient's overall outcome. Pape et al.,[85] in a series of 28 patients with a mean follow-up of 11 years, found favorable outcomes in type II, III, and IV fractures according to Ratliff's criteria.[98] Poor functional outcomes were attributed to head trauma, amputation, or peripheral neurologic damage.[85]

FIGURE 26-1 A 10-year-old boy with a fracture through a unicameral bone cyst sustained while running for a soccer ball.

In a series of 14 patients with hip fractures, all of which were caused by vehicular accidents or falls from heights, 12 patients had associated injuries including head and facial injury, other fractures, as well as visceral injury.[78] In a series of fractures from high-energy trauma, Bagatur and Zorer[5] similarly found associated injuries in 4 of their 17 patients. Infants with hip fractures and without a plausible cause for fracture should be evaluated for nonaccidental trauma by a careful history and an examination of the skin, other extremities, trunk, and head. Further skeletal radiographic imaging is often indicated, and an evaluation by a child protective team is required to diagnose life-threatening head and visceral injuries that can be easily missed in this group.

Signs and Symptoms of Hip Fractures

The diagnosis of hip fracture in a child is based on the history of high-energy trauma and the typical signs and symptoms of the shortened, externally rotated, and painful lower extremity. Clinical examination is usually obvious, and a patient with a complete fracture is unable to ambulate because of severe pain in the hip and has a shortened, externally rotated extremity. With an incomplete or stress fracture of the femoral neck, the patient may be able to bear weight with a limp and may demonstrate hip or knee pain only with extremes of range of motion, especially internal rotation. An infant with a hip fracture holds the extremity flexed, abducted, and externally rotated. Infants and newborns with limited ossification of the proximal femur

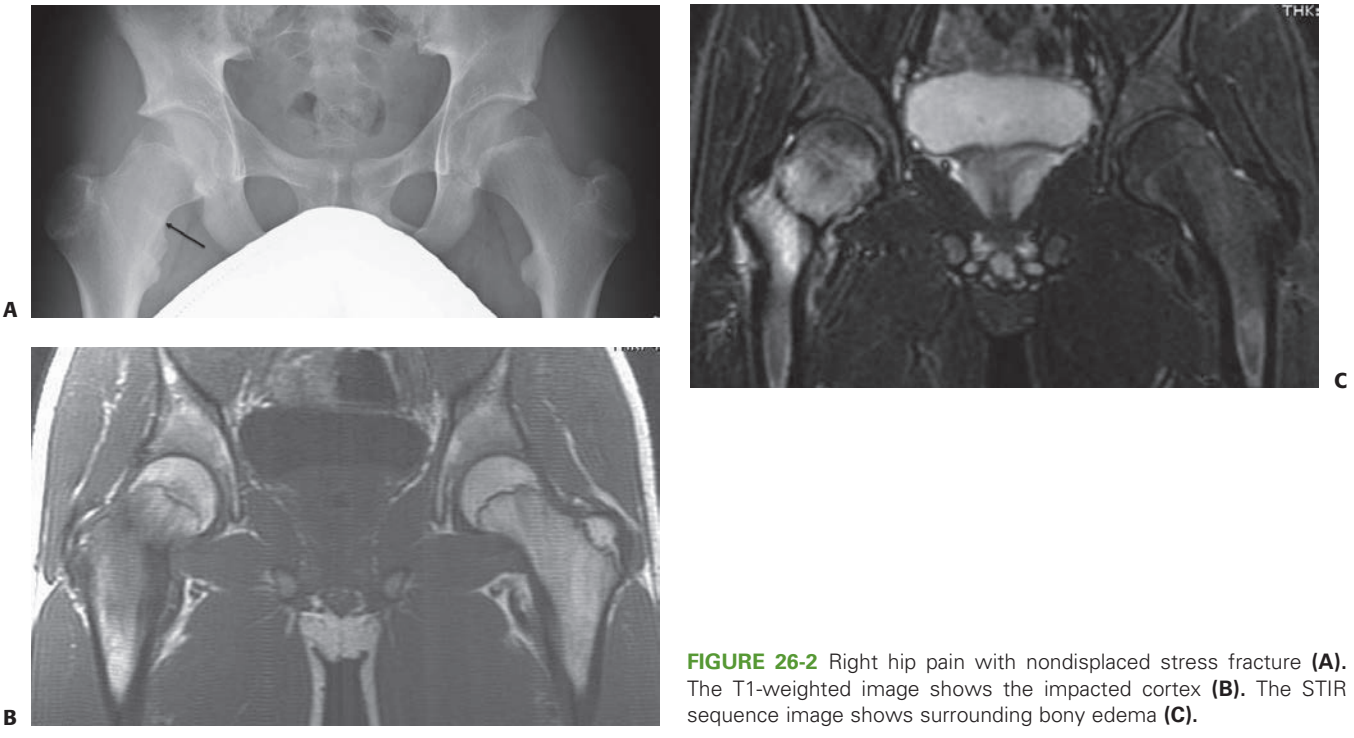

FIGURE 26-2 Right hip pain with nondisplaced stress fracture **(A).** The T1-weighted image shows the impacted cortex **(B).** The STIR sequence image shows surrounding bony edema **(C).**

can be challenging patients to diagnose with hip fractures as the differential diagnosis can include infection and congenital dislocation of the hip. In the absence of infection symptoms, pseudoparalysis, shortening, and a strong suspicion are the keys to a fracture diagnosis in this age group.

Imaging and Other Diagnostic Studies for Hip Fractures

A good-quality anteroposterior (AP) pelvic radiograph will provide a comparison view of the opposite hip if a displaced fracture is suspected. For the pelvic radiograph, the leg should be held in extension and in as much internal rotation as possible without causing extreme pain to the patient. A cross-table lateral radiograph should be considered to avoid further displacement and unnecessary discomfort to the patient from an attempt at a frog-leg lateral view. Any break or offset of the bony trabeculae near Ward triangle is an evidence of a nondisplaced or impacted fracture. Nondisplaced fracture or stress fractures may be difficult to detect on radiographs. Special studies may be required to reveal an occult fracture as case examples of further displacement of nondisplaced fracture have been reported.[40] Adjunctive studies for stress fracture diagnosis may include a magnetic resonance imaging (MRI), computed tomography (CT) scan, or a technetium bone scan which can demonstrate increased uptake at the fracture site. The typical MRI appearance of a fracture is a linear black line (low signal) on all sequences surrounded by a high-signal band of bone marrow edema and hemorrhage. The low signal represents trabeculae impaction (Fig. 26-2). MRI may detect an occult hip fracture within the first 24 hours after injury.[59] In addition, pathologic fractures may require special imaging to aid diagnosis or to fully appreciate bone quality which would impact implant placement. MRI is also a useful test in planning treatment for a pathologic fracture; this test will delineate soft tissues in and around the fracture, which can provide insight into diagnosis and delineate high-yield areas for biopsy.

In infants, an ultrasound can be used to detect epiphyseal separation. In addition, an ultrasound can determine if the patient's epiphysis is located and the presence of an effusion which may be aspirated to confirm diagnosis of sepsis. A bloody aspirate establishes the diagnosis of fracture, whereas a serous or purulent aspirate suggests synovitis or infection, respectively. If performed in the operating room, an aspiration and confirmatory arthrogram of the hip can also be useful, especially if closed reductions and cast immobilization is chosen for the newborn with physiolysis.

In a patient with posttraumatic hip pain without evidence of a fracture, other diagnoses must be considered, including Perthes disease, synovitis, spontaneous hemarthrosis, and infection. A complete blood count, erythrocyte sedimentation rate, C-reactive protein, and temperature are helpful to evaluate for infection. MRI scan is a useful test to diagnose aseptic ON as a result of Perthes disease or more remote causes of necrosis. In children under 5 years of age, developmental coxa vara can be confused with an old hip fracture.[18]

Classification of Hip Fractures

Pediatric hip fractures generally are classified by the method of Delbet (Fig. 26-3).[26] This classification system continues to be useful because it is not only descriptive but also has prognostic significance.[74] In general, more significant rates of ON and growth arrest are noted in fractures in the proximal end of the femoral neck (type I and type II injuries); whereas lower rates of ON are noted in type III and type IV

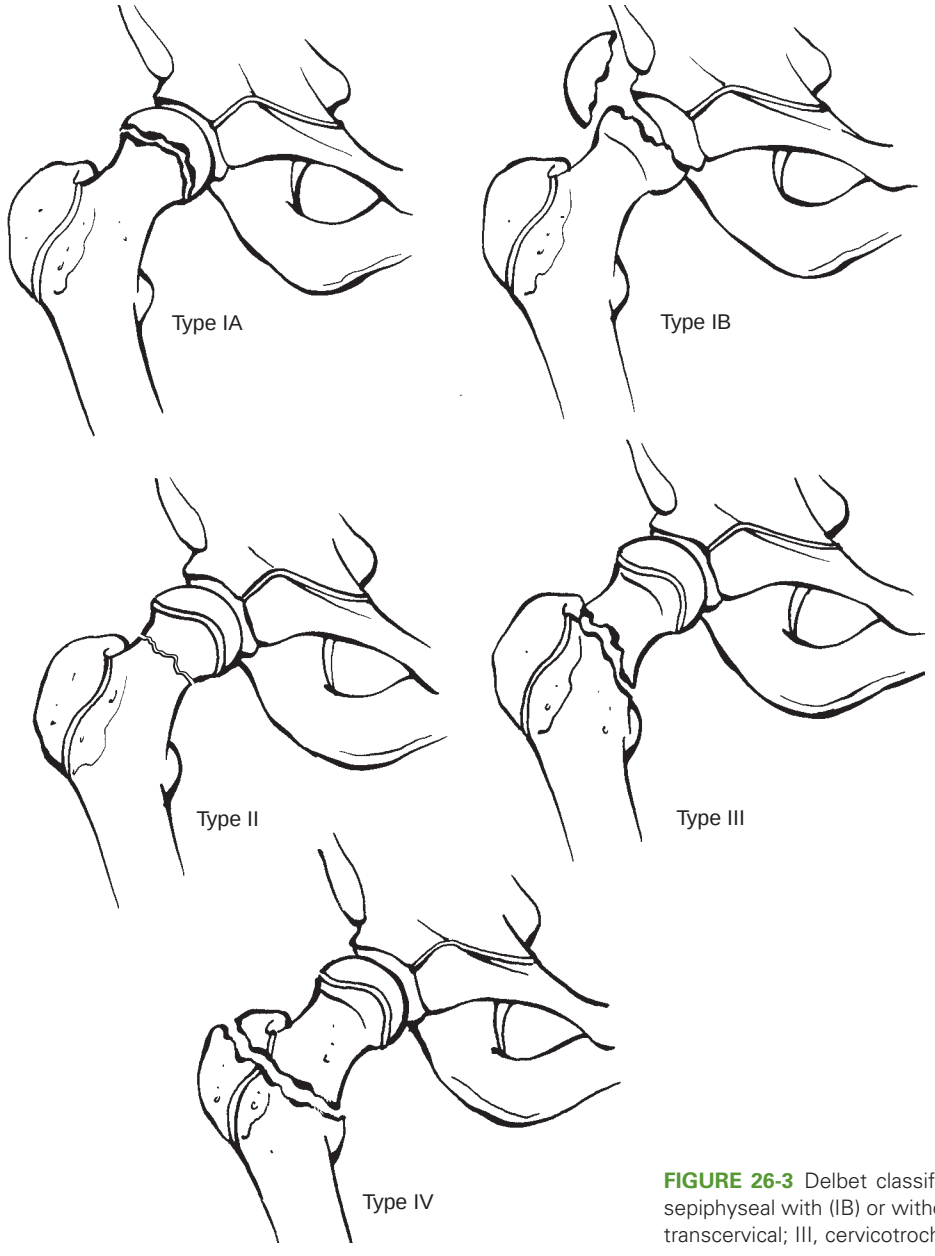

FIGURE 26-3 Delbet classification of hip fractures in children. I, transepiphyseal with (IB) or without (IA) dislocation from the acetabulum; II, transcervical; III, cervicotrochanteric; and IV, intertrochanteric.

injuries. Conversely, the latter two groups tend to have higher rates of significant varus malunion if not treated appropriately. Subtrochanteric fractures have been included by some in the discussion of proximal femoral fractures but they are not included in the Delbet classification and are discussed elsewhere.

Type I

Transphyseal fractures occur through the proximal femoral physis, with (type IA) or without (type IB) dislocation of the femoral head from the acetabulum (Fig. 26-4). Such fractures are rare, constituting 8% of femoral neck fractures in children.[58] Approximately half of type I fractures are associated with a dislocation of the capital femoral epiphysis. True transphyseal fractures tend to occur in young children after high-energy trauma[19,34] and are different from unstable slipped capital femoral epiphysis (SCFE) of the preadolescent, which usually follows a prodromal period of activity-related hip or knee pain. Unstable SCFE differs from traumatic separation as it occurs following minor trauma, which is superimposed on a weakened physis from a combination of multiple factors including obesity and subtle endocrinopathy.

Iatrogenic fracture of the physis in children and adolescents may occur during reduction of a hip dislocation (Fig. 26-5).[15,55] It is possible that these patients had unrecognized physeal injury at the time of dislocation or, alternatively, the epiphysis may be displaced with vigorous reduction methods.

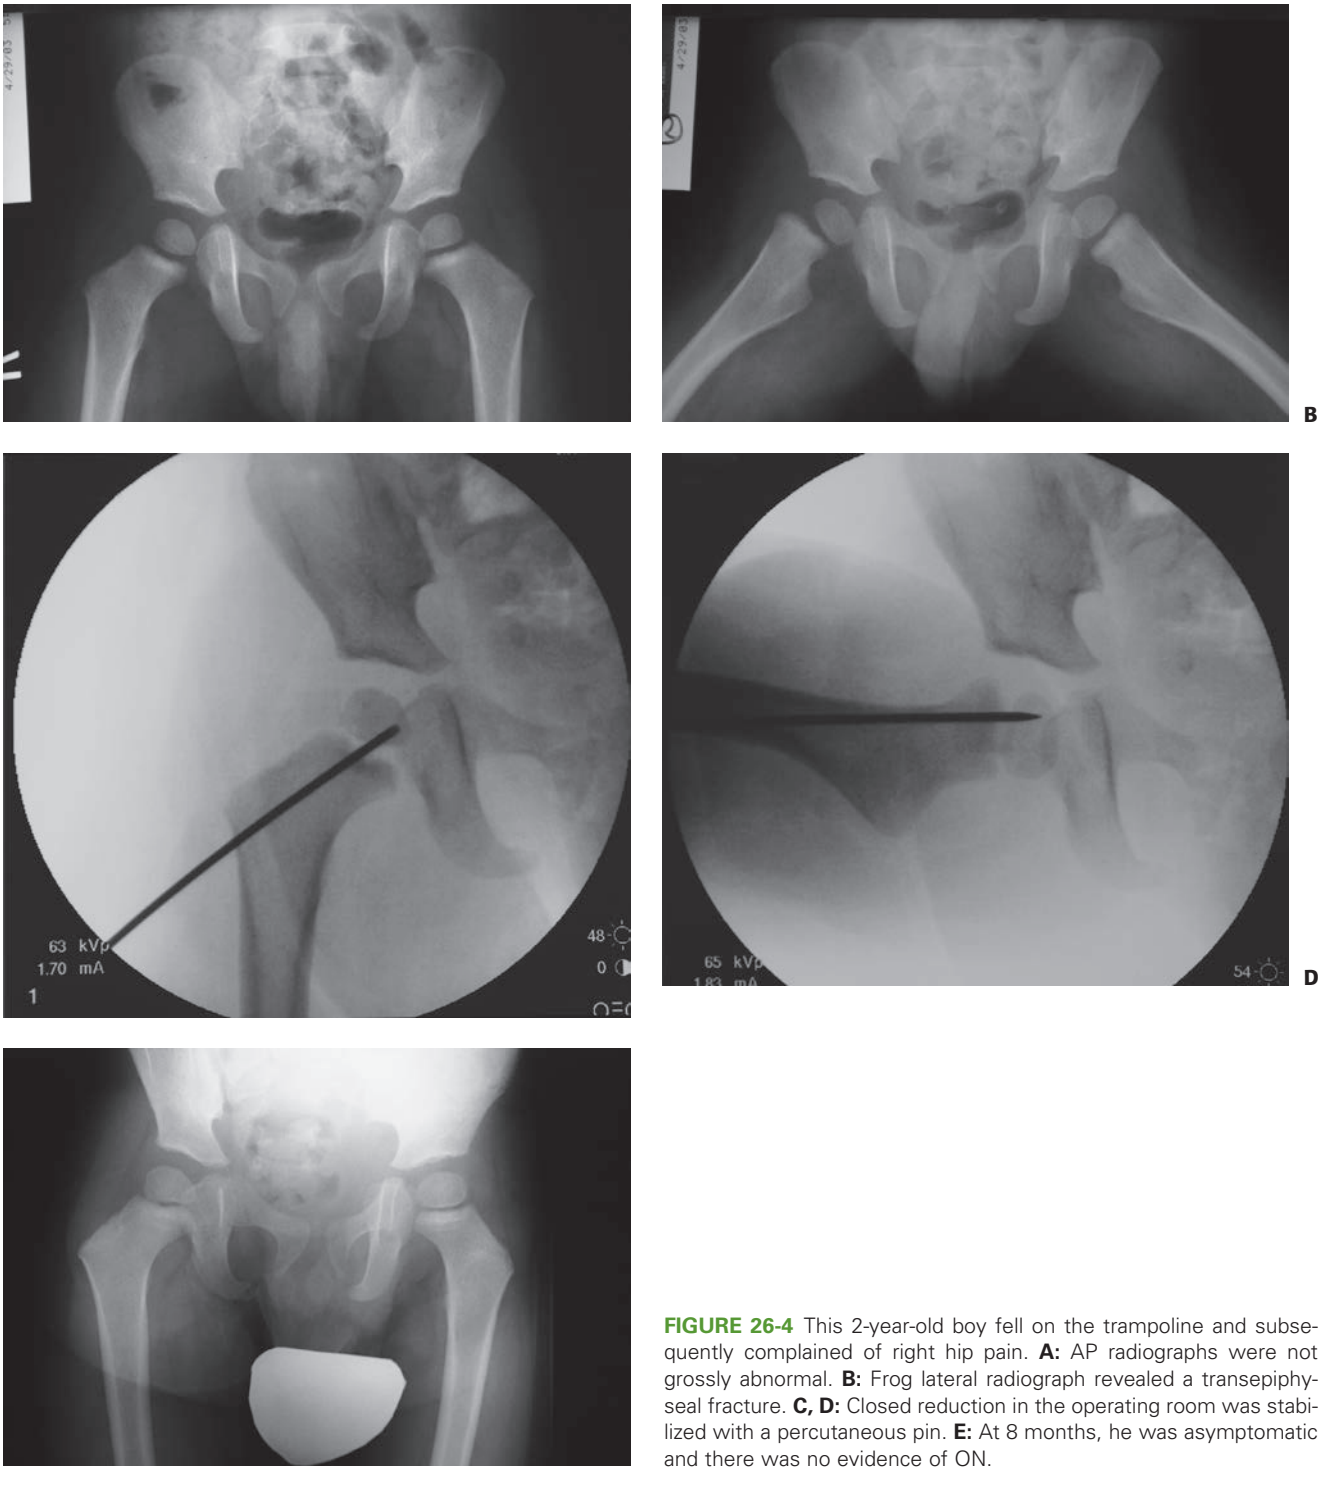

FIGURE 26-4 This 2-year-old boy fell on the trampoline and subsequently complained of right hip pain. **A:** AP radiographs were not grossly abnormal. **B:** Frog lateral radiograph revealed a transepiphyseal fracture. **C, D:** Closed reduction in the operating room was stabilized with a percutaneous pin. **E:** At 8 months, he was asymptomatic and there was no evidence of ON.

Transphyseal fractures without femoral head dislocation have a better prognosis than those with dislocation. Similarly, in children under 2 or 3 years of age, a better prognosis exists than in older children. ON in younger children is unlikely, although coxa vara, coxa breva, and premature physeal closure can cause subsequent leg length discrepancy.[18,21] In cases of femoral head dislocation in a type I fracture, the outcome is dismal because of ON and premature physeal closure in virtually 100% of patients.[19,34]

Type II

Transcervical fractures are the most common fracture type (45% to 50% of all femoral neck fractures),[58] which occur between the physis and are above the intertrochanteric line, and by

definition are considered as intracapsular femoral neck fractures. Nondisplaced transcervical fractures have a better prognosis and a lower rate of ON than displaced fractures, regardless of treatment.[19,80,98] Necrosis can still occur in minimally displaced fractures, and this may be because of the fact that it is difficult to document how much displacement occurs at the time of trauma. Moon and Mehlman[74] performed a meta-analysis of available literature and documented a 28% incidence of ON in type II fractures. The occurrence of ON is thought by these and other investigators to be directly related to fracture displacement, which may lead to disruption or kinking of the blood supply to the femoral head. In addition, the meta-analysis demonstrated higher rates of ON in children older than 10 years at the time of their injury.[80] Because the pediatric hip capsule is tough and less likely to tear, some have hypothesized that a possible etiology of vascular impairment in minimally displaced fractures is a result of intra-articular hemarthrosis leading to vessel compression from tamponade.[19,58]

Type III

Cervicotrochanteric fractures are, by definition, located at or slightly above the anterior intertrochanteric line and are the second most common type of hip fracture in children, representing about 34% of fractures.[58] It is conceivable that a certain portion of these fractures may be intra- and extracapsular as a result of anatomic differences in capsule insertion. Nondisplaced type III fractures also have a much lower complication rate than displaced fractures. Displaced type III fractures are similar to type II fractures in regard to the type of complications that can occur. For instance, the incidence of ON is 18% and is slightly less than in type II fractures[80]; the risk of ON is directly related to the degree of displacement at the time of injury.[14] Premature physeal closure occurs in 25% of patients, and coxa vara can also occur in approximately 14% of patients.[58]

Type IV

Intertrochanteric fractures account for only 12% of fractures of the head and neck of the femur in children.[58] This fracture is completely extracapsular and has the lowest complication rate of all four types. Nonunion in this fracture is rare, and Moon and Mehlman[74] documented a rate of ON of only 5%, which is much lower than in intracapsular fractures. Coxa vara and premature physeal closure have occasionally been reported.[19,58,68,97,98]

Unusual Fracture Patterns

Rarely, proximal femoral physiolysis occurs during a difficult delivery and can be confused on radiographs with congenital dislocation of the hip. Type I fracture in a neonate deserves special attention. This injury is exceedingly rare and, because the femoral head is not visible on plain radiographs the diagnosis can be difficult and the index of suspicion must be high. The differential diagnosis includes septic arthritis and hip dislocation. Plain radiographs may show a high-riding proximal femoral metaphysis on the involved side, thus mimicking a congenital hip dislocation. Ultrasonography is useful in diagnosis of neonatal physiolysis; with this test, the cartilaginous head remains in the acetabulum but its dissociation from the femoral shaft can be appreciated. The diagnosis can be missed if there is no history of trauma or if there is an ipsilateral fracture of the femoral shaft.[2] In the absence of a known history of significant trauma in a young child, nonaccidental trauma should be ruled out.[115]

Stress fractures are caused by repetitive injury and result in hip or knee pain and a limp. Pain associated with long-distance running, marching, or a recent increase in physical activity is suggestive of stress fracture. Close scrutiny of high-quality radiographs may identify sclerosis, cortical thickening, or new bone formation. Undisplaced fractures may appear as

faint radiolucencies. If radiographs are inconclusive, adjunctive tests such as MRI, CT, or bone scintigraphy may be helpful.

An unstable SCFE can be mistaken for a traumatic type I fracture; however, SCFE is caused by an underlying abnormality of the physis and occurs after trivial trauma, usually in preadolescents, whereas type I fractures usually occur in young children. Often in a SCFE there may be signs of remodeling or callous of the femoral metaphysis.

Fracture after minor trauma suggests weakened bone possibly from systemic disease, tumors, cysts, and infections. If the physical and radiographic evidences of trauma is significant but the history is not consistent, nonaccidental trauma must always be considered.[3,115] In the multiply traumatized patient, it is easy to miss hip fractures that are overshadowed by more dramatic or painful injuries. Radiographs of the proximal femur and pelvis are obtained and examined carefully in patients with femoral shaft fractures because ipsilateral fracture or dislocation of the hip is not unusual.[2]

Pathoanatomy and Applied Anatomy Relating to Hip Fractures

Ossification of the femur begins in the seventh fetal week.[34] In early childhood, only a single proximal femoral chondroepiphysis exists. During the first year of life, the medial portion of this physis grows faster than the lateral, creating an elongated femoral neck by 1 year of age. The capital femoral epiphysis begins to ossify at approximately 4 months in girls and 5 to 6 months in boys. The ossification center of the trochanteric apophysis appears at 4 years in boys and girls.[58] The proximal femoral physis is responsible for the metaphyseal growth in the femoral neck, whereas the trochanteric apophysis contributes to the appositional growth of the greater trochanter and less to the metaphyseal growth of the femur.[25] Fusion of the proximal femoral and trochanteric physis occurs at about the age of 14 in girls and 16 in boys.[52] The confluence of the greater trochanteric physis with the capital femoral physis along the superior femoral neck and the unique vascular supply to the capital femoral epiphysis makes the immature hip vulnerable to growth derangement and subsequent deformity after a fracture (Fig. 26-6).

Vascular Anatomy

Because of the frequency and sequelae of ON of the hip in children, the blood supply has been studied extensively.[24,50,57,89] Postmortem injection and microangiographic studies have provided clues to the vascular changes with age. These observations are as follows.

- At birth, interosseous continuation of branches of the medial and lateral circumflex arteries (metaphyseal vessels) traversing the femoral neck predominately supply the femoral head. These arteries gradually diminish in size as the cartilaginous physis develops and forms a barrier thus preventing transphyseal continuity of these vessels into the femoral head. Thus metaphyseal blood supply to the femoral head is virtually nonexistent by age 4.
- When the metaphyseal vessels diminish, the intracapsular lateral epiphyseal vessels predominate and the femoral head is primarily supplied by these vessels, which extend superiorly on the exterior of the neck, bypassing the physeal barrier and then continuing into the epiphysis.
- Ogden[83] noted that the lateral epiphyseal vessels consist of two branches: The posterosuperior and posteroinferior branches of the medial circumflex artery. At the level of the intertrochanteric groove, the medial circumflex artery branches into a retinacular arterial system (the posterosuperior and posteroinferior arteries). These arteries penetrate the capsule and traverse proximally (covered by the retinacular folds) along the neck of the femur to supply the femoral head peripherally and proximally to the physis. The posteroinferior and posterosuperior arteries persist throughout life and supply the femoral head. At about 3 to 4 years of age, the lateral posterosuperior vessels appear to predominate and supply the entire anterior lateral portion of the capital femoral epiphysis.

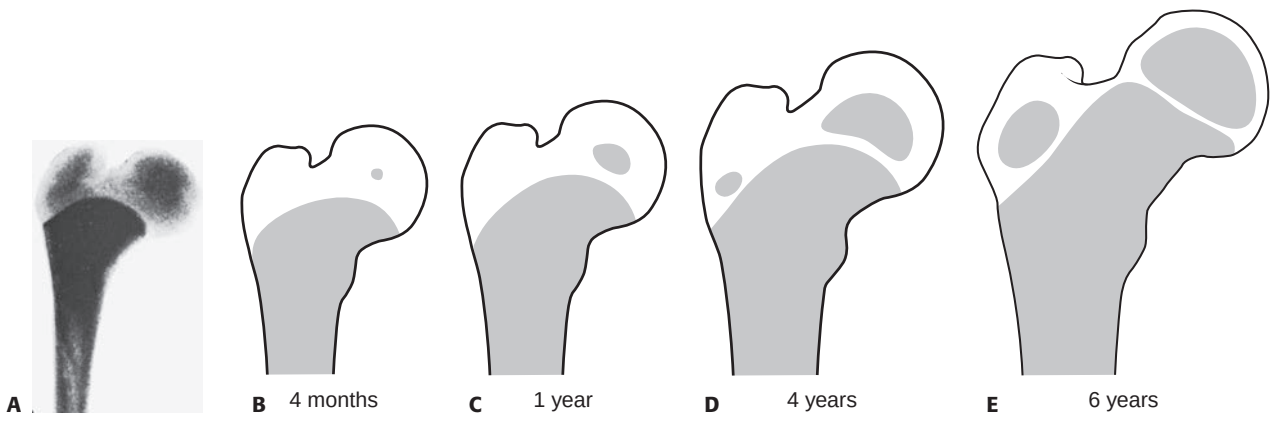

FIGURE 26-6 The transformation of the preplate to separate growth zones for the femoral head and greater trochanter. The diagram shows development of the epiphyseal nucleus. **A:** Radiograph of the proximal end of the femur of a stillborn girl, weight 325 g. **B–E:** Drawings made on the basis of radiographs. (Reprinted from Edgren W. Coxa plana. A clinical and radiological investigation with particular reference to the importance of the metaphyseal changes for the final shape of the proximal part of the femur. *Acta Orthop Scand Suppl.* 1965;84:1–129, with permission.)

- The vessels of the ligamentum teres are of virtually no importance. They contribute little blood supply to the femoral head until age 8, and then only about 20% as an adult.

The above information has clinical importance. For instance, the multiple small vessels of the young coalesce with age to a limited number of larger vessels. As a result, damage to a single vessel can have serious consequences; for example, occlusion of the posterosuperior branch of the medial circumflex artery can cause ON of the anterior lateral portion of the femoral head.[18]

It is also important for surgeons to recognize where capsulotomy should be performed to decrease iatrogenic injury to existing blood supply. It is suspected that anterior capsulotomy does not damage the blood supply to the femoral head as long as the intertrochanteric notch and the superior lateral ascending cervical vessels are avoided.

Soft Tissue Anatomy

The hip joint is enclosed by a thick fibrous capsule that is considered less likely to tear than in adult hip fractures. Bleeding within an intact capsule may lead to a tense hemarthrosis after intracapsular fracture which can theoretically tamponade the ascending cervical vessels and may have implications in the development of ON. The hip joint is surrounded on all sides by a protective cuff of musculature; as such, open hip fracture is rare. In the absence of associated hip dislocation, neurovascular injuries are rare.

The sciatic nerve emerges from the sciatic notch beneath the piriformis and courses superficial to the external rotators and the quadratus medial to the greater trochanter. The lateral femoral cutaneous nerve lies in the interval between the tensor and sartorius muscles and supplies sensation to the lateral thigh. This nerve must be identified and preserved during an anterolateral approach to the hip. The femoral neurovascular bundle is separated from the anterior hip joint by the iliopsoas. Thus, any retractor placed on the anterior acetabular rim should be carefully placed deep to the iliopsoas to protect the femoral bundle. Inferior and medial to the hip capsule, coursing from the deep femoral artery toward the posterior hip joint, is the medial femoral circumflex artery. Placement of a distal Hohmann retractor too deeply can tear this artery, and control of the bleeding may be difficult.

Treatment Options for Hip Fractures

Rationale for Management

Much of the early, classic literature on hip fractures in children documented high rates of coxa vara, delayed union, and nonunion in patients treated without internal fixation.[68,98] Canale and Bourland[18] noted that fractures treated by spica casting alone had a greater incidence of coxa vara. They attributed a lower rate of coxa vara and nonunion in some of their patients to the use of internal fixation for all transcervical fractures.[19] More recent literature supports the concept that attempted conservative treatment can result in unacceptably high rates of coxa vara.[6] These high rates of complications may be because of an underappreciation of the uniqueness of this injury and its requisite necessity for operative treatment in most patients, which is in contrast to other pediatric injuries.[6] Subsequent authors have documented lower rates of ON, coxa vara, and nonunion in patients who were aggressively treated with anatomic reduction (open or closed) and internal fixation (with or without supplemental casting) within 24 hours of injury.[5,22,37,82,87,105] A recent paper of 36 patients followed until healing concluded that patients treated with open reduction had a smaller complication rate and recommended open reduction and internal fixation (ORIF) over closed reduction and internal fixation (CRIF) whenever possible.[7] Therefore, contemporary management is directed at early, anatomic reduction of these fractures with stable internal fixation and selective use of supplemental external stabilization (casting), with the goal of minimizing devastating late complications.[22,98,111]

Nonoperative Treatment of Hip Fractures

Indications/Contraindications (Table 26-1)

TABLE 26-1 Hip Fractures

Nonoperative Treatment

Indications	Relative Contraindications
Infants and toddlers 0–2 y with stable minimally displaced type I fractures	Type I fractures >2 y
Nondisplaced type II and III fractures in younger children (0–5 y)	Displaced fractures
Nondisplaced stress fractures	Older children (>5 y with type II and III) fractures

Techniques

Nonoperative treatment in children less than 1 year may be either a Pavlik harness or abduction brace. In older children treated non-op a spica cast past the knee may be considered. There are no outcome studies on spica or brace treatment but a spica cast should only be considered in younger children up to 5 years with nondisplaced fractures. Non-operative and spica cast treatment alone is not optimal in older children as the potential for nonunion is to great not to perform internal fixation. A supplemental spica cast is recommended for children that are not near skeletal maturity secondary to the fact that internal fixation will often stop distal to the epiphyseal physis.

Operative Treatment of Hip Fractures

Indications/Contraindications for Surgical Versus Nonsurgical Treatment

Internal fixation is indicated in children with displaced femoral neck fractures. Internal fixation is also recommended for most acute nondisplaced fractures except in children where size limits the effect of internal fixation (0 to 5 years). Completely nondisplaced fractures may have percutaneous screw placement with or without capsulotomy. If there is any residual displacement after an attempted closed reduction, an open reduction should be performed. The threshold for open reduction should be any displacement to decrease the incidence of ON and nonunion.

The Watson-Jones Approach (Anterior Lateral Approach)

Preoperative Planning (Table 26-2).

TABLE 26-2 Watson-Jones Approach

Preoperative Planning Checklist

- OR table: Fracture table/flattop table to allow adequate imaging
- Position/positioning aids: The patient should have a bump on the back and posterior pelvis to allow access to the region posterior to the greater trochanter
- Fluoroscopy location: On the side opposite the operative field. If percutaneous fixation is indicated a two C-arm technique may be helpful
- Equipment: Deep retractors
- Tourniquet (sterile/nonsterile): NA
- Etc:

Surgical Approach. If open reduction is necessary, the Watson-Jones approach is a useful and direct approach to the femoral neck. A lateral incision is made over the proximal femur, slightly anterior to the greater trochanter (Fig. 26-7A). The fascia lata is incised longitudinally (Fig. 26-7B). The innervation of the tensor muscle by the superior gluteal nerve is 2 to 5 cm above the greater trochanter, and care should be taken not to damage this structure. The tensor muscle is reflected anteriorly. The interval between the gluteus medius and the tensor muscles will be used (Fig. 26-7C). The plane is developed between the muscles and the underlying hip capsule (Fig. 26-7D). If necessary, the anterior-most fibers of the gluteus medius tendon can be detached from the trochanter for wider exposure. After clearing the anterior hip capsule, longitudinal capsulotomy is made along the anterosuperior femoral neck. A transverse incision can be added superiorly for wider exposure (Fig. 26-7E). Once the hip fracture is reduced, guidewires for cannulated screws can be passed perpendicular

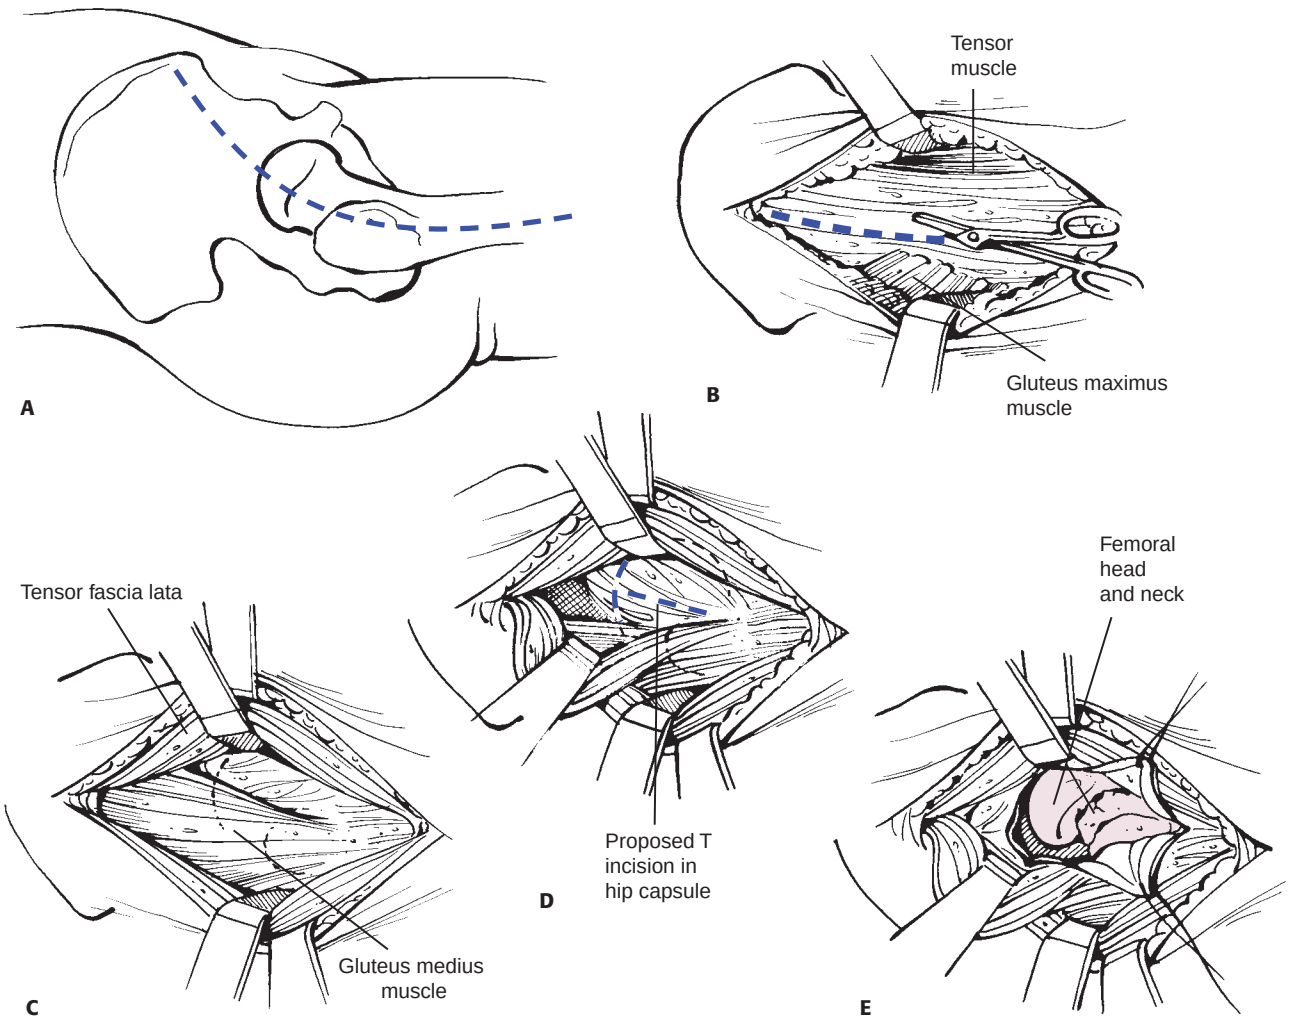

FIGURE 26-7 Watson-Jones lateral approach to the hip joint for open reduction of femoral neck fractures in children. **A:** Skin incision. **B:** Incision of the fascia lata between the tensor muscle (anterior) and gluteus maximus (posterior). **C:** Exposure of the interval between the gluteus medius and tensor fascia lata (retracted anteriorly). to the fracture along the femoral neck from the base of the greater trochanter.

The Smith-Peterson Approach (Anterior Approach)

Preoperative Planning (Table 26-3)

TABLE 26-3 Smith-Petersen Approach

Preoperative Planning Checklist

- OR table: Radiolucent
- Position/positioning aids: A "bump" under the thoracolumbar spine to the posterior-superior iliac spine to access the greater trochanter for screw insertion
- Fluoroscopy location: Opposite surgeon
- Equipment: Long retractors
- Tourniquet (sterile/nonsterile): NA
- Etc:

Surgical Approach. A longitudinal incision distal and lateral to the anterior-superior iliac spine or bikini approach can be used through the Smith-Petersen interval (Fig. 26-8). Care should be taken to identify and protect the lateral femoral cutaneous nerve. The fascia over the tensor fascia muscle is opened longitudinally. Blunt dissection is then done to expose the medial aspect of the muscle as far proximal as the iliac crest. The rectus muscle is seen and the lateral fascia of the rectus is incised and the rectus can then be retracted in a medial direction. The fascia on the floor of the rectus is incised longitudinally and the lateral iliopsoas is elevated off the hip capsule in a medial direction to expose the hip capsule. The sartorius and rectus muscles can be detached for greater exposure of the hip capsule if required. Medial and inferior retractors should be carefully placed around the femoral neck once the capsule is incised to avoid damage to the femoral neurovascular bundle and medial femoral circumflex artery, respectively. Care must be taken not to violate the intertrochanteric notch and the

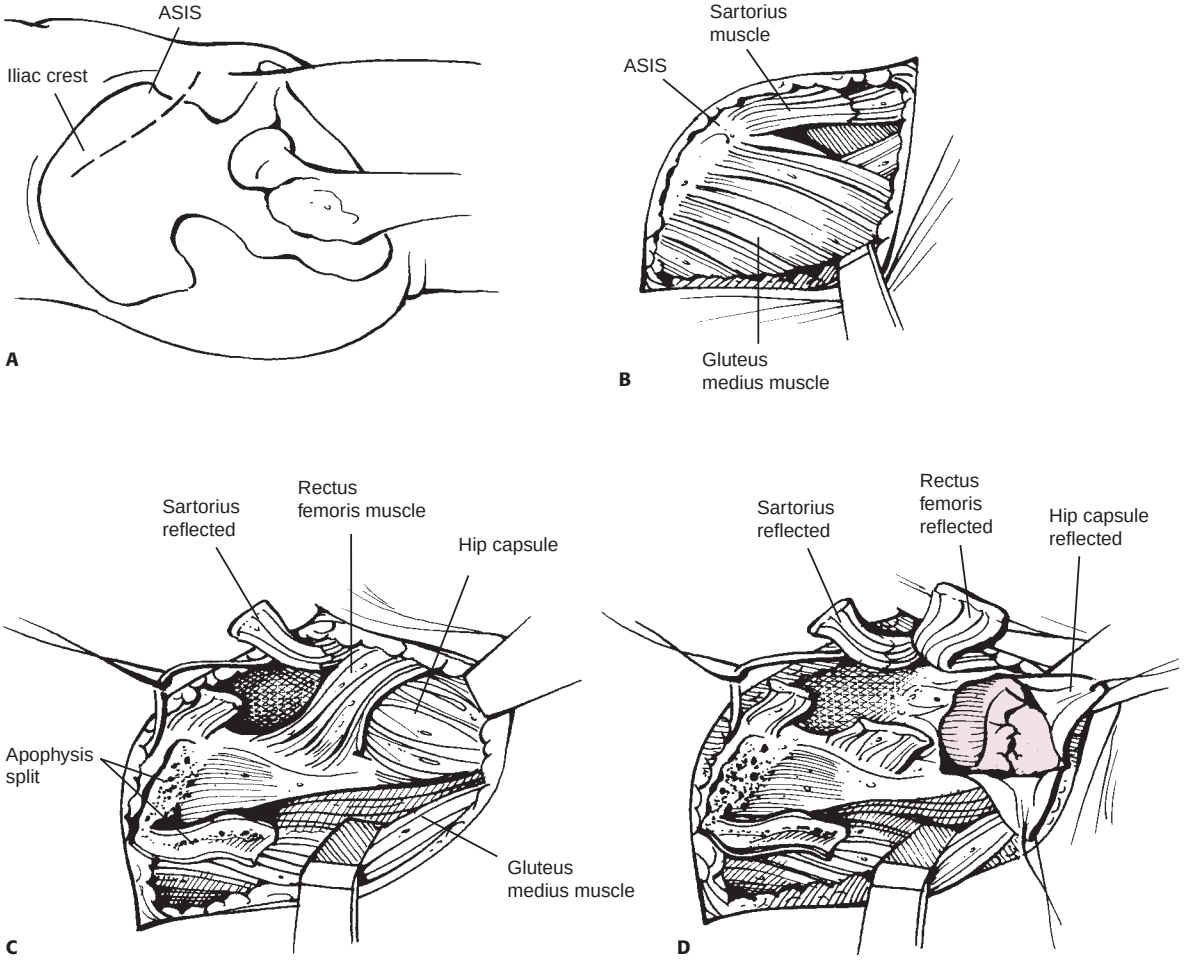

FIGURE 26-8 Smith-Petersen anterolateral approach to the hip joint. **A:** Skin incision. Incision is 1 cm below the iliac crest and extends just medial to the anterior-superior iliac spine. **B:** Skin is retracted, exposing the fascia overlying the anterior-superior iliac spine. The interval between the sartorius and the tensor fascia lata is identifiable by palpation. **C:** The sartorius is detached from the anterior-superior iliac spine. Splitting of the iliac crest apophysis and detachment of the rectus femoris (shown attached to anterior-inferior iliac spine) will facilitate exposure of the hip capsule. **D:** The hip capsule is exposed. A T incision is made to reveal the femoral head and neck.

lateral ascending vessels. Because the lateral aspect of the greater trochanter is not exposed, wires must be passed percutaneously once the hip fracture is reduced.

Lateral Approach for Decompression. In many cases, an adequate closed reduction can be obtained thus avoiding the need to open the hip joint for reduction purposes. However, the surgeon may decide to perform a capsulotomy to decompress the hip joint. The authors prefer to do this from a lateral approach. With this method, a 4-cm incision is made distal and lateral to the greater trochanter. From this incision, the fascia lata is incised and guide pins for cannulated screws are placed and screws are inserted in the standard manner. The anterior fibers of the gluteus medius are elevated allowing incision of the anterior capsule with a Cobb elevator, knife, or osteotome.

Surgical Dislocation of the Hip

Preoperative Planning (Table 26-4)

TABLE 26-4 Surgical Dislocation of the Hip

Preoperative Planning Checklist

- OR table: Radiolucent
- Position/positioning aids: Patients are positioned in the lateral position. This can be accomplished with a pegboard, beanbag, or other available positioning devices.
- Fluoroscopy location: Opposite the surgeon
- Equipment: Curved scissors are needed if the ligamentum teres is to be transected for dislocation. A saw is needed for the greater trochanteric osteotomy
- Tourniquet (sterile/nonsterile): NA

Positioning. Patients are positioned in the lateral position on a radiolucent table. The opposite leg should be well padded so there is no pressure on the peroneal nerve. An axillary roll is needed and both upper extremities should be carefully positioned to avoid any pressure or tension on the upper extremity and brachial plexus. The complete left hip and leg is draped free as high as the iliac crest.

Surgical Approach. The technique was originally described by Ganz et al.[39] A lateral incision is performed centered on the anterior third of the greater trochanter. The proximal extent of the incision is at least at the midpoint between the greater trochanter and the iliac crest. The tensor fascia is incised in the anterior third of the greater trochanter and along the anterior border of the gluteus maximus muscle. This is known as the Gibson modification[79] which protects the neurovascular bundle of the gluteus maximus. This exposes the upper vastus lateralis, gluteus medius, and greater trochanter. The leg is positioned with the hip in slight extension and internal rotation to better visualize the anatomic landmarks for this portion of the approach. The piriformis tendon is visualized deep to the posterior/distal aspect of gluteus medius. Once exposed the tendon can be slightly retracted distal to expose the inferior margin of the gluteus minimus fascia. The inferior fascia of the minimus is opened to allow the muscle to be retracted in an anterior-superior direction off the hip capsule. It is easier to visualize this interval prior to the trochanteric osteotomy. A greater trochanteric osteotomy is performed from anterior to the tip of the greater trochanter to the posterior border of the vastus lateralis ridge. The width of the osteotomy is approximately 10 to 15 mm in children. A muscular flap including the gluteus minimus, gluteus medius, osteotomized greater trochanter, vastus lateralis, and vastus intermedius is elevated sharply off the hip capsule in an anterior/superior direction. Flexion and external rotation of the operative hip will facilitate the muscle dissection. The dissection is all anterior to the piriformis tendon the majority of which should be still attached to the trochanter (not the osteotomized fragment). Keeping the piriformis tendon intact with dissection anterior to the tendon protects the retinacular branch of the medial circumflex artery. The capsule should be visualized as anterior as the medial region of the indirect tendon.

The hip capsule is then opened in a "z"-shaped fashion. The longitudinal limb is along the axis of the femoral neck in line with the iliofemoral ligament. The distal aspect is proximal but in line with the intertrochanteric ridge. The posterior limb of the capsule is opened in the capsular recess of the acetabulum as far posterior as the piriformis tendon. Therefore, the lateral and posterior capsular flap is created that protects the retinaculum as it pierces the hip capsule. Once the capsule is opened the anatomy and fracture can be visualized. If hip dislocation is indicated the leg is flexed and externally rotated and placed in a sterile leg bag. The hip is subluxated with a bone hook and curved large scissors are used to transect the ligamentum teres.

The location of the hip fracture will dictate the next step after the capsulotomy. If dislocation is warranted temporary fixation of the fracture with a threaded Kirschner wire (K-wire) is recommended for safe dislocation. Without temporary fixation damage may occur to the retinaculum that is easily visualized in the lateral and posterolateral region of the femoral neck.

After fracture fixation the hip capsule is loosely approximated. The greater trochanter is reduced and fixation with 2 to 3 screws (3.5 mm) is performed. Weight-bearing restrictions are dependent on the fracture type.

Current Treatment Options

Type I. Fracture treatment is based on the age of the child, presence of femoral head dislocation, and fracture stability after reduction. In toddlers under 2 years of age with nondisplaced or minimally displaced fractures, simple spica cast immobilization is likely to be successful. Because the fracture tends to displace into varus and external rotation, the limb should be casted in mild abduction and neutral rotation to prevent displacement. Close follow-up in the early postinjury period is critical. Displaced fractures in toddlers should be reduced closed by gentle traction, abduction, and internal rotation. If the fracture "locks on" and is stable, casting without fixation is indicated. If casting without fixation is done, repeat radiographs should be taken within days to look for displacement because the likelihood of successful repeat reduction decreases rapidly with time and healing in a young child.

If the fracture is not stable, it should be fixed with small-diameter (2-mm) smooth pins that cross the femoral neck and into the epiphysis. Use of smooth pins will theoretically decrease risk of physis injury in younger patients with a transphyseal fracture. An arthrogram *after* reduction and stabilization of the fracture may be indicated to insure alignment is anatomic. An arthrogram *prior* to reduction and pinning may obscure bony detail and hinder assessment during reduction.

Children older than 2 years should have operative fixation, even if the fracture is nondisplaced; because the complications of late displacement may be great, fixation should cross the physis into the capital femoral epiphysis. Smooth pins can be used in young children, but cannulated screws are better for older, larger children and adolescents. In this older group (>10 years) the effect of eventual limb length discrepancy is small and is a reasonable tradeoff for the superior fixation and stabilization needed to avoid complications in larger and older children.

Closed reduction of type IB fracture-dislocations may be attempted, but immediate open reduction is necessary if a single attempt at closed reduction is unsuccessful. Internal fixation is mandatory. The surgical approach should be from the side to which the head is dislocated, generally posterolateral. Parents must be advised in advance about the risk of ON.

Postoperative spica cast immobilization is mandatory in all but the oldest and most reliable adolescents who have large-threaded screws crossing the physis. Fixation may be removed shortly after fracture healing to enable further growth in patients.

Type II and Type III. Intracapsular femoral neck fractures mandate anatomic reduction and, in most cases, internal fixation. In rare cases, children under 5 years of age with nondisplaced and completely stable type II and cervicotrochanteric fractures can be managed with spica casting and close follow-up to detect varus displacement in the cast.[29,58,68] However, in almost all cases, internal fixation is recommended by most investigators for nondisplaced transcervical fractures[40,58] because the risk of late displacement in such fractures far outweighs the risk of percutaneous screw fixation, especially in young children.[16]

Displaced neck fractures should be treated with anatomic reduction and stable internal fixation to minimize the risk of late complications. Coxa vara and nonunion were frequent in several large series of displaced transcervical fractures treated with immobilization but without internal fixation.[6,19,68] However, when an anatomic closed or ORIF was used, the rates of these complications were much lower.[19,37,82,111]

Gentle closed reduction of displaced fractures is accomplished with the use of longitudinal traction, abduction, and internal rotation. Open reduction frequently is necessary for displaced fractures and should be done through a Watson-Jones surgical approach.

Internal fixation with cannulated screws is done through a small lateral incision with planned entry above the level of the lesser trochanter. Two to three screws should be placed; if possible, the most inferior screw will skirt along the calcar with the remaining screws spaced as widely as possible.[15] Usually, the small size of the child's femoral neck will accommodate only two screws. Care should be taken to minimize unnecessary drill holes in the subtrochanteric region because they increase the risk of subtrochanteric fracture.

In type II fractures, physeal penetration may be necessary for purchase[58,82]; the sequelae of premature physeal closure and trochanteric overgrowth are much less than those of nonunion, pin breakage, and ON. Treatment of the fracture is the first priority, and any subsequent growth disturbance and leg length discrepancy are secondary. Consideration may be given to simultaneous capsulotomy or aspiration of the joint to eliminate pressure from a hemarthrosis at the time of surgery.

Displaced cervicotrochanteric fractures have been shown to have a complication rate similar to that for type II fractures and should be treated similarly. If possible, screws should be inserted short of the physis in type III fractures. Fixation generally does not need to cross the physis in type III fractures. Alternatively, a pediatric hip compression screw or a pediatric locking hip plate[62,102] can be used for more secure fixation of distal cervicotrochanteric fractures in a child over 5 years of age particularly if there is a smaller region for screw purchase lateral and distal to the fracture. Spica casting is routine in most type II and III fractures, except in older children where the screws can cross the physis.[37]

Type IV. Good results can be obtained after closed treatment of most intertrochanteric fractures in younger children, regardless of displacement. Traction and spica cast immobilization are effective.[15] Instability or failure to maintain adequate reduction and polytrauma are indications for internal fixation. Older children (>10 years) or those with significant displacement can be treated with ORIF (Fig. 26-9). A pediatric hip screw or pediatric hip locking plate provides the most rigid internal fixation for this purpose. Smaller hip screw devices have made ORIF an option in children younger than 10 years. This may avoid the period of spica cast treatment and a more anatomic alignment.

Author's Preferred Treatment for Hip Fractures

Type I

Nondisplaced or minimally displaced stable fractures in toddlers up to age 2 should be treated in a spica cast without internal fixation. The limb should be casted in a position of abduction and neutral rotation to prevent displacement into varus. If the fracture requires reduction or moves significantly during reduction or casting maneuvers, then internal fixation is mandatory. Two-millimeter smooth K-wires are inserted percutaneously to cross the physis. We recommend two or three wires. Wires should be cut off and bent below the skin for retrieval under a brief general anesthetic when the fractures healed. We do not recommend leaving the wires outside the skin. Frequent radiographs are necessary to check for migration of the pins into the joint space. A spica cast is always applied in this age group and should remain in place for at least 6 weeks.[37] Even if type I fractures in children older than 2 years are anatomically reduced, these patients should always have stabilization with internal fixation. While K-wires are appropriate for small

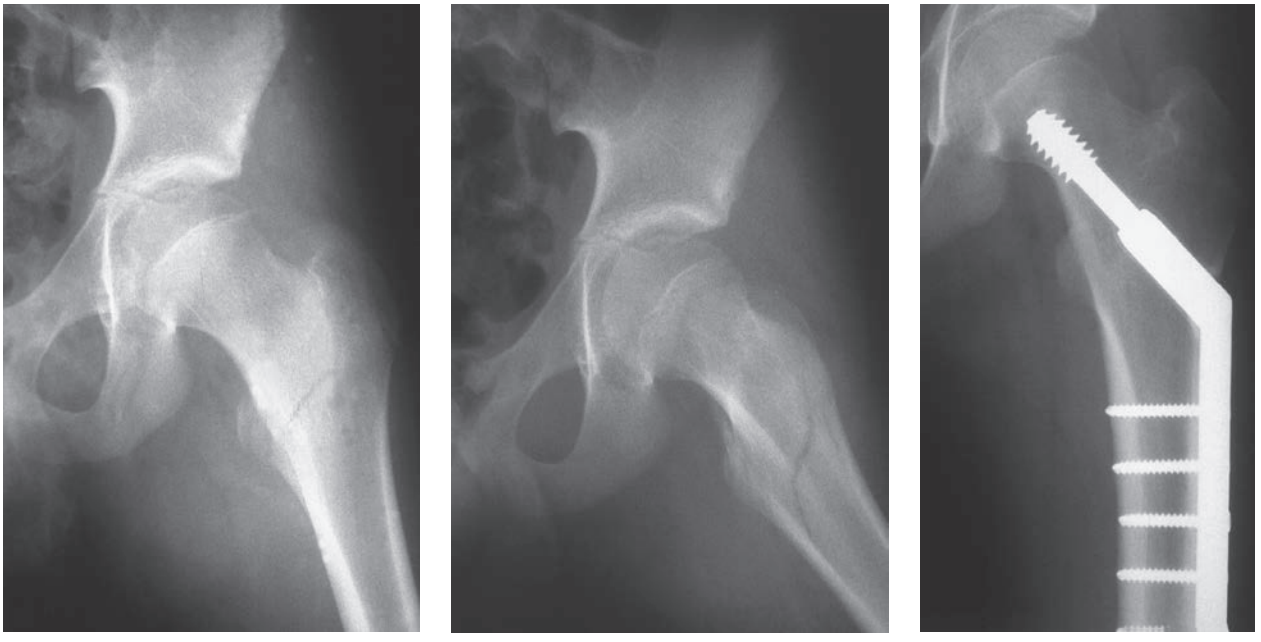

FIGURE 26-9 **A:** A 14-year-old boy who fell from a tree swing sustained this nondisplaced left intertrochanteric hip fracture. **B:** Lateral radiograph shows the long spiral fracture. **C:** Three months after fixation with an adult sliding hip screw.

children, 4- to 7.3-mm cannulated screws crossing the physis can be considered in older, larger children after closed reduction. Fluoroscopically placing a guide pin across the femoral head and neck allows one to locate the proper site for a small incision overlying the lateral femur in line with the femoral neck. Two guide pins are placed into the epiphysis, and the wires are overdrilled to the level of the physis (but not across to avoid growth arrest as much as possible). The hard metaphysis and lateral femoral cortex are tapped (in contrast to elderly patients with osteoporosis) to the level of the physis and stainless steel screws are placed.

If gentle closed reduction cannot be achieved, an open approach is preferred for type IA fractures. For type IB fractures, the choice of approach is dictated by the position of the femoral epiphysis. If it is anterior or inferior, a Watson-Jones approach should be used. On the other hand, most type IB fractures are displaced posteriorly, in which case a posterior approach should be selected. A surgical dislocation approach may also be used to give complete visualization of the hip and retinacular vessels. Under direct vision, the fracture is reduced and guidewires are passed from the lateral aspect of the proximal femur up the neck perpendicular to the fracture; predrilling and tapping are necessary before the insertion of screws. All children are immobilized in a spica cast.

Older children and adolescents will usually require similar reduction methods on a fracture table, and the fracture is stabilized after closed or, if needed, open reduction. Larger 6.5- or 7.3-mm screws are needed and are placed after predrilling and tapping over the guide pins. Through a lateral incision, the screws are placed, and an anterior capsulotomy is performed. Such stout fixation usually obviates the need for spica casting in an adolescent but, if future patient compliance or fracture stability is in doubt, a spica cast is used. The lateral position is utilized for the surgical dislocation approach. The fracture can be reduced without the need for a traction table in the surgical dislocation approach.

Types II and III

In all cases, we attempt a closed reduction. It is critical that the fracture be reduced anatomically to decrease the potential of nonunion and AVN. If unsuccessful, a reduction can be performed through a Watson-Jones approach because it provides direct exposure of the femoral neck for gentle fracture reduction. If there is experience with the surgical dislocation approach this will give the surgeon visualization for fracture reduction and fixation. Both approaches allow the fracture to be anatomically reduced under direct vision. Once the fracture is visualized and anatomically reduced, guidewires are then placed up the femoral neck perpendicular to the fracture. If possible, penetration of the physis should be avoided.[21,36] However, in most unstable type II fractures, penetration of the physis may be necessary to achieve stability and avoid the complications associated with late displacement.[15,82] Good fixation of type III fractures generally is possible without penetration of the physis. With the surgical dislocation approach, the reduction can usually be performed without dislocation of the femoral head. If femoral head dislocation is required the fracture and femoral head should be provisionally reduced and fixed prior to subluxation and transecting the ligamentum teres to prevent traction on the retinaculum with the dislocation. Once dislocated a guidewire can be placed retrograde through the fovea.

Type II and III fractures should be stabilized with 4- to 4.5-mm cannulated screws in small children up to age 8. After the age of 8, fixation with 6.5-mm cannulated screws is appropriate. Two or three appropriately sized screws should be used, depending on the size of the child's femoral neck. As in type I fractures, we recommend placing at least two guide pins, and predrilling and tapping of the femoral neck is necessary to avoid displacement of the fracture while advancing the screws. Finally, we believe that if the physis is not crossed with implants, supplementary spica casting is needed to prevent malunion or nonunion.

Type IV

Undisplaced type IV fractures in children younger than 3 to 4 years are treated without internal fixation with immobilization in a spica cast for 12 weeks. Great care is needed to cast the limb in a position that best aligns the bone (Fig. 26-10A, B). Frequent radiographic examination is necessary to assess for late displacement, particularly into varus. In some cases, it may be difficult to assess reduction in a spica cast so that alternative testing such as a limited CT scan may be useful to compare to intraoperative positioning (Fig. 26-10 C, D). Displaced type IV fractures in all children more than 3 years should be treated with internal fixation with a pediatric or juvenile compression hip screw or pediatric locking hip plate placed into femoral neck short of the physis. It is important to place an antirotation wire before drilling and tapping the neck for the dynamic hip screw. Closed reduction often is possible with a combination of traction and internal rotation of the limb. If open reduction is necessary, a lateral approach with anterior extension to close reduce the fracture is preferred.

Postoperative Care

In general, we believe supplementary casting should be considered for the majority of patients with proximal femoral fractures. For instance, casting is indicated in all type I fractures except in the rare adolescents who have been treated with two to three large screws that cross the physis and who will be obviously compliant with restricted weight bearing. For type II and III fractures, we recommend a hip spica cast to be used for at least 6 weeks in all patients whose implants do not cross the femoral physis. This recommendation makes sense when one considers that in children younger than 10, we try to avoid crossing the physis, and these patients usually do well with these casts. On the other hand, children older than 12 years can be treated with transphyseal fixation that will be stable enough to avoid cast fixation and which coincidently also tends to be poorly tolerated in this age group. For children 10 to 12 years, the use of a postoperative cast depends on the stability of fracture fixation and the patient's compliance; if either is in doubt, a single hip spica cast is used.

Type IV fractures treated with a hip screw and side plate do not require cast immobilization. Formal rehabilitation usually is unnecessary unless there is a severe persistent limp, which may be due to abductor weakness. Stiffness is rarely a problem in the absence of ON.

Potential Pitfalls and Preventative Measures (Table 26-5)

TABLE 26-5 Hip Fractures

Potential Pitfalls and Prevention

Pitfalls	Preventions
Pitfall #1: Nonunion	Prevention 1a: Anatomic reduction, open the fracture site if necessary Prevention 1b: Stable internal fixation, cross the physis if necessary Prevention 1c: Spica cast supplemental immobilization for children <10 or 10–12 if there is a concern for stabilization
Pitfall #2: Avascular necrosis	Prevention 2a: Urgent reduction >24 hrs Prevention 2b: Open reduction or capsulotomy if reduction is closed Prevention 2c: Anatomic reduction
Pitfall #3: Physeal arrest	Prevention 3a: Stop the fixation distal to the physis but do not compromise stability. The majority of type III and IV fractures can achieve stable fixation without crossing the physis. Prevention 3b: If the stability of fracture fixation is not enough with implants distal to the physis the surgeon must cross the physis. Prevention 3c: Consider removal of implants once the fracture has bony union.

Summary of Key Points

- For young, small patients, the operation should be done on a radiolucent operating table rather than on a fracture table, which is more appropriate for older and larger adolescents.
- Because the femoral bone in children is harder than the osteoporotic bone in elderly patients, predrilling and pretapping are necessary for insertion of all screws.
- Multiple attempts at wire placement should be avoided because they result in empty holes in the subtrochanteric region of the femur. This predisposes to late subtrochanteric fracture below or at the level of the screw heads after removal of the spica cast.
- A hip spica cast must be used to supplement internal fixation in all patients who are younger than 10 years. For older patients, if the stability of the fracture is questionable or if the child's compliance is doubtful, the surgeon should not hesitate to apply a hip spica cast. The quality of reduction and the stability of the fixation have a direct impact on the occurrence of nonunion.[37,68,82,98]
- Growth of the femur and the contribution of the proximal femoral physis are important; however, this physeal contribution to growth is only 13% of the entire extremity, or 3 to 4 mm per year on average. Once the decision for internal fixation of a fracture of the head or neck of the femur is made, stable fixation of the fracture is a higher priority than preservation of the physis. If stability is questionable, the internal fixation device should extend into the femoral head for rigid, stable fixation, regardless of the type of fracture or the age of the child.
- Anatomic reduction is imperative to decrease the incidence of nonunion and perhaps avascular necrosis.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Hip Fractures (Table 26-6)

TABLE 26-6 Hip Fractures

Common Adverse Outcomes and Complications

Avascular necrosis
Malunion (coxa vara)
Physeal arrest
Nonunion

ON is the most serious and frequent complication of hip fractures in children and is the primary cause of poor results after fractures of the hip in children.[72] Its overall prevalence is approximately 30%, based on the literature.[22,58,84] The risk of ON is highest after displaced type IB, II, and III fractures (Fig. 26-11).[15] In the meta-analysis by Moon and Mehlman,[79] the incidence of ON in type I through type IV is 38%, 28%, 18%, and 5%, respectively. In addition to location of the fracture (via Delbet classification), ON is believed to be increased with increased fracture displacement and older age at the time of injury.[70] Several studies report lower rates of ON in their series of patients

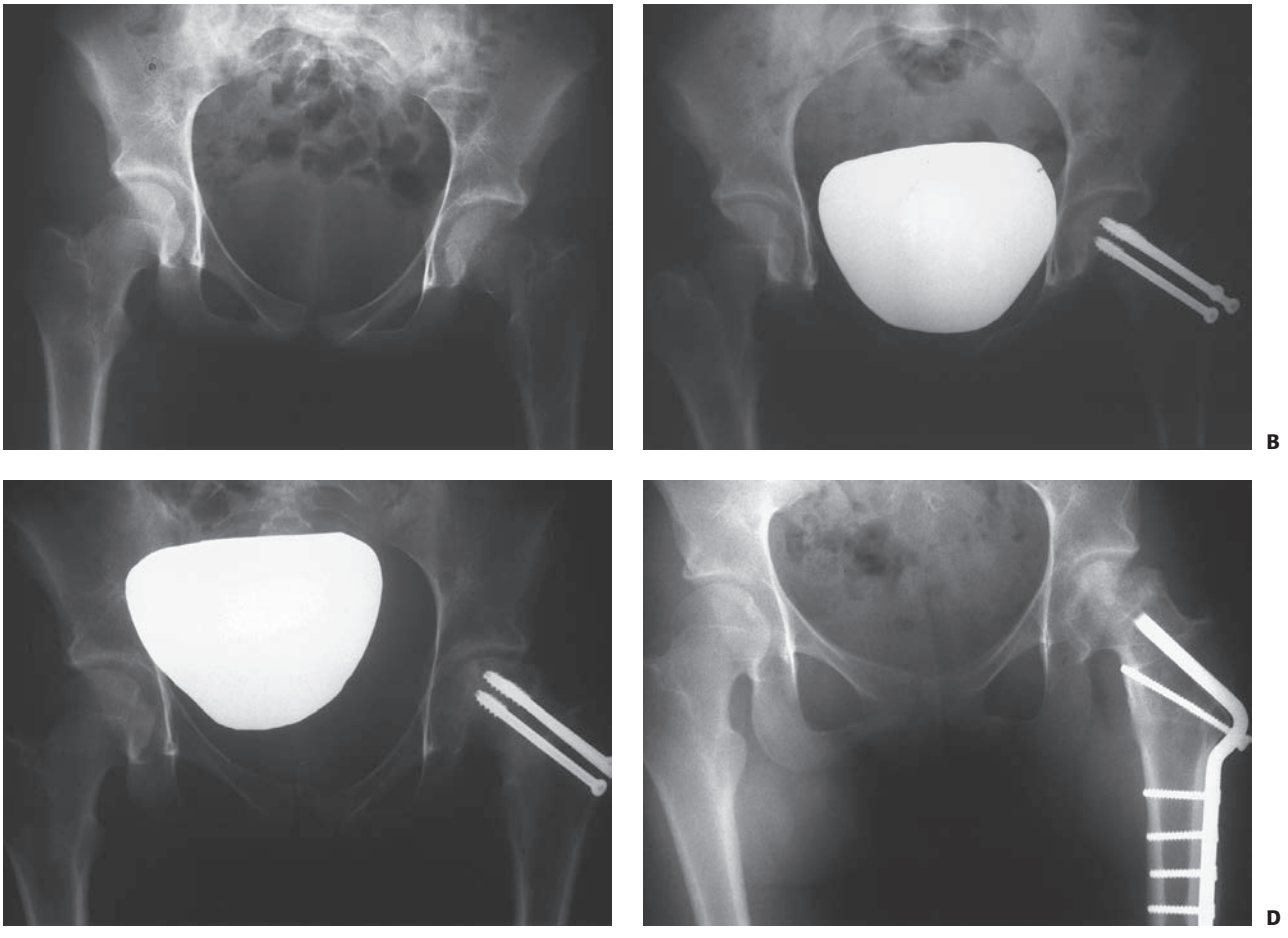

FIGURE 26-11 **A:** A 14-year-old girl with a type II fracture of the left femoral neck. **B:** After fixation with three cannulated screws. **C:** ON with collapse of the superolateral portion of the femoral head. **D:** After treatment with valgus osteotomy.

treated within 24 hours of injury with prompt reduction and internal fixation.[22,37,111] This approach to early reduction and stabilization may decrease ON by preventing further injury to the tenuous blood supply, and open reduction or capsulotomy may decrease intra-articular pressure caused by fracture hematoma.[58,84,112] The later concept has equivocal support in the literature with some papers reporting that aspirating the hematoma may decrease the intracapsular pressure and increase blood flow to the femoral head[22,84]; others suggest that this may have little effect.[58,74,90] A final important factor that may reduce ON is stability and quality of reduction: This is highlighted in a recent 30-year experience of hip fractures from Mayo Clinic.[105] In this paper, ON was associated with inadequate reduction and use of older implant styles, yet timing and adding a capsulotomy was not a factor in ON. In our institution, we recognize that the die may already be cast at the time of injury, but we still advocate emergent anatomic reduction and stabilization of the fracture to reduce risk of ON. ON has been classified by Ratliff as follows: Type I, involvement of the whole head; type II, partial involvement of the head; and type III, an area of necrosis of the femoral neck from the fracture line to the physis (Fig. 26-12).[98] Type I is the most severe and most common form and has the poorest

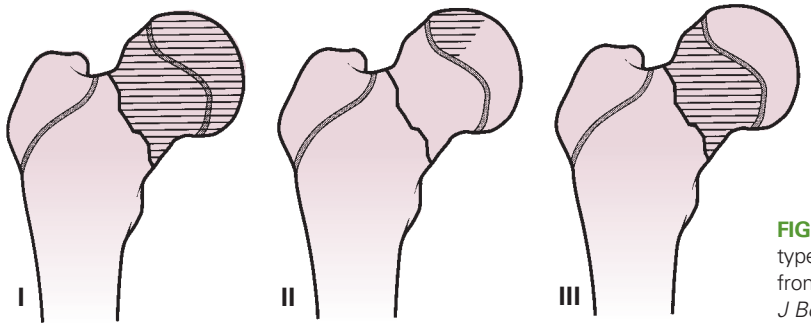

FIGURE 26-12 The three types of ON. Type I, whole head; type II, partial head; and type III, femoral neck. (Reprinted from Ratliff AH. Fractures of the neck of the femur in children. *J Bone Joint Surg Br.* 1962;44:528–542, with permission.)

prognosis. Type I probably results from damage to all of the retinacular epiphyseal vessels, type II from localized damage to one or more of the lateral epiphyseal vessels near their insertion into the anterolateral aspect of the femoral head, and type III from damage to the superior metaphyseal vessels. Type III is rare but has a good prognosis provided the fracture goes on to heal.[98] Signs and symptoms of ON usually develop within the first year after injury, but many patients may not become symptomatic for up to 2 years.[58,97] Some authors have utilized bone scanning for early detection of ON as further collapse may be prevented with use of bisphosphonate therapy. Ramachandran et al.[89] treated 28 patients with early bone scan changes of ON from SCFE or femoral neck fracture. The group was treated with an intravenous bisphosphonate (pamidronate or zoledronate) for an average of 20 months, which greatly improved the outcome at 3-year follow-up.[96] The long-term results of established ON are likely related to age of the patient and extent and location of the necrosis within the head; results are usually poor in over 60% of patients.[19,29,38,87] There is no clearly effective treatment for established posttraumatic ON in children.[58,97] Older children (more than 10 years) tend to have worse outcomes than younger children. Treatment of ON is controversial and inconclusive and is beyond the scope of this text. Ongoing research includes the role of redirectional osteotomy,[71] distraction arthroplasty with external fixation, core decompression, vascularized fibular grafting (Fig. 26-13), and direct bone grafting.

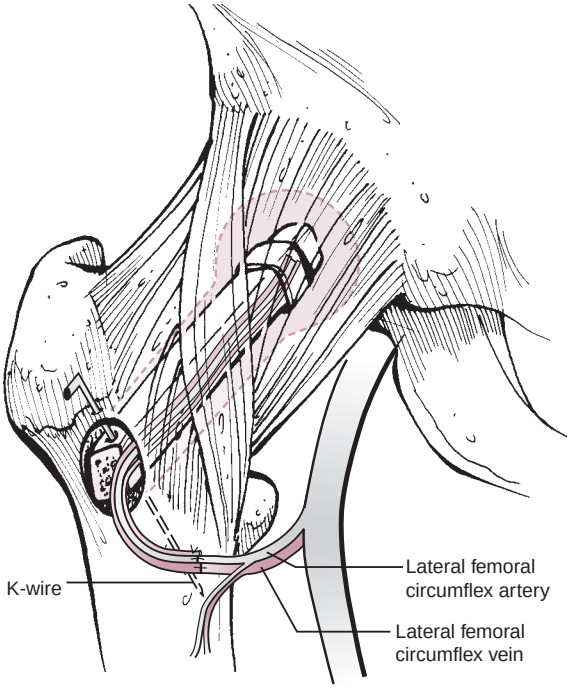

FIGURE 26-13 Vascularized fibular grafting for osteonecrosis of the femoral head. (Redrawn after Aldrich JM III, Berend KR, Gunneson EE, et al. Free vascularized fibular grafting for the treatment of post-collapse osteonecrosis of the femoral head. *J Bone Joint Surg Am.* 2004;86:87–101, with permission.)

Coxa Vara in Hip Fractures

The prevalence of coxa vara has been reported to be approximately 20% to 30% in nine series[58,63]; although it is significantly lower in series in which internal fixation was used after reduction of displaced fractures.[19] Coxa vara may be caused by malunion, ON of the femoral neck, premature physeal closure, or a combination of these problems (Fig. 26-14). Severe coxa vara raises the greater trochanter in relation to the femoral head, causing shortening of the extremity and leading to inefficiency

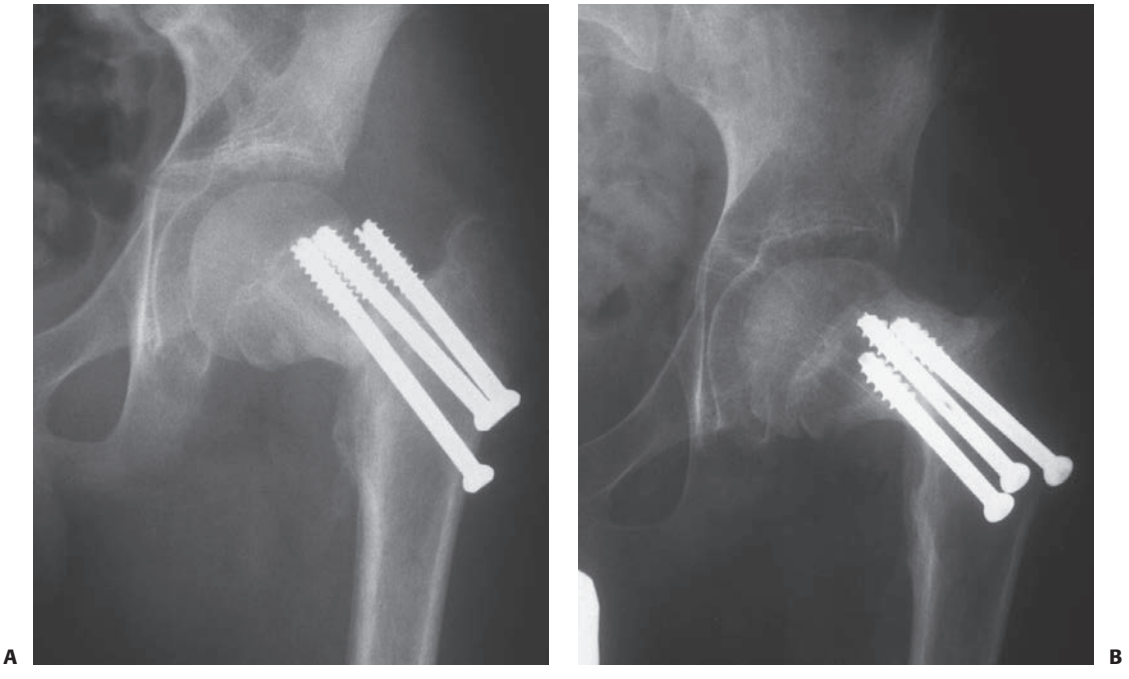

FIGURE 26-14 **A:** A 12-year-old boy with a type III left hip fracture. Poor pin placement and varus malposition are evident. **B:** The fracture united in mild varus after hardware revision.

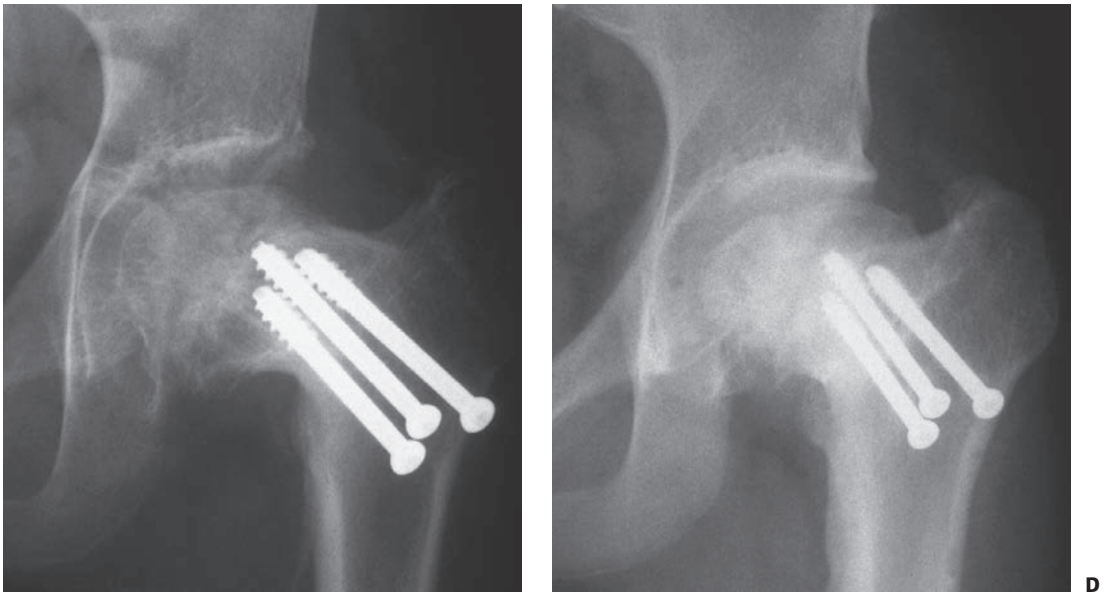
(*continues*)



C D

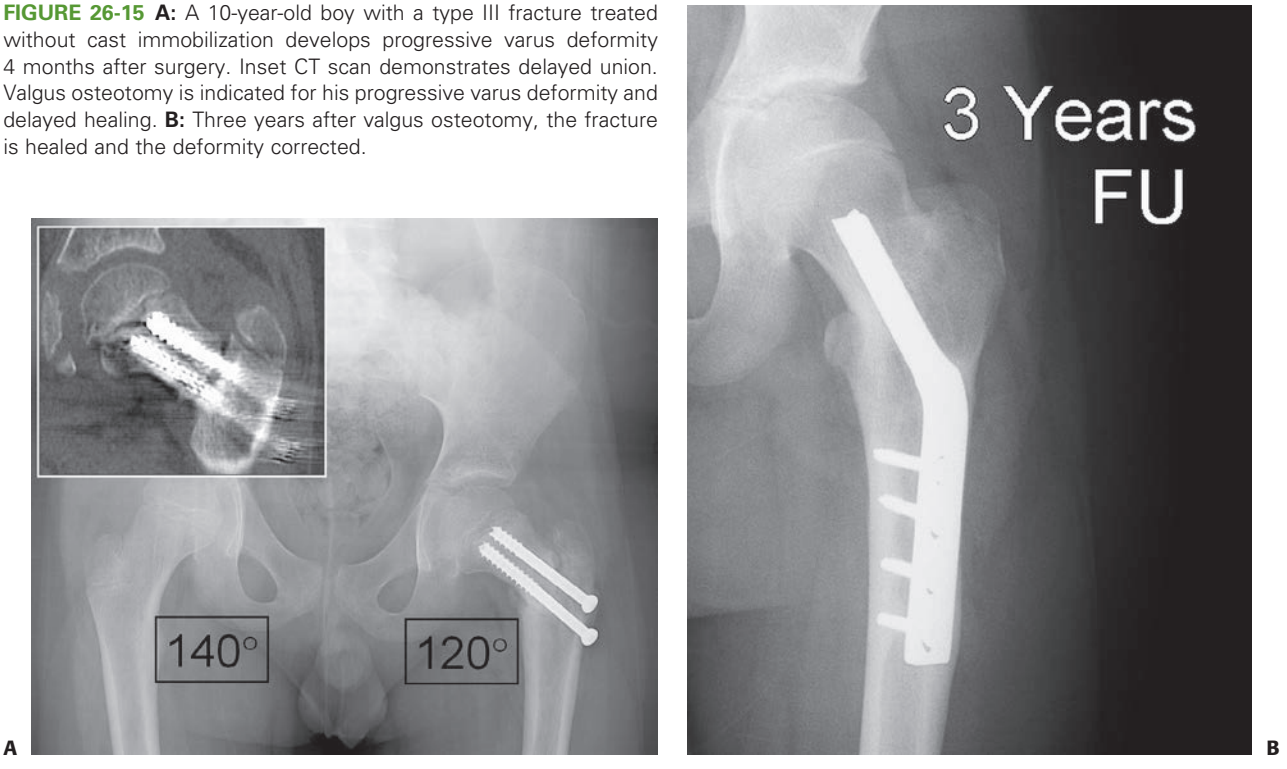
FIGURE 26-14 (*continued*) **C:** Fourteen months after injury, collapse of the weight-bearing segment is evident. **D:** Six years after injury, coxa breva and trochanteric overgrowth are seen secondary to osteonecrosis, nonunion, and premature physeal closure.

of the abductors. Remodeling of an established malunion may occur if the child is less than 8 years, or with a neck–shaft angle greater than 110 degrees. Older patients with progressive deformity may not remodel and subtrochanteric valgus osteotomy may be considered to heal nonunion, and restore limb length and the abductor moment arm (Fig. 26-15).[58,67]

Premature Physeal Closure in Hip Fractures

Premature physeal closure has occurred after approximately 28% of fractures.[58] The risk of premature physeal closure increases with penetration by fixation devices or when ON is present. It is most common in patients who have type II or III ON (Fig. 26-14).[97,98]

FIGURE 26-15 **A:** A 10-year-old boy with a type III fracture treated without cast immobilization develops progressive varus deformity 4 months after surgery. Inset CT scan demonstrates delayed union. Valgus osteotomy is indicated for his progressive varus deformity and delayed healing. **B:** Three years after valgus osteotomy, the fracture is healed and the deformity corrected.



A B

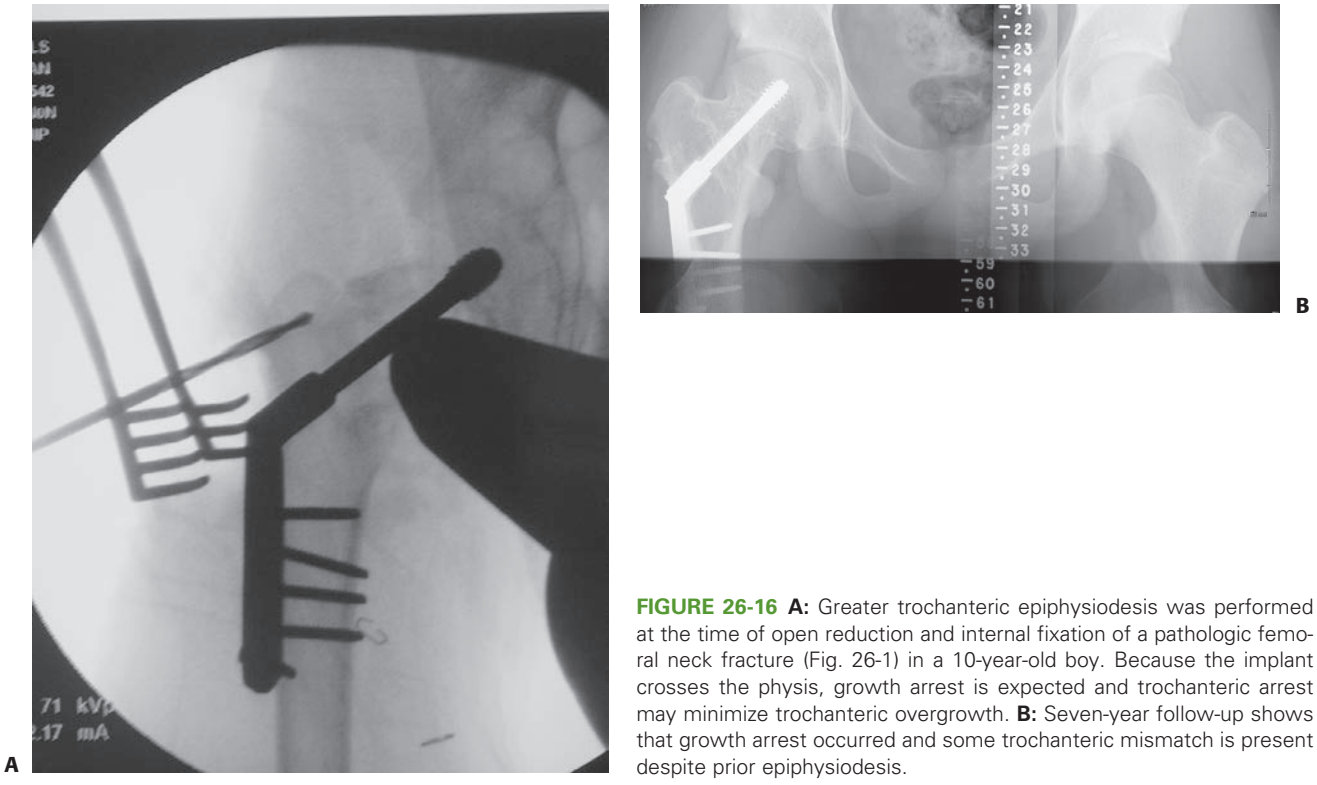


FIGURE 26-16 **A:** Greater trochanteric epiphysiodesis was performed at the time of open reduction and internal fixation of a pathologic femoral neck fracture (Fig. 26-1) in a 10-year-old boy. Because the implant crosses the physis, growth arrest is expected and trochanteric arrest may minimize trochanteric overgrowth. **B:** Seven-year follow-up shows that growth arrest occurred and some trochanteric mismatch is present despite prior epiphysiodesis.

The capital femoral physis contributes only 13% of the growth of the entire extremity and normally closes earlier than most of the other physes in the lower extremity. As a result, shortening because of premature physeal closure is not significant except in very young children.[15,60] Treatment for leg length discrepancy is indicated only for significant discrepancy (2.5 cm or more projected at maturity).[58] If femoral growth arrest is expected because of the implant use or injury to the physis, the surgeon may consider concomitant greater trochanteric epiphysiodesis to maintain a more normal articular trochanteric relationship (Fig. 26-16).

Nonunion in Hip Fractures

Nonunion occurs infrequently, with an overall incidence of 7% of hip fractures in children.[58] Nonunion is a complication seen in types II and III fractures and is not generally seen after type I or type IV fractures. The primary cause of nonunion is failure to obtain or maintain an anatomic reduction.[15,17] After femoral neck fracture in a child, pain should be gone and bridging new bone should be seen at the fracture site by 3 months after injury. A CT scan may be helpful to look for bridging bone. If no or minimal healing is seen by 3 to 6 months, the diagnosis of nonunion is established. Nonunion should be treated operatively as soon as possible. Either rigid internal fixation or subtrochanteric valgus osteotomy should be performed to allow compression across the fracture (Fig. 26-17).[67,68] Because the approach necessary for bone grafting is extensive, it should be reserved for persistent nonunion. Internal fixation should extend across the site of the nonunion, and spica cast immobilization should be used in all but the most mature and cooperative adolescents.

Other Complications in Hip Fractures

Infection is uncommon after hip fractures in children. The reported incidence of 1%[1,8,10] is consistent with the expected infection rate in any closed fracture treated surgically with ORIF. Chondrolysis is exceedingly rare and has been reported only in two series.[5,38] Care must be taken to avoid persistent penetration of hardware into the joint, which can cause chondrolysis in conditions such as SCFE. Finally, SCFE has been reported after fixation of an ipsilateral femoral neck fracture.[59]

Summary, Controversies, and Future Directions Related to Hip Fractures

Pediatric femoral neck fractures have a relatively small incidence of recurrence compared to other lower extremity fractures but the potential for complications is much greater. Except for very young children the majority of these fractures should be treated with ORIF to assure an anatomic reduction. For CRIF to be successful the fracture must be reduced nearly anatomic. Fracture reduction should be done urgently (<24 hours). An anterior approach, anterior lateral approach or surgical dislocation is the chosen approach depending on the surgeon's experience and the type of fracture. Open surgical dislocation allows direct visualization of the fracture and the retinaculum, which may have some beneficial effect on the incidence of AVN but this is yet to be proven. There are a variety of fixation methods

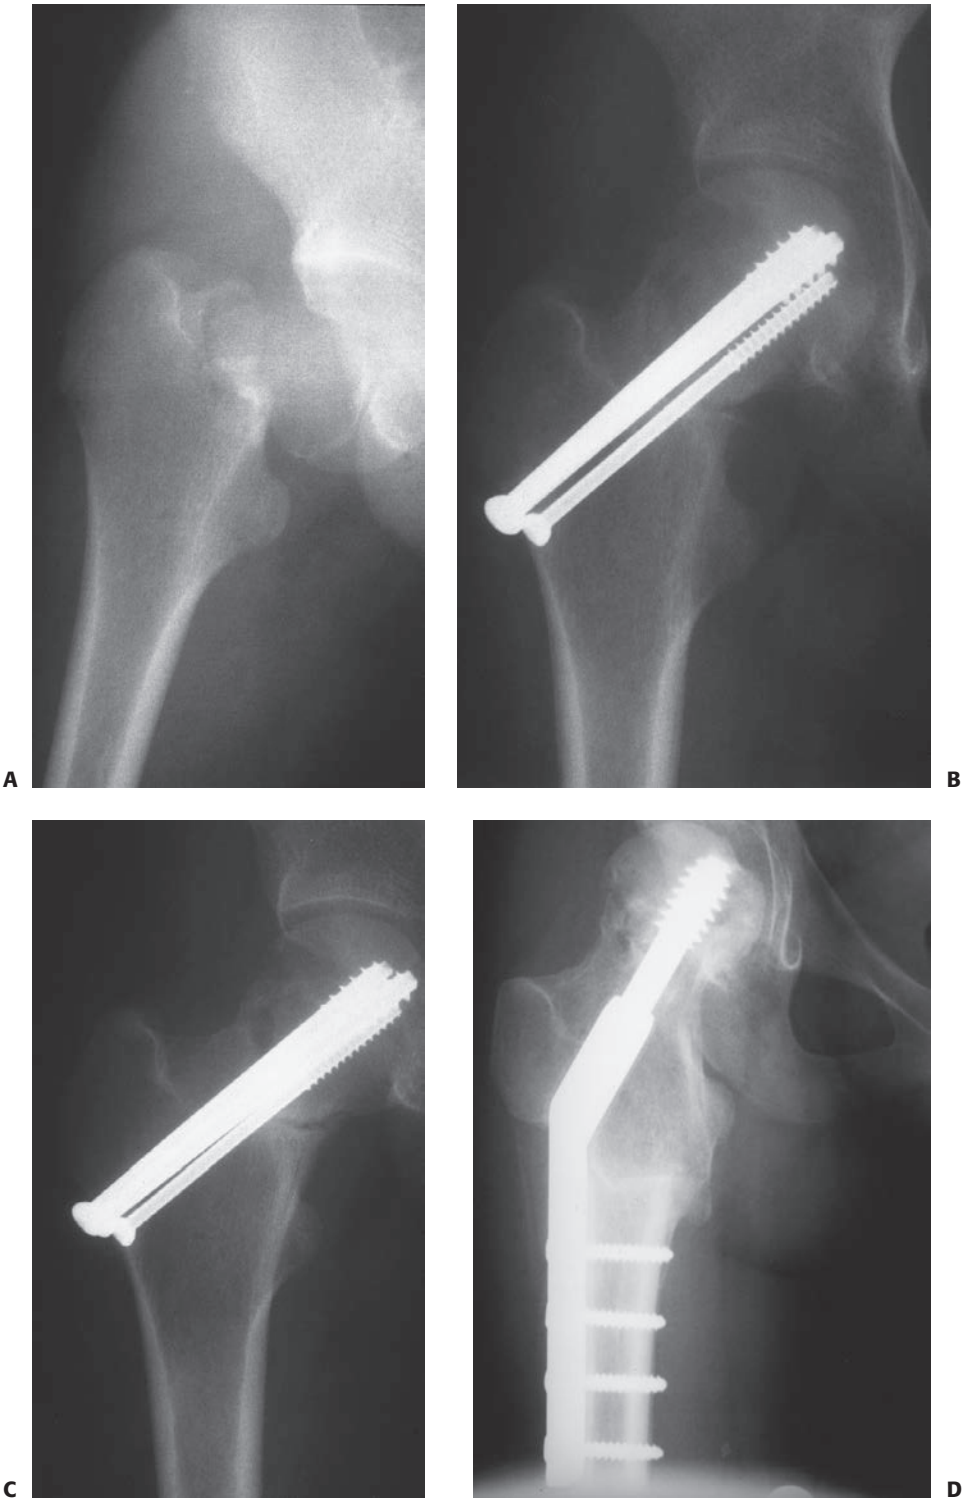

FIGURE 26-17 **A:** A 15-year-old girl with a markedly displaced type II femoral neck fracture. **B:** She underwent open reduction and internal fixation with two 7.3-mm cannulated screws and one 4.5-mm cannulated screw. Primary bone grafting of a large defect in the superior neck was also performed. **C:** Radiograph at 5 months showing a persistent fracture line. **D:** Six weeks after valgus intertrochanteric osteotomy. The fracture is healing.

once the fracture is anatomically reduced. The goal is to avoid fixation across the physis but if the patient is older (>10 to 12 years) or fixation would otherwise be inadequate the rule is to cross the physis as fracture stability and union are more critical. In the future there may be better strategies to manage AVN should it occur.

Stress Fractures of the Femoral Neck

Stress fractures of the femoral neck are extremely uncommon in children, and only a few cases have been published in the English-language literature. In one study of 40 stress fractures in children, there was only one femoral neck stress fracture.[31] The rarity of such fractures underscores the need for a high index of suspicion when a child has unexplained hip pain. The differential can be long for hip pain in children, and early diagnosis and treatment are essential to avoid complete fracture with displacement.

Mechanism

Stress fractures of the femoral neck in children usually result from repetitive cyclic loading of the hip, such as that produced by a new or increased activity. A recent increase in the repetitive activity is highly suggestive of the diagnosis. An increase in intensity of soccer,[12] and an increase in distance running are examples of such activities. Younger children often present with a limp or knee pain and may not have a clear history of increased activity.[70] Underlying metabolic disorders or immobilizations that weaken the bone may predispose to stress fracture. There is the increased awareness of vitamin D deficiency in children that may predispose to a femoral neck stress fracture.[83] In adolescent female athletes, amenorrhea, anorexia nervosa, and osteoporosis have been implicated in the development of stress fractures of the femoral neck.[49]

The usual presentation is that of progressive hip or groin pain with or without a limp. The pain may be perceived in the thigh or knee and may be mild enough so that it does not significantly limit activities. In the absence of displacement, examination typically reveals slight limitation of hip motion with increased pain, especially with internal rotation. Usually plain radiographs reveal the fracture, but in the first 4 to 6 weeks after presentation, plain films may be negative. If there are no changes or only linear sclerosis, a bone scan will help identify the fracture. MRI has been documented as a sensitive test for undisplaced fractures of the femoral neck. If a sclerotic lesion is seen on plain radiographs, the differential diagnosis should include osteoid osteoma, chronic sclerosing osteomyelitis, bone infarct, and osteosarcoma. Other causes of hip pain, include SCFE, Legg–Calvé–Perthes disease, infection, avulsion injuries of the pelvis, eosinophilic granuloma, and bony malignancies. Stress fractures unrelieved by rest or treatment may progress with activity to complete fracture with displacement.[113] For this reason, prompt diagnosis and treatment are important.

Classification

Femoral neck stress fractures have been classified into two types: Compression fractures and tension fractures.[31] The compression type appears as reactive bone formation on the inferior cortex without cortical disruption. This type rarely becomes completely displaced but may collapse into a mild varus deformity,[33] and compression types have been reported to progress to complete fracture without early treatment (Fig. 26-18).[113] The tension type is a transverse fracture line appearing on the superior portion of the femoral neck. This type is inherently unstable because the fracture line is perpendicular to the lines of tension. Tension stress fractures have not been reported in children but may occur in skeletally mature teenagers.[113]

Treatment

Compression-type fractures generally can be treated with a period of nonweight bearing on crutches. Partial weight bearing can be allowed at 6 weeks with progression to full weight bearing at 12 weeks provided that the pain is resolved and there

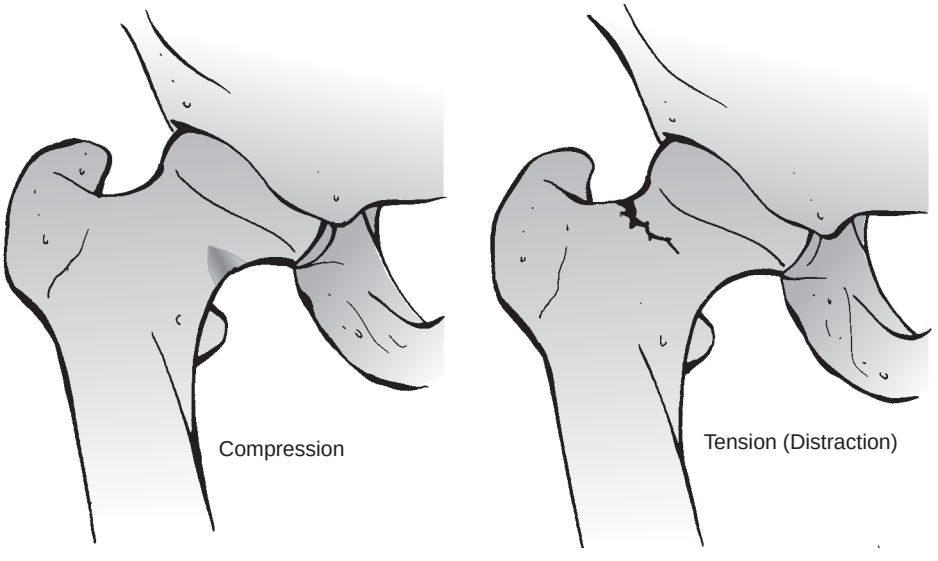

FIGURE 26-18 A line drawing of stress fractures, comparing compression **(A)** and tension **(B)** types.

is radiographic evidence of healing. Close follow-up and careful evaluation is mandatory to insure that the fracture heals without propagation. Underlying conditions should be evaluated and addressed. In small or uncooperative children, spica casting may be necessary. Displacement into varus, however minimal, mandates internal fixation. Tension fractures are at high risk for displacement and should be treated with in situ compression fixation using cannulated screws.

Complications

Coxa vara is the most common complication of untreated compression-type fractures. Acute displacement of this type also has been described.[95] Once displaced, the stress fracture is subject to all the complications of type II and type III displaced femoral neck fractures.

Introduction to Hip Dislocations in Children

Traumatic hip dislocations are uncommon injuries in children, constituting less than 5% of pediatric dislocations.[69] In one study, the author identified only 15 cases over a 20-year period at a large trauma center.[4] The character of the injury tends to vary in those children under age 6 commonly suffer isolated hip dislocation from a low-energy injury, whereas older children require a high-energy mechanism to dislocate the hip, and these injuries are often associated with more severe trauma.[4,8,41,48,88,103] Most hip dislocations in children can be reduced easily, and long-term outcome is generally good with prompt and complete reduction. Delay in reduction or neglected dislocations routinely do poorly, with a high incidence of AVN.[7,10] Incomplete reductions can occur from interposed soft tissue or bony fragments, and postoperative imaging is mandatory to insure complete reduction.[23,73] Difficult reductions or those that occur during the early teenage years (with a widened proximal femoral physis) should be performed with anesthesia, muscle relaxation, and the use of fluoroscopy to ensure that physeal separation does not occur.[55,87] Open reduction may be needed if the hip cannot be reduced or if there is a femoral head fracture or an incarcerated fragment. Incomplete reductions may be treated open or arthroscopically.[64] Complications, although uncommon, may occur, and these patients should be closely followed for recurrent subluxation, dislocation, and AVN.[4,9,48,103]

Assessment of Hip Dislocation in Children

Mechanisms of Injury for Hip Dislocations in Children

The mechanism of injury in children with hip dislocation varies. Posterior hip dislocations are the most common[8,103,107] and generally occur when a force is applied to the leg with the hip flexed and slightly adducted (Fig. 26-19). Anterior dislocations comprise fewer than 10% of hip dislocations (Fig. 26-20).[4,103] Anterior dislocations can occur superiorly or inferiorly and result from forced abduction and external rotation. If the hip is extended while undergoing forced abduction and external rotation, it will dislocate anteriorly and superiorly; if the hip is flexed while abducted and externally rotated, the femoral head tends to dislocate anteriorly and inferiorly. In very rare cases, the femoral head may dislocate directly inferiorly, a condition known as luxatio erecta femoris or infracotyloid dislocation. Although this condition is extremely rare, it tends to occurs more commonly in children than adults.[101]

FIGURE 26-19 A typical posterior dislocation of the hip.

In younger children, hip dislocations can occur with surprisingly little force, such as a fall while at play. The mechanism for hip dislocations in older children and adolescents is similar to that of adults in that significant trauma is needed. In a French study,[4] the authors assessed children with hip dislocations and divided them into two groups by age: Those under 6 years (seven patients) and those aged 6 and older (seven patients). All the children under age 6 group had low-energy mechanisms and isolated hip dislocations without other injuries, but often had predisposing factors, such as hyperlaxity, coxa valga, or decreased acetabular coverage (Fig. 26-21). In the over 6-year-old group, all the dislocations were a result

FIGURE 26-20 An anterior (inferior) dislocation of the hip.

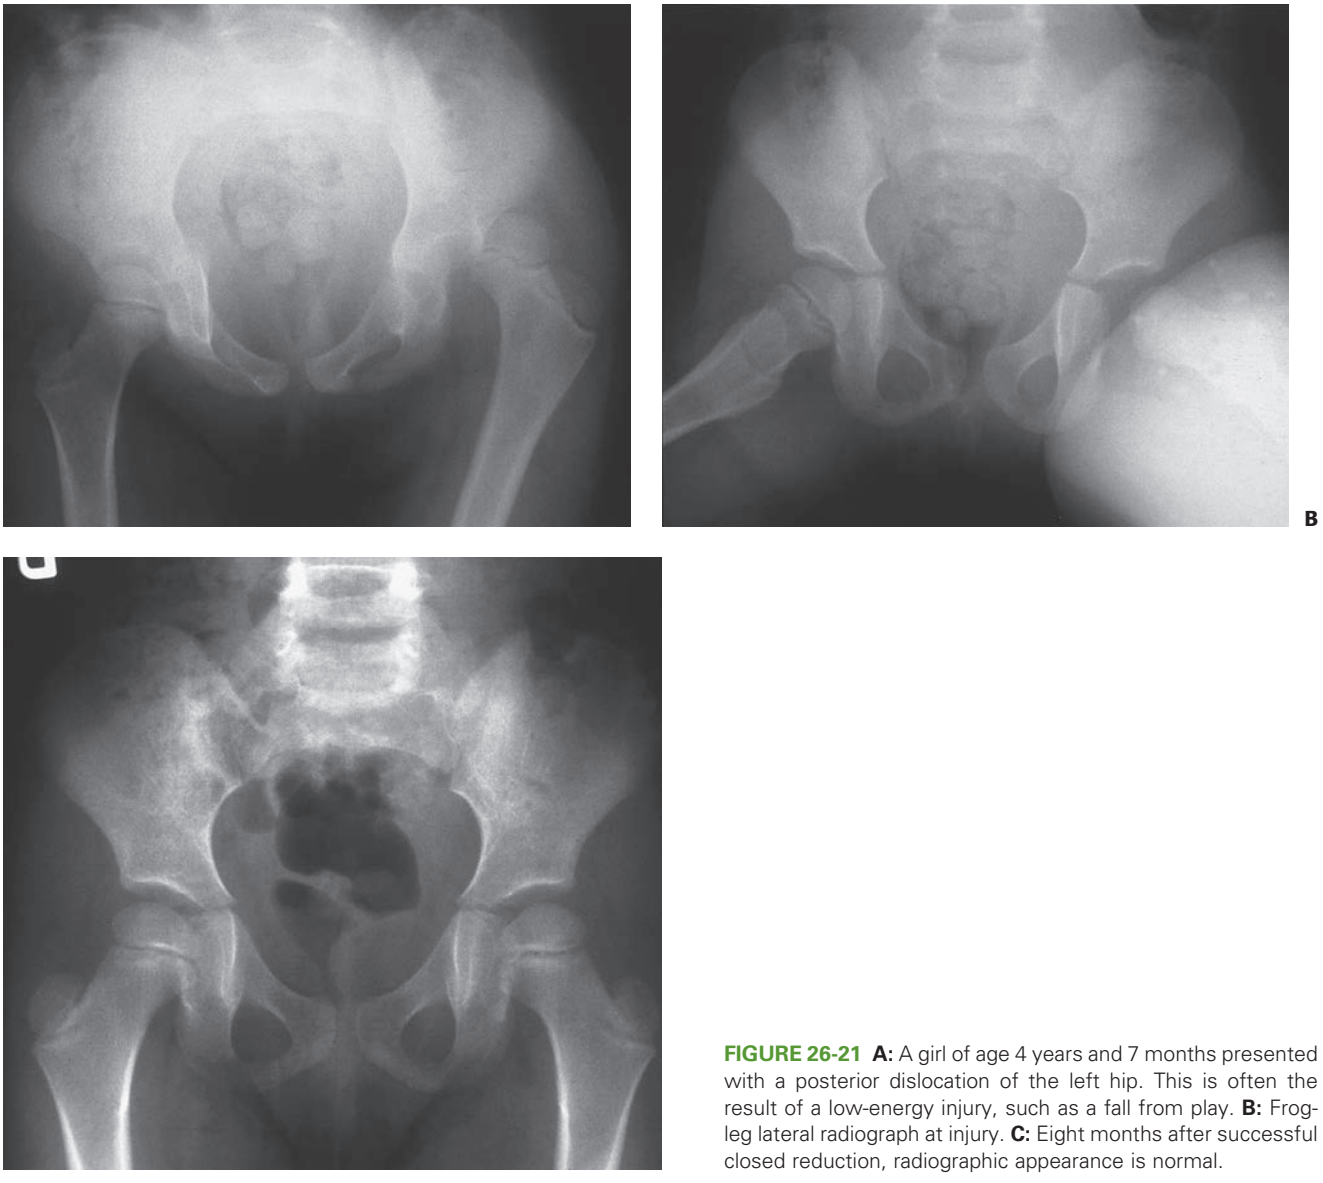

FIGURE 26-21 **A:** A girl of age 4 years and 7 months presented with a posterior dislocation of the left hip. This is often the result of a low-energy injury, such as a fall from play. **B:** Frog-leg lateral radiograph at injury. **C:** Eight months after successful closed reduction, radiographic appearance is normal.

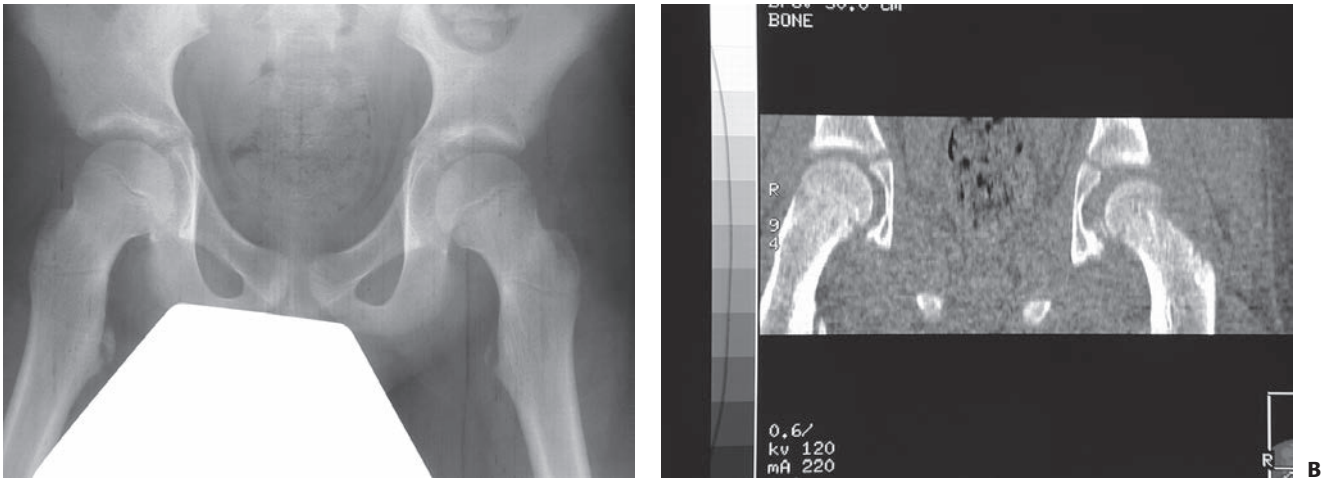
of higher-energy injuries and often had associated injuries.[4] Football and motor vehicle accidents are the most common etiology, combining for over 50% of the dislocations in older children and adolescents.[75,76]

Associated Injuries with Hip Dislocations in Children

Older children with dislocations due to a high-energy mechanism of injury often present with associated injuries. In one study of 42 patients, there were 17 fractures in nine patients and one closed head injury. Of the 17 fractures, 6 were posterior acetabular wall factures and 1 required ORIF.[76] Careful evaluation of this injury in younger children with MRI is important because standard radiographic assessments and CT may underestimate the size of the fragment.[100] Posterior dislocations of the femoral head can result in injury to the sciatic nerve in about 10% of adults and 5% of children. Partial recovery occurs in 60% to 70% of patients.[27] The function of the sciatic nerve should be specifically tested at the time of the initial assessment and after reduction.

Anterior dislocations can damage the femoral neurovascular bundle, and femoral nerve function and perfusion of the limb should be assessed. Tears of the capsule or acetabular labrum occur and prevent concentric reduction of the hip. Postreduction imaging must be carefully evaluated to ensure that there is no interposed soft tissue, such as the labrum or capsule, or osteochondral fragments. Rupture of the ligamentum teres is common in hip dislocations and can rarely be a cause of residual pain in some patients.[17]

In addition, ipsilateral knee injuries commonly occur in high-energy injuries. One study evaluated the ipsilateral knees in 28 adults who had a traumatic hip dislocation and found



A B

FIGURE 26-22 Spontaneously reduced left hip but with persistent pain. The joint space on the left is widened **(A).** The CT scan shows interposed soft tissue in the left hip **(B).**

that 75% had knee pain and 93% had MRI evidence of a knee injury; effusion, bone bruise, and meniscal tears were the most common findings.[104]

Signs and Symptoms of Hip Dislocations in Children

The injured child has pain and inability to ambulate. Children sometimes feel the pain in the knee rather than in the hip. The hallmark of the clinical diagnosis of dislocation of the hip is abnormal positioning of the limb, which is not seen in fracture of the femur. Dislocations may spontaneously reduce, leaving the child with an incompletely reduced hip that is commonly misdiagnosed. Price et al.[88] reported on three children who presented with a history of trauma and an incongruous hip. In all cases, the diagnosis was originally missed.[94]

Imaging and Other Diagnostic Studies for Hip Dislocations in Children

Plain radiographs combined with the physical examination as described above usually confirm the diagnosis of a dislocated hip. Traumatic dislocations with spontaneous reductions may be more subtle and are often missed. Radiographs should be examined for fracture of the acetabular rim and proximal femur, which may be associated with dislocation. Any asymmetry of the joint space (Fig. 26-22), as compared to the contralateral hip, is a common finding with interposed tissue. MRI or CT scanning is useful for evaluating the acetabulum and may be useful in localizing intra-articular bony fragments or soft tissue interposition after reduction.[54,73,76] The identification of nonbony fragments is difficult by CT without the use of concomitant arthrography.[54] MRI is useful for evaluating soft tissues that may be interposed between the femoral head and acetabulum and has an advantage over plain radiographs and CT scan to detect cartilage fractures and defects prior to complete ossification of the acetabulum.[53] MRI is especially helpful in nonconcentric reductions when the initial direction of dislocation is unknown, and in younger children with less bone ossification (Fig. 26-23).[73,100]

Spontaneous reduction may occur after hip dislocation,[81,91,94] and the diagnosis is commonly missed if it is not considered. The presence of air in the hip joint, which may be detectable on CT scan of the pelvis, is evidence that a hip dislocation has occurred.[36] Dislocation and spontaneous reduction with interposed tissue can occur and lead to late arthropathy if untreated.[91] Widening of the joint space on plain radiographs suggests the diagnosis. In patients with hip pain, a history of trauma, and widening of the joint space, consideration should be given to MRI to rule out dislocation with spontaneous relocation incarcerating soft tissue. If incarcerated soft tissues or osseous cartilage fragments are found, open or arthroscopic removal is required to obtain concentric reduction of the hip.[64]

Classification of Hip Dislocations in Children

Hip dislocations in children are generally classified depending on where the femoral head lies in relation to the pelvis, namely posterior, anterior-superior, anterior-inferior, or infracotyloid.[61] The dislocation is posterior more than 90% of the time. The Stewart–Milford classification is based on associated fractures. Grade I is defined as dislocation without an associated fracture or only a small bony avulsion of the acetabular rim, grade II is a posterior rim fracture with a stable hip after reduction, grade III is a posterior rim fracture with an unstable hip (Fig. 26-24), and grade IV is a dislocation that has an associated fracture of the femoral head or neck.

Fracture-dislocation of the hip involving the femoral head or the acetabulum is much more unusual in children than in adults. Older adolescents may sustain adult-type fracture dislocations of the hip, and these are most commonly classified by the methods of Pipkin.[92] He classified the head fractures as occurring either caudal to the fovea with a resultant small

FIGURE 26-23 Right hip pain after a fall. The plain film shows no significant abnormality at time of injury **(A).** Persistent pain prompted an MRI 2 months after injury, which showed an interposed labrum in the joint **(B, C).**

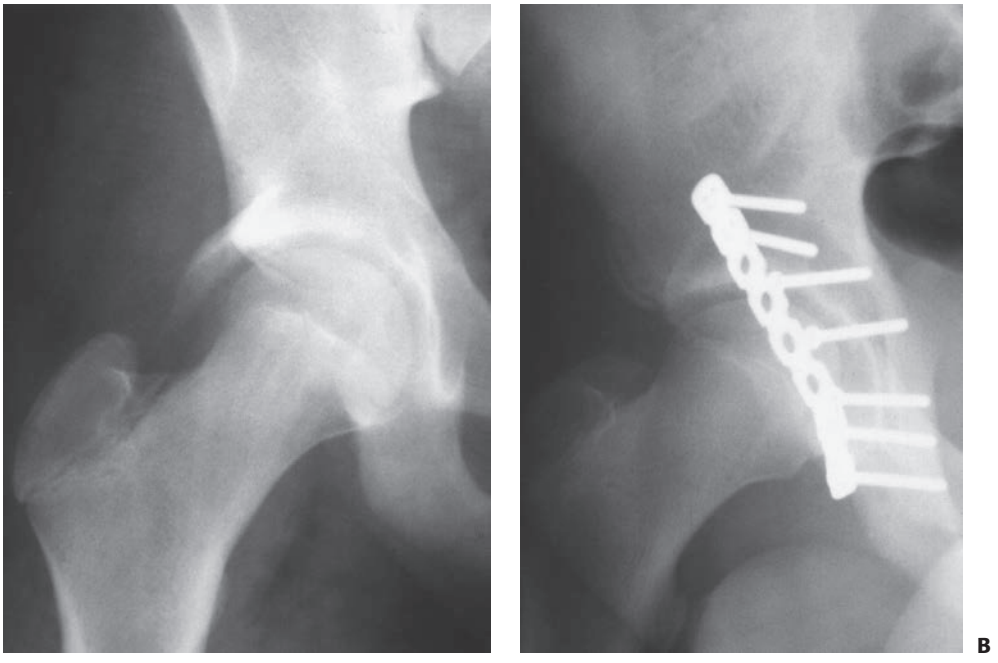


FIGURE 26-24 A: A 12-year-old boy was tackled from behind in football. The right hip was dislocated. Reduction was easily achieved, but the hip was unstable posteriorly as a result of fracture of the posterior rim of the acetabulum. This is the most common fracture, occurring with hip dislocation. **B:** The fracture and capsule were fixed via a posterior approach.

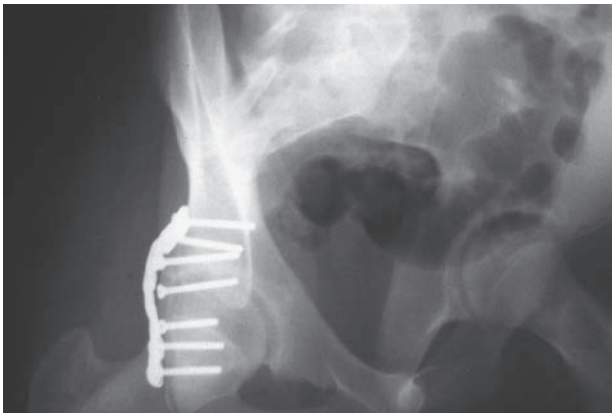
(*continues*)



C

FIGURE 26-24 (*continued*) **C:** Oblique view shows reconstitution of the posterior rim.

fragment (type 1) (see Fig. 21-24, Fig. 26-25), cranial to the fovea with a resultant large fragment (type 2), any combined femoral head and neck fracture (type 3), and any femoral neck fracture with an acetabular fracture (type 4). *The youngest patient in his series from* 1957 was 20, and most of these fractures were because of the relatively new phenomena of traffic accidents.

Habitual dislocation of the hip has been described in children. In this condition, the child can actually voluntarily dislocate the hip. Many factors may contribute to this ability, including generalized ligamentous laxity or hyperlaxity disorders, excessive anteversion of the femur and acetabulum, and coxa valga.[110] A commonly confused condition is snapping of the iliotibial band over the greater trochanter, and often the patient will describe this as "dislocating their hip." Yet, the hip remains well seated both before and after the snap, which can be quite dramatic. The more common iliotibial band snapping can usually be differentiated from a true hip dislocation by examination, or if needed, radiographs with the hip "in" versus "out." A snapping iliotibial band will demonstrate a well-seated hip on both radiographs.

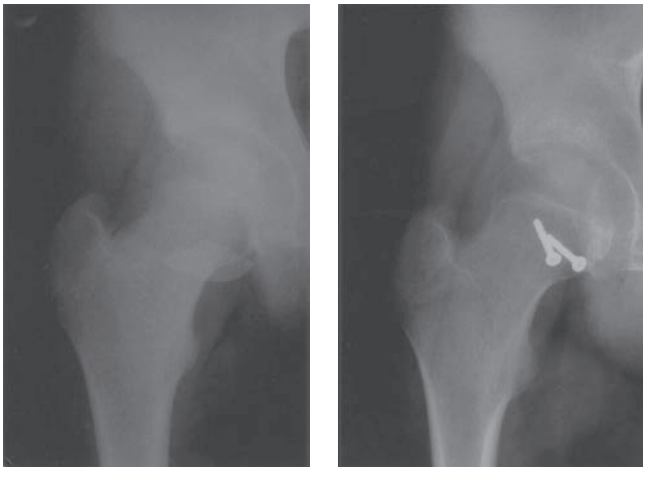


FIGURE 26-25 **A:** A posterior dislocation associated after reduction with a femoral head fracture caudal to the ligamentum teres (Pipkin type 2). This is uncommon in children. This was treated with open reduction and internal fixation, with follow-up radiographs taken 1 year after the injury **(B).**

Pathoanatomy and Applied Anatomy Relating to Hip Dislocations in Children

The hip joint is a synovial ball and socket joint formed by the articulation of the rounded head of the femur and the cup-like acetabulum of the pelvis. If this is injured early in childhood, the growth of the acetabulum can be affected and result in acetabular dysplasia[14,108] or impingement.[42,47,86]

Treatment Options for Hip Dislocations in Children

The immediate goal in the treatment of a dislocated hip is to obtain concentric reduction as soon as possible. Reduction of a pediatric or adolescent hip dislocation should be considered an orthopedic emergency. Generally, closed reduction should be attempted initially. Successful closed reduction can be achieved with intravenous or intramuscular sedation in the emergency room in many patients.[99] However, there is a risk of separating the femoral epiphysis from the femoral neck. Hence, complete muscle relaxation and the ability to urgently open the hip is often helpful, and this is best provided in the operating room with a general anesthetic. Open reduction is indicated if closed reduction is unsuccessful or incomplete. In children, especially in their early teenage years, cases of proximal physeal separation with attempted closed reduction have been reported, and therefore, the uses of fluoroscopy to assess the stability of the proximal femoral physis is highly recommended.[55,87]

Several methods of closed reduction have been described for reduction of posterior dislocations. With any type of dislocation, traction along the axis of the thigh coupled with gentle manipulation of the hip often affects reduction after satisfactory relaxation of the surrounding muscles.

Allis[30] described a maneuver in which the patient is placed supine and the surgeon stands above the patient. For this reason, either the patient must be placed on the floor or the surgeon must climb onto the operating table. The knee is flexed to relax the hamstrings. While an assistant stabilizes the pelvis, the surgeon applies longitudinal traction along the axis of the femur and gently manipulates the femoral head over the rim of the acetabulum and back into the acetabulum.

The gravity method of Stimson[106] entails placing the patient prone with the lower limbs hanging over the edge of a table. An assistant stabilizes the patient while the surgeon applies gentle downward pressure with the knee and hip flexed 90 degrees, in an attempt to pull the femoral head anteriorly over the posterior rim of the acetabulum and back into the socket. Gentle internal and external rotations may assist in the reduction.

Operative Treatment of Hip Dislocation in Children

If satisfactory closed reduction cannot be obtained using reasonable measures or the reduction is not concentric because of bone/soft tissue, it is appropriate to proceed with open reduction and inspection of the joint, to remove any obstructing soft tissues, and identify intra-articular osteochondral fragments. The approach for open reduction is the approaches discussed in the prior section (anterior, posterior, surgical dislocation) dependent on the direction of dislocation and surgeon experience. Surgeons with extensive hip arthroscopic experience can perform arthroscopic treatment of interposed soft tissue limiting a concentric reduction. In a nonreducible hip, imaging can be performed prior to reduction but it should not delay treatment. As mentioned previously, children in their early teenage years, cases of proximal physeal separation with attempted closed reduction have been reported, and therefore, the uses of fluoroscopy to assess the stability of the proximal femoral physis is highly recommended.[55,87]

Author's Preferred Treatment for Hip Dislocations in Children

Urgent closed reduction by applying traction in line with the femur and gently manipulating the femoral head back into the acetabulum should be performed. A controlled reduction with sedation or general anesthesia and muscle relaxation in the operating room is preferable, and aggressive techniques should not be attempted without muscle relaxant. The use of fluoroscopy to monitor the reduction, especially in children over 12 with open physis, is important to insure that proximal femoral epiphysiolysis does not occur. Surgery is indicated for dislocations that are irreducible or for nonconcentric reductions. We recommend and MRI should be considered after reduction to assess for interposing fragments of bone, cartilage, or soft tissue.

Surgical Procedures

Open reduction of a posterior dislocation should be performed through a posterolateral (Kocher–Langenbeck) approach or surgical dislocation approach. For the Kocher–Langenbeck approach the patient is positioned in the lateral decubitus position with the dislocated side facing up. The incision is centered on and just posterior to the greater trochanter and goes up into the buttock. Generally, a straight incision can be made with the hip flexed approximately 90 degrees. Once the fascia lata is incised, the femoral head can be palpated beneath or within the substance of the gluteus maximus muscle. The fibers of the gluteus maximus can then be divided by blunt dissection, exposing the dislocated femoral head. The path of dislocation is followed through the short external rotator muscles and capsule down to the acetabulum. The sciatic nerve lies on the short external rotators and should be identified and inspected. The piriformis may be draped across the acetabulum, obstructing the view of the reduction. It may be necessary to detach the short external rotators to see inside the joint. After the joint is inspected, repair of the fracture of the posterior acetabular rim can be performed in the standard fashion.

Anterior dislocations should be approached through an anterior approach. This can be done through a bikini incision that uses the interval between the sartorius and the tensor fascia lata. The deep dissection follows the defect created by the femoral head down to the level of the acetabulum.

A surgical dislocation approach would be particularly useful for hips that are reduced and are not concentric. The approach was described in detail with the last section. Patients are placed in the lateral decubitus position. The tensor fascia is opened distal to the trochanter and fascia proximal to the trochanter is incised on the anterior border of the gluteus maximus (Gibson modification). A trochanteric osteotomy is performed 10 to 15 mm in depth from anterior to the tip of the greater trochanter to the posterior portion of the vastus lateralis insertion. The capsule is exposed by elevation of the gluteus minimus along with the gluteus medius, vastus lateralis, vastus intermedius, and the mobilized trochanteric fragment. The dissection is performed anterior to the piriformis tendon and facilitated by flexion and external rotation of the hip. Once the capsule is exposed a capsulotomy is performed in a "z" fashion with the posterior border of the capsulotomy along the acetabular edge to protect the retinacular vessels. Placing the leg in a sterile anterior leg bag should easily dislocate the hip. The epiphysis should be provisionally pinned with a smooth K-wire if there is any concern of epiphysiolyis.

The femoral head and acetabulum should be inspected for damage. Any small intra-articular fragments should be removed. The labrum and capsule should be inspected for repairable tears. Labral fragments that cannot be securely replaced should be excised, but repair should be attempted. Frequently, the labrum or hip capsule is entrapped in the joint. In the anterior approach the femoral head should be dislocated and any interposed soft tissue extracted. A Schanz screw or bone hook may be needed to displace the femur enough to see inside the joint in the anterior approach. Any bony fragments displaced from the femoral head of the acetabulum should have reduction and fixation if the size is significant. In younger hips the cartilaginous labral–chondral junction may be displaced from the bony rim. Suture anchor repair through the base of the labrum should be performed.

The hip joint is then reduced under direct vision. The capsule should be repaired and in surgical dislocation the greater trochanter is reduced and secured with screws. Postreduction radiographs should be taken to confirm concentric reduction. If the joint appears slightly widened, repeat investigation is indicated to rule out interposed tissue. Slight widening may be because of fluid in the hip joint or decreased muscle tone, and this may improve over the next few days.

Open injuries should be treated with immediate irrigation and debridement. The surgical incision should incorporate and enlarge the traumatic wound. Inspection should proceed as detailed above. Capsular repair should be attempted if the hip

joint is not contaminated. The wound should be left open or should be well drained to prevent invasive infection. As in all open fractures, intravenous antibiotics should be administered and patients should be screened for tetanus.

After reduction, a short period of immobilization should be instituted. In younger children, a spica cast can be used for 4 to 6 weeks; older cooperative children can be treated with hip abduction orthosis, total hip precautions and gradually return to ambulation with crutches.[48,96,99]

Potential Pitfalls and Preventative Measures (Table 26-7)

TABLE 26-7 Hip Fractures

Potential Pitfalls and Prevention

Pitfalls	Preventions
Pitfall #1: Osteonecrosis	Prevention 1a: Urgent reduction Prevention 1b: Decompress the hip capsule by opening the hip capsule.
Pitfall #2: Noncentric reduction	Prevention 2a: Postreduction imaging with a CT or an MRI. In younger children the impediments to a concentric reduction may be cartilaginous, therefore, an MRI would be preferred over a CT scan Prevention 2b: Open hip reduction to remove or fix impediments to a concentric reduction. Prevention 2c: Athroscopic fixation or removal of soft tissue impediments to a concentric reduction.
Pitfall #3: Epiphysiolyis	Prevention 3a: In older children with an open physis it is critical to assure the physis is intact prior to reduction, and gentle reduction should be performed under general sedation and muscle relation with fluoroscopic evaluation to lessen the chance of the epiphysis separating from the metaphysis during the reduction. Prevention 3b: None

- Reduce the hip urgently. The most devastating outcome is ON, and prolonged time to reduction (more than 6 hours) appears to be the greatest risk factor. In multitrauma patients, this concept needs to be expressed to the trauma team so that it can be prioritized properly.
- Look for associated fractures and other injuries. In older children, it is important to evaluate the posterior rim of the acetabulum after posterior dislocation to rule out fracture. Relying on plain radiographs and CT may underestimate the extent of damage to the posterior wall of the acetabulum in children because of the incomplete ossification of the pediatric bone. MRI may be required to adequately assess the posterior wall of the acetabulum in children.[100]
- Fractures at other sites in the femur must be considered. It is important to obtain radiographs that show the entire femur to rule out ipsilateral fracture. Careful evaluation of the entire patient is needed especially for high-energy injuries that result in a hip dislocation in older children and adults.
- Separation of the capital femoral epiphysis and femoral neck fracture has been reported in association with dislocation of the hip and the attempted reduction. Children in their early teenage years, aged 12 to 16, should have reduction performed with fluoroscopy under general anesthesia when possible. This strategy may avoid the possibility of displacing the proximal femoral epiphysis (with attendant increased ON risk) during attempted closed reduction (Fig. 26-26).
- Spontaneous relocation of a dislocation of the hip may occur with subsequent soft tissue or osteocartilaginous interposition. Failure to appreciate the presence of hip dislocation may lead to inadequate treatment. Traumatic hip subluxation may go undetected or may be treated as a sprain or strain if the diagnosis is not considered.[81,94] After dislocation and spontaneous reduction, soft tissue may become interposed in the hip joint potentially resulting chronic arthropathy. In a child with posttraumatic hip pain without obvious deformity, the possibility of dislocation–relocation must be considered.
- Always image the hip for evaluation of interposed tissue after reduction. The incidence of widened joint space after hip reductions is as high as 26%.[73] After reduction, hemarthrosis may initially cause the hip joint to appear slightly wider on the affected side, but this should decrease after a few days. If the hip fails to appear concentric, the possibility of interposed soft tissue must be considered and MRI or CT scan should be performed.[44,51,91,99,109]
- Long-term follow-up is important in children who undergo hip dislocation. Injury to the triradiate cartilage may cause acetabular dysplasia with growth.[13] ON, although uncommon, may lead to early arthrosis, and this may not be identified radiographically for several years. If there has been a significant delay in time to reduction or the patient is otherwise at higher risk for ON, then consideration of a bone scan or MRI to evaluate for ON may be warranted, especially if early treatment with bisphosphonates is considered.

Management of Expected Adverse Outcomes and Unexpected Complications Related to Hip Dislocations in Children

ON occurs in about 10% of hip dislocations in children (Fig. 26-27).[45,76,85,107] Urgent relocation may decrease the incidence of this complication.[41,76,107] The risk of ON is probably also related to the severity of initial trauma.[107] If the force of hip dislocation is so strong as to disrupt the obturator externus muscle, the posterior ascending vessels may be torn.[85] In the rare case of dislocation with an intact capsule, increased intracapsular pressure as a result of hemarthrosis may have a role in developing ON.[99] The type of postreduction care has not been shown to influence the rate of ON.

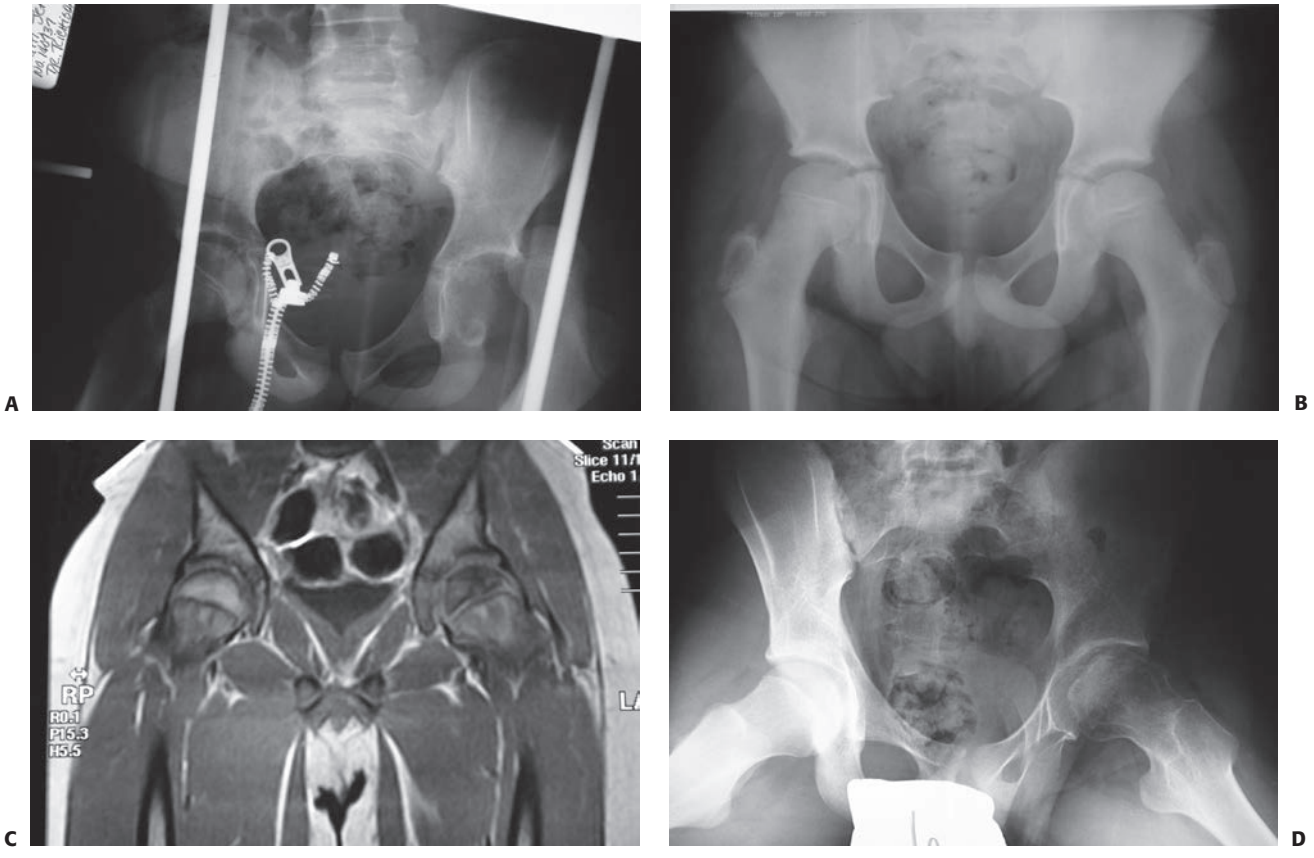

FIGURE 26-26 **A:** An 11-year-old boy dislocated his left hip while wrestling. **B:** The hip was easily reduced. **C:** After 5 months, hip pain led to an MRI, which shows ON of the capital femoral epiphysis. **D:** At 10 months after injury, there are typical changes of ON despite nonweight bearing.

Early technetium bone scanning with pinhole-collimated images detects ON as an area of decreased uptake. Findings on T2-weighted images are abnormal but of variable signal intensity. MRI may be falsely negative if performed within a few days of injury[93]; conversely, many perfusion defects seen on MRI spontaneously resolve after several months.[46,93] As treatment for early ON develops this algorithm may change, and early assessment maybe considered for those at high risk of ON. If hips are followed by serial radiographs for ON, it is recommended that they be studied for at least 2 years after dislocation, because radiographic changes may appear late.[8]

If ON develops, pain, loss of motion, and deformity of the femoral head are likely.[10] ON in a young child resembles Perthes disease and may be treated like Perthes disease.[10] Priorities are to maintain mobility and containment of the femoral head to maximize congruity after resolution. ON in older children should be treated as in adults and may require hip fusion, osteotomy, or reconstruction. If identified early, medical treatment with bisphosphonates or revascularization techniques, such as a vascularized fibular bone graft, can be considered.[1,106]

Chondrolysis

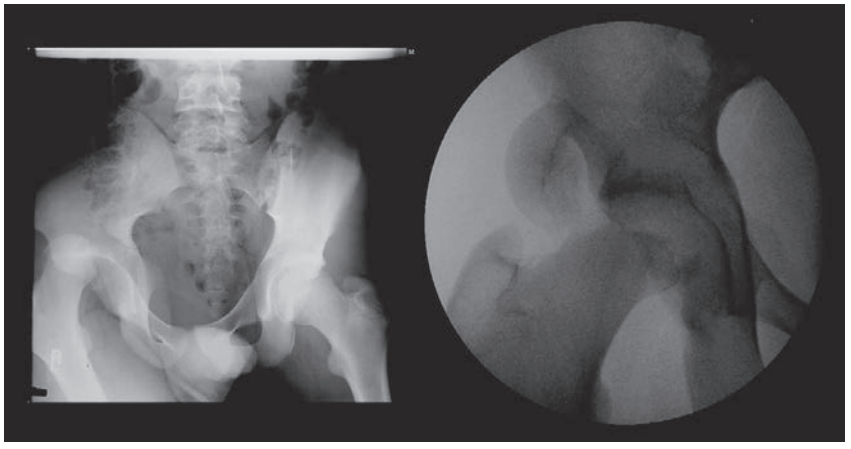
Chondrolysis has been reported after hip dislocation in up to 6% of children[45,51,56,88] and probably occurs as a result of articular damage at the time of dislocation. Chondrolysis cannot be reversed by medical means, and treatment should be symptomatic. Anti-inflammatory medicines and weight-relieving devices should be used as needed. Hip joint distraction with a hinged external fixator may improve range of motion and decrease pain.[32] If the joint fails to reconstitute, fusion or reconstruction should be considered.

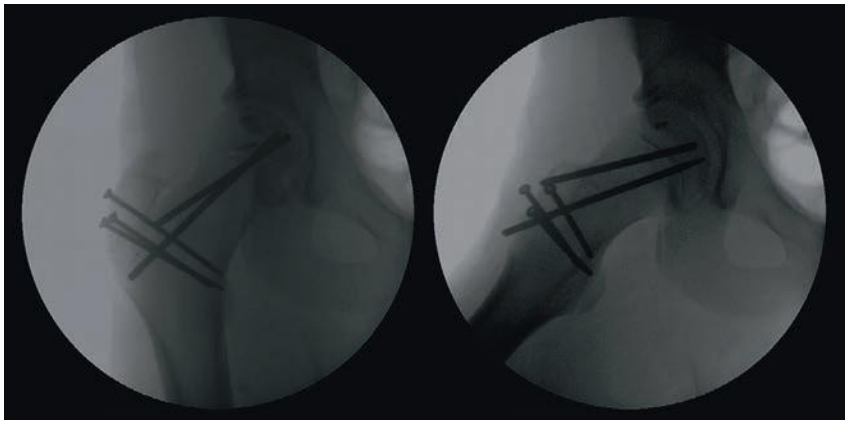
Coxa Magna

Coxa magna occasionally occurs after hip dislocation. The reported incidence ranges from 0% to 47%.[45,56,88] It is believed to occur as a result of posttraumatic hyperemia.[88] In most children, this condition is asymptomatic and does not require any treatment.[88] There is no intervention that will prevent coxa magna.

Habitual Dislocation

Habitual or voluntary dislocation of the hip usually is unrelated to trauma. Many factors may contribute to this ability, including generalized ligamentous laxity, excessive anteversion of the femur and acetabulum, and coxa valga. Initial management should include counseling the child to cease the activity (with or without psychiatric counseling) and observation. If episodes of dislocation persist, permanent changes such as secondary





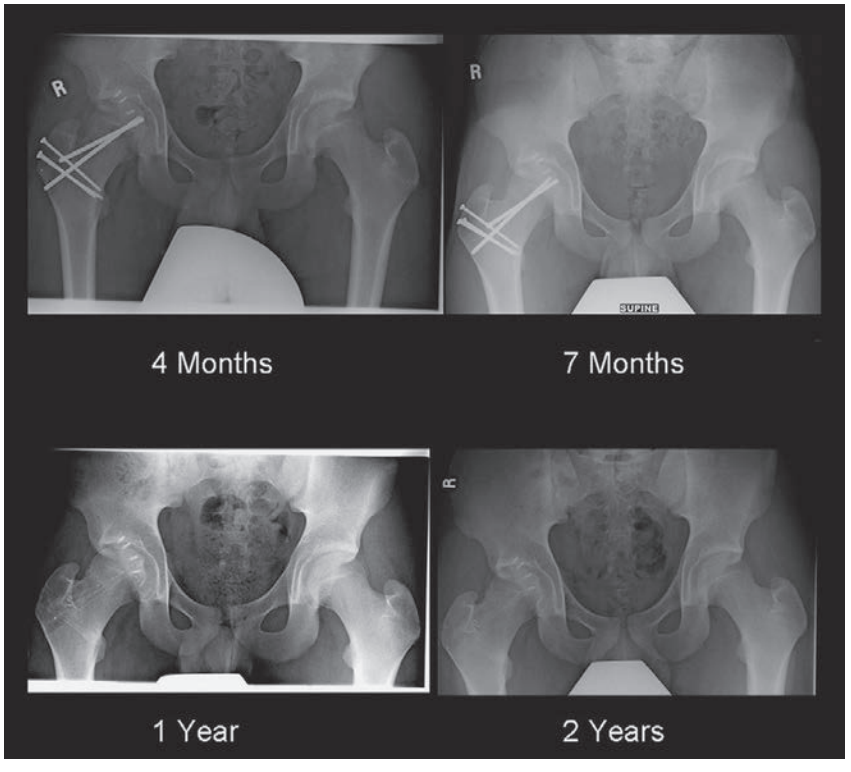


FIGURE 26-27 **Top: A:** Anteroposterior radiograph of the pelvis, showing dislocation of the right hip. **B:** Anteroposterior radiograph of the right hip, showing the physeal separation after attempted closed reduction. **Middle:** Anteroposterior **(A)** and lateral **(B)** radiographs made after surgical dislocation, reduction, and fixation of the epiphysis through a trochanteric flip osteotomy**. Bottom:** Anteroposterior radiographs made during the 2-year period after surgical reconstruction. (From Schoenecker JG, Kim Y, Ganz R. Treatment of traumatic separation of the proximal femoral epiphysis without development of osteonecrosis: A report of two cases. *J Bone Joint Surg Am.* 2010;92:973–977, with permission.)

capsular laxity or osteocartilaginous deformation of the hip may occur. These changes may lead to pain, residual subluxation, or degenerative joint disease. Conservative treatment should be initially attempted and may include simple observation with or without psychiatric counseling or immobilization with cast or brace. Hip stabilization by surgical means may be indicated for persistent painful episodes of hip despite conservative treatment.[89,110] Knight et al. recently reported their 10-year follow-up of Down syndrome patients with habitual subluxation treated with a varus/derotation intertrochanteric osteotomy. They recommend surgery in these patients before age 7 and attempting to get the neck/shaft angle to 105 degrees to prevent later hip abnormality.[65] Therefore, corrective surgery, if considered, should be performed only to correct specific anatomic abnormality and perhaps in patients with known ligamentous laxity. Surgery may include capsular plication, although bony correction with redirectional pelvic osteotomy, or osteotomy of the proximal femur would likely be more effective.[110]

Heterotopic Ossification

Heterotopic ossification can result after closed reduction of hip dislocations in children. In one study, three children (all under 16 years of age) developed heterotopic ossification, one of which required surgical excision.[76]

Interposed Soft Tissue

Interposed tissues may cause nonconcentric reduction or result in complete failure of closed reduction. Muscle, bone, articular cartilage, and labrum have been implicated.[20,41,44,51,94,109] An MRI provides information on obstacles to complete reduction and the direction of the initial dislocation.[44,109] Open reduction generally is necessary to clear impeding tissues from the joint.[20,44,51,88,94,109] Untreated nonconcentric reduction may lead to permanent degenerative arthropathy.

Late Presentation

Not all hip dislocations in children cause severe or incapacitating symptoms. Ambulation may even be possible. As a result, treatment may be delayed or the diagnosis missed until shortening of the limb and contracture are well established, making reduction difficult. Nearly all patients with a delayed treatment of traumatic hip dislocation develop ON.[7,66] Prolonged heavy traction may be considered as method to effect reduction.[48] If this fails, preoperative traction, extensive soft tissue release, or primary femoral shortening should be considered if open reduction is required. Open reduction will likely be difficult and will not always be successful. Even if the hip stays reduced, progressive arthropathy may lead to a stiff and painful hip. The likelihood of a good result decreases with the duration of dislocation.

Nerve Injury

The sciatic nerve may be directly compressed by the femoral head after a posterior dislocation of the hip in 2% to 13% of patients.[35,103,107] If the hip is expediently reduced, nerve function returns spontaneously in most patients.[35,51] If the sciatic palsy is present prior to reduction, the nerve does not need to be explored unless open reduction is required for other reasons. If sciatic nerve function is shown to be intact and is lost during the reduction maneuver, the nerve should be explored to ensure that it has not displaced into the joint. Other nerves around the hip joint are rarely injured at dislocation. Treatment is generally expectant unless laceration or incarceration is suspected; if so, exploration is indicated.

Recurrent Dislocation

Recurrence after traumatic hip dislocation is rare but occurs most frequently after posterior dislocation in children under 8 years of age[7,43] or in children with known hyperlaxity (Down syndrome, Ehlers–Danlos disease). The incidence of recurrence is estimated to be less than 3%.[88] Recurrence can be quite disabling, and in the long term may result in damage to the articular surfaces as a result of shear damage to the cartilaginous hip. Prolonged spica casting (at least 3 months) may be effective.[77] Surgical exploration with capsulorrhaphy can be performed if conservative treatment fails.[7,43,61] Prior to hip reconstruction, an MRI or arthrography is recommended to identify a capsular defect or redundancy.[7] In older children, recurrent dislocation can occur as a result of a bony defect in the posterior rim of the acetabulum similar to that in adults and may require posterior acetabular reconstruction.

Vascular Injury

Impingement on the femoral neurovascular bundle has been described after anterior hip dislocation in children, and this may occur in 25% of patients.[107] The hip should be relocated as soon as possible to remove the offending pressure from the femoral vessels. If relocation of the hip fails to restore perfusion, immediate exploration of the femoral vessels is indicated.

Summary, Controversies, and Future Directions Related to Hip Dislocations in Children

The treatment for hip disorders is evolving. We now have new surgical and medical treatment options for hip disorders such as surgical hip dislocation and hip arthroscopy. Although most do not directly apply to the urgent reduction of hip dislocations, they are applicable to the sequelae that occur. The use of bisphosphonates and other medications that inhibit bone resorption is an active area of research and may have direct effects on limiting collapse of the femoral head if ON occurs.[1] This could soon change our paradigm for the evaluation of a hip after reduction of a dislocation, and early MRI or bone scans may be indicated.

A host of surgical methods are available to manage deformity as a result of necrosis or hip instability. Techniques to increase vascularity, such as vascularized bone grafting, remain a controversial method to improve the natural history. Hinged distraction across the hip is now more commonly performed and much easier technically, given the newer generation of external fixation devices designed just for this purpose. Hinged distraction may play a role as a primary treatment (i.e., for chondrolysis)

or as an adjunct to other techniques.[32] Hip arthroscopy is much more commonly performed and allows for a much less invasive approach to removing loose bodies in the hip and assessing and treating soft tissue injuries.[15,64] Together, these new techniques offer future opportunities to decrease the severity of known complications and potentially improve functional outcomes. Time and follow-up will be required to determine if these methods improve the natural history of these posttraumatic sequelae.

27 FEMORAL SHAFT FRACTURES

John M. Flynn and David L. Skaggs

Femur fractures are common.[60,122] When subtrochanteric and supracondylar fractures are included, the femoral shaft represents about 1.6% of all bony injuries in children. Fractures are more common in boys (2.6:1), and occur in an interesting bimodal distribution with a peak during the toddler years (usually from simple falls) and then again in early adolescence (usually from higher-energy injury).[62,77,86,112] A recent Swedish incidence study[78] also showed a seasonal bimodal variation, with the peak in March and in August.

Although pediatric femoral shaft fractures create substantial short-term disability, with attention to detail and modern techniques, these major injuries can generally be treated successfully with few long-term sequelae. Over the past 20 years, there has been a dramatic and sustained trend toward the operative stabilization of femoral shaft fractures in school-aged children using flexible intramedullary nails, external fixation, locked intramedullary nails, and more recently, submuscular plate fixation. These advances have decreased the substantial early disability for the children as well as the family's burden of care during the recovery period.

Anatomy of Femoral Shaft Fractures

Through remodeling during childhood, a child's bone changes from primarily weak woven bone to stronger lamellar bone.[180] Strength also is increased by a change in geometry (Fig. 27-1). The increasing diameter and area of bone result in a markedly increased area moment of inertia, leading to an increase in strength. This progressive increase in bone strength helps explain the bimodal distribution of femoral fractures. In early childhood, the femur is relatively weak and breaks under load conditions reached in normal play. In adolescence,

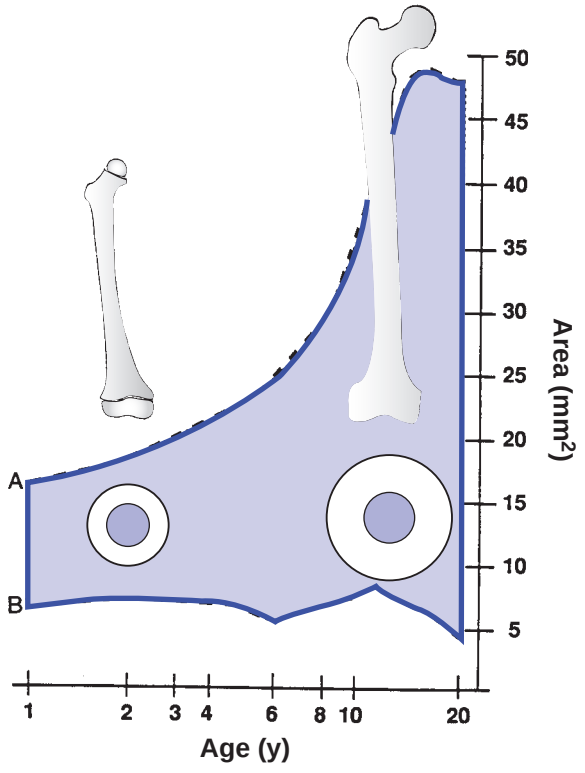

FIGURE 27-1 The *shaded area* represents cortical thickness by age-group. This rapid increase in cortical thickness may contribute to the diminishing incidence of femoral fractures during late childhood. (Redrawn from Netter FH. The Ciba collection of medical illustrations. *Musculoskeletal System*. I. *Anatomy, Physiology, and Metabolic Disorders*. Vol 8. Summit, NJ: Ciba-Geigy; 1987, with permission.)

high-velocity trauma is required to reach the stresses necessary for fracture.

Mechanism of Injury of Femoral Shaft Fractures

The etiology of femoral fractures in children varies with the age of the child. Before walking age, up to 80% of femoral fractures may be caused by abuse.[11,18,69,184] In a study of over 5,000 children at a trauma center, Coffey et al.[37] found that abuse was the cause of only 1% of lower extremity fractures in children older than 18 months, but 67% of lower extremity fractures in children younger than 18 months.

Baldwin et al.[8] found three primary risk factors for abuse in young children presenting with a femur fracture: A history suspicious for abuse, physical or radiographic evidence of prior injury, and age under 18 months. Children with no risk factors had only a 4% chance of being a victim of abuse, whereas children with all three risk factors had a 92% chance that their femur fractures with result of abuse.

Older children are unlikely to have a femoral shaft fracture caused by abuse, because their bone is sufficiently strong to tolerate forceful blows, or is able to resist torque without fracture. In older children, femoral fractures are most likely to be caused by high-energy injuries; motor vehicle accidents account for over 90% of femur fractures in this age group.[42,77,121] Pathologic femur fractures are relatively rare in children, but may occur because of generalized osteopenia in infants or young children with osteogenesis imperfecta. Osteogenesis imperfecta should be considered when a young child, with no history suggestive of abuse or significant trauma, presents with a femoral shaft fracture.[111] Radiologic evaluation is often insufficient to diagnose osteogenesis imperfecta; skin biopsy, collagen analysis, and bone biopsy may be required to make a definitive diagnosis. Generalized osteopenia also may accompany neurologic diseases, such as cerebral palsy or myelomeningocele, leading to fracture with minor trauma in osteopenic bone.[62,105,111] Pathologic fractures may occur in patients with neoplasms, most often benign lesions such as nonossifying fibroma, aneurysmal bone cyst, unicameral cyst, or eosinophilic granuloma. Although pathologic femur fractures are rare in children, it is essential that the orthopedist and radiologists study the initial injury films closely for the subtle signs of primary lesions predisposing to fracture, particularly in cases of low-energy injury from running or tripping. Radiographic signs of a pathologic fracture may include mixed lytic–blastic areas disrupting trabecular architecture, break in the cortex and periosteal reaction in malignant lesions such as osteosarcoma, or better-defined sclerotic borders with an intact cortex seen in benign lesions such as nonossifying fibroma (Fig. 27-2).

Stress fractures may occur in any location in the femoral shaft.[28,101,137] In this era of high-intensity, year-round youth sports, orthopedists are more commonly encountering adolescents with femoral stress fractures from running, soccer, and basketball.[23] Although uncommon (4% of all stress fractures in children), femoral shaft or femoral neck stress fractures should be considered in a child with thigh pain because an unrecognized stress fracture may progress to a displaced femoral fracture. A high index of suspicion is important, because even nontraditional sports can lead to stress fractures with extreme overuse; a recent report of bilateral femoral stress fractures were reported in a Rollerblade enthusiast.[201]

Diagnosis of Femoral Shaft Fractures

The diagnosis of pediatric femoral shaft fractures is usually not subtle: There is a clear mechanism of injury, a deformity and swelling of the thigh, and obvious localized pain. The diagnosis is more difficult in patients with multiple trauma or head injury and in nonambulatory, severely disabled children. A physical examination usually is sufficient to document the presence of a femur fracture. In patients lacking sensation (myelomeningocele), the swelling and redness caused by a fracture may mimic infection.

In the setting of a femur fracture, a comprehensive physical examination should be performed looking for other sites of injury. Hypotension rarely results from an isolated femoral fracture. Waddell's triad of femoral fracture, intra-abdominal or intrathoracic injury, and head injury are associated with high-velocity automobile injuries. Multiple trauma may necessitate rapid stabilization of femoral shaft fractures[121,164] to facilitate overall care. This is particularly true with head injury and vascular disruption.

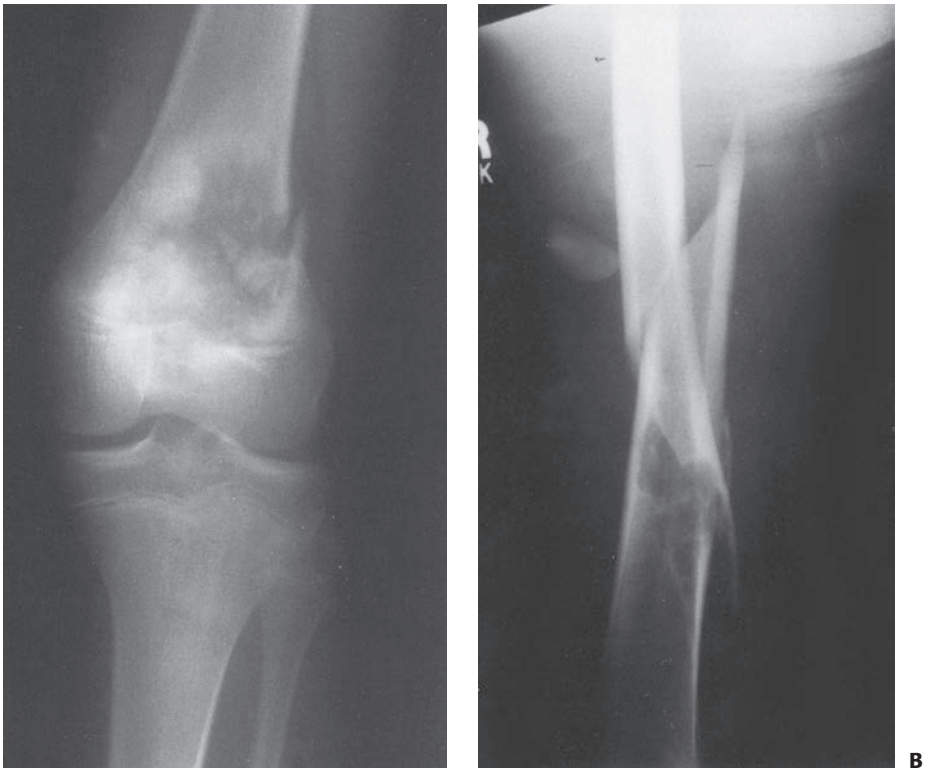

FIGURE 27-2 A: Femoral fracture through a poorly demarcated, mixed, osteoblastic, osteolytic lesion—an osteosarcoma. **B:** Sclerotic borders of this lesion in the distal femur are typical of a pathologic fracture through a nonossifying fibroma.

The hemodynamic significance of femoral fracture has been studied by two groups.[35,124] Hematocrit levels below 30% rarely occur without multisystem injury. A declining hematocrit should not be attributed to closed femoral fracture until other sources of blood loss have been eliminated.[35,124]

X-Ray Findings of Femoral Shaft Fractures

Radiographic evaluation should include the entire femur, including the hip and knee, because injury of the adjacent joints is common. An anteroposterior (AP) pelvis x-ray is a valuable supplement to standard femoral shaft views, because there may be associated intertrochanteric fractures of the hip, fractures of the femoral neck, or physeal injuries of the proximal femur.[14,30] Distal femoral fractures may be associated with physeal injury about the knee, knee ligament injury, meniscal tears,[204] and tibial fractures.[116]

Plain x-rays generally are sufficient for making the diagnosis. In rare circumstances, bone scanning and magnetic resonance imaging (MRI) may be helpful in the diagnosis of small buckle fractures in limping children or stress fractures in athletes. The orthopedist should carefully evaluate radiographs for comminution or nondisplaced "butterfly" fragments, second fractures, joint dislocations, and pathologic, as these findings can substantially alter the treatment plan.

Classification of Femoral Shaft Fractures

Femoral fractures are classified as (a) transverse, spiral, or short oblique; (b) comminuted or noncomminuted; and (c) open or closed. Open fractures are classified according to Gustilo's system.[81] The presence or absence of vascular and neurologic injury is documented and is part of the description of the fracture. The most common femoral fracture in children (over 50%) is a simple transverse, closed, noncomminuted injury.

The level of the fracture (Fig. 27-3) leads to characteristic displacement of the fragments based on the attached muscles. With subtrochanteric fractures, the proximal fragment lies in abduction, flexion, and external rotation. The pull of the gastrocnemius on the distal fragment in a supracondylar fracture produces an extension deformity (posterior angulation of the femoral shaft), which may make the femur difficult to align.

Treatment of Femoral Shaft Fractures

Treatment of femoral shaft fractures in children depends on two primary considerations: Age (Table 27-1) and fracture pattern. Secondary considerations, especially in operative cases, include the child's weight, associated injuries, and mechanism of injury. Economic concerns,[40,59,153,156,195] the family's ability to care for a child in a spica cast or external fixator, and the advantages and disadvantages of any operative procedure also are important factors. Kocher et al.[110] summarized the current evidence for pediatric femur fracture treatment in a clinical practice guideline summary.

Treatment Variation with Age for Femoral Shaft Fractures

Infants

Femoral shaft fractures in infants are usually stable because their periosteum is thick. In fractures occurring in infancy,

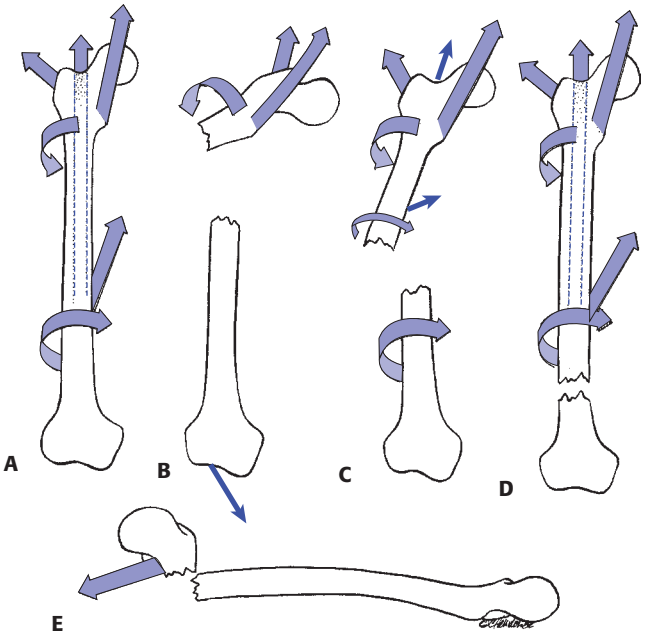

FIGURE 27-3 The relationship of fracture level and position of the proximal fragment. **A:** In the resting unfractured state, the position of the femur is relatively neutral because of balanced muscle pull. **B:** In proximal shaft fractures the proximal fragment assumes a position of flexion (iliopsoas), abduction (abductor muscle group), and lateral rotation (short external rotators). **C:** In midshaft fractures the effect is less extreme because there is compensation by the adductors and extensor attachments on the proximal fragment. **D:** Distal shaft fractures produce little alteration in the proximal fragment position because most muscles are attached to the same fragment, providing balance. **E:** Supracondylar fractures often assume a position of hyperextension of the distal fragment because of the pull of the gastrocnemius.

management should include evaluation for underlying metabolic bone abnormality or abuse. Once these have been ruled out, most infants with a proximal or midshaft femoral fracture are comfortably and successfully treated with simple splinting to provide some stability and comfort, with a Pavlik harness to improve the resting position of the fracture. For the rare unstable fracture, the Pavlik harness may not offer sufficient stabilization. Morris et al.[149] reported a group of eight birth-related femoral fractures in 55,296 live births. Twin pregnancies, breech presentation, and prematurity were associated with birth-related femur fractures. The typical fracture is a spiral fracture of the proximal femur with flexion of the proximal fragment. With thick periosteum, and remarkable remodeling potential, newborns rarely need a manipulative reduction of their fracture, nor rigid external immobilization. For femoral fractures with excessive shortening (>1 to 2 cm) or angulation (>30 degrees), spica casting may be used. Traction rarely is necessary in this age group.

Preschool Children

In children 6 months to 5 years of age, early spica casting (Fig. 27-4) is the treatment of choice for isolated femur fractures with less than 2 cm of initial shortening (Fig. 27-5). In low-energy fractures, the "walking spica" is ideal (Fig. 27-6). Femur fractures with more than 2 cm of initial shortening or marked instability and fractures that cannot be reduced with early spica casting require 3 to 10 days of skin or skeletal traction. Internal or external fixation is rarely needed in children less than 5 years of age. In rare circumstances, external fixation can be used for children with open fractures or multiple trauma. Intramedullary fixation is used in children with metabolic bone disease that predisposes to fracture or after multiple fractures, such as in osteogenesis imperfecta, or following multitrauma. Flexible nailing can be used in the normal-sized preschool child[20] but is rarely necessary. Larger children (in whom reduction cannot be maintained with a spica cast) occasionally may benefit from flexible intramedullary nailing, traction, or in rare cases, submuscular plating.

TABLE 27-1 Treatment Options for Isolated Femoral Shaft Fractures in Children and Adolescents

Age	Treatments
Birth to 24 mos	Pavlik harness (newborn to 6 mos) Early spica cast Traction → spica cast (very rare)
24 mos–5 y	Early spica cast Traction → spica cast External fixation (rare) Flexible intramedullary nails (rare)
6–11 y	Flexible intramedullary nails Traction → spica cast Submuscular plate External fixation
12 y to maturity	Trochanteric entry intramedullary rod Flexible intramedullary nails Submuscular plate External fixation (rare)

Treatment choices are influenced by fracture pattern, the child's weight, the presence of other injuries (head, chest, abdominal, etc.) and associated soft tissue trauma.

Children 5 to 11 Years of Age

In children 5 to 11 years of age, many different methods can be used successfully, depending on the fracture type, patient characteristics, and surgeon skill and experience.[60] For the rare, minimally displaced fracture, early spica casting usually produces satisfactory results, although cast wedging or a cast change may be necessary to avoid excessive shortening and angulation. In children with unstable, comminuted fractures, traction may be necessary prior to cast application. Although traction and casting is still a very acceptable and successful method of managing femur fractures in young school-age children, the cost and the social problems related to school-age children in casts have resulted in a strong trend toward fracture fixation. Spica cast management is generally not used for children with multiple trauma, head injury, vascular compromise, floating knee injuries, significant skin problems, or multiple fractures. Flexible

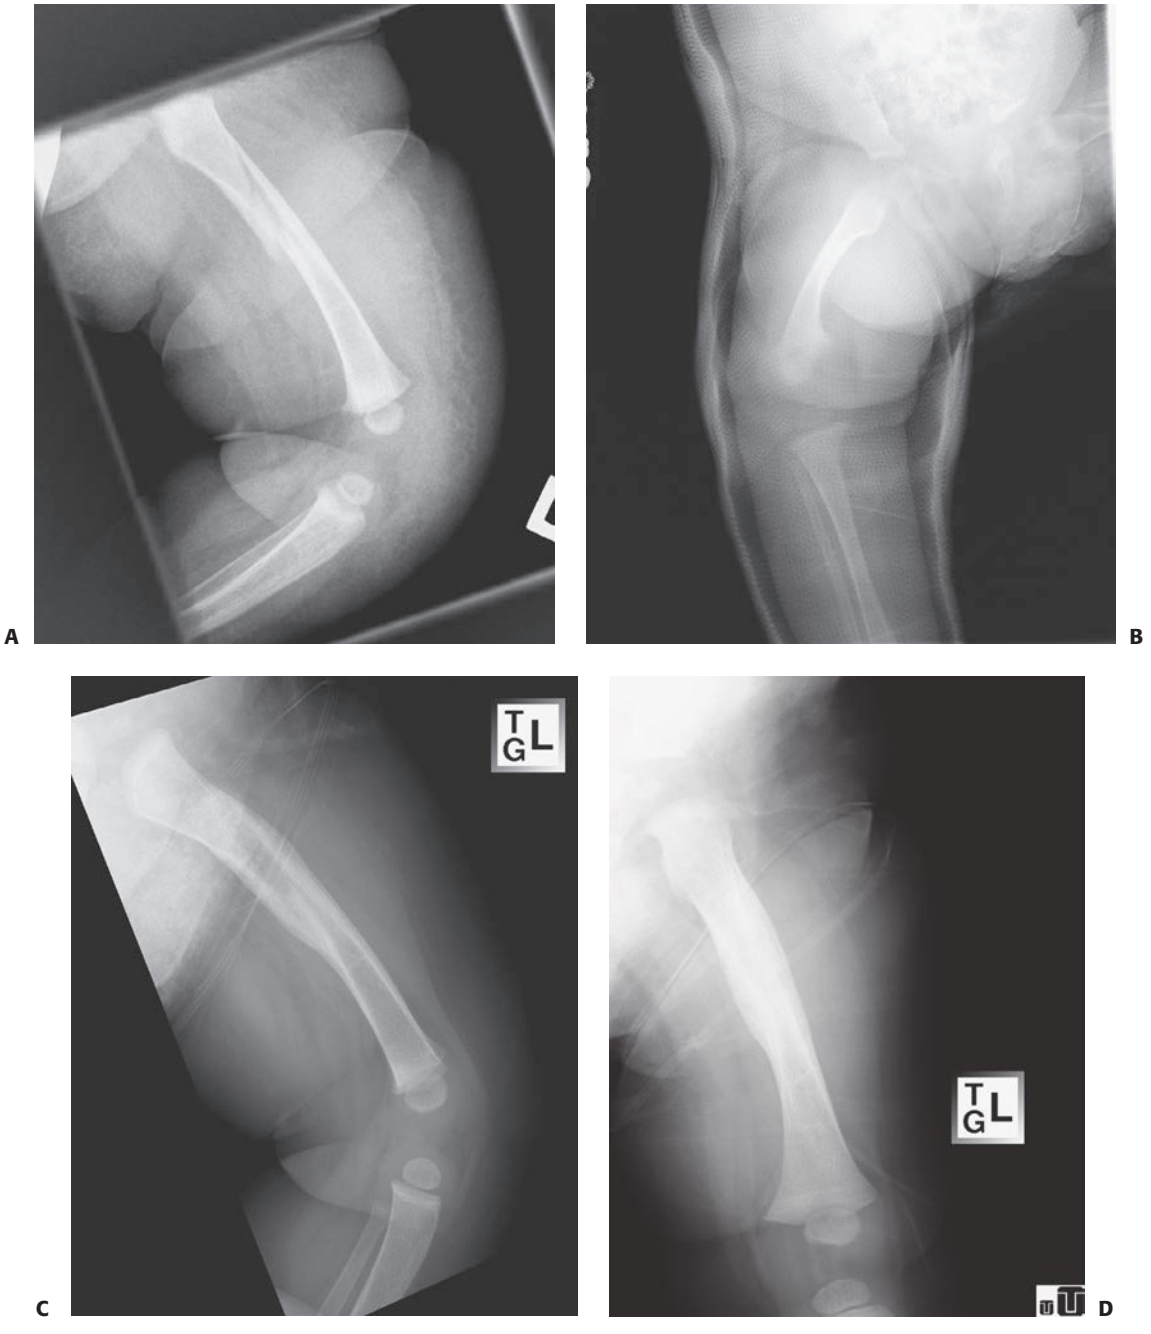

FIGURE 27-4 **A:** This 7-month old sustained a low-energy spiral femoral shaft fracture. **B:** Treatment was in a spica cast. **C, D:** Excellent healing with abundant callus at only 4 weeks after injury.

intramedullary nails are the predominant treatment for femur fractures in 5- to11-year olds, although submuscular plating and external fixation have their place, especially in length-unstable fractures, or in those difficult to manage fractures in the proximal and distal third of the femoral shaft.

Age 11 to Skeletal Maturity

Trochanteric entry, locked intramedullary nailing is now the primary mode of treatment for femur fractures in the preadolescent and adolescent age groups. Several studies designed to refine the indications for flexible intramedullary nailing have concluded that although most results are excellent or satisfactory in children older than 11, complications rise significantly when this popular technique is used for bigger and older children. In an international multicenter, retrospective study, Moroz et al.[148] found a statistically significant relationship between age and outcome, with children older than 11 years or heavier than 49 kg faring worse. Sink et al.[187] found a much higher rate of complications in length-unstable fractures. Fortunately, surgeons can now select from several

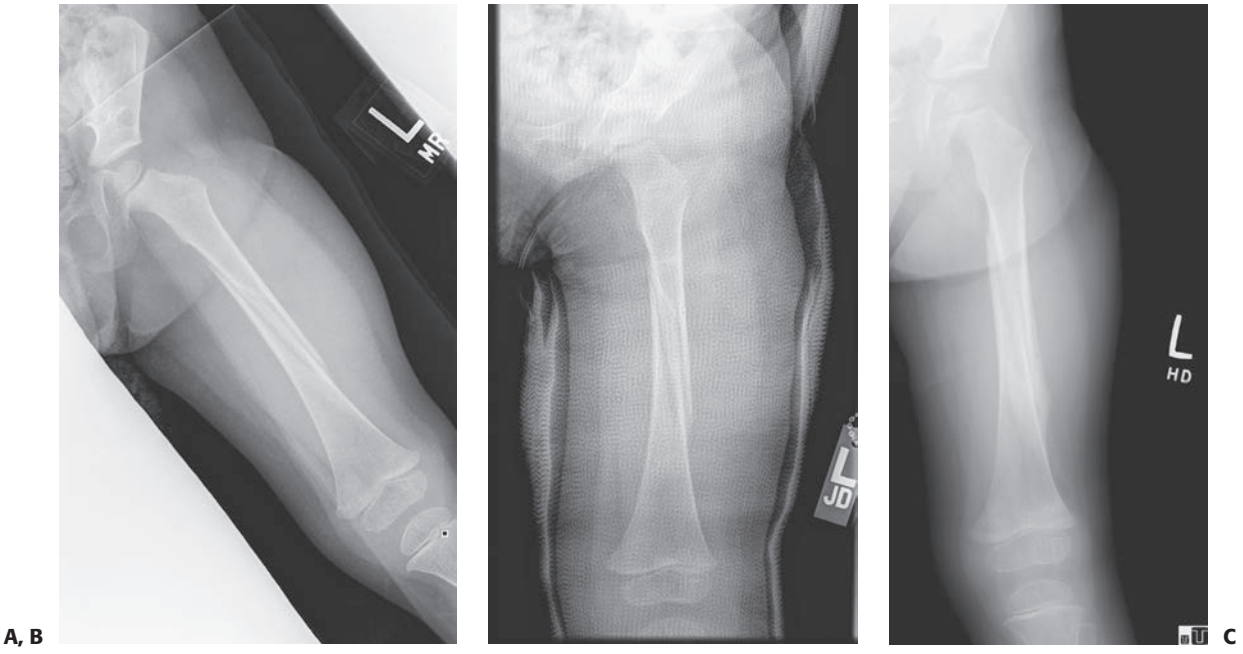

FIGURE 27-5 **A:** This 2-year-old sustained a low-energy spiral femoral shaft fracture, ideal for walking spica treatment. **B:** Immediately after reduction, note the lateral mold at the fracture site. **C:** Six weeks after injury, there is anatomic alignment, minimal shortening, and good callus formation.

FIGURE 27-6 A 4-year old with a minimally displaced midshaft femur fracture treated with a walking spica cast, shown here 4 weeks after injury.

different trochanteric entry nails that allow a relatively safe, lateral entry point, with the stability of proximal and distal locking. With this new information and technology, locked intramedullary nailing is used commonly for obese children of ages 10 to 12, and most femoral shaft fractures in children of ages 13 to skeletal maturity.

Treatment Variation with Fracture Pattern for Femoral Shaft Fractures

In addition to age, the treating surgeon should consider fracture pattern, especially when choosing implant. Elastic nailing is ideal for the vast majority of length-stable midshaft femur fractures in children between the ages of 5 and 11 years old. For length-unstable fractures, the risk of shortening and malunion increases substantially when elastic nailing is used.[186] Length-unstable fractures are best treated with locked trochanteric entry nailing in older children, external fixation in younger children, or submuscular plating in either of these age cohorts.

Treatment Options for Femoral Shaft Fractures

Pavlik Harness for Femoral Shaft Fractures

Stannard et al.[194] popularized the use of the Pavlik harness for femur fractures in infants. This treatment is ideal for a proximal or midshaft femoral fracture that occurs as a birth-related injury. Reduction can be aided by a loosely wrapping cotton cast padding around the thigh if greater stability is needed. In a newborn infant in whom a femur fracture is noted in

the intensive care unit or nursery, the femur is immobilized with simple padding or a soft splint. For a stable fracture, this approach may be sufficient and will allow intravenous access to the feet if needed. The Pavlik harness can be applied with the hip in moderate flexion and abduction. This often helps align the distal fragment with the proximal fragment (Fig. 27-7). Evaluation of angulation in the coronal plane (varus–valgus) is difficult because of hyperflexion. Stannard et al.[194] reported acceptable alignment in all patients with less than 1 cm of shortening. Morris et al.[149] showed that all treatments, including traction, spica cast, and Pavlik harness, are effective and resulted in satisfactory outcome in all patients regardless of treatment.

Podeszwa et al.[162] reported infants treated with a Pavlik had higher pain scores when compared to a immediate spica cast; however, none of the Pavlik patients had skin problems but one-third of the spica patients did.

Spica Cast Treatment for Femoral Shaft Fractures

Spica casting[97,192] is usually the best treatment option for isolated femoral shaft fractures in children under 6 years of age, unless there is (a) shortening of more than 2 cm, (b) massive swelling of the thigh, or (c) an associated injury that precludes cast treatment. Several centers have adopted spica application in the emergency department as their standard treatment for infants and toddlers. Mansour et al.[128] compared spica cast placement in the emergency department versus the operating room, and concluded that the outcome and complications were similar, but the children treated in the operating room had longer hospital stays and significantly higher hospital charges. Cassinelli et al.[33] treated 145 femur fractures, all in children younger than age 7, with immediate spica cast application in the emergency department. All children younger than 2 years of age, and 86.5% of children of ages 2 to 5 years old, met acceptable alignment parameters on final radiographs. Rereduction in the operating room was needed in 11 patients. The investigators concluded that initial shortening was the only independent risk factor associated with lost reduction.

The advantages of a spica cast include low cost, excellent safety profile, and a very high rate of good results, with acceptable leg length equality, healing time, and motion.[54,96]

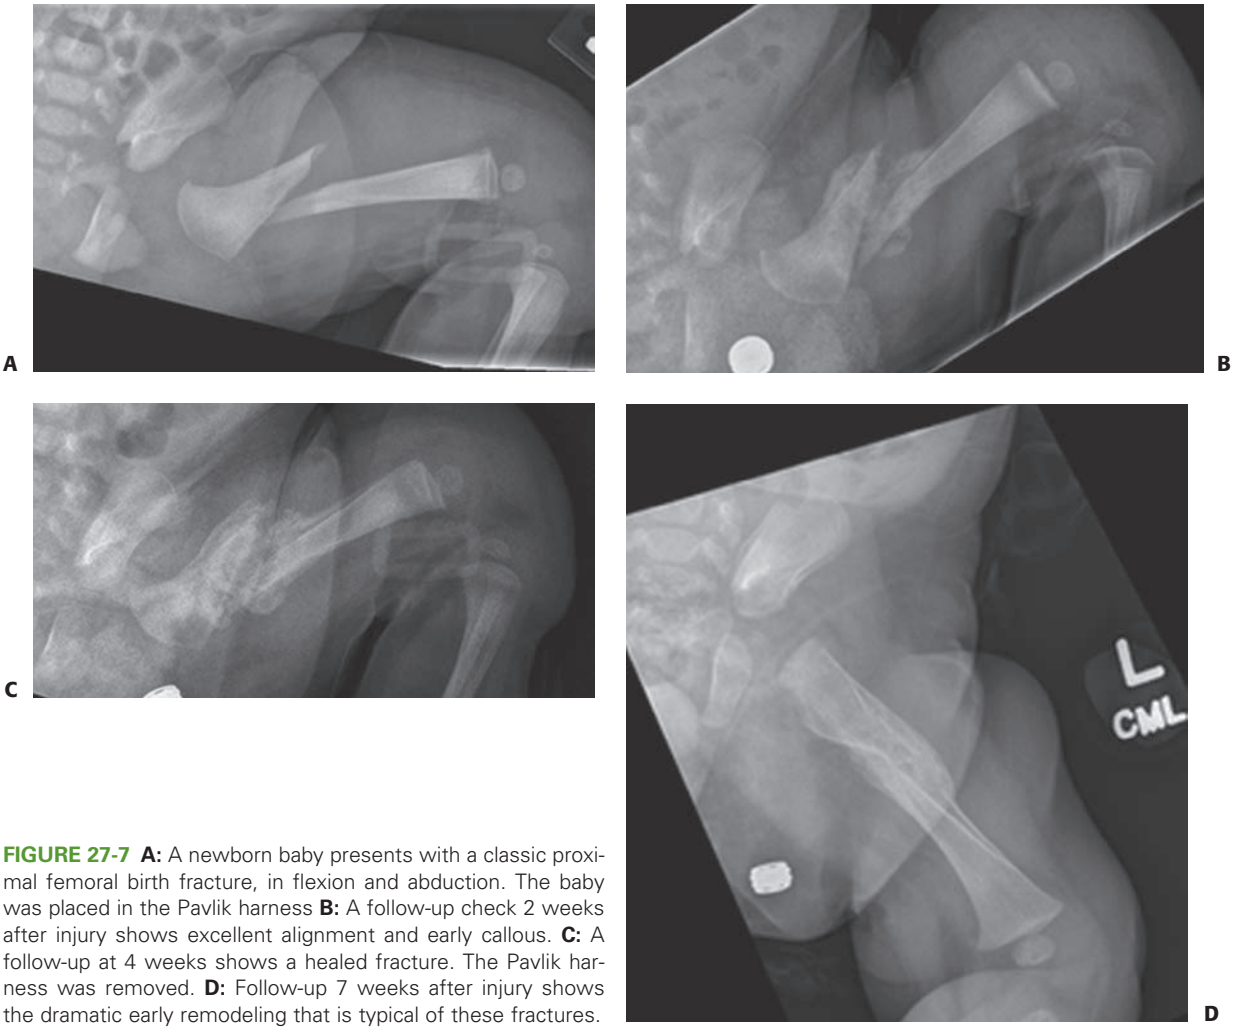

FIGURE 27-7 **A:** A newborn baby presents with a classic proximal femoral birth fracture, in flexion and abduction. The baby was placed in the Pavlik harness **B:** A follow-up check 2 weeks after injury shows excellent alignment and early callous. **C:** A follow-up at 4 weeks shows a healed fracture. The Pavlik harness was removed. **D:** Follow-up 7 weeks after injury shows the dramatic early remodeling that is typical of these fractures.

TABLE 27-2 Acceptable Angulation

Age	Varus/Valgus (degrees)	Anterior/Posterior (degrees)	Shortening (mm)
Birth to 2 y	30	30	15
2–5 y	15	20	20
6–10 y	10	15	15
11 y to maturity	5	10	10

Hughes et al.[90] evaluated 23 children ranging in age from 2 to 10 years who had femur fractures treated with early spica casting to determine the impact of treatment on the patients and their families. The greatest problems encountered by the family in caring for a child in a spica cast were transportation, cast intolerance by the child, and hygiene. In a similar study, Kocher[109] used a validated questionnaire for assessing the impact of medical conditions on families demonstrated that for family, having a child in a spica cast is similar to having a child on renal dialysis. They found that the impact was greatest for children older than 5 years, and when both parents are working. Such data should inform the decisions of orthopedic surgeons and families who are trying to choose among the many options for young school-age children.

Illgen et al.,[95] in a series of 114 isolated femoral fractures in children under 6 years of age, found that 90-degree/90-degree spica casting was successful in 86% without cast change or wedging, based on tolerance of shortening less than 1.5 cm and angulation less than 10 degrees. Similar excellent results have been reported by Czertak and Hennrikus[41] using the 90/90 spica cast.

Thompson et al.[197] described the telescope test in which patients were examined with fluoroscopy at the time of reduction and casting. If more than 3 cm of shortening could be demonstrated with gentle axial compression, traction was used rather than immediate spica casting. By using the telescope test, these researchers decreased unacceptable results (>2.5 cm of shortening) from 18% to 5%. Shortening is acceptable, but should not exceed 2 cm. This is best measured on a lateral x-ray taken through the cast. If follow-up x-rays reveal significant varus (>10 degrees) or anterior angulation (>30 degrees), the cast may be wedged. However, Weiss et al.[211] noted that wedging of 90/90 spica casts can cause peroneal nerve palsy, especially during correction of valgus angulation (a problem that rarely occurs). For unacceptable position, the fracture can be manipulated and a new cast applied, or the cast can be removed and the patient placed in traction to regain or maintain length. Angular deformity of up to 15 degrees in the coronal plane and up to 30 degrees in the sagittal plane may be acceptable, depending on the patient's age (Table 27-2). Finally, if shortening exceeds 2 cm, traction or an external fixator can be used (Fig. 27-8).

The position of the hips and knees in the spica cast is controversial. Some centers prefer a spica cast with the hip and knee flexed 90 degrees each. Studies have shown that the results from the sitting spica cast are good.[133,143] The child is placed in a sitting position with the legs abducted about 30 degrees on either side. The synthetic material used for the cast gives it sufficient strength so that no bar is required between the legs. This not only allows the child to be carried on the parent's hip but also aids in toiletry needs, making bedpans unnecessary. Also, a child who can sit upright during the day can attend school in a wheelchair. More recently, with reports about compartment syndrome of the leg after using the 90/90 spica cast, several centers have moved to a cast in which the hip and knee are more extended (about 45 degrees each) and the bottom of the foot cut out to prevent excessive shortening.[134] Varying the amounts of hip and knee flexion in the spica cast based on the position of the fracture also has been recommended: The more proximal the fracture, the more the hip should be flexed.[192]

FIGURE 27-8 A proximal spiral femur fracture, which failed treatment with pins and plaster, and was salvaged with an external fixator.

Recently, there has been a resurgence of interest in the "walking spica cast" (Fig. 27-6). Epps et al.[51] reported on immediate single leg spica cast for pediatric femoral diaphyseal fracture. In a series of 45 children, 90% of the children pulled to stand and 62% of the children walked independently by the end of treatment. Fifty percent of patients were able to return to school or day care while in the cast. Only two children had unacceptable shortening, and two required repeat reduction. Flynn et al.[57] performed a prospective study of low-energy femoral shaft fractures in young children, comparing a walking spica cast to a traditional spica cast. Although the outcome with the two treatment method was similar, the walking spica cast resulted in substantially lower burden of care for the family. Children with a walking spica are more likely to have their cast wedged in clinic to correct early loss of reduction. Practitioners of the single leg, or walking spica, have learned to use the technique only on toddlers with very stable, low-energy fractures. The cast must be extensively reinforced at the hip. With the hip and knee much more extended, the single leg spica not only improves function and ease of care, but also avoids a technique that has been associated with compartment syndrome in several children (see below).[113,151] Increasingly, the walking spica is considered the best treatment for low-energy femur fractures in toddlers.[57,117]

Spica Cast Application: Technique

The cast is applied in the operating room or, in some centers, the sedation unit or Emergency Department.[128] For the sitting spica cast technique, a long leg cast is placed with the knee and ankle flexed at 90 degrees (Fig. 27-9B). Knee flexion greater than 60 degrees improved maintenance of length and reduction.[95] However, if one applies excessive traction to maintain

FIGURE 27-9 (*continued*) D: Using a standard spica table, a 1½ spica cast is applied with the hip flexed 90 degrees and abducted 30 degrees.

length (Fig. 27-10), the risk of compartment syndrome is unacceptably high. Less traction, less knee flexion, and accepting slightly more shortening is a reasonable compromise. Extra padding, or a felt pad, is placed in the area of the popliteal fossa. The knee should not be flexed after the padding is placed because the lump of material in the popliteal fossa may create vascular obstruction (Fig. 27-9**A**). Because most diaphyseal fractures lose reduction into varus angulation while in a spica cast, a valgus mold at the fracture site is recommended (Fig. 27-9C). The patient is then placed on a spica table, supporting the weight of the legs with manual traction, and the remainder of the cast is applied with the hips in 90 degrees of flexion and 30 degrees of abduction, holding the fracture out to length (Fig. 27-9D). It is mandatory to avoid excessive traction because compartment syndromes and skin sloughs have been reported. The leg should be placed in 15 degrees of external rotation to align the distal fragment with the external rotation of the proximal fragment. After the spica cast is in place, AP and lateral x-rays are obtained to ensure that length and angular and rotational alignment are maintained. We observe all patients for 24 hours after spica application to be sure that the child is not at risk for neurovascular compromise or compartment syndrome. Gore-Tex liners can be used to decrease the skin problems of diaper rash and superficial infection. Several centers have found that this has been beneficial, justifying the cost of a Gore-Tex liner.

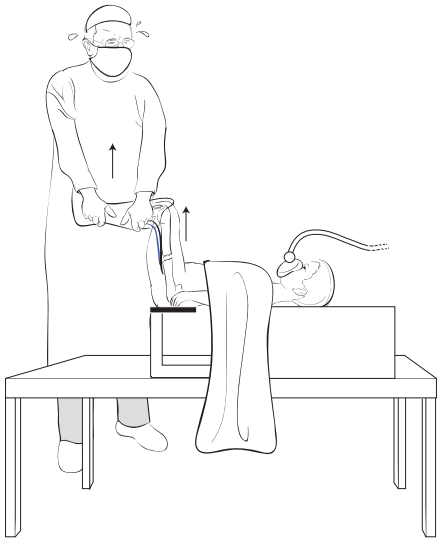

FIGURE 27-10 The dangers of pulling upward on the calf when applying a spica: This upward pull, which is used to reduce the fracture, can be dangerous, because it puts pressure on the gastrocnemius muscle and the other posterior leg structures, such as the femoral artery and femoral vein. (Reprinted from Skaggs D, Flynn J. Trauma about the pelvis/hip/femur. *Staying Out of Trouble in Pediatric Orthopaedics*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:105.)

For the single leg spica or "walking spica" technique, the long leg cast is applied with approximately 45 degrees of knee flexion, and when the remaining cast is placed, the hip is flexed 45 degrees and externally rotated 15 degrees. The hip should be reinforced anteriorly with multiple layers of extra fiberglass. The pelvic band should be fairly wide so that the hip is controlled as well as possible. A substantial valgus mold is important to prevent varus malangulation. We leave the foot out, stopping the distal end of the cast in the supramalleolar area, which is protected with plenty of extra padding. Seven to 10 days after injury, the child returns to clinic anticipating the need for cast wedging, if radiographs show the very common mild increase in shortening and varus angulation. Most toddlers pull to a stand and begin walking in their walking cast about 2 to 3 weeks after injury.

If excessive angulation occurs, the cast should be changed, with manipulation in the operating room. Casts can be wedged for less than 15 degrees of angulation. If shortening of more than 2 cm is documented, the child should be treated with cast change, traction, or conversion to external fixation, using lengthening techniques if the shortening is not detected until the fracture callus has developed. When conversion to external fixation is required, we recommend osteoclasis (either closed or open if needed) at the time of the application of the external fixator, with slow lengthening over a period of several weeks (1 mm per day) to reestablish acceptable length (Fig. 27-8).

Generally, the spica cast is worn for 4 to 8 weeks, depending on the age of the child and the severity of the soft tissue damage accompanying the fracture. Typically, an infant's femoral shaft fracture will heal in 3 to 4 weeks; and a toddler's fracture will heal in 6 weeks. After the cast is been removed, parents are encouraged to allow their children to stand and walk whenever the child is comfortable; most children will need to be carried or pushed in a stroller for a few days until hip and knee stiffness gradually results. Most joint stiffness resolves spontaneously in children after a few weeks. It is unusual to need formal physical therapy. In fact, aggressive joint range-of-motion exercises with the therapist immediately after cast removal make children anxious, and may prolong rather than hasten recovery. A few follow-up visits are recommended in the first year after femur fracture, analyzing gait, joint range of motion, and leg lengths.

Traction and Casting

Since as early as the 18th century, traction has been used for management of femur fractures. Vertical overhead traction with the hip flexed 90 degrees and the knee straight was introduced by Bryant in 1873,[25,38] but this often resulted in vascular insufficiency,[154] and it is now rarely used for treatment of femoral fractures. Modified Bryant traction, in which the knee is flexed 45 degrees, increases the safety of overhead skin traction.[55]

Traction prior to spica casting is indicated when the fracture is length unstable and the family and surgeon agree that nonoperative measures are preferred. In general, skeletal traction then Spica casting is not currently used for children who are older than 12 years of age, because of the significant risk of shortening and angular malunion; in children older than 12 years of age, internal fixation is recommended. Children who rapidly shortened in an early spica cast can be salvaged with cast removal and subsequent traction. The limit of skin traction is the interface between skin and tape or skin and foam traction boot. Skin complications, such as slough and blistering, usually occur when more than 5 lb of traction is applied. When more than 5 lb of traction is required, or simply for ease in patient management, skeletal traction can be used to maintain alignment.[5]

The distal femur is the location of choice for a traction pin.[5,48,177] Although proximal tibial traction pins have been recommended by some clinicians,[92] growth arrest in the proximal tibial physis and subsequent recurvatum deformity have been associated with their use (Fig. 27-11). Also, knee ligament and meniscal injuries that sometimes accompany femoral fractures may be aggravated by the chronic pull of traction across the knee.

Traction Pin Insertion: Technique

After preparation of the thigh circumferentially from the knee to the midthigh, the limb is draped in a sterile manner. The knee is held in the position in which it will remain during traction; that is, if 90/90 traction is being used, the traction pin should be inserted with the knee bent 90 degrees. Because this technique is typically used in very young children, traction pin is placed in the operating room under general anesthesia. The technique is safest and most efficient if it is done with fluoroscopic x-ray control for optimal pin location. The location of pin insertion is 1 fingerbreadth above the patella with the knee extended or just above the flare of the distal femur. A small puncture wound is made over the medial side of the femur. A medial-to-lateral approach is used so that the traction pin does not migrate into the area of the femoral artery that runs through Hunter canal on the medial side of the femur. The best traction pin is the largest available threaded Steinmann pin. The pin is placed parallel to the joint surface[5] to help maintain alignment while in traction. After the pin protrudes through the lateral cortex of the femur, a small incision is made over the tip of the pin. The pin is then driven far enough through the skin to allow fixation with a traction bow. If 90/90 traction is used, a short leg cast can be placed with a ring through its midportion to support the leg. Alternatively, a sling to support the calf may be used. If a sling is used, heel cord stretching should be performed while the patient is in traction.

After the skeletal traction pin has been placed in the distal femur, traction is applied in a 90/90 position (the hip and knee flexed 90 degrees) (Fig. 27-12) or in an oblique position (the hip flexed 20 to 60 degrees). If the oblique position is chosen, a Thomas splint or sling is necessary to support the leg. The fracture may be allowed to begin healing in traction, and x-rays should be obtained once or twice a week to monitor alignment and length. In preschool age children, traction will be necessary for 2 to 3 weeks; in school-age children, a full 3 weeks of traction is usually necessary before the fracture is stable enough to permit casting. In a child under 10 years of age, the ideal fracture position in traction should be less than 1 cm of shortening and slight valgus alignment to counteract the tendency to angulate into varus in the cast and the eventual overgrowth that

FIGURE 27-11 This tomogram shows a bony bridge caused by a tibial traction pin that was placed for femoral fracture.

FIGURE 27-12 In 90-degree/90-degree traction, a femoral pin is used and the lower leg and foot are supported with a short leg cast or a sling.

may occur (average 0.9 cm). If this method is used for adolescents (11 years or older), normal length should be maintained.

Spica Casting, with Traction Pin Incorporated

In rare circumstances, a child's femur fractures best treated by spica casting, incorporating a traction pin in the cast to maintain fracture length. This technique may be particularly useful in an environment where there are limited resources. In a study by Gross et al.,[68] 72 children with femoral fractures were treated with early cast brace/traction management. In this technique, a traction pin is placed in the distal femur and then incorporated in a cast brace. The traction pin is left long enough to be used for maintaining traction while the patient is in the cast brace or traction is applied directly to the cast. The patient is allowed to ambulate in the cast brace starting 3 days after application. Radiographs are taken of the fracture in the cast brace to document that excessive shortening is not occurring. The patient then is returned to traction in the cast brace until satisfactory callus is present to prevent shortening or angular deformity with weight bearing. The technique was not effective in older adolescents with midshaft fractures but achieved excellent results in children 5 to 12 years of age. The average hospital stay was 17 days.

Complications of Spica Casting

Comparative studies and retrospective reviews have demonstrated unsatisfactory results in a small, yet significant, percentage of patients treated with skeletal traction.[84,92,108,169] Recently, increased attention has been focused on the risk of compartment syndrome in children treated in 90/90 spica cast.[151] Mubarak et al.[151] presented a multicenter series of nine children with an average age of 3.5 years who developed compartment syndrome of the leg after treatment of a low-energy femur fracture in a 90/90 spica cast. These children had extensive muscle damage and the skin loss around the ankle (Fig. 27-13). The authors emphasize the risk in placing an initial below knee cast, then using that cast to apply traction while immobilizing the child in the 90/90 position. The authors recommend avoiding traction on a short leg cast, leaving the foot out, and using less hip and knee flexion (Fig. 27-14).

Flexible Intramedullary Nail Fixation for Femoral Shaft Fractures

In most centers, flexible intramedullary nailing is the standard treatment for midshaft femur fractures in children between the ages of 5 and 11 years old. The flexible intramedullary nailing technique can be performed with either stainless steel nails[168,209] or titanium elastic nails.

The popularity of flexible intramedullary nailing results from its safety, efficacy, and ease of implant removal. The flexible nailing technique offers satisfactory fixation, enough stress at the fracture site to allow abundant callous formation, and relatively easy insertion and removal. The implants are inexpensive and the technique has a short learning curve. The primary limitation of flexible nailing is the lack of rigid fixation. Length-unstable fractures can shorten and angulate, especially in older and heavier children. Compared to children with rigid fixation, children who have their femur fracture treated with flexible nailing clearly have more pain and muscle spasm in the early postoperative period. The surgeon should take this into consideration in planning the early rehabilitation.

As the flexible nailing technique has become more popular, there have been many studies to refine the technique and indications, and to elucidate the inherent limitations of fixation with flexible implants. Mechanical testing of femoral fracture fixation systems showed that the greatest rigidity is provided by an external fixation device and the least by flexible intramedullary rodding.[115] Stainless steel rods are stiffer than titanium in bending tests. A study comparing steel to titanium flexible nails found a higher complication rate in the titanium group.[209] They reported that a typical 3.5-mm stainless steel nail has the same

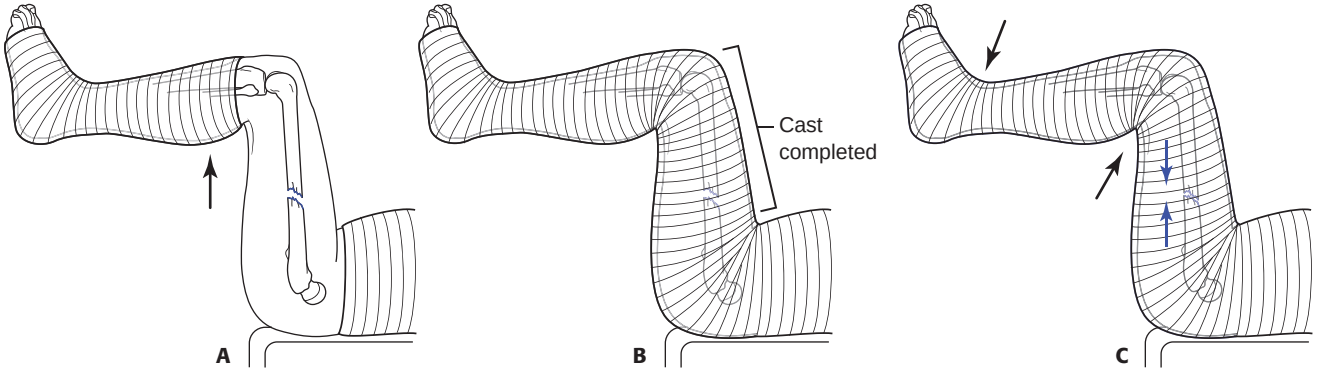

FIGURE 27-13 This drawing shows the pathogenesis of leg compartment syndrome caused by improper application of a spica cast. **A:** In the original description, a short leg cast was applied first, and used to pull the fracture out to length, as shown in this drawing. **B:** As the cast was completed, traction held on the short leg cast portion put pressure in the popliteal fossa. **C:** After the child awakens from general anesthesia, there is shortening of the femur from muscular contraction which causes the thigh and leg to slip somewhat back into the spica. This causes pressure to occur at the corners of the cast. (Reprinted from Mubarak SJ, Frick S, Sink E, et al. Volkmann contracture and compartment syndromes after femur fractures in children treated with 90/90 spica casts. *J Pediatr Orthop.* 2006;26(5):570.)

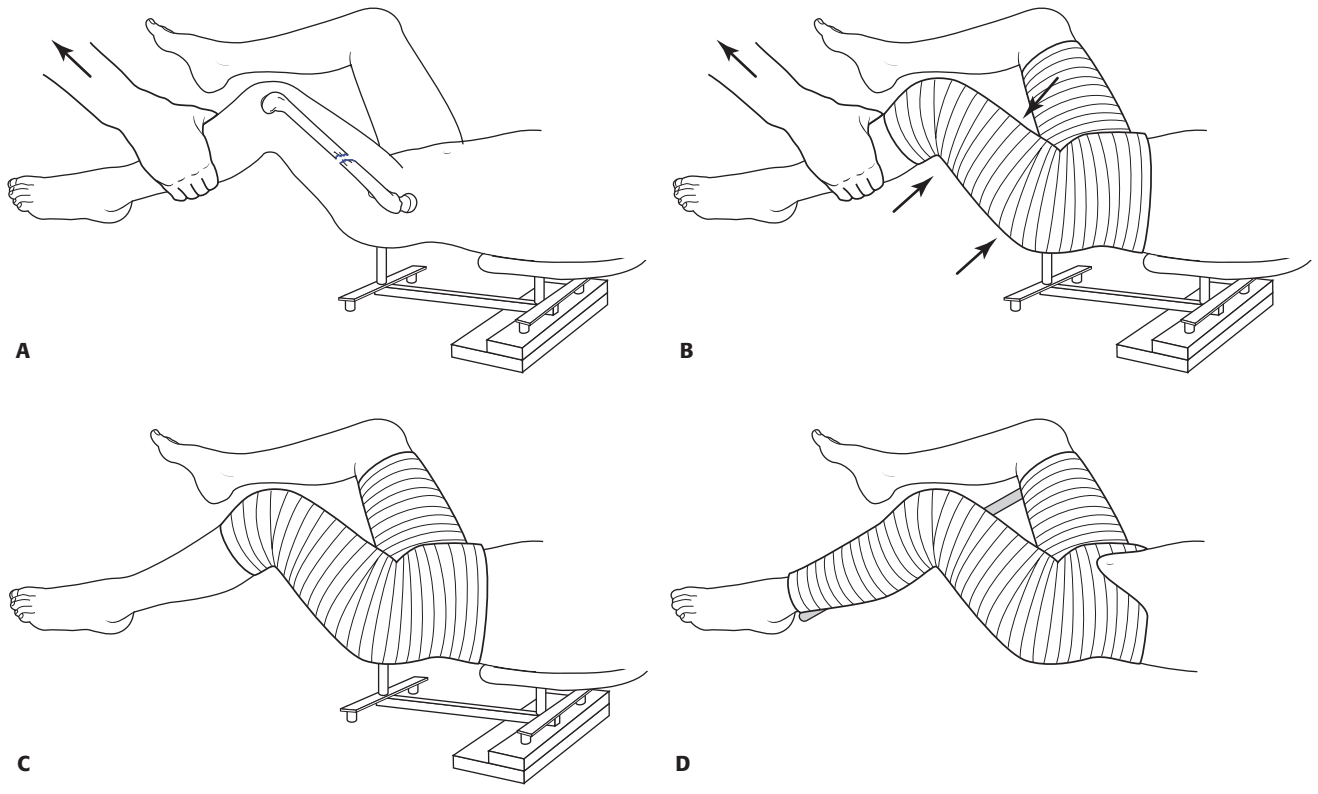

FIGURE 27-14 Authors recommended technique of spica cast application. **A:** The patient is placed on a child's fracture table. The leg is held in about 45-degree angle of flexion at the hip and knee with traction applied to the proximal calf. **B:** The 1½ spica is then applied down to the proximal calf. Molding of the thigh is accomplished during this phase. **C:** The x-rays of the femur are obtained and any wedging of the cast that is necessary can occur at this point in time. **D:** The leg portion of the cast and the cross bar are applied. The belly portion of the spica is trimmed to the umbilicus. (Reprinted from Mubarak SJ, Frick S, Sink E, et al. Volkmann contracture and compartment syndromes after femur fractures in children treated with 90/90 spica casts. *J Pediatr Orthop*. 2006;26(5):571.)

strength as a 4 mm diameter titanium nail. Lee et al.[115] analyzed a group of synthetic fractured femurs instrumented with Enders rods and determined that there was sufficient axial and torsional stiffness to allow "touch-down weight bearing" despite fracture type. Gwyn et al.[71] similarly showed that 4-mm titanium rods impart satisfactory torsional stability regardless of fracture pattern. Recognizing this flexibility, the French pioneers[114,120] of elastic nailing stressed the critical importance of proper implant technique, including prebending the nails so that the apex of the bend was at the fracture site, and so that the two implants balance one another to prevent bending and control rotation. Frick et al.[61] found there to be greater stiffness and resistance to torsional deformation when retrograde nails are contoured into a double C pattern than with the antegrade C and S configuration. Sagan et al.[178] noted that apex anterior malunion is less likely if at least one nail has its shoe tip point anteriorly, such that the nail is in procurvatum.

The prevailing technique for flexible nail insertion at most centers throughout the world has been retrograde, with small medial and lateral incisions just above the distal femoral physis. However, some prefer an antegrade technique, with entry in the subtrochanteric area. The primary advantages of a proximal insertion site are a fewer knee symptoms postoperatively. Bourdelat[21] compared retrograde and antegrade (ascending and descending) flexible intramedullary rodding in a group of 73 femoral fractures. An antegrade transtrochanteric approach was recommended by Carey and Galpin,[31] who reported excellent results in 25 patients without growth arrest of the upper femur and no osteonecrosis. Satisfactory alignment and fracture healing were obtained in all patients.

Retrograde intramedullary nailing with Ender nails or titanium nails has been reported by Ligier et al.,[120] Mann et al.,[127] Heinrich et al.,[79] Herscovici et al.,[85] and others.[31,104,135] Heinrich et al.[79] recommended a 3.5-mm Ender nail in children 6 to 10 years of age and a 4-mm nail in children over 10 years of age. Ligier et al.[120] used titanium nails ranging from 3 to 4 mm inserted primarily in a retrograde fashion. Heinrich et al.[80] recommended flexible intramedullary nails for fixation of diaphyseal femoral fractures in children with multiple system injury, head injury, spasticity, or multiple long bone fractures. Flynn et al.[58] published the first North American experience with titanium elastic nails. In this multicenter study, 57/58 patients had an excellent or satisfactory result, there was no loss of rotational alignment, but four patients healed with

an angular malunion of more than 10 degrees. Narayanan et al.[152] looked at one center's learning curve with titanium elastic nails, studying the complications of 79 patients over a 5-year period. Nails that were bent excessively away from the bone led to irritation at the insertion site in 41. The center also had eight malunions and two refractures. They noted that complications could be diminished by using rods with similar diameter and contour, and by avoiding bending the distal end of the nail way from the bone and out into the soft tissues. Luhmann et al.[123] reported 21 complications in 43 patients with titanium elastic nails. Most of the problems were minor, but a hypertrophic nonunion and a septic joint occurred in their cohort. They suggested that problems could be minimized by using the largest nail possible and leaving only 2.5 cm out of the femoral cortex.

Flexible nails are removed after fracture union at most centers. However, some surgeons choose to leave the implants permanently. There is a theoretical concern that if flexible nails are left in young children, they will come to lie in the distal diaphysis as the child grows older. This may create a stress riser in the distal diaphysis, leading to a theoretical risk of fracture (Fig. 27-15). Morshed et al.[150] performed a retrospective analysis of 24 children treated with titanium elastic nails and followed for an average of 3.6 years. The original plan with these children was to retain their implants. However, about 25% of the children had their nails removed for persistent discomfort.

FIGURE 27-15 **A:** A few years after titanium lasting nailing, the nails have migrated proximally with growth, creating a stress riser and the subsequent insufficiency fracture. **B.** The refracture was treated with removal of the old nails and replacement with longer implants.

Fixation with Flexible Intramedullary Nails: Technique

Preoperative Planning. The ideal patient for flexible intramedullary nailing is the child between the ages of 5 and 11 years old with a length-stable femur fracture, in the mid-80% of the diaphysis (Fig. 27-16), who has a body weight less than 50 kg.[148] Unstable fracture patterns can also be treated with

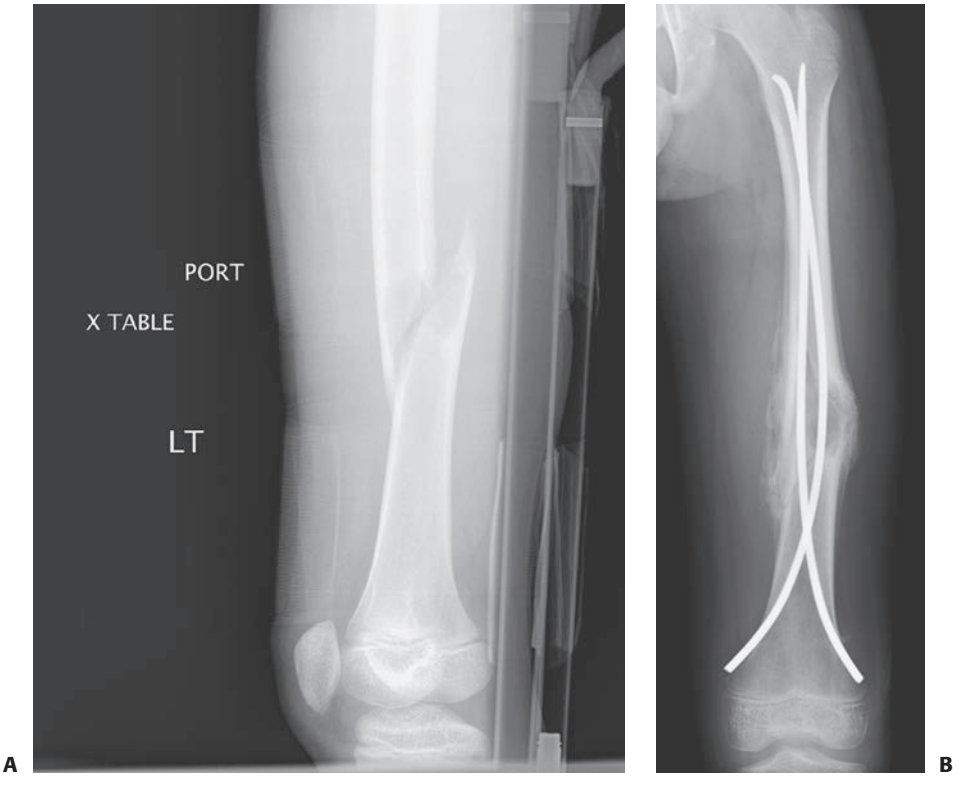

FIGURE 27-16 Titanium elastic nailing of the midshaft femur fracture through a benign lytic defect. **A:** Portable radiograph of a short oblique femur fracture through a benign lytic defect. **B:** AP radiograph taken several weeks after surgery that show the fracture well aligned with titanium elastic nail internal fixation and early callus at the fracture site.
