CHAPTER

10 Ultrasonography and Nuclear Medicine

Frederic Rahbari-Oskoui • Andrew T. Taylor • William Charles O'Neill

Sonography and nuclear medicine are important tools in the evaluation of the kidneys and urinary tract. Due to its simplicity and ready availability, sonography is usually the initial imaging performed and, in many cases, the only examination required. The low cost and portability of modern equipment enable sonography to be an office-based or bedside procedure performed by the practitioner, adding to its convenience and attractiveness. Nuclear medicine can obtain important functional data and complements other imaging modalities that cannot provide this information. This functional assessment can be critical for clinical decisions and often avoids the necessity of invasive testing. This chapter reviews the advantages, disadvantages, and indications for each modality in the kidneys and urinary tract along with the basics of interpretation and common findings.

ULTRASONOGRAPHY

The introduction and extensive use of ultrasonography over the past four decades has dramatically simplified the diagnostic evaluation of the urinary tract. The acoustic properties, limited spectrum of pathology, and ease of visualization of the kidneys—coupled with the safety, simplicity, lack of radiation, and low cost—of sonography make it the initial modality of choice. The improved portability and affordability of equipment and availability of training provide an opportunity for nephrologists to become skilled at this technique, thereby enhancing the diagnosis and care of their patients.

Sonographic images are acquired by analyzing the amplitude and interval of reflected pulses of high-frequency sound. Time is converted to depth and amplitude is converted to brightness (echogenicity) to yield a pixel-based image. Highly reflective structures such as a stone appear bright and cast a dark, distal shadow. In contrast, fluid collections such as cysts do not reflect sound and appear dark but enhance the echogenicity of distal tissue (distal enhancement or through transmission).[1] Tissues such as renal parenchyma have an intermediate echogenicity related to backscatter of sound from the microscopic architecture. Indications for ultrasound imaging of the kidneys and the bladder are diverse and include evaluation of acute renal failure, chronic kidney disease (CKD), cystic diseases, pain, hematuria, severe hypertension, urinary tract infections, and guidance for kidney biopsies.

Imaging and Normal Appearance of the Kidneys

The adult kidney contains several lobules, each consisting of a rim of cortex surrounding a medullary pyramid that terminates in a papilla protruding into a minor calyx. The lobules fuse in utero or shortly after birth in most individuals. The cortex between two pyramids is called a column of Bertin. Minor calyces converge into major calyces that, in turn, converge to form the renal pelvis. The portion of the kidneys that is not parenchyma or urinary space is the sinus, which, in adults, is filled with adipose tissue (Fig. 10.1). Longitudinal views of the kidney are obtained in the supine position with the probe positioned so that the upper pole appears on the left side of the image. In the longitudinal plane, the normal kidney has a characteristic oval shape with a hypoechoic (dark) rim of cortex and medulla surrounding the echogenic (bright) sinus fat[2–4] that obscures the calyces and blood vessels (Fig. 10.2). The medullary pyramids are slightly less echogenic than the cortex[2] and can often be discerned. They are particularly prominent when cortical echogenicity is increased. Transverse images are obtained perpendicular to the longitudinal axis and the kidney appears circular at each pole and C-shaped through the center due to the break in the parenchyma where the ureter and vessels enter, thereby providing the best views of the renal pelvis and hilum.

The appearance of the kidneys is subject to normal variations related primarily to incomplete fusion of the ranunculi. These include complete duplication of the collecting system, which appears as a band of cortex separating the sinus fat into two compartments (Fig. 10.3) and is present in 5% of kidneys, and hypertrophied columns of Bertin, where the cortex extends into the sinus but does not completely bridge

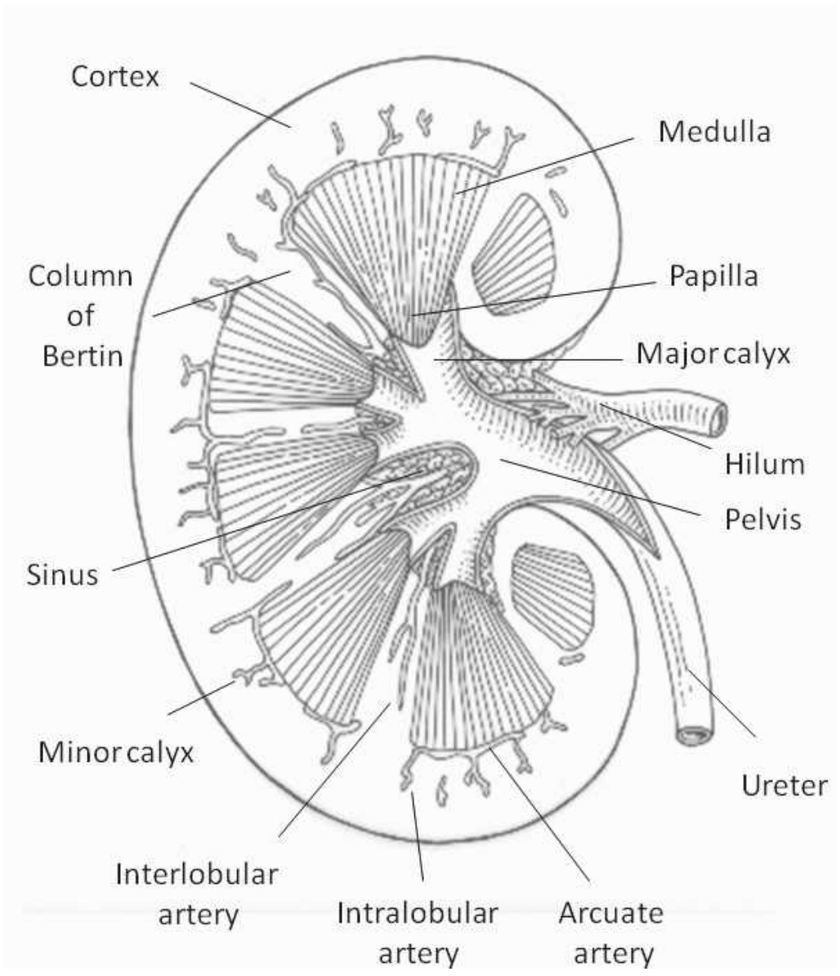

FIGURE 10.1 Intrarenal anatomy, midline coronal section. (Adapted from O'Neill WC. Sonographic evaluation of renal failure. *Am J Kidney Dis*. 2000;35:1021, with permission.)

it (Fig. 10.4) and is present in 15% of kidneys.[5,6] Junctional parenchymal defects are the most subtle manifestation of incomplete fusion, presenting as a wedge-shaped defect in the outer cortex filled with echogenic fat that is continuous with the renal sinus fat by a thin strand.[6] In some individuals, the lobules fail to completely fuse and persist into adulthood. These so-called fetal lobulations appear as regularly spaced convexities, each containing a pyramid.[7] Lobulation may reappear in chronic kidney disease due to atrophy of the columns of Bertin (Fig. 10.5).

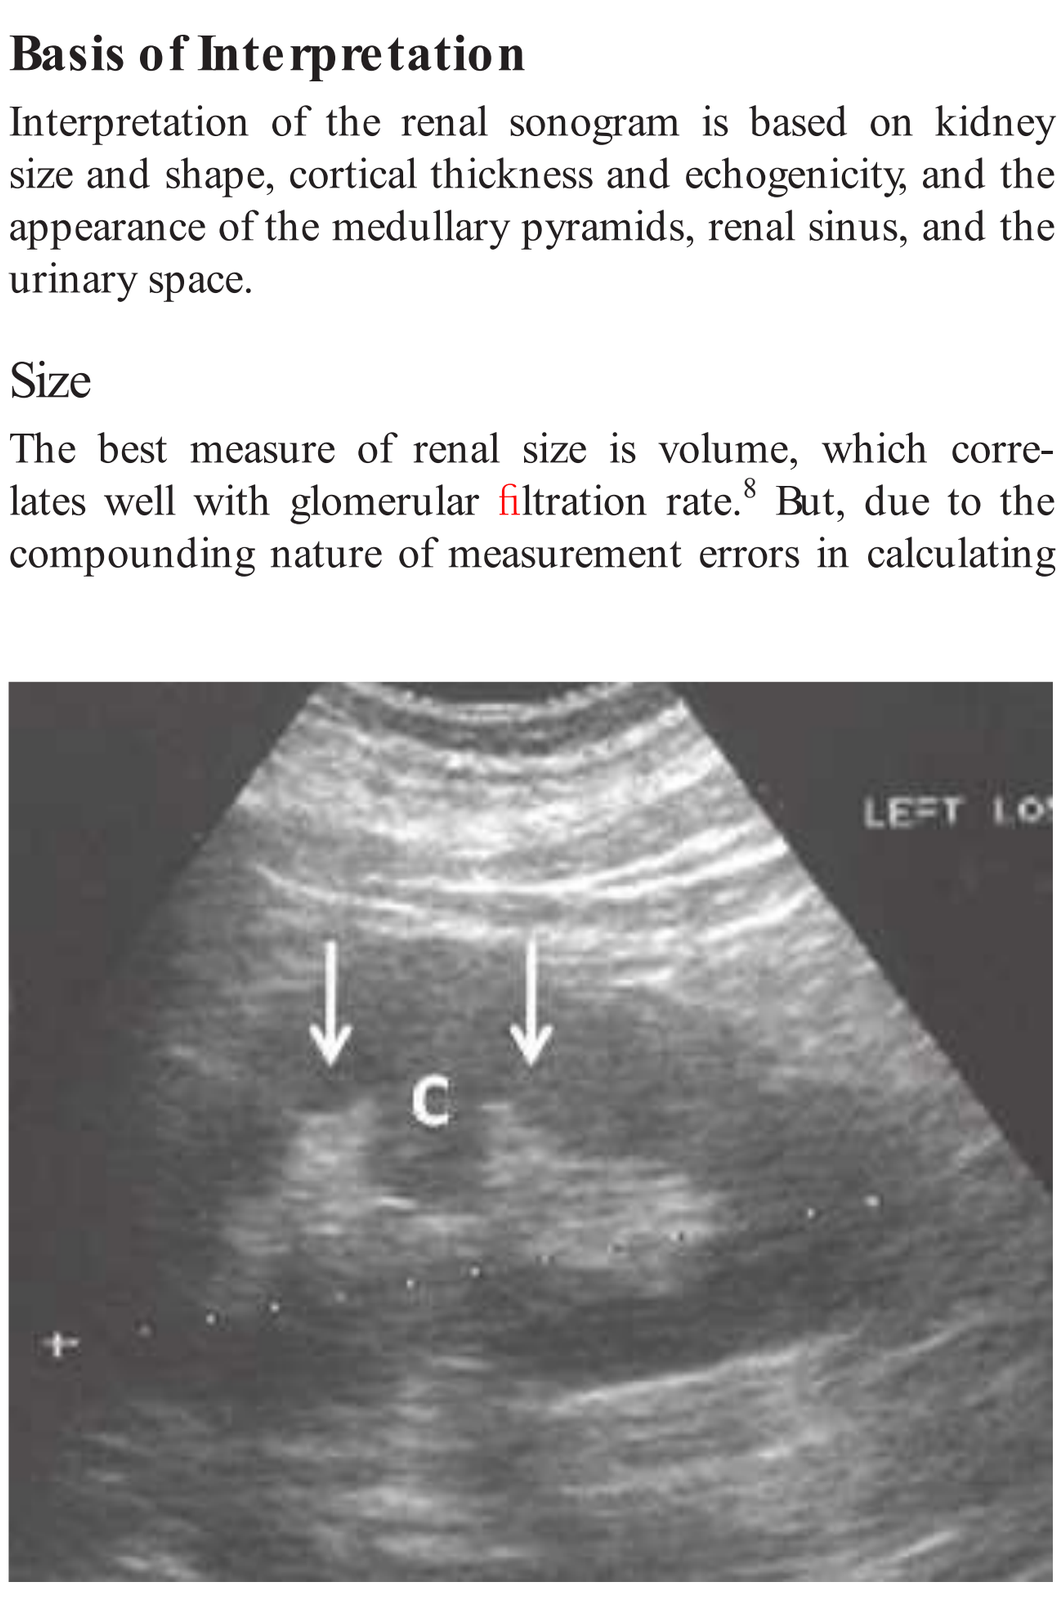

FIGURE 10.3 Duplication of the collecting system. Longitudinal view of the kidney showing a band of tissue (*arrow*) demarcating two separate renal sinuses (*S*).

Basis of Interpretation

Interpretation of the renal sonogram is based on kidney size and shape, cortical thickness and echogenicity, and the appearance of the medullary pyramids, renal sinus, and the urinary space.

Size

The best measure of renal size is volume, which correlates well with glomerular filtration rate.[8] But, due to the compounding nature of measurement errors in calculating

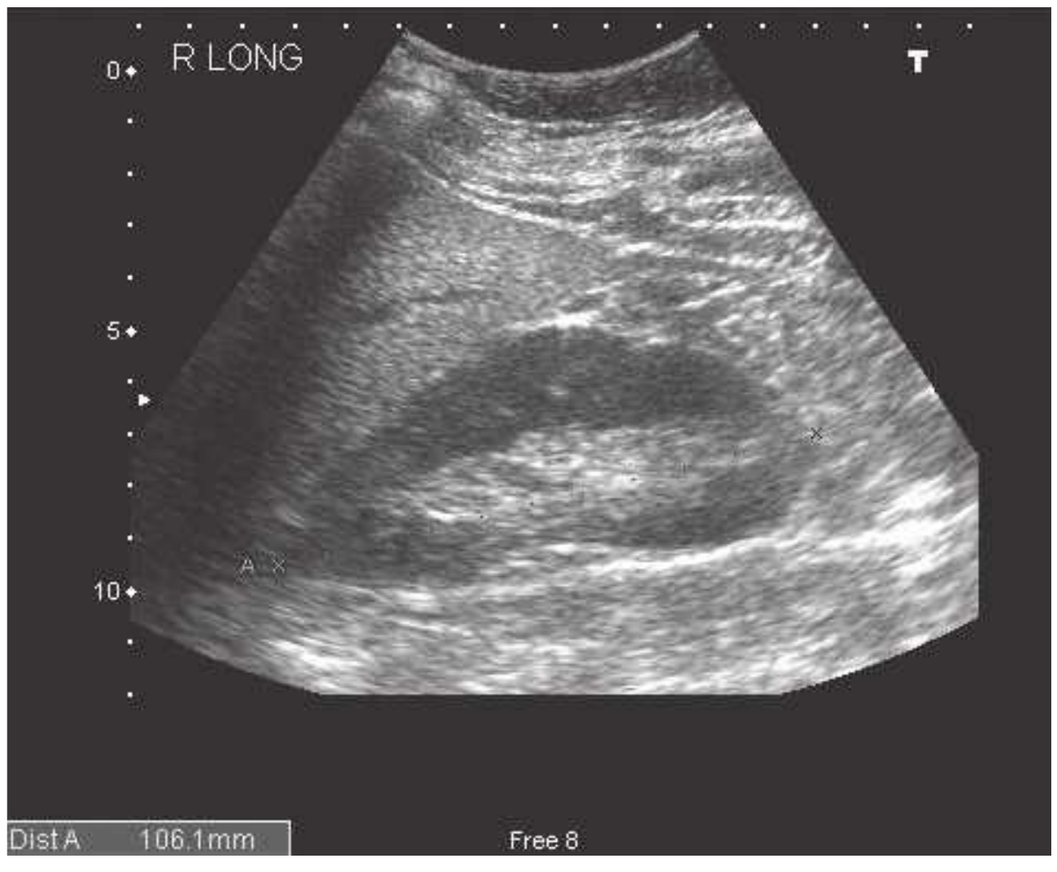

FIGURE 10.2 Longitudinal image of a normal right kidney. Compared to the liver, the renal parenchyma appears as a relatively hypoechoic, oval rim around the echogenic sinus fat.

FIGURE 10.4 Hypertrophied column of Bertin. Longitudinal image of the left kidney showing cortex (*C*) protruding into the renal sinus between two medullary pyramids (*arrows*).

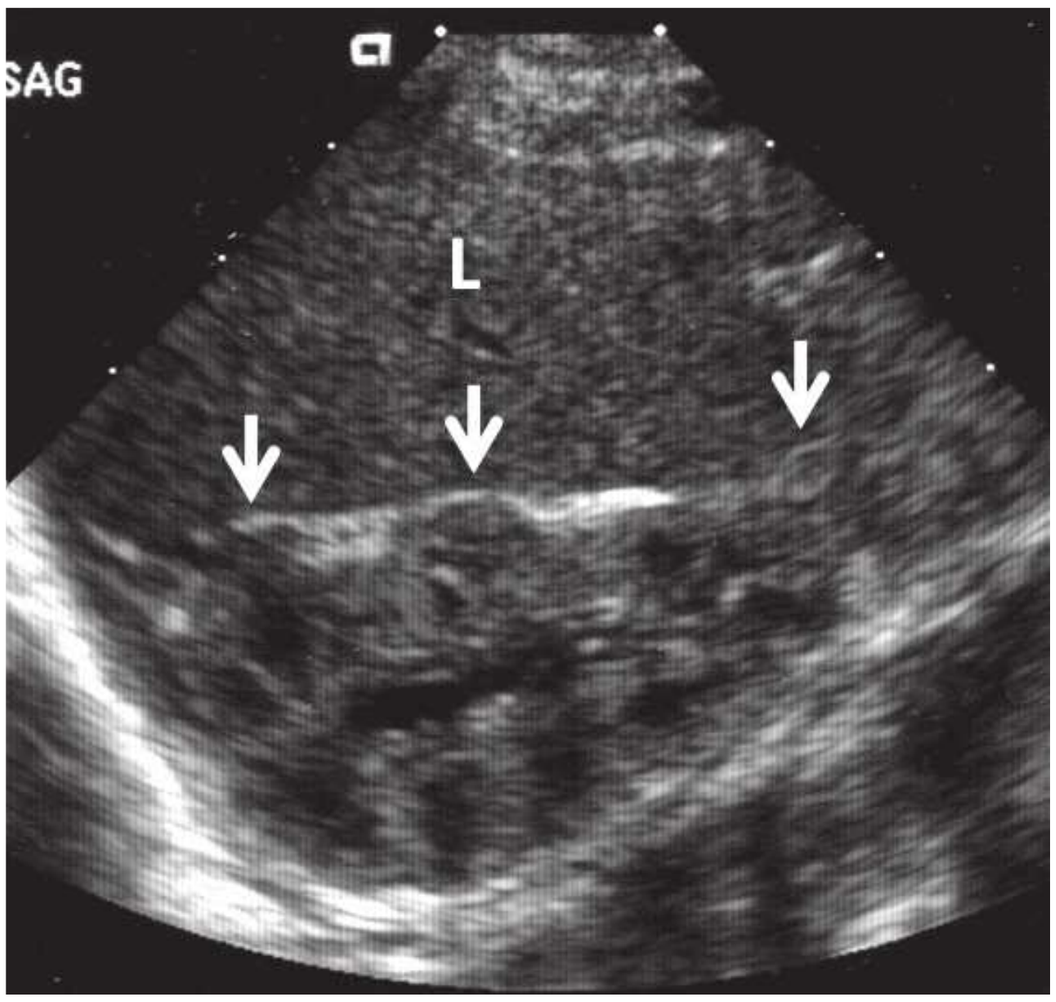

FIGURE 10.5 Normal neonatal kidney. Longitudinal view of the right kidney in a neonate showing accentuated lobules (*arrows*) and the medullary pyramid centered within each lobule. The cortex is more echogenic than the liver and there is no sinus fat.

volume, and the good correlation between maximum kidney length and renal volume,[9,10] maximum renal length is preferred for assessment of renal size on sonograms. Additional measurements in the transverse axes are very inaccurate and of no utility. Renal length averages 11 cm in adults,[10] and 10 cm to 12 cm is a useful range for normal renal length at average body height. Because the variability in measurements is 5%,[9] differences up to 1 cm may not be significant. The variability may be greater in children, comprising as much as 2 to 3 years in the comparison of kidney length to age.[11] Kidney length correlates best with body height in both adults and children (Fig. 10.6A)[10,12–14] and, after correction for body height, does not vary between sexes. Kidney length rapidly increases during the first year of life with a more gradual enlargement up to about 18 years[14,15] (Fig. 10.6B). Progressive enlargement occurs during pregnancy that resolves by 12 weeks postpartum, due primarily to parenchymal enlargement—although some pelvocaliceal enlargement occurs, particularly in the right kidney.[16] Proper interpretation of kidney size must take into account the effect of these nonpathologic factors. Compensatory hypertrophy is common in solitary kidneys in children (up to 80%–90% increase in volume),[17,18] and after nephrectomy in adults (5%–30% increase).[19,20] Enlargement of the kidneys occurs in nephritis and infiltrative diseases, often accompanied by a rounded shape and increased echogenicity.

Cortical Thickness

The thickness of the renal cortex is measured from the renal capsule to either the outer border of the medullary pyramids or to the arcuate arteries. A normal value of 9.3 ± 1.1 mm was obtained in 23 renal transplant donors.[21] If medullary pyramids are not discernible, the parenchymal thickness between the sinus fat and the renal capsule (mean value of 15 to 16 mm) may be used.[10] However, both parameters can vary within a kidney and are difficult to measure precisely. Cortical thinning is a sign of advanced chronic kidney disease. Increased cortical thickness is usually due to edema or

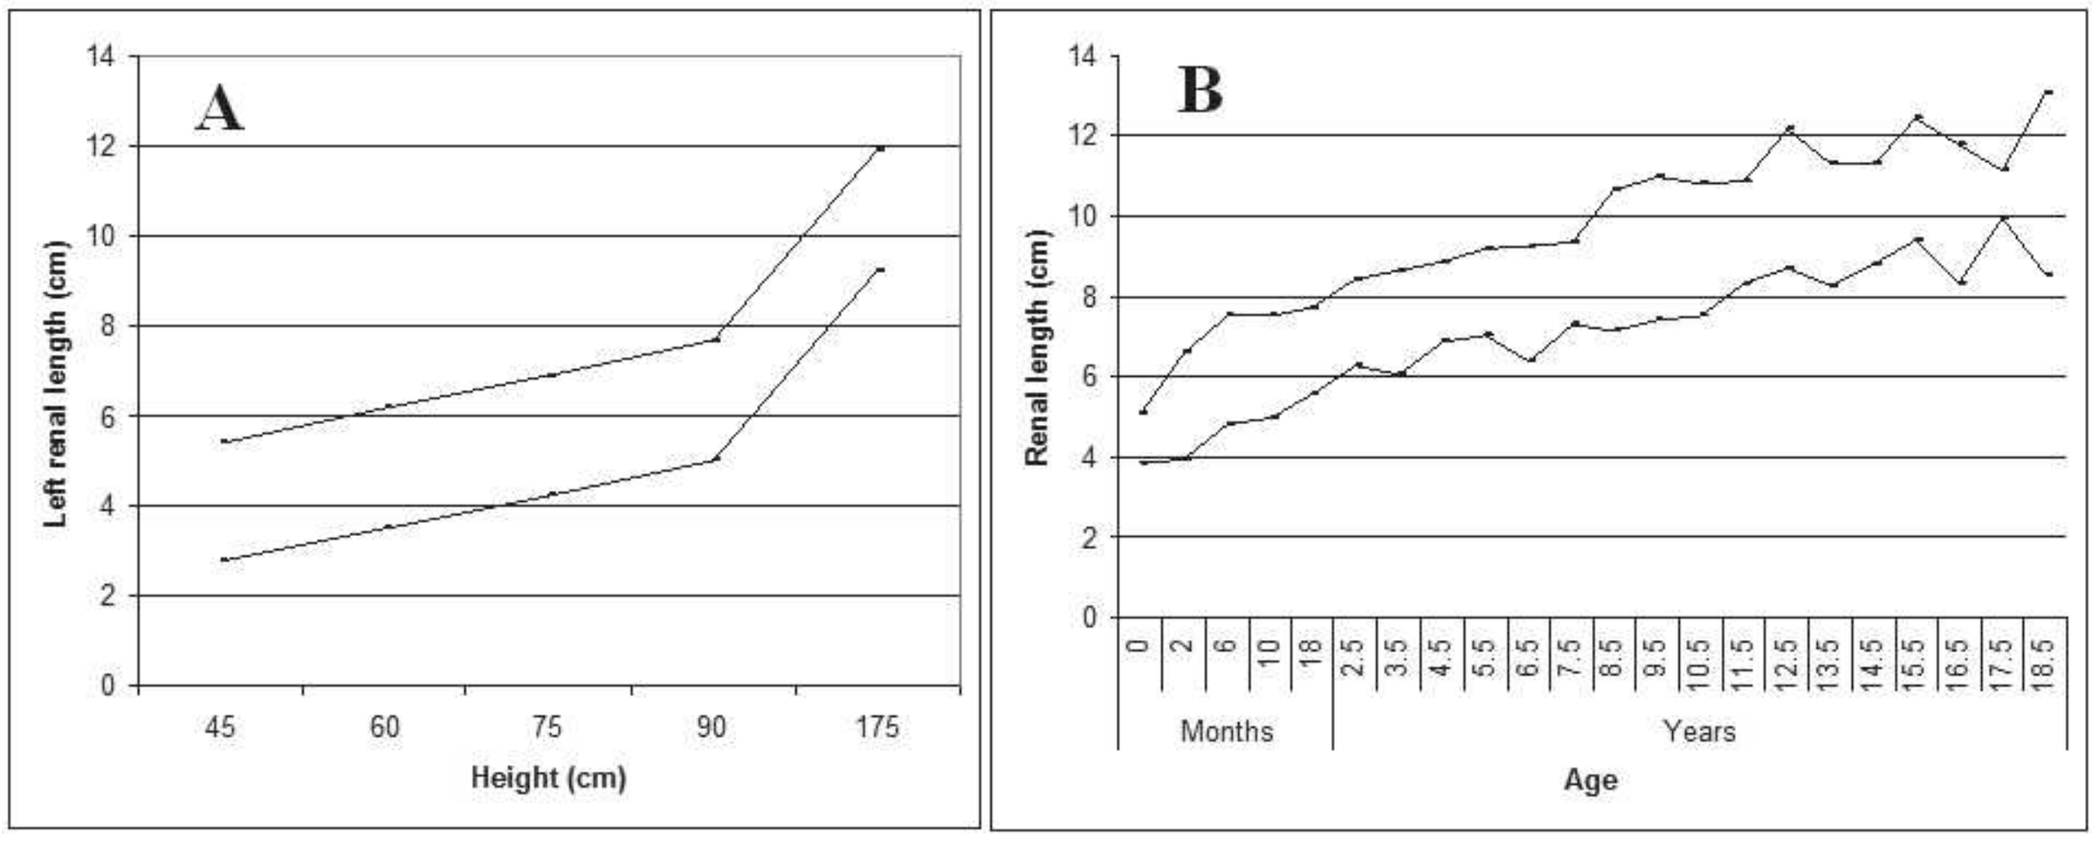

FIGURE 10.6 **A:** Nomogram of renal length based on body height showing 95% confidence limits for maximum length of the left kidney as a function of body height in children. (Adapted from O'Neill WC. *Atlas of Renal Ultrasonography*. Philadelphia: WB Saunders; 2011, with permission.)

inflammation and is often accompanied by kidney enlargement, a globular shape, and obliteration of the sinus fat.

Cortical Echogenicity

Comparison of renal cortex to the liver or spleen, at the same depth, is the basis for determination of cortical echogenicity. Renal cortical echogenicity depends on age and is often greater than liver echogenicity in neonates but should be less than or equal to[22,23] that of the liver or spleen by 6 months of age.[24] After several years of age, the renal cortical echogenicity should always be less than the liver. Fibrosis, infiltrating cells, and tubular debris and dilation can increase echogenicity. Transmission artifacts related to overlying fluid and ribs, and increased hepatic echogenicity in steatosis or cirrhosis, can bias the interpretation of cortical echogenicity.

Medullary Pyramids

The medulla should be less echogenic than the cortex but visibility depends on overlying structures and the frequency of sound. Medullary disease usually causes increased echogenicity.

Renal Sinus

The neonatal kidney contains very little fat but the normal renal sinus in adults should exhibit only echogenic fat. Occasionally, the calyces are visible in otherwise normal kidneys, particularly during a brisk diuresis[25,26] or during pregnancy.[27,28] Blood vessels may also be visible, particularly in children and young adults or in states of increased central venous pressure.

Parenchymal Diseases

Glomerular or tubulointerstitial disorders usually present with diffuse changes in the kidneys. However, the changes can be similar in different disorders and the kidneys may appear normal. Thus, interpretation is very dependent on the clinical findings.

The most common parenchymal disorder that causes acute kidney injury is acute tubular necrosis (ATN). The renal sonogram can be normal in ATN[29–31] but increased cortical echogenicity and cortical expansion have been observed in both animal and human studies,[32–35] especially with nephrotoxic ATN,[32,35,36] whereas an enlarged hypoechoic cortex may be more typical of ischemic ATN.[6,32] The cortical enlargement presumably represents edema whereas increases in cortical echogenicity may be due to cellular and proteinaceous casts and debris within the tubules. The degree of renal enlargement has been shown to inversely correlate with recovery time from ATN.[34] In general, sonography is rarely useful in the workup of acute renal failure when the clinical picture suggests ATN and urinary obstruction is unlikely. However, it may be helpful in identifying underlying chronic kidney disease in this setting.

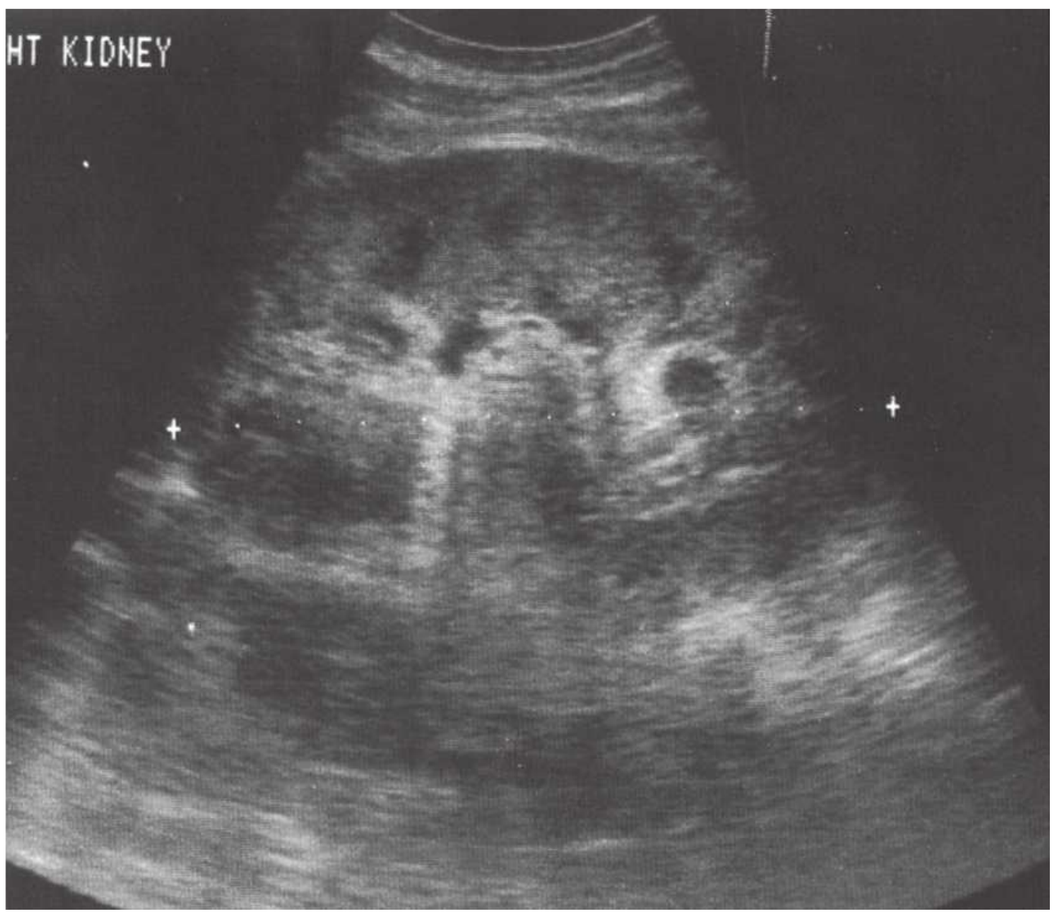

FIGURE 10.7 Acute glomerulonephritis. Longitudinal view of the right kidney showing a globular kidney with diminished sinus fat indicating cortical swelling. Note the prominence of the medullary pyramids due to increased cortical echogenicity.

Glomerulopathies

Although sonography is usually normal in glomerular diseases, acute glomerulonephritis and thrombotic microangiopathies can appear as cortical enlargement and increased cortical echogenicity.[30,31,37,38] When taken in the context of chronic renal failure, even a normal cortical thickness is suggestive of glomerular disease (diabetic nephropathy) because other disorders usually lead to cortical thinning.[39] The cortex is typically normal in membranous nephropathy or immunoglobulin A (IgA) nephropathy.[30,31,40] In severe glomerulonephritis, the kidney may take a rounded shape and echogenic appearance that is barely recognizable as a kidney (Fig. 10.7). Enlarged, echogenic kidneys can also be seen in HIV nephropathy,[41,42] amyloidosis, and preeclampsia.[43]

Tubulointerstitial Disease

Acute interstitial nephritis produces enlarged echogenic kidneys[30,44,45] that have the same appearance as glomerulonephritic kidneys. Chronic interstitial nephritis, particularly analgesic nephropathy (Fig. 10.8), presents with hyperechoic medullary pyramids, often with cortical atrophy.[31,46,47] At a more advanced stage, papillary necrosis and calcifications may be seen.[47–50] Medullary echogenicity can also be increased by uric acid deposition and nephrocalcinosis (Fig. 10.9), sickle hemoglobinopathies, Sjögren syndrome, and chronic hypokalemia.[51] Although acute pyelonephritis rarely produces renal failure, chronic pyelonephritis may cause chronic kidney disease and present with focal cortical scarring and thinning of the cortex often accompanied by caliectasis (Fig. 10.10). Xanthogranulomatous pyelonephritis may lead to enlarged, cystic appearing kidneys.[52,53]

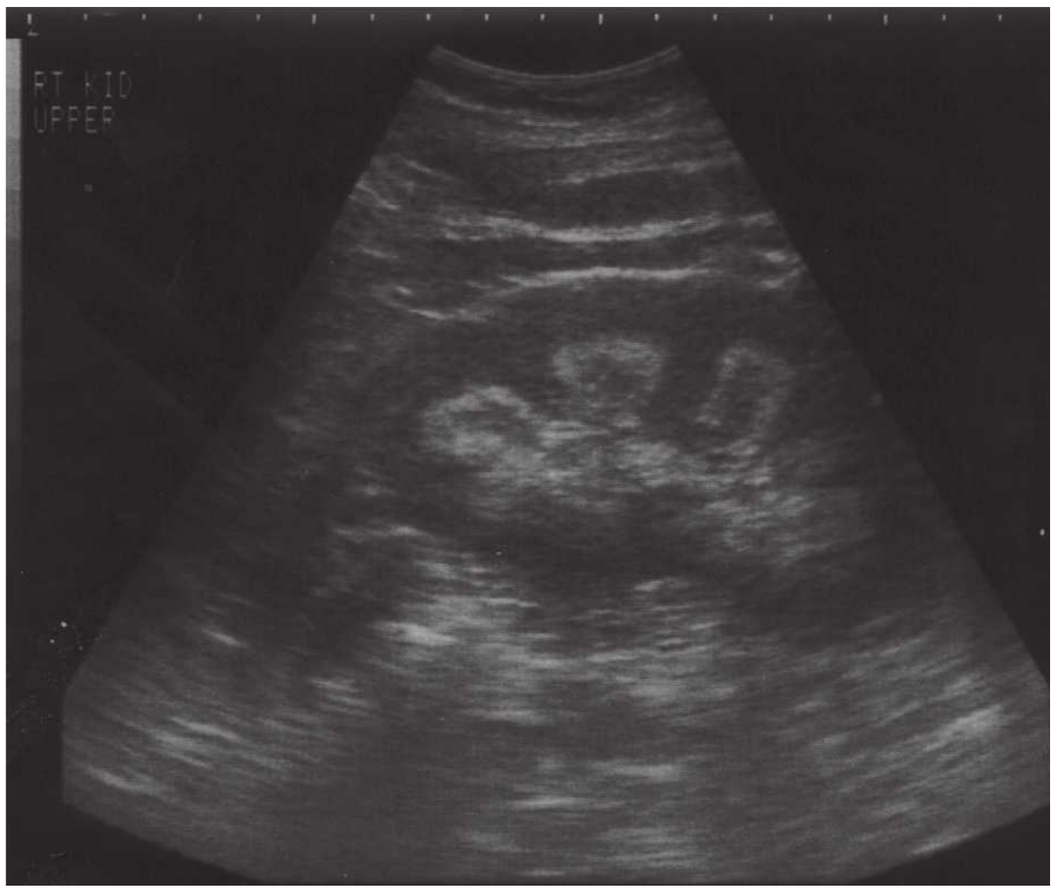

FIGURE 10.8 Analgesic nephropathy. Longitudinal view of the right kidney showing hyperechoic pyramids with relative sparing of the central portions.

Renal atrophy is usually the consequence of long standing renal disease or congenital defects, and presents as small kidneys with a thin cortex and accentuated lobulations (Fig. 10.11). The presence of renal atrophy does not provide any information on the underlying renal pathology but usually indicates that a renal biopsy will be uninformative.

Cysts

Cysts are fluid-filled structures with an epithelial lining usually originating from renal tubules. The typical sonographic features of cysts (anechoic structures with distal enhancement) make them very easily discernible by ultrasonography. The most common type of cyst is a sporadic acquired cyst, which can be present without any kidney disease. Cysts can be simple (Fig. 10.12) or complex (Fig. 10.13), with

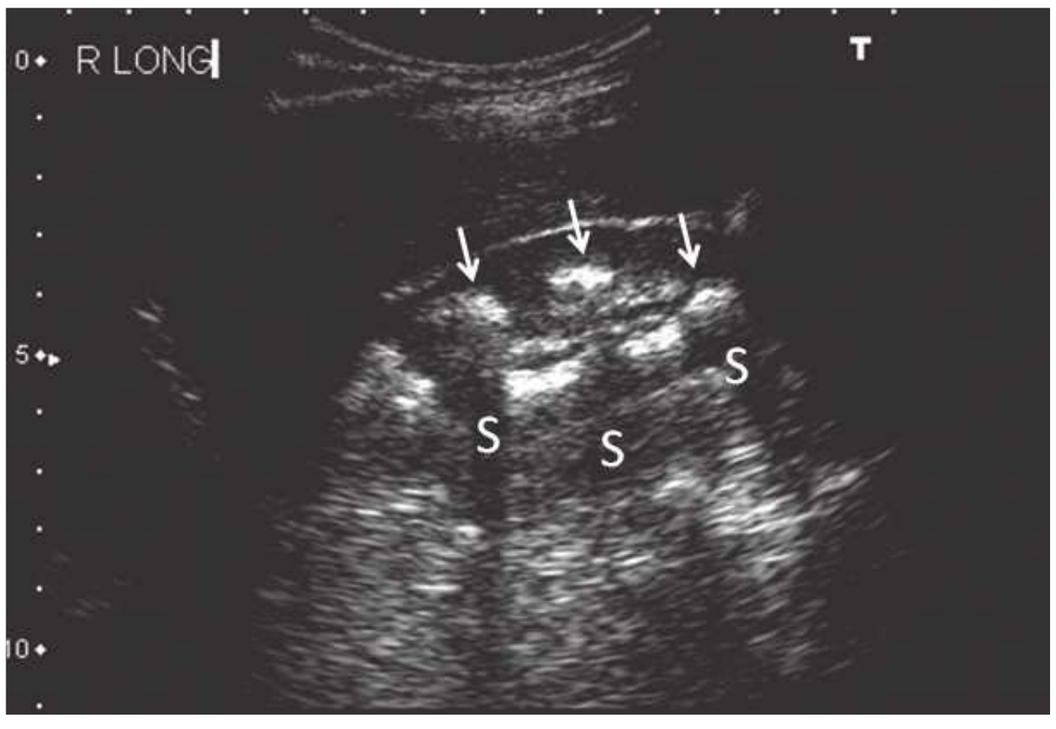

FIGURE 10.9 Nephrocalcinosis. Longitudinal image of the right kidney showing multiple calcifications in the inner medullae (*arrows*) producing acoustic shadows (*S*).

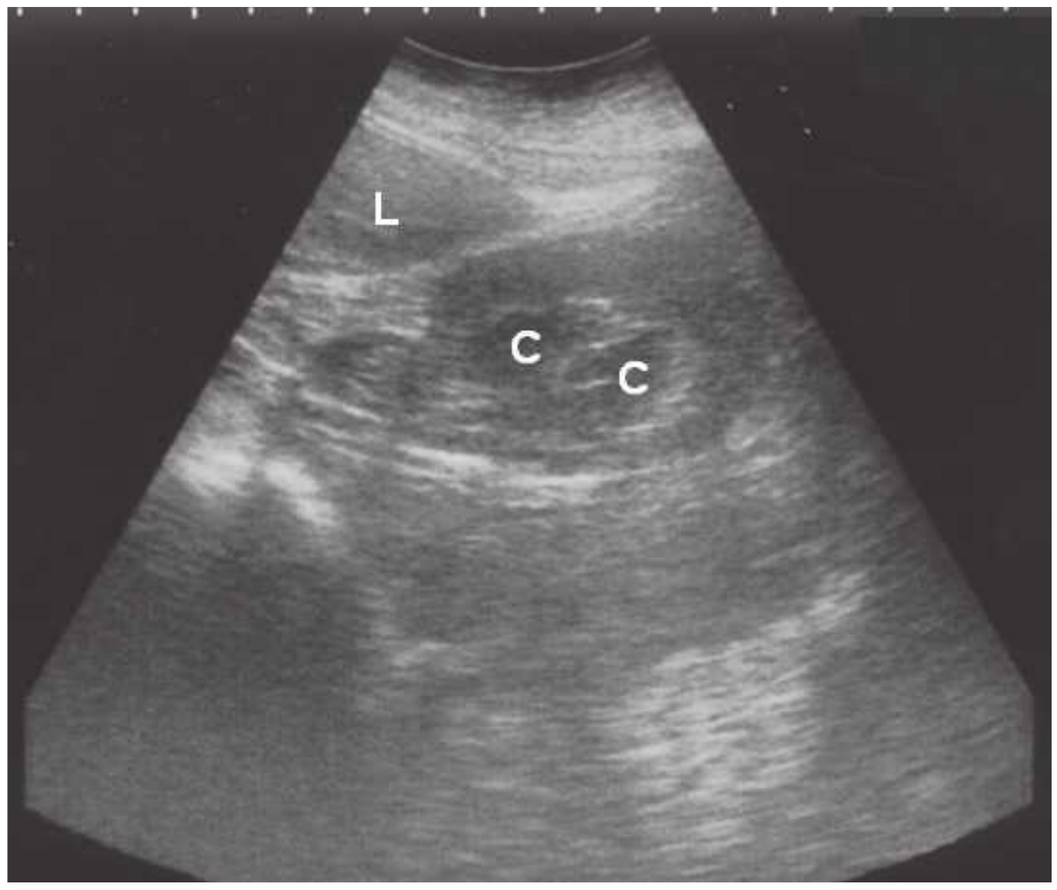

FIGURE 10.10 Chronic pyelonephritis. Longitudinal view of the right kidney shows caliectasis of the lower pole (*C*), and loss of parenchyma with scarring of the upper pole (*arrows*). *L*, liver.

the criteria for complexity including thickening of the wall, calcifications, more than two septations, and luminal echogenicity. Even though the great majority of complex cysts are benign, any complex cyst should be closely followed up with ultrasound or additional imaging studies (computed tomography [CT] and magnetic resonance imaging [MRI]), given the possibility of cystic renal cell carcinomas.[54]

Acquired cystic kidney disease (ACKD) and autosomal dominant polycystic kidney disease (ADPKD) are the most common types of multicystic renal disease. ACKD is often encountered in patients with advanced chronic kidney disease (CKD) or end-stage renal disease (ESRD). Cysts are

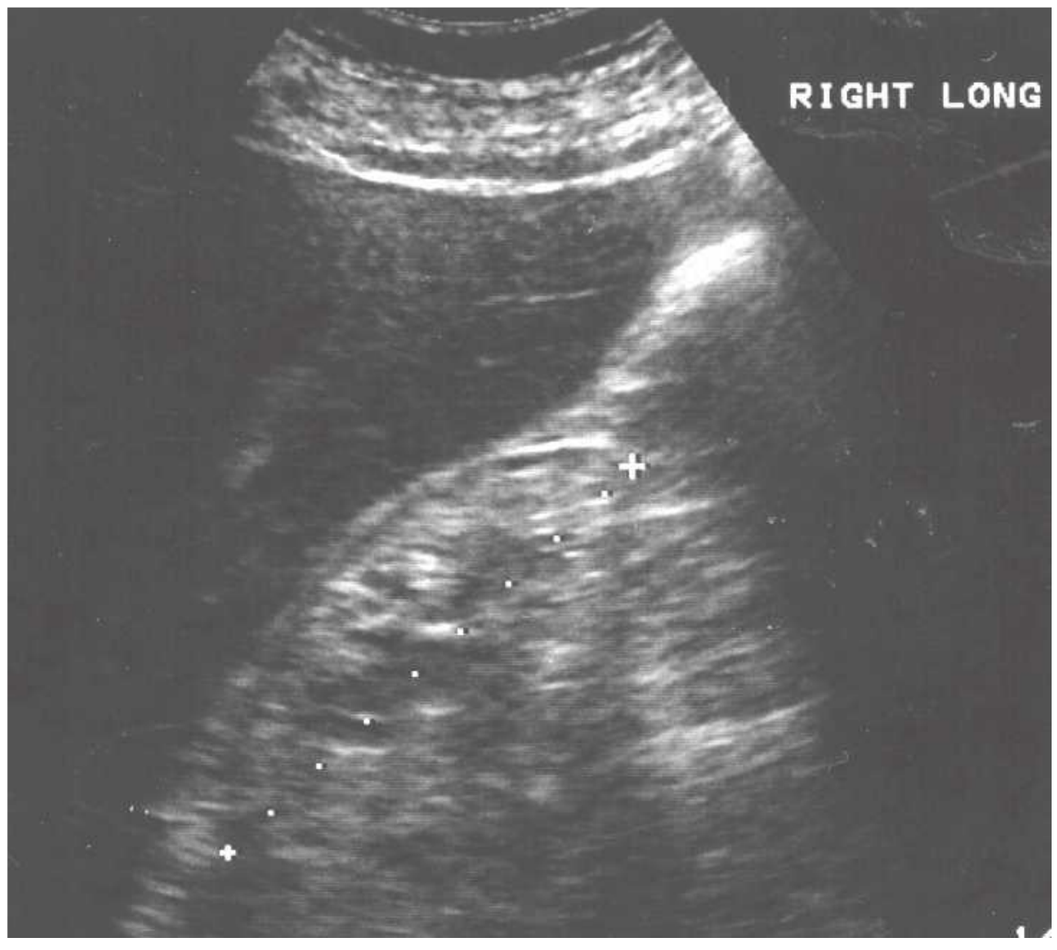

FIGURE 10.11 Renal atrophy. Longitudinal image of the right kidney showing a small kidney with a thin and hyperechoic cortex.

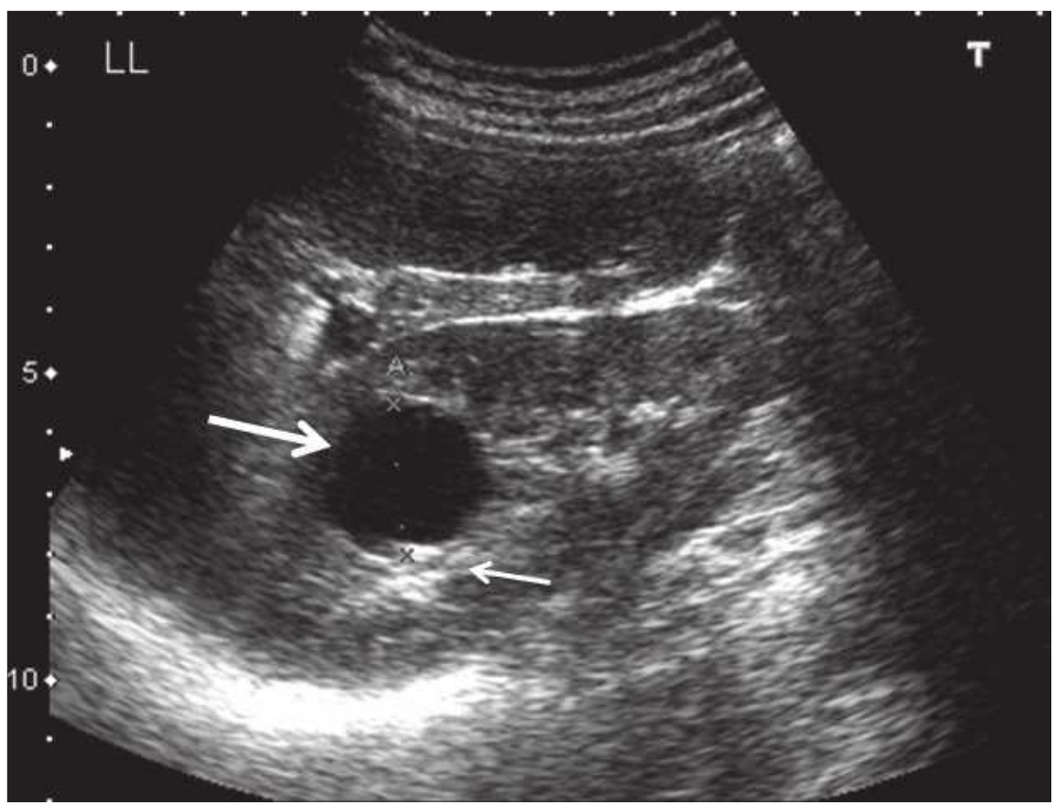

FIGURE 10.12 Simple cyst. Longitudinal image of the left kidney showing a round hypoechoic structure (*large arrow*) in the lower pole, which presents with distal acoustic enhancement (*small arrows*), consistent with a simple cyst.

typically of smaller size and the kidney is usually echogenic and small[55] (Fig. 10.14). ADPKD is the most common inherited cause of renal failure, and sonography is the cornerstone of diagnosis using specific criteria established by Ravine et al.[56] The performance of these criteria was found to be suboptimal in the PKD-2 genotype and revised unified criteria have recently been published by an international group of investigators (Table 10.1).[57]

The pathognomonic sonographic appearance of ADPKD includes presence of multiple bilateral renal cysts (Fig. 10.15) and liver cysts (in 83%–90% of patients)[58] with

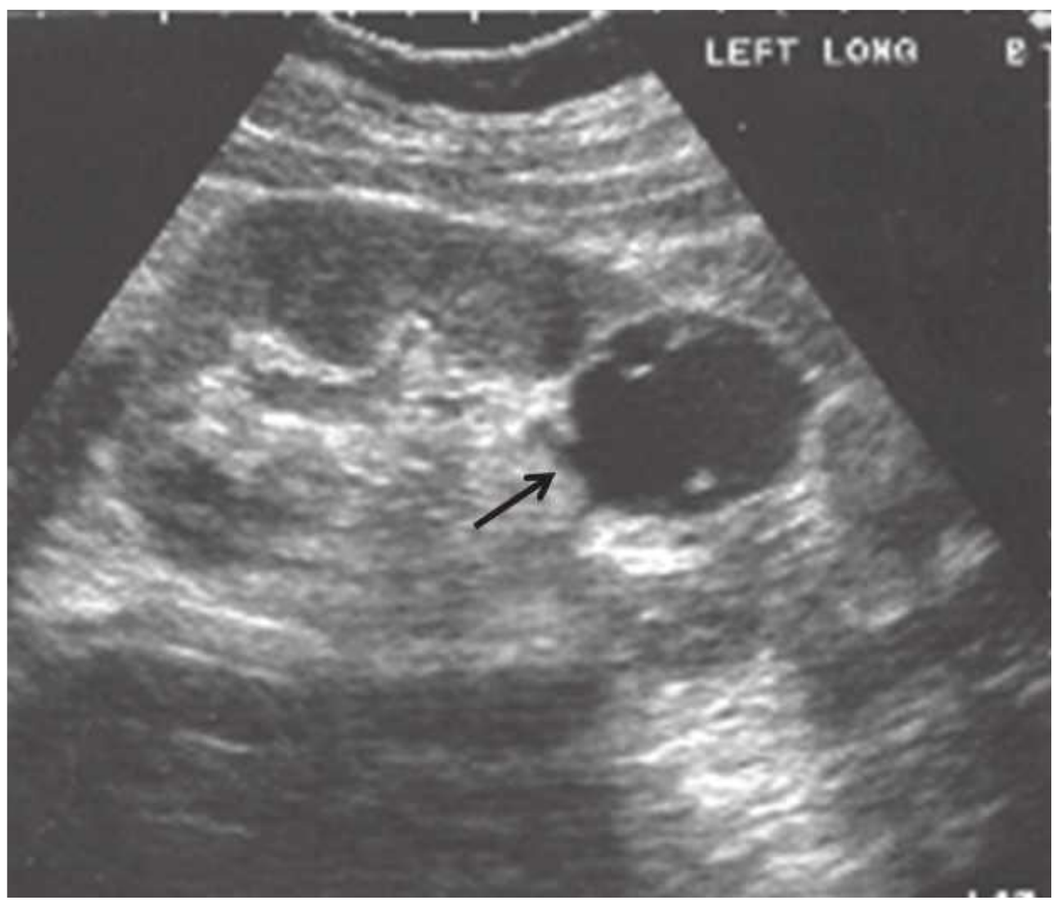

FIGURE 10.13 Complex cyst. Longitudinal view of the left kidney shows a cyst with an irregular wall (*black arrow*) and several internal echoes.

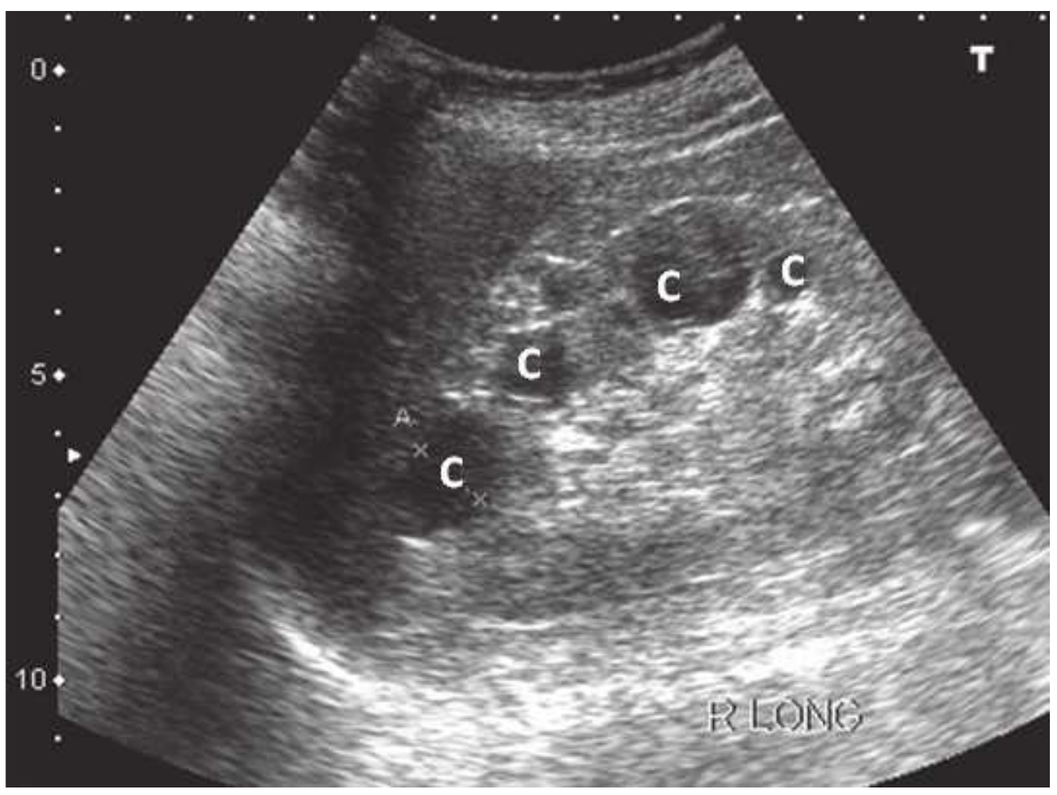

FIGURE 10.14 Acquired cystic kidney disease. Longitudinal view of the right kidney showing multiple cysts (*c*) with an intervening echogenic cortex.

significant renal enlargement. Other multicystic diseases such as medullary cystic kidney disease (MCKD), juvenile nephronophthisis, ACKD, or medullary sponge kidney[59,60] do not present with renomegaly. Multiple cysts with renal enlargement can be seen in von Hippel-Lindau disease, tuberous sclerosis, and multicystic dysplastic disease. Complex cysts are also commonly seen in ADPKD and the main etiologies are intracystic hemorrhage and infection. Even though renal cell carcinoma can be seen in this ADPKD, these patients are not at increased risk.[61]

Urinary Obstruction

Urinary obstruction typically results in hydronephrosis: a dilatation of the collecting system which may be predominantly seen in the minor calyces, the major calyces, or both. More atypical cases may present with minimal dilatation of the collecting system, particularly in the acute setting.[62] Hydronephrosis is only an anatomic diagnosis and may not indicate urinary obstruction. Brisk diuresis (such as in diabetes insipidus), papillary necrosis, and pregnancy can all result in nonobstructive calyceal dilatation.[28,62–64] Grading systems for severity of the hydronephrosis have proven to be of limited clinical utility because the degree of hydronephrosis may correlate poorly with the extent of obstruction. When obstruction is the primary cause of renal failure, it is always associated with hydronephrosis. In acute obstruction, the cortex is intact (Fig. 10.16) whereas chronic obstruction can lead to marked thinning of the cortex (Fig. 10.17). Failure to visualize the proximal ureter suggests obstruction at the ureteropelvic junction, whereas a dilated proximal ureter (hydroureter) (Fig. 10.16) indicates either obstruction at the level of the ureter or bladder. A large postvoid bladder indicates urinary retention, where sometimes the distal ureters can also be visualized (Fig. 10.18), whereas an empty bladder with dilatation of the distal ureters suggests obstruction

10.1 Performance Characteristics of Ultrasonographic Diagnostic Criteria for Autosomal Dominant Polycystic Kidney Disease in At-Risk Individuals Without Information on Genotype

Age Group (years)	Diagnostic Criterion	NPV	PPV	Accuracy
15–29	≥1 renal cyst	0.908	0.966	0.934
	≥2 renal cysts	0.877	0.992	0.924
	≥3 renal cysts	0.855	1.0	0.912
30–39	≥2 renal cysts in each kidney	0.875	1.0	0.922
	≥1 renal cyst	0.983	0.94	0.962
	≥2 renal cysts	0.97	0.979	0.974
	≥3 renal cysts	0.964	1.0	0.984
40–59	≥2 renal cysts in each kidney	0.948	1.0	0.965
	≥1 renal cyst	1.0	0.897	0.960
	≥2 renal cysts	1.0	0.967	0.988
	≥3 renal cysts	0.984	0.965	0.978

NPV, negative predictive value; PPV, positive predictive value.

at the bladder inlet. Recognition of hydronephrosis can be difficult in polycystic kidney disease (PKD), where massive cyst formation can prevent or obscure calyceal dilatation and more subtle signs should be sought (Fig. 10.19). This is an important cause of acute renal failure and can be due to stones or blood clots from cyst rupture. Radioisotope scanning may confirm obstruction when sonographic findings are not characteristic.

Occasionally, peripelvic cysts may also mimic hydronephrosis (Fig. 10.20). These are actually dilated lymphatics and, because they track with the blood vessels, can sometimes have a branching pattern. A rim of sinus fat separating the "cysts" from the parenchyma and the absence of a dilated ureter are useful hints toward peripelvic cysts. Another differential diagnosis for hydronephrosis is venous engorgement often seen in cases of volume overload or renal vein thrombosis. In general, the renal vein branches before entering the renal sinus (bush appearance) whereas the collecting system branches in the sinus (pruned tree appearance). The presence of venous pulsations and the tracking of the vein medially to the vena cava, as well as the

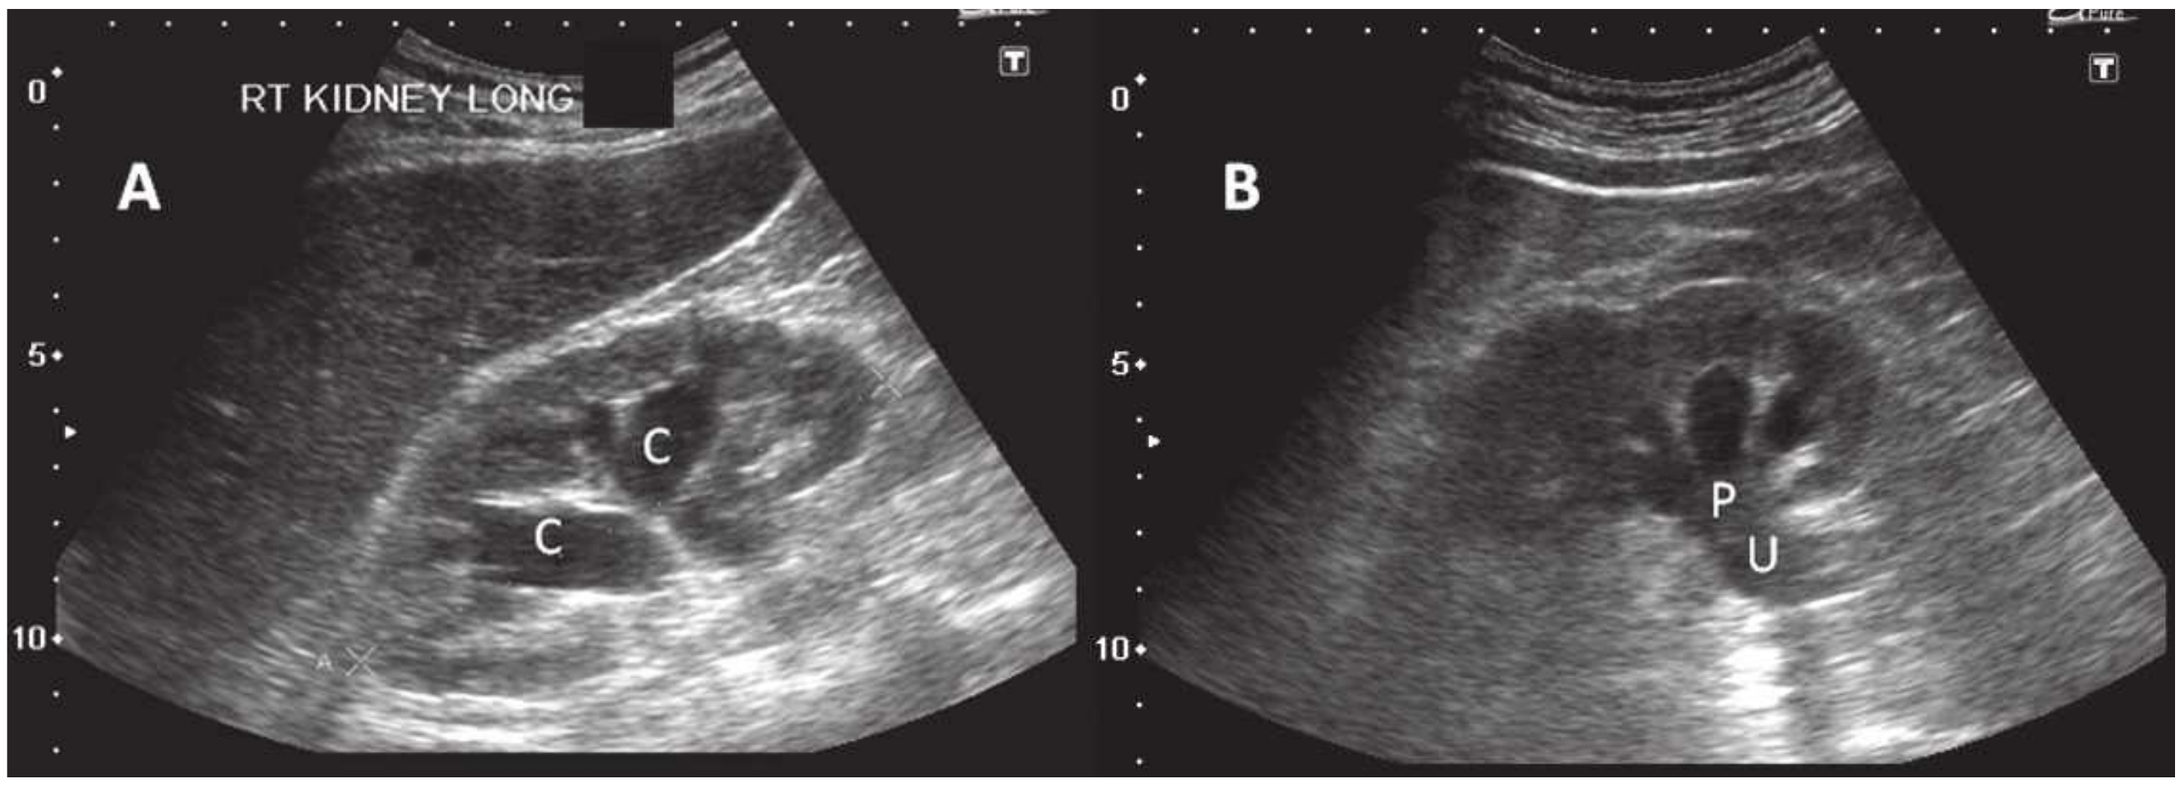

FIGURE 10.16 Acute hydronephrosis with hydroureter. Longitudinal image of the right kidney showing dilatation primarily of the major calyces (*C*) with some enlargement of the minor calyces and with conserved parenchymal thickness. The dilatation of the pelvis (*P*) and ureter (*U*) is easily visualized.

use of Doppler sonography, can differentiate blood vessels from the urinary tract. Occasionally, the renal pelvis is situated outside the sinus (extrarenal pelvis) appearing as a dilated proximal ureter but without any calyceal enlargement (Fig. 10.21).

The urinary bladder should be carefully examined by sonography in all patients with hydronephrosis. Additional indications are anuria, hematuria, pain, and urinary tract infections. The bladder is located in the midline, posterior to the symphysis pubis, and contains no luminal structures. When full, it appears as an anechoic fluid collection that is oval in transverse plane and becomes more elongated in the sagittal plane. The bladder volume is calculated by using the following formula for ellipsoid structures[65]:

$$\text{Volume} = 0.523 \times \text{length} \times \text{width} \times \text{depth}$$

A normal bladder is usually empty after a complete void and should not contain more than 10 mL of urine. A postvoid residual volume of more than 50 mL is associated with a threefold risk of urinary retention in males and is often used as a threshold for the diagnosis of urinary retention.[66] Hyperechoic structures such as stents, Foley catheters, bladder stones (Fig. 10.22), tumors, and blood

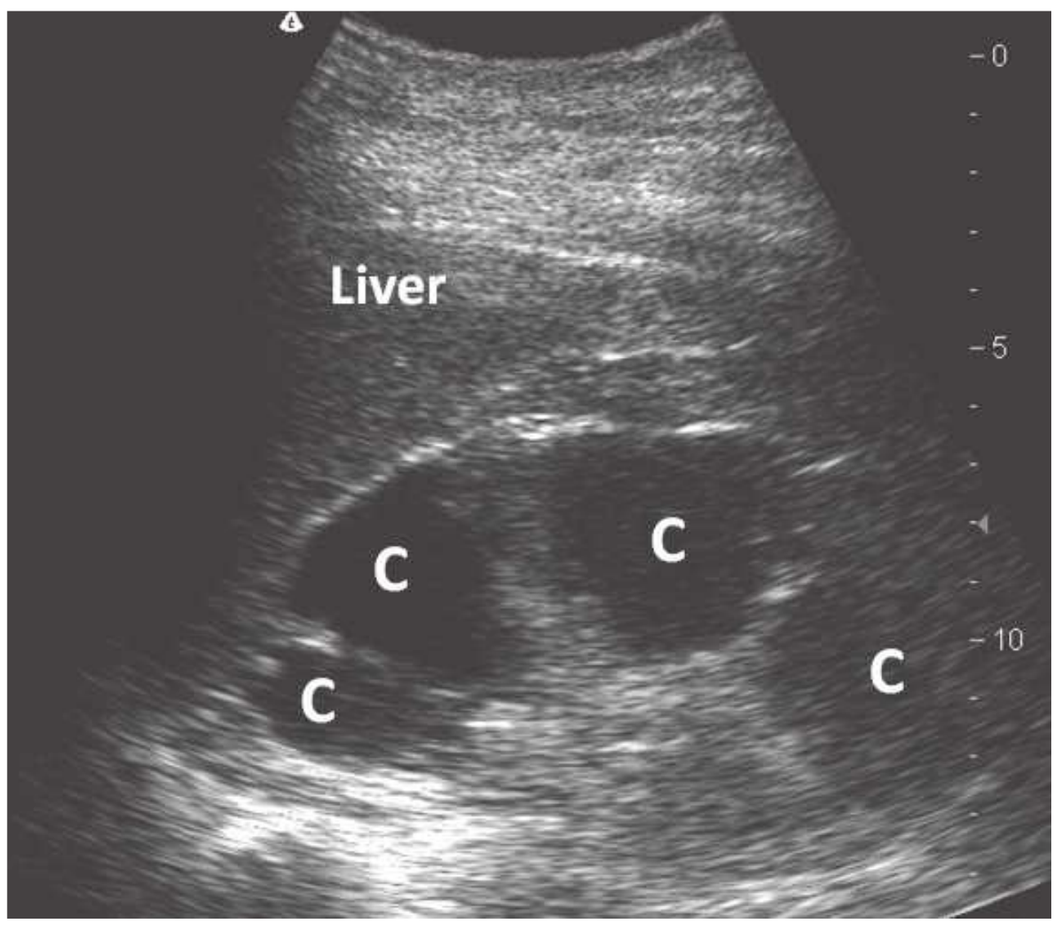

FIGURE 10.17 Chronic hydronephrosis. Longitudinal view of the right kidney showing dilated calyces that extend to the renal capsule, indicative of an extremely thin cortex.

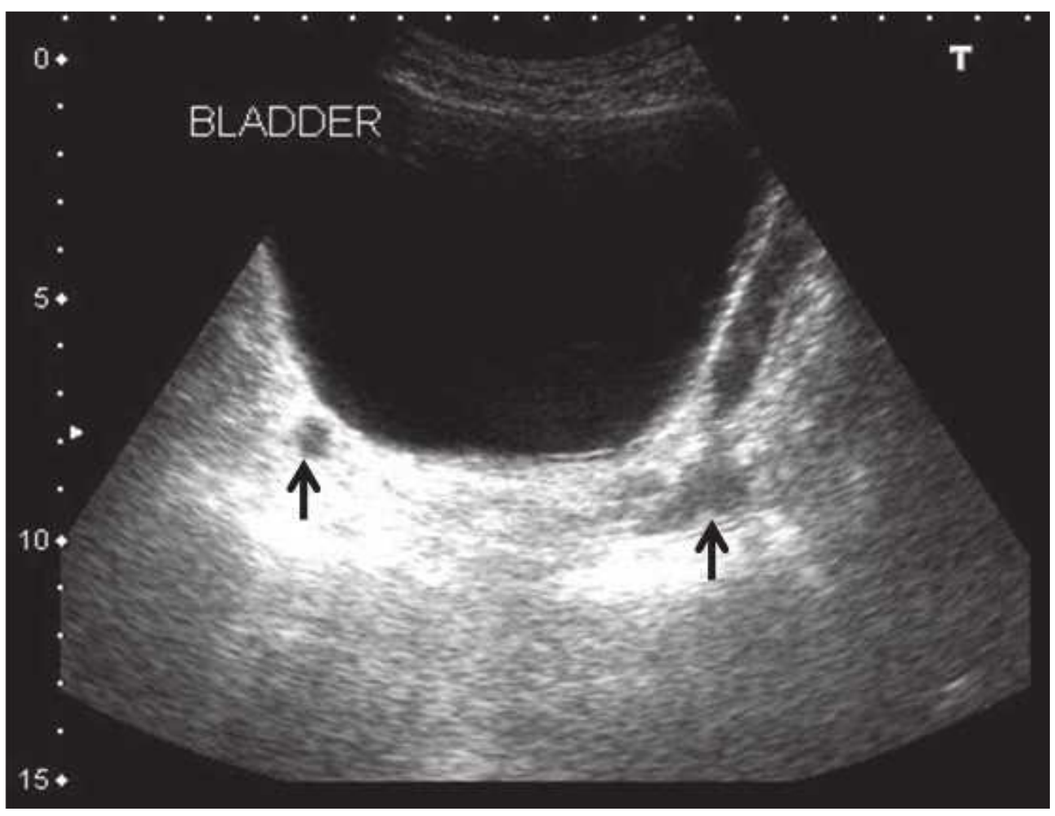

FIGURE 10.18 Urinary bladder retention. Transverse view showing an extremely dilated bladder. The distal ureters (*arrows*) are visible posterior to the bladder.

FIGURE 10.19 Hydronephrosis in autosomal dominant polycystic kidney disease. Converging dilated calyces (*C*) are apparent in this young patient who presented with major hemorrhagic cyst rupture and acute renal failure due to ureteral clots. Hydronephrosis resolved after ureteral stent placement. The multitude of cysts and disruption of the normal anatomy often make detection of hydronephrosis difficult.

clots (Fig. 10.23) may be visible in the bladder. The presence of urinary jets from a ureter proves its patency. Ureteral stents may transmit bladder pressure back to the kidney, resulting in hydronephrosis. Thus, the diagnosis of stent obstruction requires an empty bladder.

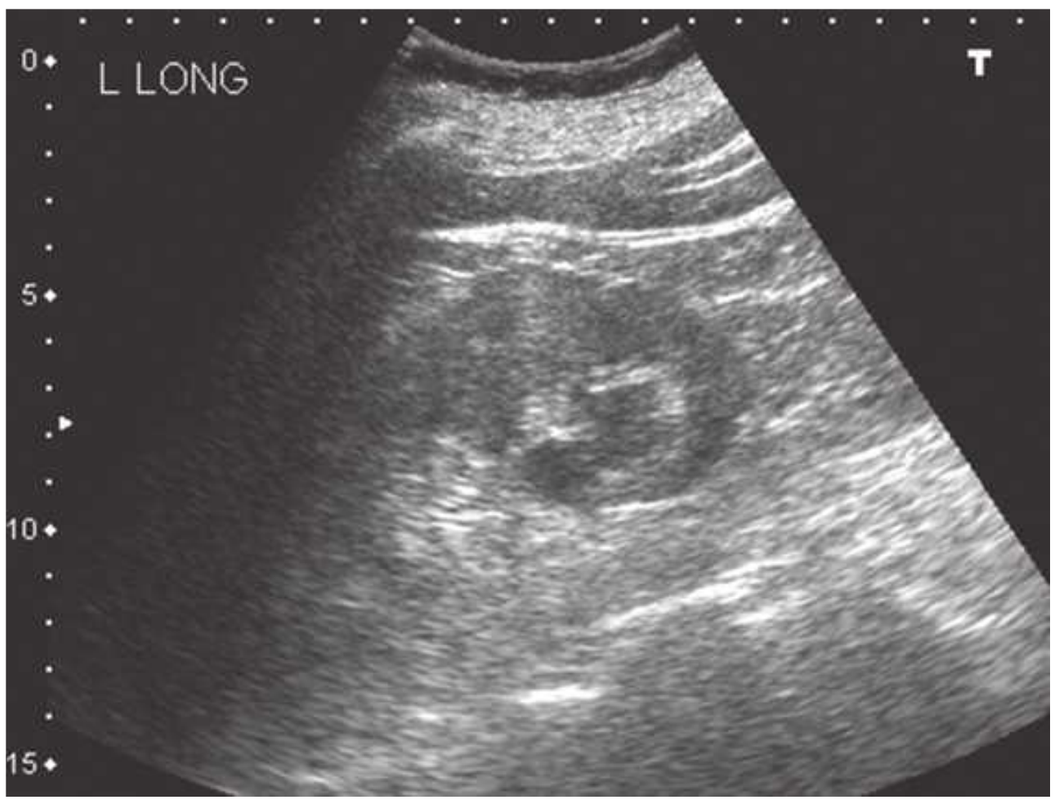

FIGURE 10.20 Peripelvic cyst. Longitudinal view of the left kidney showing a hypoechoic structure where the renal pelvis is expected to be seen. The absence of calyceal dilatation and presence of the echogenic sinus fat interposed between the cyst and the parenchyma are indicative of peripelvic cysts rather than hydronephrosis.

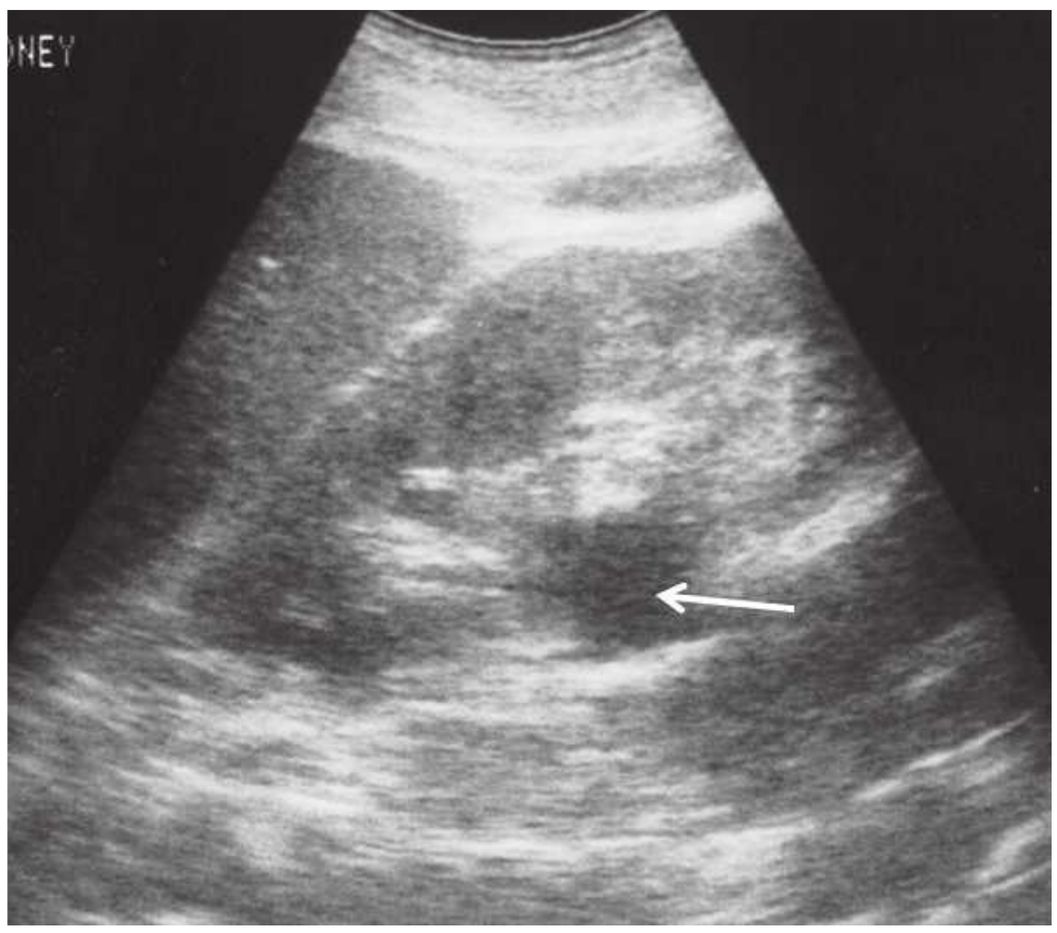

FIGURE 10.21 Extrarenal pelvis. Longitudinal view of the left kidney. There is apparent dilatation of the initial proximal ureter with no further hydroureter. Although the major calyces can be seen converging into the extrarenal renal pelvis, there is no enlargement of the minor calyces.

Kidney Stones and Calcifications

Stones typically reflect most of the sound, rendering them echogenic with a distal shadow and very easily discernible by ultrasonography no matter what the composition. However, both findings may not be present and small kidney stones

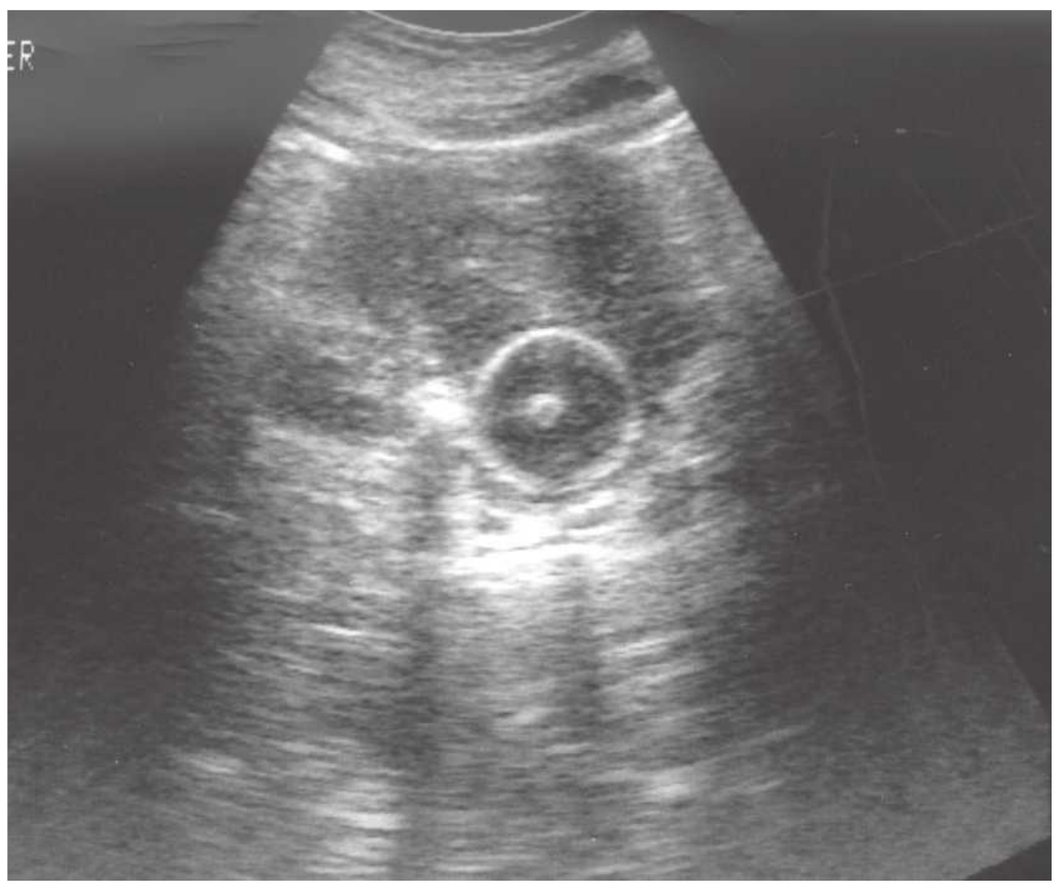

FIGURE 10.22 Foley catheter and bladder stone. Transverse view of the bladder shows a perfectly round shaped circle with echogenic walls (inflated balloon) surrounding the central echogenic catheter. Adjacent to the left side of the Foley catheter, a small opacity with a posterior shadow represents a bladder stone.

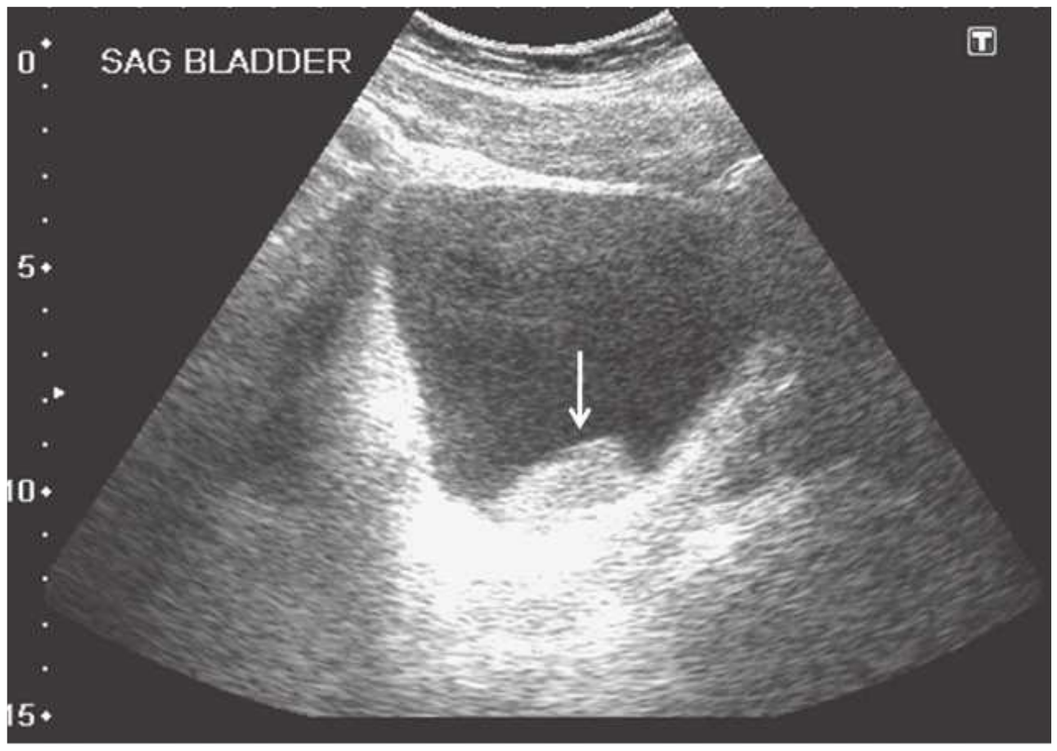

FIGURE 10.23 Clot in the bladder. Sagittal view of a distended bladder containing a hyperechoic mass, representing a blood clot (*arrow*).

and ureteral stones may not be visible. Stones are seen in the urinary space (Fig. 10.24) and may be associated with urinary obstruction, hydronephrosis, and urinary tract infection. Staghorn calculi typically fill the entire calyceal system but can appear as multiple stones on single images (Fig. 10.25).

In nephrocalcinosis (Fig. 10.9) and papillary necrosis, the calcification is in the renal medulla and not the urinary space but this distinction can sometimes be difficult. The differential diagnosis also includes ureteral stents, which typically are not as echogenic and yield less distinct shadows.

Neoplasms

Renal neoplasms are usually discovered incidentally or during the workup for pain or hematuria. Special attention

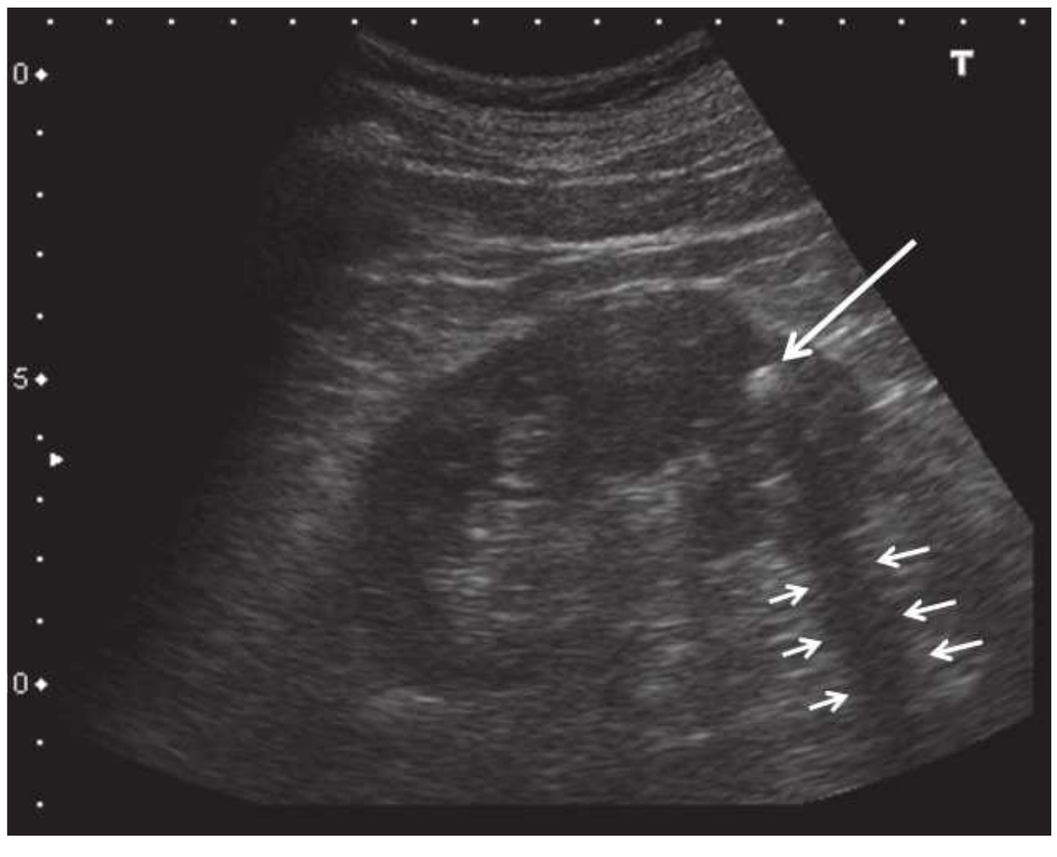

FIGURE 10.24 Kidney stone. Longitudinal view showing a hyperechoic stone (*large arrow*) in the lower pole that casts an acoustic shadow (*small arrows*).

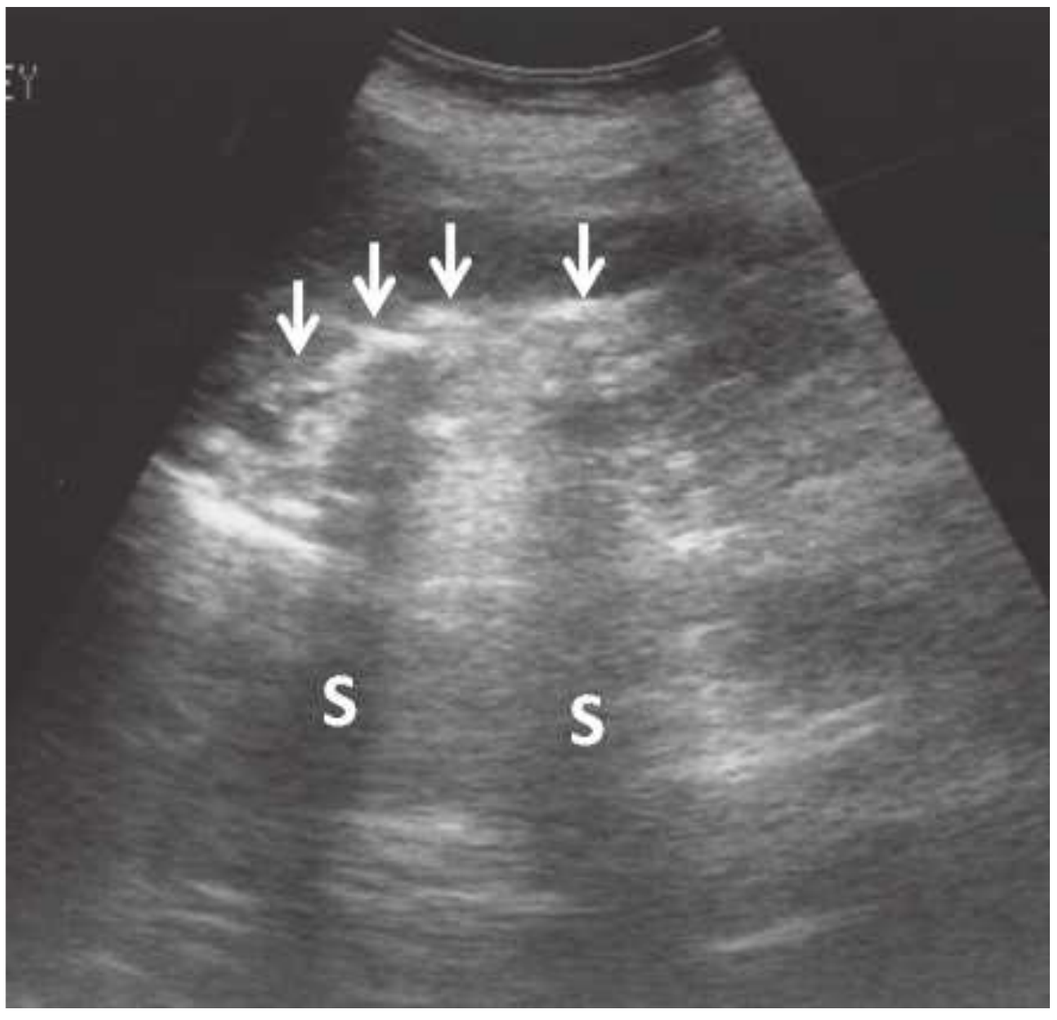

FIGURE 10.25 Staghorn calculus. Longitudinal image of the right kidney showing a long curvilinear echogenicity in the renal sinus with dense acoustic shadows (*S*).

should be given to rule out cysts, transmission artifacts, and normal variants such as lobulation and hypertrophied columns of Bertin.[67] Although the absence of blood flow by Doppler ultrasound may point to a cyst, additional imaging is almost always indicated because sonography can rarely identify the cause of a solid lesion.

Renal Cell Carcinoma

The typical sonographic appearance of renal cell carcinoma is of a well-demarcated hypoechoic mass that distorts the renal contour (Fig. 10.26), but tumors can be isoechoic (and more difficult to visualize) and can be hyperechoic when small (<3 cm). About 10% of renal cell carcinomas have a cystic appearance.[68]

Transitional cell carcinoma is a tumor of the renal pelvis that typically presents as a relatively hypoechoic mass within the renal sinus, separated from parenchyma by fat tissue.[69–71] They can also contain echogenic areas and occasionally can be diffusely infiltrative.

Angiomyolipoma

Sporadic angiomyolipomas (AMLs) are the most commonly encountered tumors in kidneys (autopsy incidence of 11%, more commonly seen in middle-aged women)[72] but multiple AMLs can be observed in tuberous sclerosis. They are not malignant but may cause hemorrhage. The typical presentation is of a very echogenic parenchymal mass (due to the high fat content) with an acoustic shadow in 33% of cases[73] (Fig. 10.27).

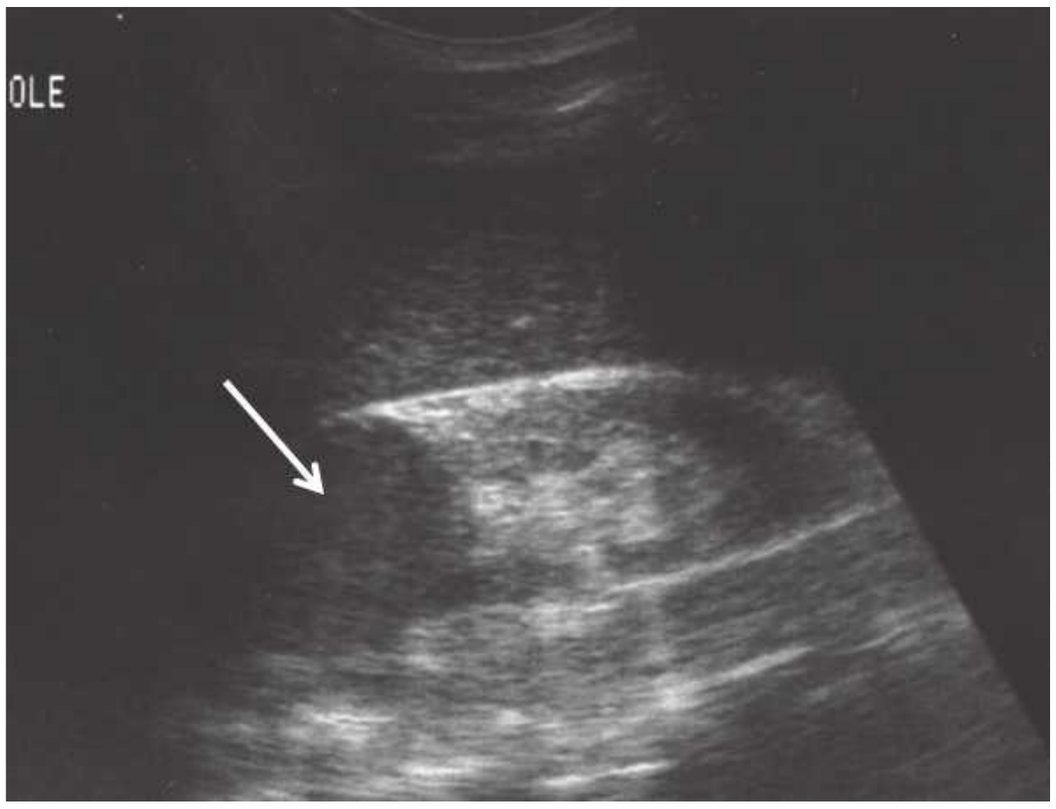

FIGURE 10.26. Renal cell carcinoma. Longitudinal view of the left kidney shows a hypoechoic mass (*arrow*) in the upper pole which was confirmed to be a renal cell carcinoma.

FIGURE 10.27 Angiomyolipoma. Longitudinal view of the left kidney shows a small, brightly echogenic mass in the cortex (*arrowhead*) without any distal shadowing.

Metastasis and Infiltrative Neoplastic Diseases

Infiltration of the kidneys is common in lymphomas (20% on CT scan,[74] 50% on autopsies[75]). They can cause acute renal failure by obstruction or diffuse infiltration.[76] The typical appearance is of multiple hypoechoic masses but a "perirenal halo" is also a classic but more unusual occurrence.[77] Leukemias can also infiltrate the kidney. Other solid tumors (e.g., lung cancer) may metastasize to the kidney, in which case they tend to be focal and nodular and are not distinguishable from other tumors.

Infections

Sonography is not indicated in most routine cases of pyelonephritis. Indications include male gender, children, failure to resolve, complications, and frequent recurrence. Pyelonephritis is usually lobular, appearing as a poorly defined hypoechoic area corresponding to a lobule, but it occasionally is diffuse. This can progress to abscesses which are usually single or multiple, heterogenous masses. The differential diagnosis includes complex cysts and neoplasms, which may require CT or MR for diagnosis.

Hemorrhage

Renal hemorrhage usually appears as perirenal or subcapsular hematomas and usually results from percutaneous kidney biopsy, surgery, or trauma. Initially they may appear as anechoic fluid collections but typically they are heterogeneous with fluid and solid components.

Transplanted Kidneys

Although many aspects of sonography are similar in native and transplanted kidneys, important differences exist due to anatomic considerations. The allograft is usually placed in the right pelvic fossa, aligned along the incision with the hilum oriented inferiorly and posteriorly, but a variety of other orientations can be encountered especially in obese patients, repeat transplantations, and combined kidney-pancreas transplantation. The donor artery and vein are anastomosed to the external iliac (or the common iliac) vessels and the ureter is anastomosed to the superolateral wall of the bladder (Fig. 10.28). When two kidneys are transplanted en bloc, portions of the donor aorta and vena cava are retained and anastomosed to the recipient vessels.[78,79] The kidney is often placed within the peritoneum when combined with a pancreas transplant. In very young children, the kidney may be placed posterior to the cecum with anastomosis of the donor vessels to the great vessels.[79] The anatomic relationships are readily apparent on sonograms. The psoas muscle and iliac vessels lie posteriorly and are usually imaged transversely on longitudinal scans of the allograft. The former can be identified by its contraction when the leg is flexed at the hip, and the latter are frequently pulsatile. The ureter and renal vessels are often visible even in normal allografts. The ureter courses medially, usually lying directly under the lower (medial) pole, whereas the renal vein travels posteriorly. The bladder lies medially and can easily be mistaken for a perirenal fluid collection. The peritoneum is superior and occasionally anterior to the allograft, typically appearing as a

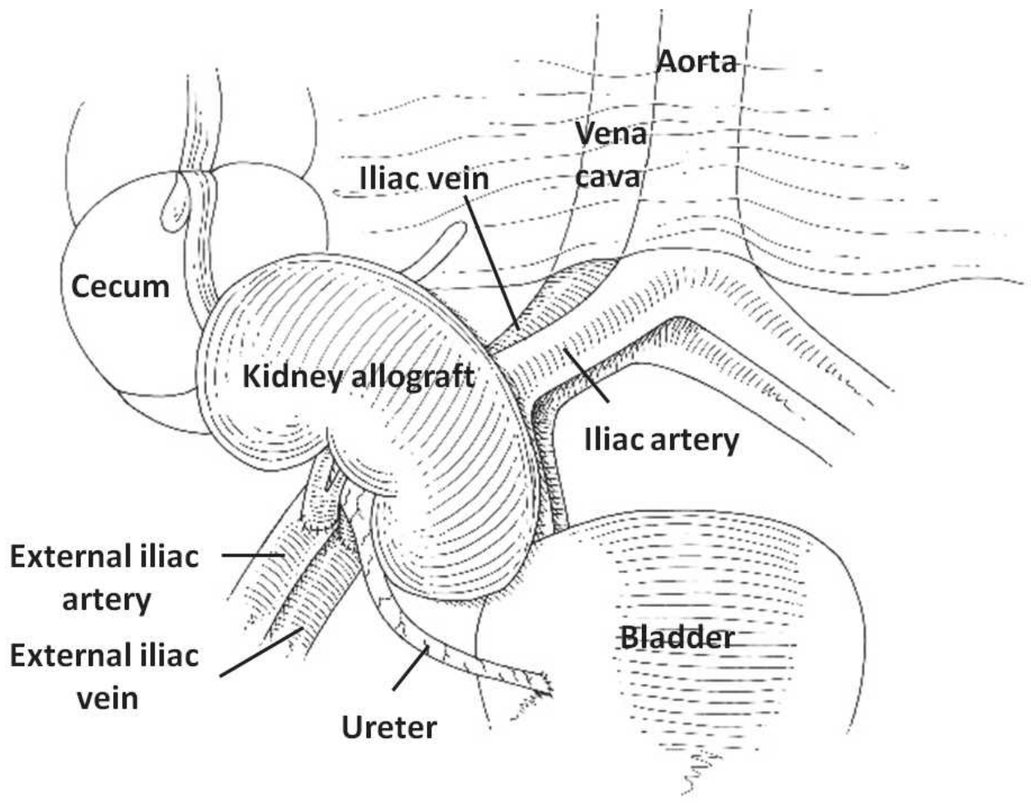

FIGURE 10.28 Anatomic relationships of the kidney. (Adapted from O'Neill WC. *Atlas of Renal Ultrasonography*. Philadelphia: WB Saunders; 2011, with permission.)

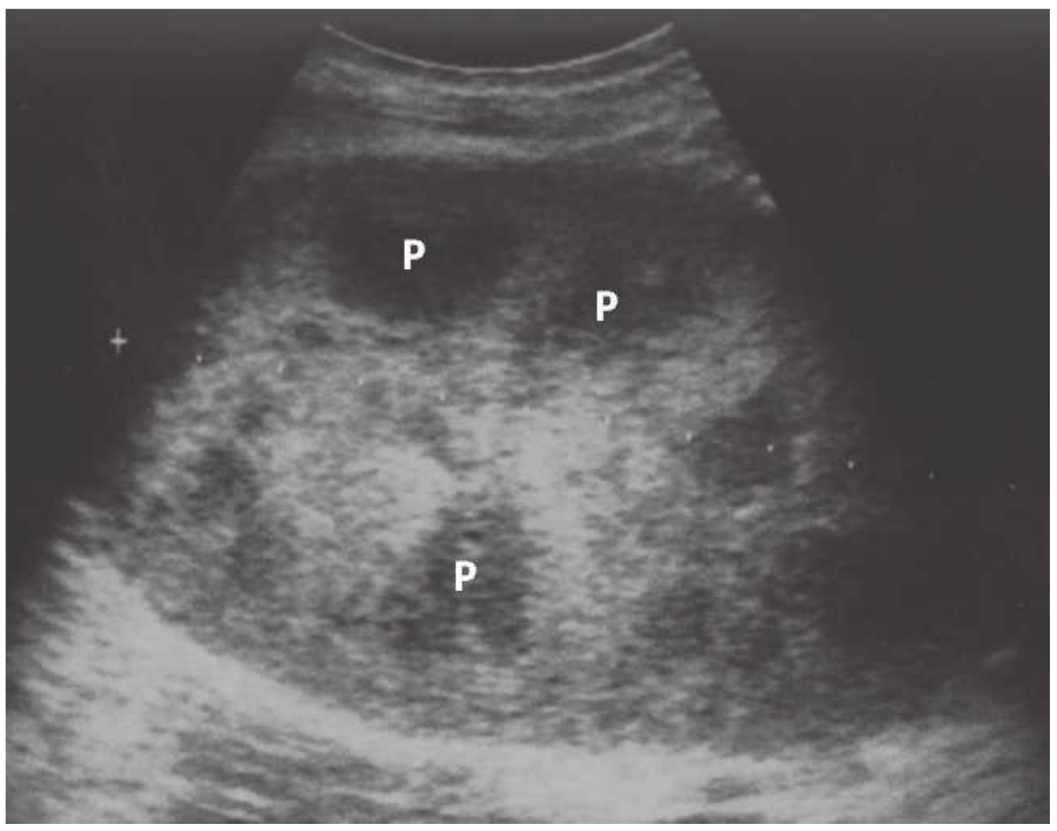

FIGURE 10.29 Acute rejection, longitudinal scan. The kidney is swollen and globular and the cortex is brightly echogenic, rendering medullary pyramids (*P*) very prominent.

beaklike projection over the allograft, and is easily identified by the peristalsis of the bowel loops.

Sonography of the transplanted kidney is indicated in most cases of acute renal failure[80] and can easily diagnose thrombosis of the renal artery or vein, urinary obstruction, and urine leaks in the immediate postoperative period. Other, nonspecific findings can suggest acute rejection. Sonography can be helpful in guiding percutaneous biopsy, diagnosing fluid collections, measuring residual bladder volume, and identifying ureteral stents.

Allograft Parenchymal Disease

The visualization of renal allografts is easier than native kidneys but suffers from the inability to evaluate two important parameters: renal size and echogenicity. Measurement of renal length is problematic due to the frequent inability to capture the entire length of the kidney in one view and the uncertainty of its significance due to both donor-dependent and recipient-dependent variables. Renal size can increase up to 40% during the 6 first months after transplantation.[81–83] Evaluation of echogenicity is difficult due to the lack of an adjacent reference organ. The only useful clues are prominence of the medullary pyramids and, when echogenicity is markedly increased, blending of the allograft with the surrounding tissue. Because of these limitations and also the simplicity of allograft kidney biopsy, size and echogenicity are usually not considered in clinical decisions.

The most common causes of allograft failure are acute tubular necrosis (related to harvesting or storage), acute rejection, drug toxicity, chronic allograft nephropathy, and recurrent disease, but sonographic findings lack sensitivity and specificity in diagnosing any of these. In particular, kidneys often appear normal in mild and even moderate cases of rejection. When present, findings consist of cortical swelling and increased echogenicity (due to cellular infiltration). Allograft enlargement is fairly specific for acute rejection[83–90] but can occur with ATN and recurrent nephritis (Fig. 10.29). Infections (pyelonephritis and BK virus) can also cause allograft failure but sonographic findings are nonspecific.

Urinary Obstruction of the Allograft

The frequent occurrence of urinary tract obstruction is the principal reason for performing sonography in most transplant patients presenting with acute renal failure. In the immediate postoperative period, the ureter may be obstructed by intraluminal blood clots, kinking, or external compression by edema or hematomas. Urinary retention, lymphoceles, and ureteral strictures are responsible for most other cases,[91,92] but are rarely seen when ureteral stents are routinely placed during transplantation. Acute rejection within the ureter may also obstruct urine flow.[93,94] Ultrasonography is an excellent test to diagnose obstruction in allografts with a sensitivity of almost 100%.[95] Specificity is lower because hydronephrosis is not always an indication of obstruction because small degrees of calyceal dilatation are easily and commonly seen in otherwise normal allografts. Mild, and even moderate, dilatation may not be a manifestation of urinary obstruction,[92,96] but dilatation of the minor calyces and ureter are usually indicative of obstruction (Fig. 10.30). Sonography is also very useful in pinpointing the site of obstruction. Hydronephrosis without dilatation of the proximal ureter indicates obstruction at the ureteropelvic junction, which may be caused by extrinsic compression by a lymphocele or ureteral strictures.[97] In both cases, there is usually abrupt tapering of the renal pelvis. A common site for strictures is in the distal segment or near the anastomosis

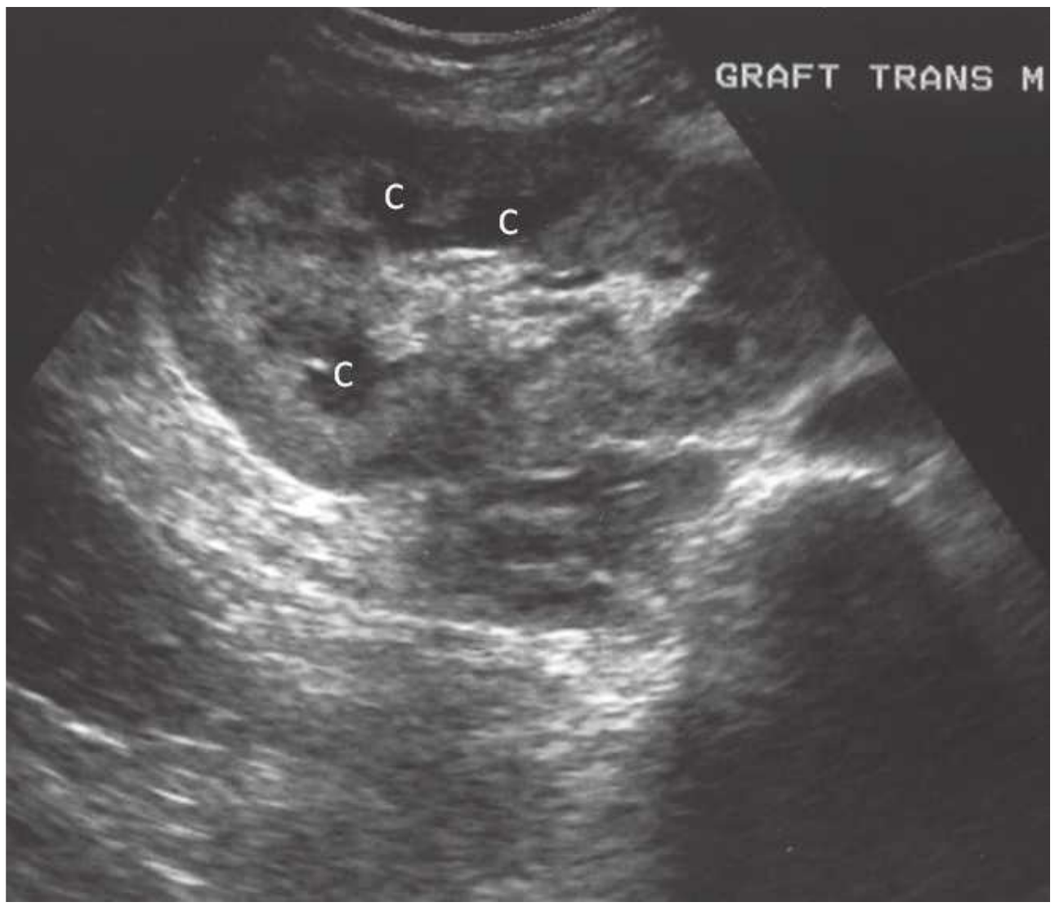

FIGURE 10.30 Mild hydronephrosis of the allograft kidney. Transverse view of the allograft shows mild dilatation of the calyces (*C*), consistent with mild hydronephrosis.

with the bladder.[91,97] In this setting the dilated ureter can be followed to the bladder and remains dilated when the bladder is emptied.

Thickening of the calyceal or ureteral walls is not uncommon and can be mistaken for luminal dilatation. This is usually caused by edema (Fig. 10.31) and has a fine echo pattern as opposed to anechoic urine. A fine central line presumably representing apposition of the luminal surfaces is occasionally seen.[98] Edema is frequently associated with stents and may also be caused by ureteral rejection.[93] Calyceal thickening was initially thought to be a sign of acute rejection but is now known to be nonspecific.[99,100] Additional causes of echogenicity within the collecting system are stents, hemorrhage, stones, and infection.

Fluid Collections and the Kidney Allograft

Fluid collections consisting of blood, urine, or lymph can be complications of transplant surgery.[95] Sonography cannot distinguish different types of fluid but the location, shape, internal structure, and the clinical presentation can all help in making the correct diagnosis. Additional studies such as examination of aspirated fluid and pyelography or radionuclide scanning to detect extravasation of urine may be needed. Care must be taken to distinguish fluid collections from the bladder or ascites.

Lymphoceles are the most common fluid collections encountered near renal allografts, with a frequency as high as 20%.[91,101] Half occur in the first 10 months after surgery but they can occur as late as 4 years.[101] They are usually not diagnosed unless they compress the ureter or the iliac vein and spontaneous resolution is a common feature.[101] In general, two types of lymphoceles are observed, consistent with different origins.[91,92,101] Most commonly they arise from donor lymphatics and are seen immediately adjacent to the allograft and have a propensity to obstruct the proximal ureter. They often appear as triangular-shaped fluid collections adjacent to the normal pelvis (Fig. 10.32) but can attain any shape and even surround the allograft when large. Less commonly, lymphoceles arise from native lymphatics disrupted during anastomosis of the donor vessels. They are in proximity to the iliac vein and have a tendency to obstruct the venous drainage of the leg, producing ipsilateral edema.[92,102]

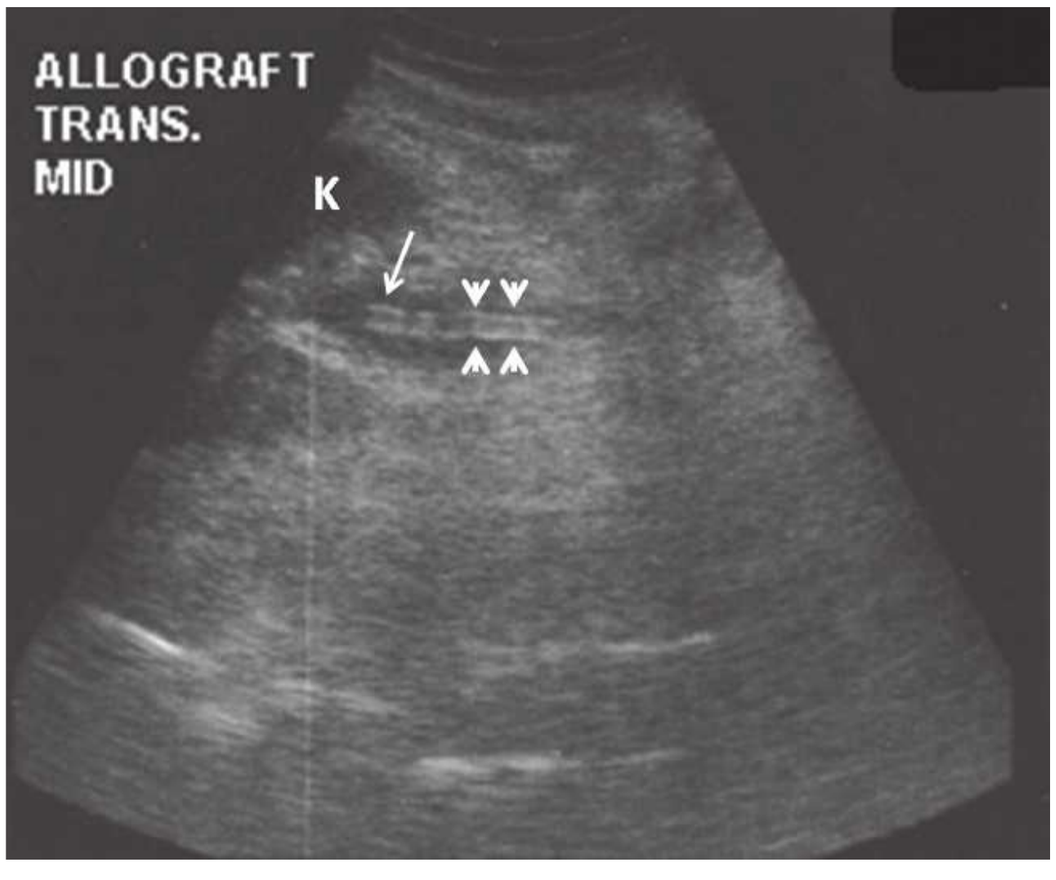

FIGURE 10.31 Urinary leak and ureteral stent. Transverse view of the allograft kidney (*K*) shows a small urine leak (*arrow*) surrounding a ureteral stent (*arrowheads*), medial to the allograft.

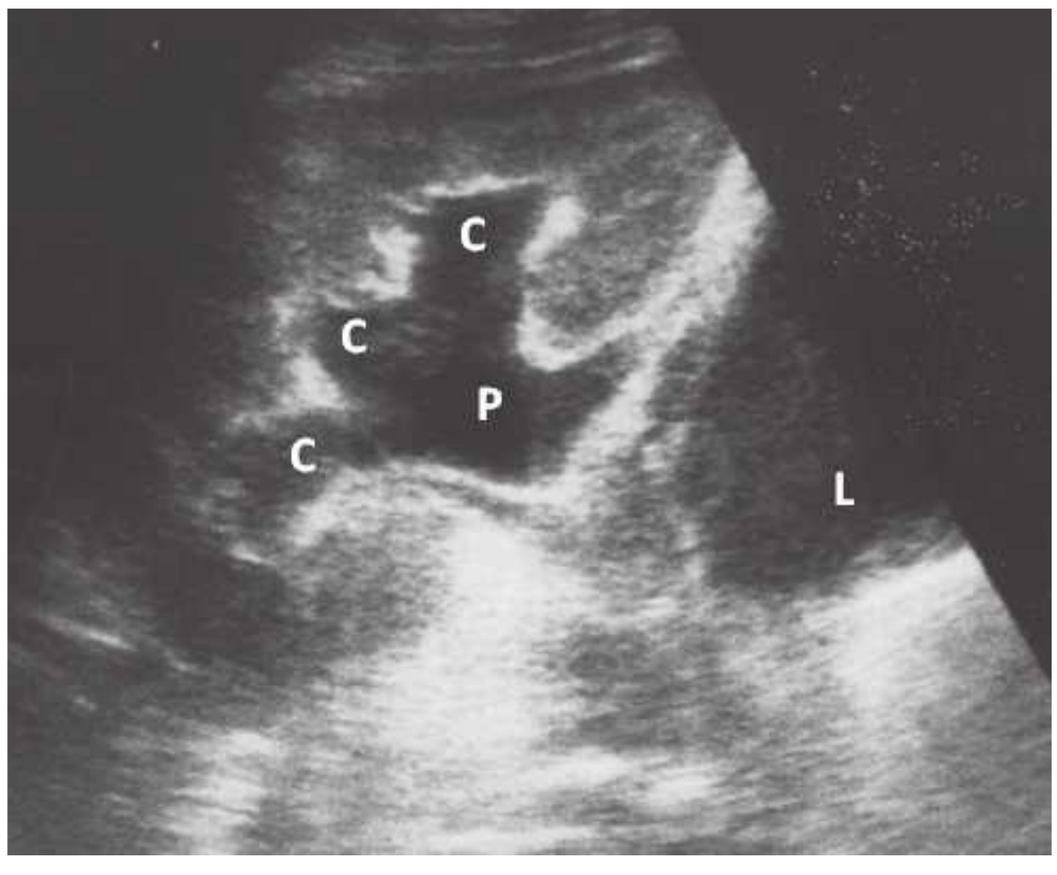

FIGURE 10.32 Large lymphocele with hydronephrosis. The lymphocele (*L*) presents as a hypoechoic collection medially situated vis-à-vis the allograft and causing obstruction of the ureter resulting in dilatation of calyces (*C*) and renal pelvis (*P*).

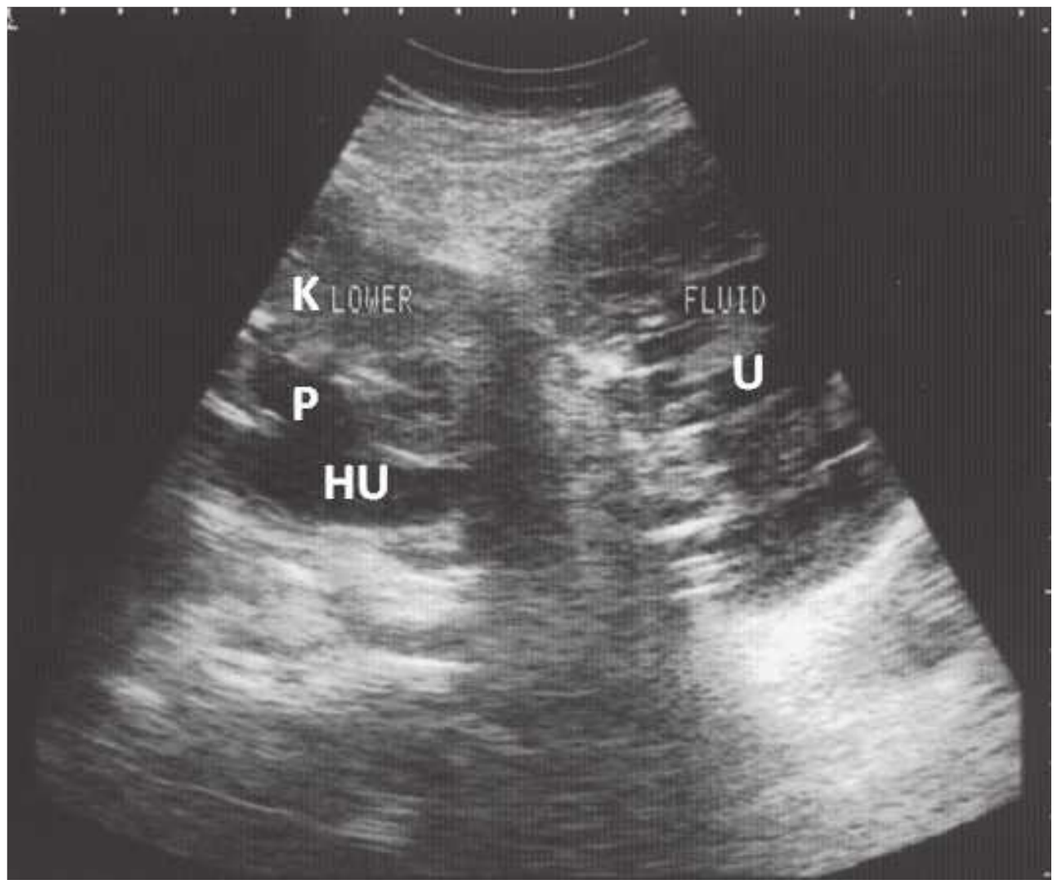

FIGURE 10.33 Large urinoma, longitudinal scan. The urinoma (*U*) appears as a large, complex fluid collection medial to the allograft (*K*). Hydroureter (*HU*) and renal pelvis dilatation (*P*) are common with urine leaks.

FIGURE 10.34 Seroma (*S*) appears as a complex fluid collection containing echogenic material in the subcutaneous tissue anterior to the allograft (*K*).

Urinomas, arising from urine leaks, need to be considered when fluid collections are seen within several weeks after surgery.[91] Tenderness and fever occur in one half and one quarter of patients, respectively,[103] but acute renal failure or delayed graft function can also be seen. Urinomas are usually adjacent to the ureter, but they can dissect along tissue planes and form seemingly separate collections, usually medial or anterior to the allograft and even surrounding it (Fig. 10.33). The appearance can be identical to that of a lymphocele, but often the margins are irregular and indistinct. Dilatation of the collecting system proximal to the leak is common.[102,103]

Hematomas are commonly seen in sonograms performed in the first few weeks after transplantation[91,92] but can also be seen after percutaneous biopsy. The typical appearance is of a heterogeneous mass containing both liquid (anechoic) and solid (echogenic) components. Echogenicity may increase with the level of organization of the clot.

Seromas are related fluid collections that are extremely common in the immediate postoperative period. These serosanguineous collections usually follow tissue planes anterior to the allograft and thus appear linear, often with septations (Fig. 10.34). They generally have little clinical significance and resolve spontaneously, and are important only in the differential diagnosis of other types of fluid collections.

Doppler Ultrasonography of the Kidneys

Doppler ultrasound measures the shift in frequency when sound strikes a moving object. This shift is dependent on the angle of the sound beam relative to the direction of flow, so that it is maximal when the sound is parallel to the flow and absent when the sound is perpendicular. In practice, the scanning angle should ideally be no greater than 60 degrees because large errors in velocity occur above this. This becomes critically important in evaluating the renal artery. The Doppler signal can be displayed in several formats. A small region can be selected (e.g., the lumen of a blood vessel) and velocity versus time displayed as a graph (pulse wave Doppler). Alternatively, a larger region can be selected and the velocities displayed on a color scale superimposed on the B-mode image (color flow Doppler). These modes can be combined (duplex Doppler). Lastly, the signal can be displayed in a vectorless form (power Doppler) where the color scale indicates the speed but not the direction. This last mode is useful for demonstrating the presence or absence of flow, and has the advantage of being less dependent on the angle of insonation.

In the kidney, Doppler sonography is used primarily to determine whether masses are vascular and to diagnose vascular disorders, particularly renal artery stenosis. The main renal artery and vein branch into segmental (also called interlobular) vessels at the renal hilum, which is located just outside of the medial aspect of the mid kidney. The segmental vessels travel through the renal sinus directly to the parenchyma, usually without further branching. They course through the columns of Bertin between the medullary pyramids, branching into the arcuate vessels at the corticomedullary junction. Evaluation of the renal vasculature usually consists of two separate examinations: (1) direct visualization and measurement of velocity in the renal artery or vein; and (2) analysis of wave forms in intrarenal arteries.

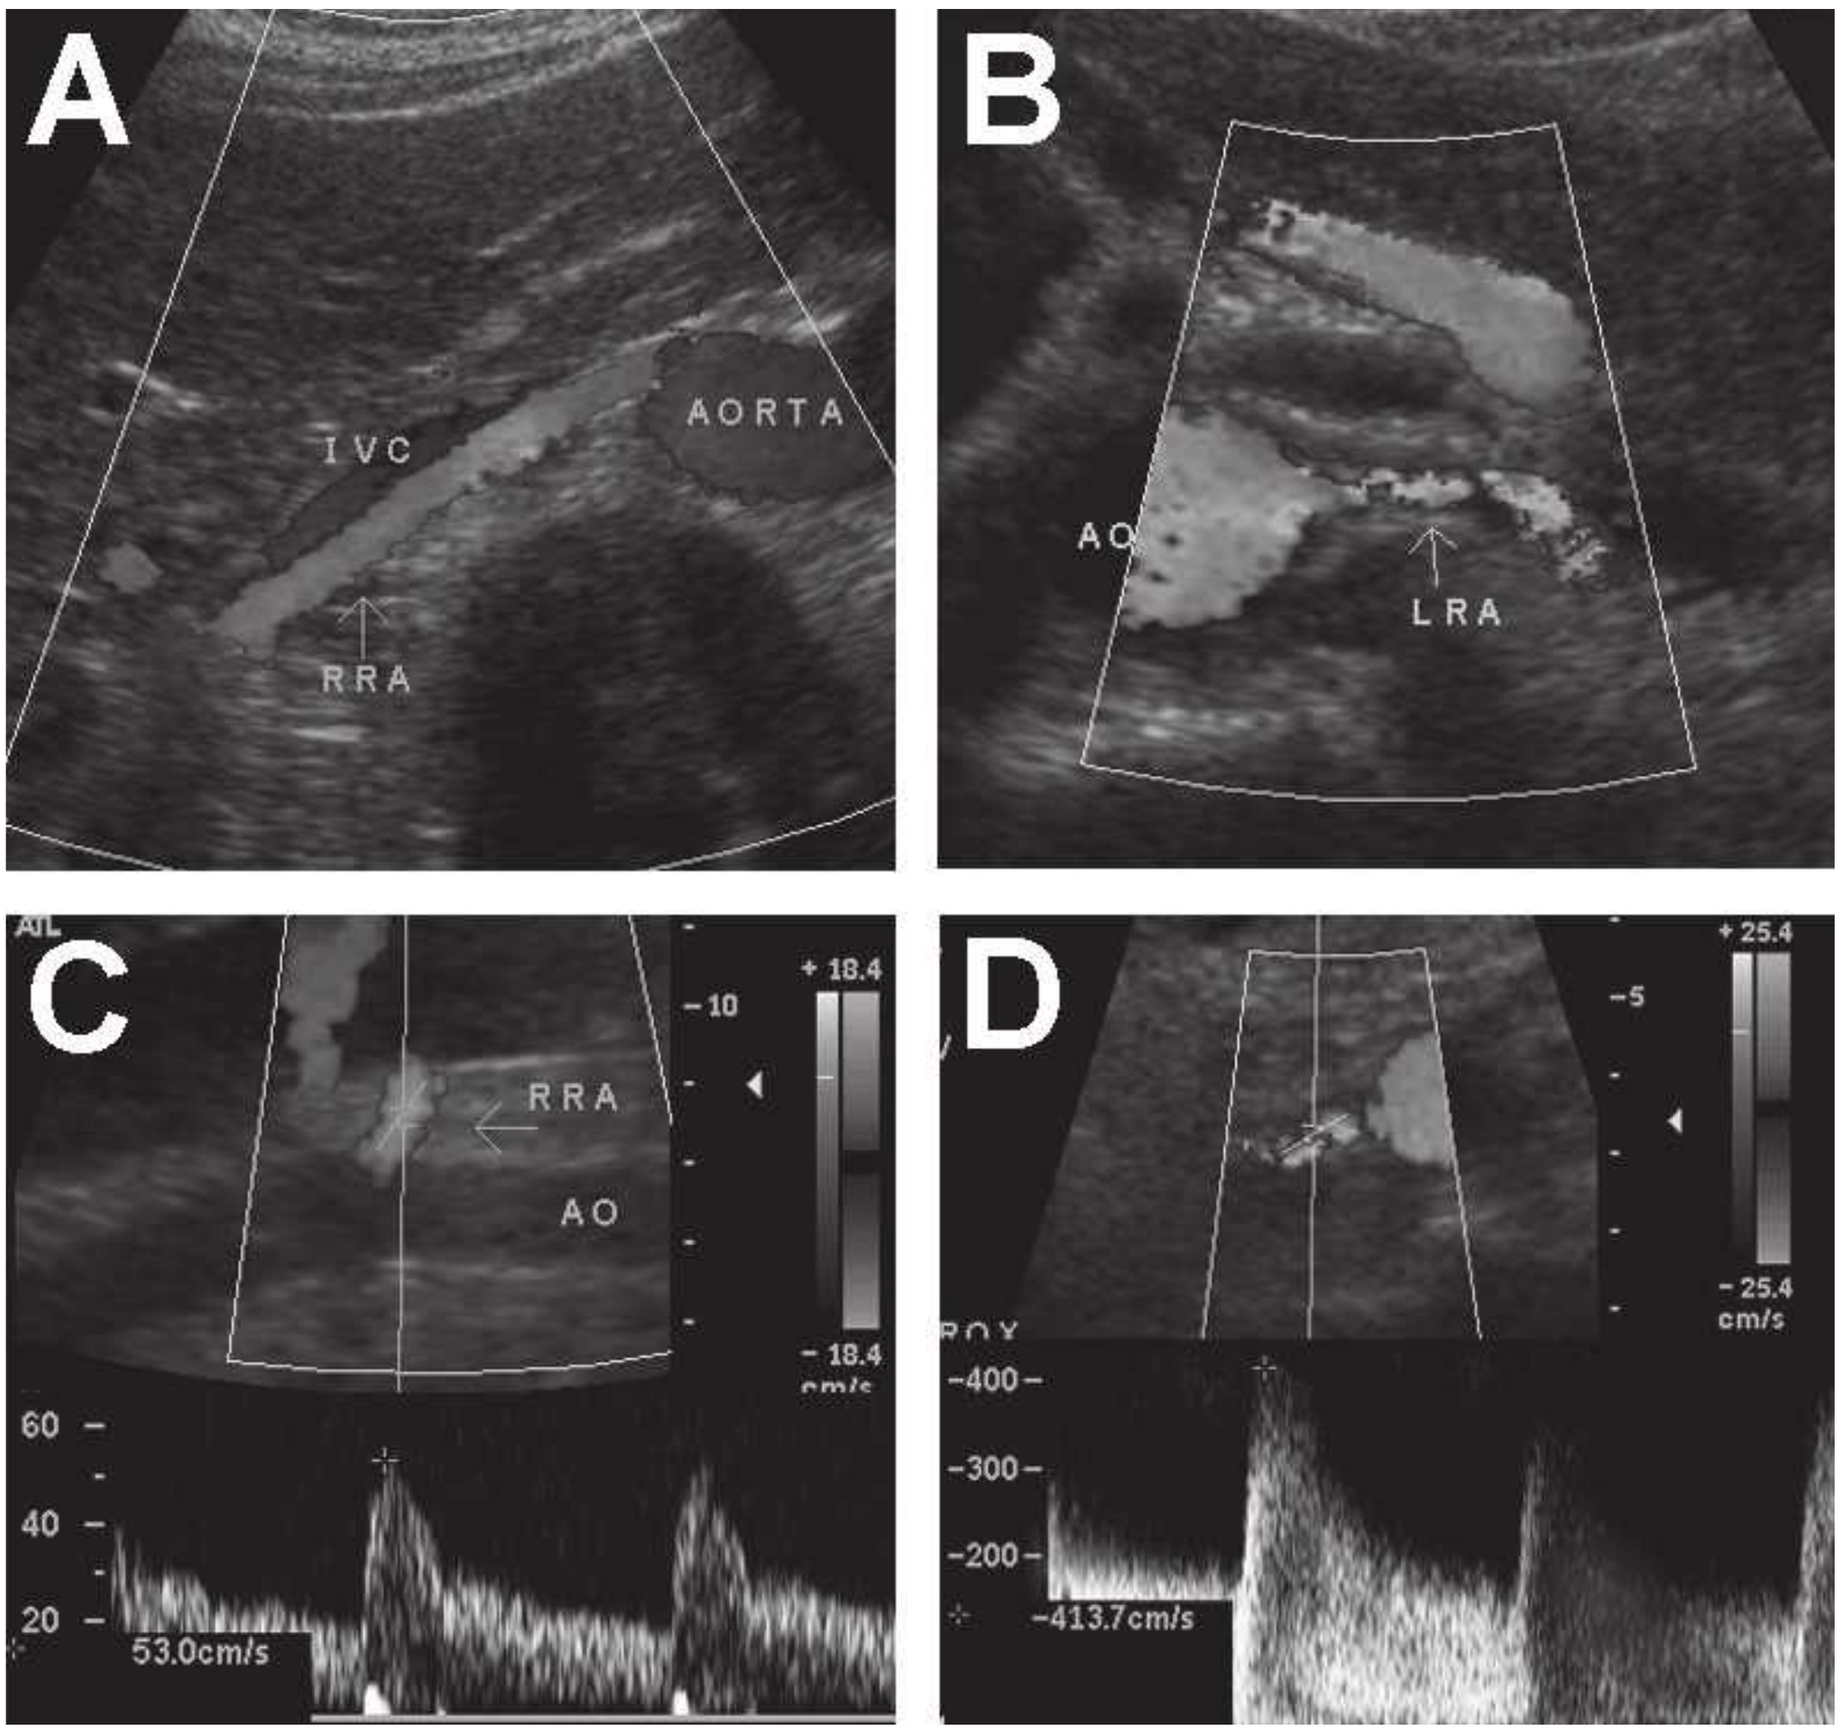

FIGURE 10.35 Renal artery Doppler. **A:** Normal right renal artery, midline transverse image. **B:** Stenotic left renal artery, midline transverse image. Note the turbulent flow (speckled color pattern) and the poststenotic dilatation. **C:** Normal right renal artery, coronal view, with a peak systolic velocity of 53 m per second. **D:** Stenotic right renal artery, midline transverse view. The peak systolic velocity averages well over 300 m per second. (Images courtesy of Sue Zellman, RDMS, RVT.)

Renal Artery Doppler

Examination of the renal artery is usually performed to rule out stenosis but should be reserved for patients with a high index of suspicion due to the poor performance of Doppler ultrasound. This can be a challenging examination in many patients because of overlying bowel gas, difficulty in achieving an angle less than 60 degrees, and the presence of multiple renal arteries in 30% of individuals. As many as a third of examinations may be inadequate.[104] The artery is examined by color flow Doppler from the aorta to the renal hilum, looking for narrowing, poststenotic dilatation, and turbulent, high velocity flow (Fig. 10.35). The diagnosis of significant renal artery stenosis is suggested by peak blood velocities greater than 2.0 meters per second (Fig. 10.36), and/or a ratio of peak systolic velocities in the renal artery and aorta above 3.5.

Intrarenal Arteries

Examination of the intrarenal arteries (segmental or interlobular) is limited to analysis of the waveforms, which can provide information on blood flow in the larger vessels. In renal artery stenosis, systolic flow can be dampened, leading to a delay in the peak flow (Fig. 10.36). In renal vein thrombosis, increased distal resistance can reduce diastolic flow. There may even be reversal of diastolic flow, which is virtually pathognomonic for renal vein thrombosis. Because most waveform analysis is based on indices (one portion of the wave compared to another) or on time, rather than on absolute velocity, it is independent of the angle of insonation. It is therefore a far easier study to perform but the evidence obtained is indirect.

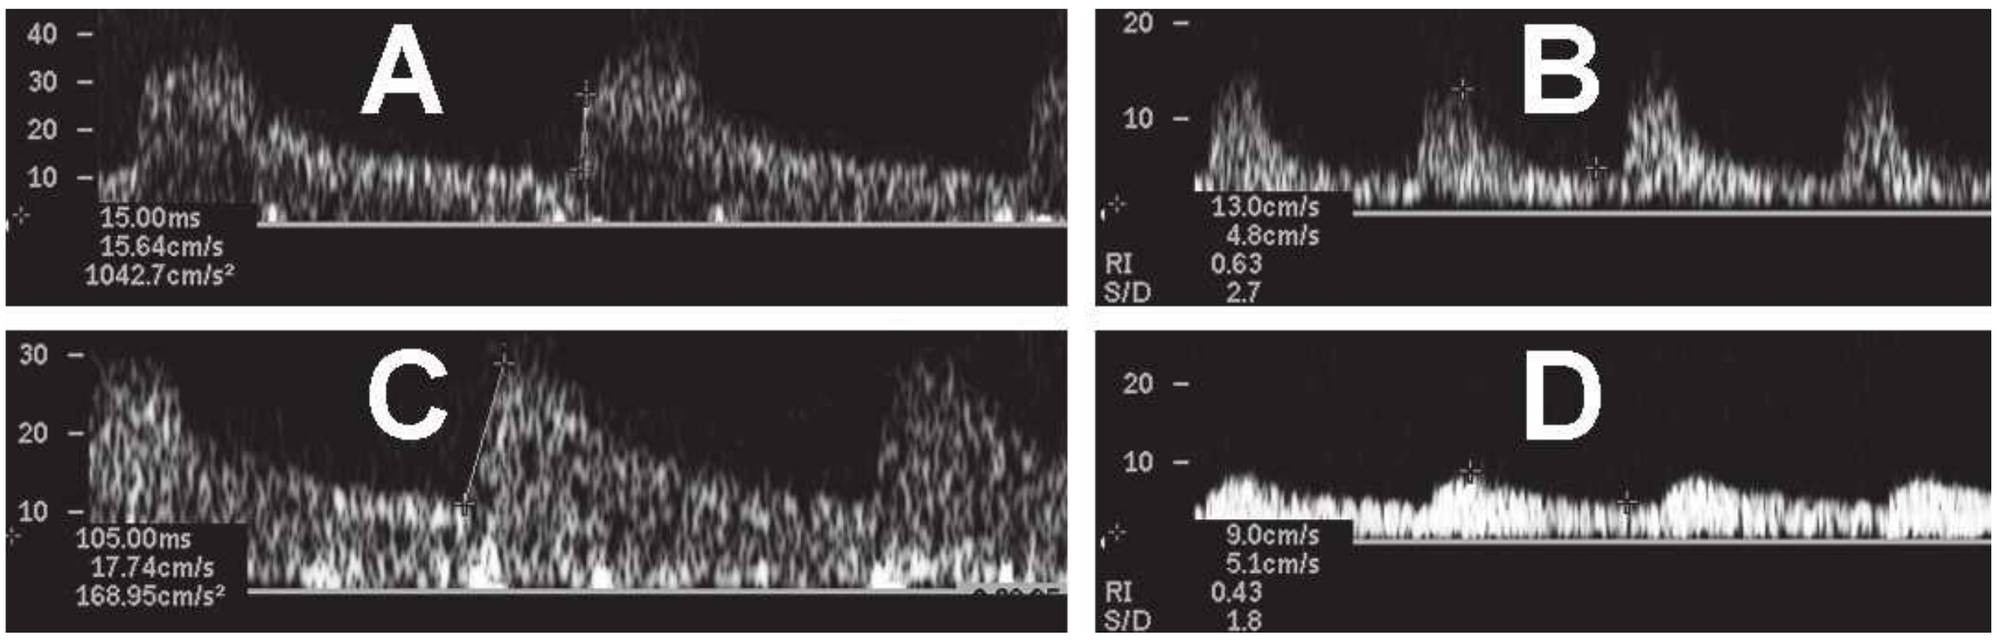

FIGURE 10.36 Intrarenal Doppler waveforms. **A:** Normal segmental artery with maximum systolic acceleration of approximately 1000 m per sec^2. **B:** Normal intraparenchymal artery. **C:** Segmental artery with maximum systolic acceleration less than 200 m per sec^2, indicative of renal artery stenosis. **D:** Intraparenchymal artery showing marked delay and blunting (tardus-parvus) of the systolic peak consistent with severe renal artery stenosis. (Images courtesy of Sue Zellman, RDMS, RVT.)

Renal Artery Stenosis

A number of Doppler parameters have been applied to the diagnosis of renal artery stenosis including direct measurements and indices of velocity and acceleration, indices of resistance and pulsatility, or combinations of these.[105] Although good results have been published using renal artery Doppler as a screening test for renal artery stenosis, a large meta-analysis showed that CT angiography and MR angiography performed significantly better.[106]

Parenchymal Disease

Much attention has been focused on duplex Doppler as a diagnostic tool for renal disease but the findings are nonspecific. Resistive index has been proposed as a parameter to predict outcomes after revascularization of stenotic kidneys,[107] but this approach is flawed because the resistive index is influenced by systemic parameters such as heart rate and pulse wave velocity.[108,109] Doppler indices are of no utility in the diagnosis of acute rejection in transplanted kidneys.[110,111]

Renal Vein Doppler

The main renal veins are often visible in adults and can be prominent in children or young adults, in patients with heart failure, and in inflamed kidneys. The right renal vein tracks directly from the inferior vena cava to the right kidney whereas the left renal vein has a longer course, passing just underneath the origin of the superior mesenteric artery. Renal vein thrombosis presents as enlarged, echogenic kidneys with clot sometimes visible within the lumen of the renal vein, best detected by power Doppler. When limited to the intrarenal vessels, the thrombus may not be visible. Duplex Doppler may reveal absent flow in the renal vein although this can be difficult to determine due to the lack of pulsatility in venous flow.

The Role of the Nephrologist

Because sonography is the most common imaging modality in patients with kidney disease and is essential to their management, nephrologists should consider incorporating this tool into their practice. The simplicity, the low cost and portability of the equipment, and the availability of training all make this a realistic goal. Certification in the performance and interpretation of renal sonograms can be obtained from the American Society of Diagnostic and Interventional Nephrology (www.ASDIN.org). Even if they are not performing the procedure themselves, nephrologists must have a comprehensive understanding of sonography of the kidneys and the urinary tract because interpretation frequently requires clinical input and correlation.

NUCLEAR MEDICINE IMAGING OF THE KIDNEYS

Radionuclide renal scintigraphy provides important functional data to assist in the diagnosis and management of patients with a variety of suspected genitourinary problems. Requesting a renal scan, however, is not always straightforward because there are five different renal radiopharmaceuticals and several imaging protocols. Renal scintigraphy is also complicated by the fact that there can be marked differences in scan quality at different institutions despite using the same radiopharmaceutical, the same equipment, and identical billing. To ensure that the patient receives the most appropriate study, the clinical question must be clearly specified. In addition, referring physicians should be familiar with the elements that make up a quality study, the different procedures and their limitations, the principal radiopharmaceuticals and the rationale for their use, as well as the terminology and quantitative parameters often included in the report. To achieve these goals, this section describes the available radiopharmaceuticals, the basic renal scan, and the quantitative indices used to interpret the study; it also reviews clearance measurements, the primary scan indications (Table 10.2), essential information needed by patients, radiation exposure, and includes a short discussion of renal scan applications in selected clinical settings.

10.2 Scans and Primary Clinical Indications

I. Basic Renogram
- To assess renal function and urodynamics
- To determine the percent of total renal function contributed by each kidney

II. Diuresis Renogram
- To diagnose or exclude urinary tract obstruction

III. ACE Inhibition (RVH or Captopril) Renogram
- To diagnose or exclude renovascular hypertension

IV. Renal Transplant Scintigraphy
- To evaluate arterial flow and function
- To help diagnose rejection and acute tubular necrosis
- To detect urinary leak, infarct, or outflow obstruction

V. Renal Cortical Scintigraphy
- To detect or exclude pyelonephritis
- To determine the percent of the total renal function contributed by each kidney

VI. Radionuclide Cystography
- To detect, quantitate, and monitor reflux
- To evaluate asymptomatic siblings of children with reflux

ACE, angiotensin-converting enzyme; RVH, renovascular hypertension.

Radiopharmaceuticals

The radiopharmaceuticals available for assessment of renal function and anatomy can be grouped into three broad categories: radiopharmaceuticals filtered by the glomerulus, tracers primarily secreted by the renal tubules, and those retained in the renal tubules for long periods of time.

^{99m}Tc-DTPA (Glomerular Filtration)

^{99m}Tc-DTPA (technetium-99m diethylenetriamine pentaacetic acid) is the only renal radiopharmaceutical available for routine imaging that is purely filtered by the glomerulus; consequently, it is the only imaging radiopharmaceutical that can be used to measure glomerular filtration rate (GFR).[112] In normal subjects, the extraction fraction of DTPA (the percentage of the tracer extracted with each pass through the kidney) is approximately 20%; this extraction fraction is relatively low compared to the extraction fraction of tubular tracers (40%–50%).

^{51}Cr-EDTA (Glomerular Filtration)

^{51}Cr-EDTA (chromium-51 ethylenediamine-tetraacetic acid) is used to measure GFR.[112] Chromium-51 does not emit enough photons to be used for imaging and the tracer is not available in the United States.

^{125}I-iothalamate (Glomerular Filtration)

^{125}I-iothalamate is used to measure GFR.[112] Iodine-125 does not emit a photon of sufficient energy to be useful for renal imaging.

^{99m}Tc-MDP (Glomerular Filtration)

^{99m}Tc-MDP (methylene diphosphonate) is a bone imaging tracer but it is cleared by glomerular filtration. Measurements of relative renal uptake (relative GFR) can be obtained at the time of a bone scan using standard renal software.

^{123}I- and ^{131}I-OIH (Tubular Secretion)

Iodine-123 and iodine-131 orthoiodohippurate (OIH) are cleared primarily by the proximal tubules although a small component is filtered by the glomeruli. The clearance of OIH is approximately 500–600 mL per minute in subjects with normal kidneys; this clearance is often described as the effective renal plasma flow (ERPF).[113] There is a common misconception that the ERPF (OIH clearance) is equivalent to renal plasma flow or, at least, proportional to renal plasma flow. The clearance of OIH and the clearance of ^{99m}Tc tubular tracers have two components: (1) delivery to the kidney (renal plasma flow) and (2) extraction from the plasma and transport to the tubular lumen (tubular function). These parameters do not always change in a proportional fashion. Because of poor imaging characteristics, the potential for delivering a high radiation dose, and/or unfavorable logistics, ^{123}I- and ^{131}I-OIH are no longer commercially available in the United States.[114,115]

^{99m}Tc-MAG3 (Tubular Secretion)

^{99m}Tc-mercaptoacetyltriglycine (MAG3) is highly protein-bound and is removed from the plasma almost exclusively by the organic anion transporter 1 (OAT1) located on the basolateral membrane of the proximal renal tubules.[113,116,117] The extraction fraction is 40% to 50%,[116] more than twice that of DTPA. Because of its more efficient extraction, MAG3 is preferred over DTPA in patients with suspected obstruction and impaired renal function and is used in approximately 70% of the renal scans performed in the United States.[118–122]

The MAG3 clearance averages about 320 mL/min/1.73 m^2 in adults under age 40 and decreases by approximately 1% per year after age 40.[123,124] The clearance of MAG3 is highly correlated with the clearance of OIH, and MAG3 clearance can be used as an independent measure of renal function.[112,113]

^{99m}Tc-L,L and D,D-EC (Tubular Secretion)

^{99m}Tc-L,L and D,D ethylene dicysteine (EC) are enantiomers—both are excellent renal radiopharmaceuticals with clearances

slightly higher than MAG3.[125,126] Although D,D-EC is cleared more rapidly than LL-EC,[127] LL-EC was first described and is available in several countries as a kit formulation.

^{99m}Tc-DMSA (Cortical Retention)

^{99m}Tc-DMSA (dimercaptosuccinic acid) is an excellent cortical imaging agent that is used primarily in pediatrics to evaluate relative function, pyelonephritis, and renal scarring.[128,129] Approximately 40% of the injected dose is retained by the renal tubules within 1 hour after injection; the remainder is slowly excreted in the urine over the subsequent 24 hours.

^{99m}Tc-GH (Cortical Retention and GFR)

^{99m}Tc-GH (glucoheptonate) is cleared both by glomerular filtration and tubular secretion. Most of the dose is rapidly excreted but 10% to 15% of the injected dose remains in the renal tubules allowing delayed, high-resolution static images to be obtained. GH tends to be used if DMSA is unavailable.

Basic Renal Scan and Renogram Curve

The basic renal scan is performed by injecting 1 to 10 mCi (37–370 MBq) of ^{99m}Tc-MAG3 or ^{99m}Tc-DTPA into a peripheral vein with the patient supine. Images are acquired dynamically for 20 to 30 min and postvoid views of the kidneys and bladder are often obtained at the conclusion of the study. Images are usually displayed at 1-, 2-, or 3-minute intervals as the radioactive tracer is removed from the blood, transits the kidney, and enters the bladder (Fig. 10.37A). Data are recorded on the computer for subsequent analysis, and renogram curves are obtained by placing a region of interest (ROI) over each kidney and generating time-activity curves for each ROI from the time of injection to end of the study.

Quantitative Indices

The more common quantitative indices and their clinical relevance are discussed here.

1. Relative function: The relative uptake of the radiopharmaceutical provides a measure of differential renal function (the specific function depends on the radiopharmaceutical) and should be reported. For MAG3 and DTPA, the measurement is usually made by placing an ROI over each kidney and measuring the radioactivity during the 1 to 2, 1 to 2.5, or 2 to 3 minute period postinjection. Because of radiotracer present in blood and the interstitial space of the kidney, as well as in the tissues anterior and posterior to the kidney, a background correction needs to be performed to correct for nonrenal counts present in the renal region of interest. Automated perirenal backgrounds (see Fig. 10.37A,B) and C-shaped backgrounds are preferred over background regions placed inferior to the kidney.[119,130] The 95% confidence interval for the relative uptake of MAG3 in the presence of normal renal function ranges from 42% to 58%.[123]
2. GFR, ERPF, and MAG3 clearance measurements: Measurement of GFR, effective renal plasma flow (ERPF), or MAG3 clearance may be obtained, depending on available software, protocols, and expertise (see discussion of clearance measurements).
3. Whole kidney versus cortical ROIs: The whole kidney ROI consists of an ROI placed around the entire kidney including the renal pelvis. Quantitative values generated using this ROI will be affected by retention of tracer in both the kidney parenchyma and renal pelvis. Thus retention may be due to pathologic states such as diabetic nephropathy or obstruction but may also occur in nonpathologic states such as a nonobstructed dilated collecting system or mild dehydration. To obtain a better assessment of parenchymal function, ROIs can be limited to the renal cortex (parenchyma), thereby excluding any activity retained in the pelvis or calyces (Fig. 10.37).
4. Time-to- peak or T_{max}: The time-to-peak or T_{max} simply refers to the time from radiopharmaceutical injection to the peak height of the renogram curve. MAG3 and DTPA renograms normally peak by 5 minutes and decline to half-peak height by 15 minutes postinjection; however, physiologic retention of the tracer in the renal calyces or pelvis can alter the shape of the whole kidney renogram curve in normal kidneys and lead to prolonged values for the time-to-peak, 20 min/max count ratio, and T1/2.
5. The T1/2: The T1/2 refers to the time it takes for the activity in the kidney to fall to 50% of its maximum value (see suspected obstruction).
6. Postvoid kidney counts/maximum or 1 to 2 minute kidney counts: In evaluating suspected obstruction, simple ratios that incorporate gravity-facilitated drainage from the kidneys such as counts in the postvoid kidney divided by the maximum counts in the kidney or counts at 1 to 2 minutes appear to provide more robust measurements of drainage than the T1/2.[131–134]
7. 20 min/max count ratio: The 20 min/max count ratio is the ratio of the kidney counts at 20 minutes to the maximum (peak) counts; this measurement provides an index of the transit time and parenchymal function and is often obtained for both whole kidney and cortical (parenchymal) ROIs. For MAG3, the normal 20 min/max count ratio for cortical ROIs averages 0.19 with standard deviations of 0.07 and 0.04 for the right and left kidneys, respectively.[123] If the patient is not dehydrated and the 20 min/max count ratio for the cortical ROI exceeds 0.35 (greater than two to three standard deviations above the mean), the kidney is likely to be abnormal. With the tubular agents, this index can be useful in monitoring patients with suspected urinary tract obstruction and renovascular hypertension.[135–137]

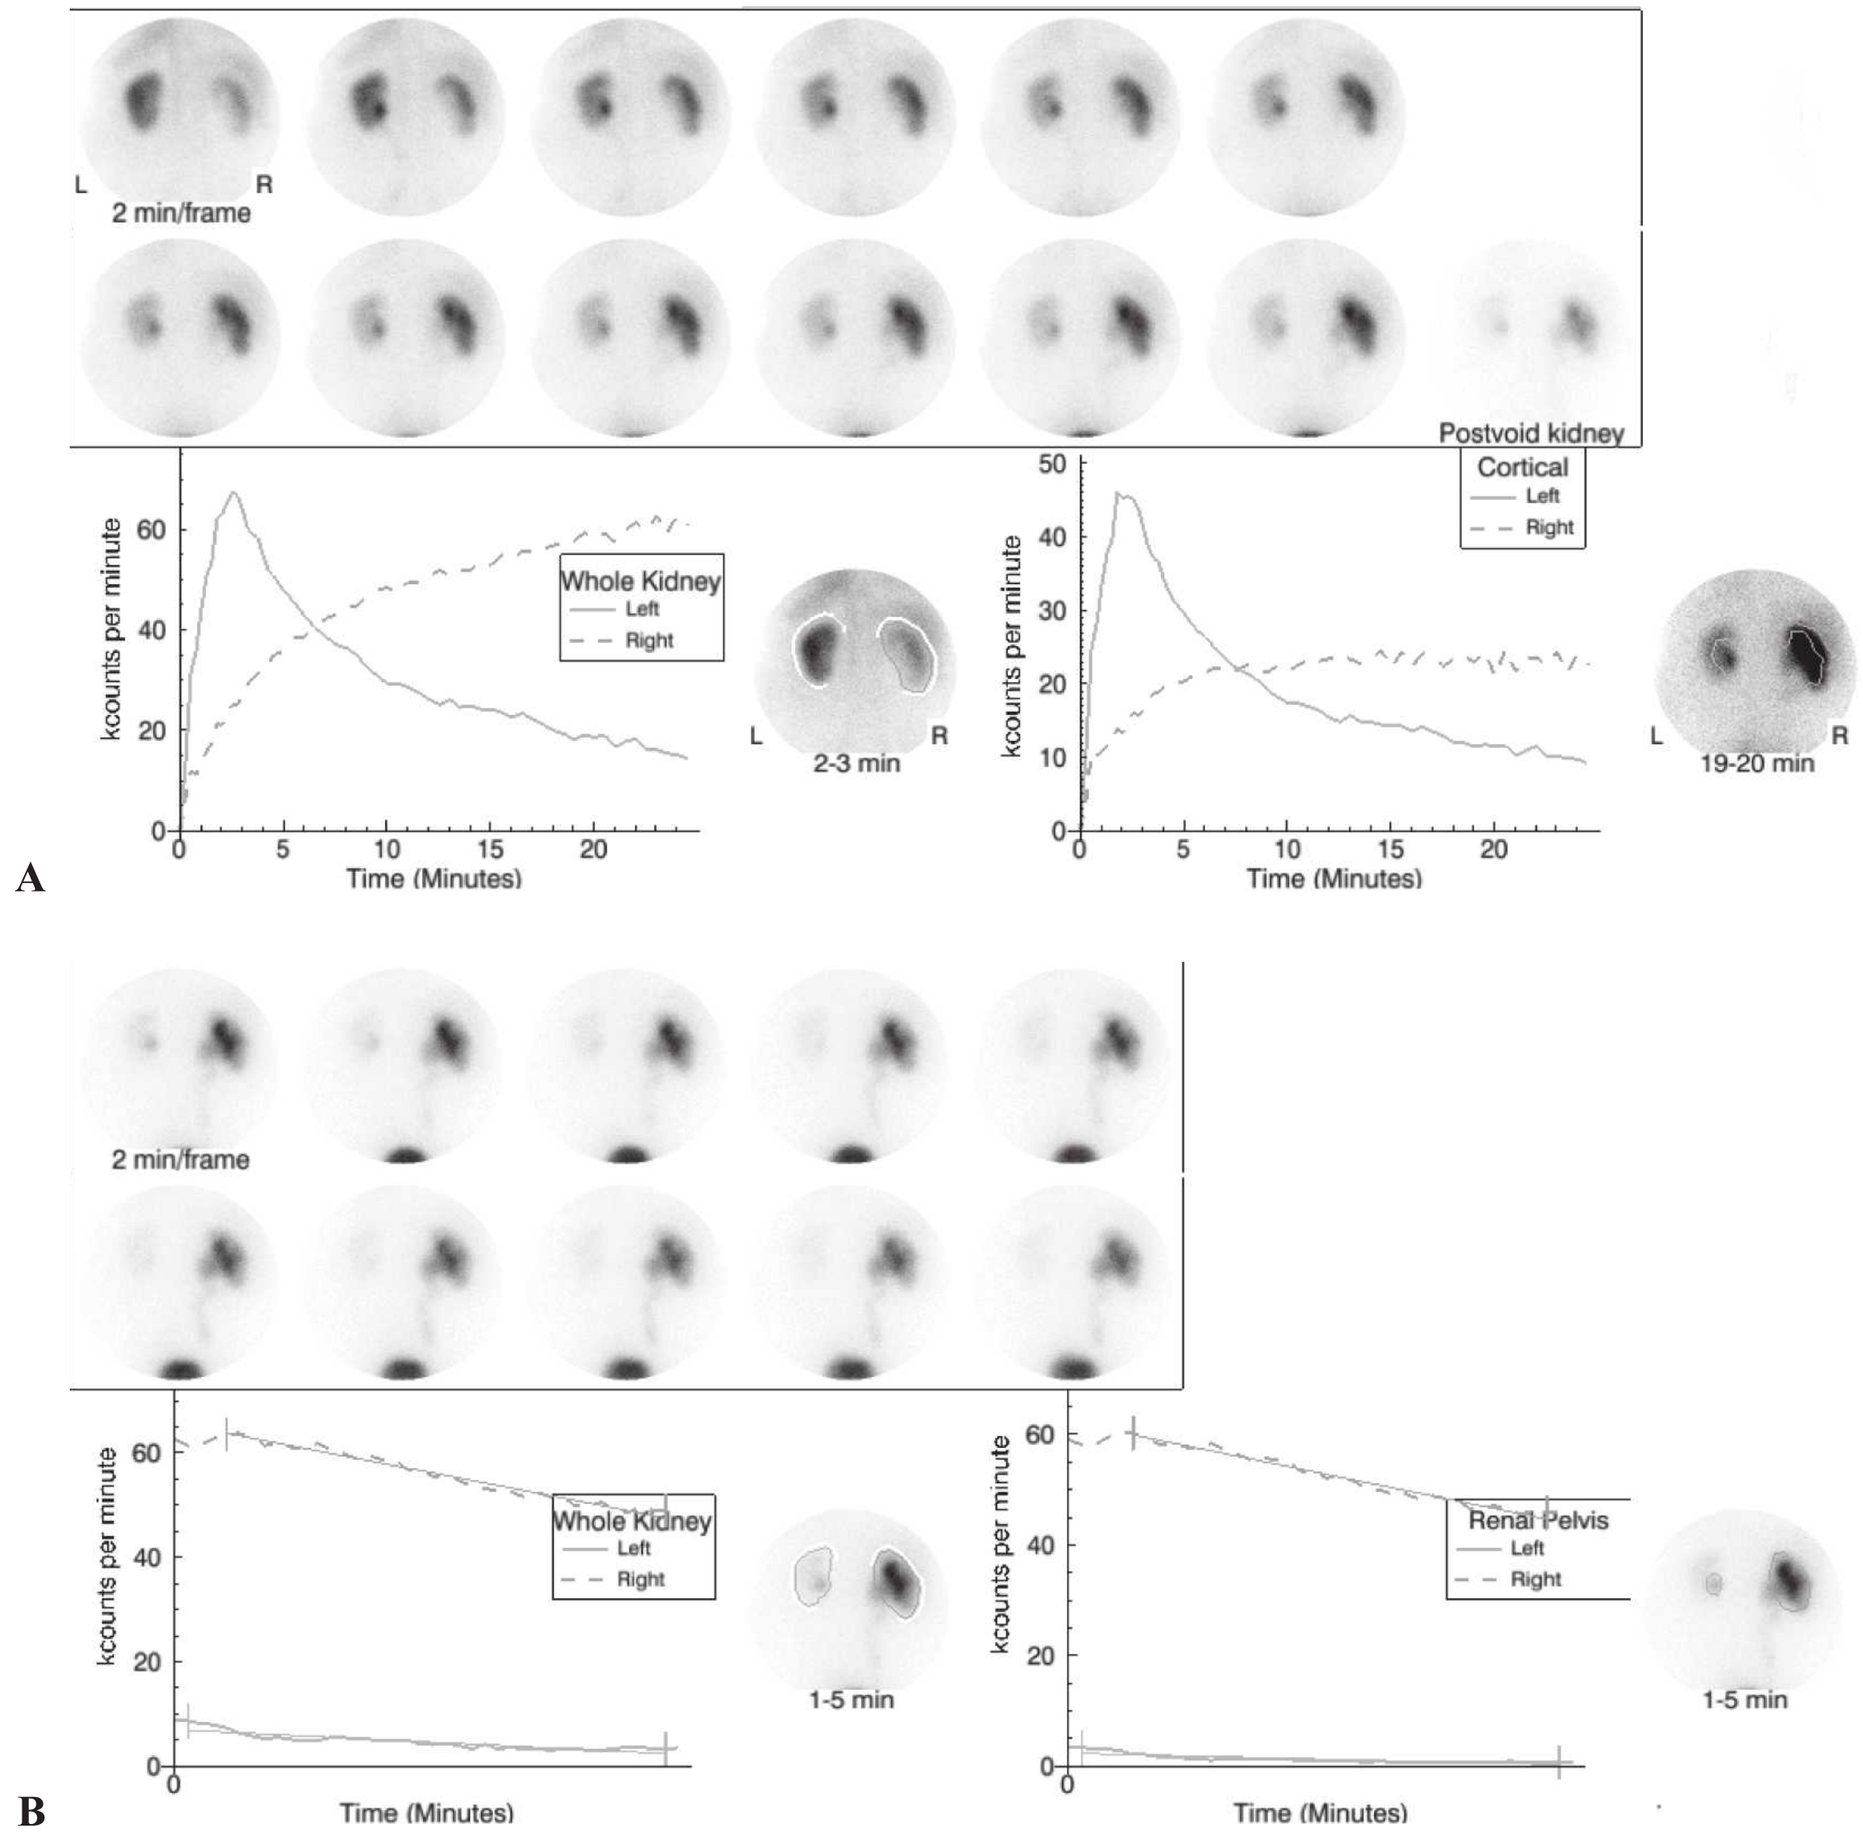

FIGURE 10.37 A 70-year-old man was referred for a renal scan because of suspected obstruction of the right kidney. The patient received an intravenous injection of 9.2 mCi (340 MBq) of ^{99m}Tc MAG3. **A:** The upper panel shows sequential 2-minute MAG3 images in a posterior projection; the final image in the series is a postvoid image. The lower left panel shows the whole kidney renogram curves (*blue*, left kidney; *green*, right kidney); the lower right panel shows cortical renogram curves. The relative uptake was 74% in the left kidney, 24% in the right kidney; the MAG3 clearance was 231 mL/min/1.73 m^2. The images and renogram curve for the left kidney are normal. There is retention of the MAG3 in the right renal collecting system with a rising renogram curve. **B:** To further investigate the possibility of obstruction in the right kidney, the patient received an intravenous injection of 40 mg furosemide followed by an additional 20 minutes of imaging. The upper panel shows sequential 2-minute images following furosemide administration. The lower left panel shows the whole kidney renogram curve and the lower right panel shows the renogram curve with the regions of interest placed around the retained tracer in the collecting system. There is very little MAG3 remaining in the left kidney (*blue*); the post-furosemide images show continuing retention in the right renal collecting system with very slow washout (T1/2 = 36 minutes for the region of interest over the collecting system) consistent with obstruction. (See Color Plate.)

8. Residual urine volume: Residual urine volume can be measured based on the counts in pre- and postvoid ROIs over the bladder and a measurement of the voided volume.[138] This is a relatively easy measurement to perform, is routine at some institutions, and may detect unsuspected urinary retention. The main source of error is tracer remaining in the renal pelvis which subsequently drains into the bladder after voiding; this problem can be detected by looking at the last kidney image in the study.
9. Urine flow rate: The rate of urine flow can be useful in assessing the adequacy of hydration and the adequacy of diuresis following furosemide administration. Assuming a constant postvoid volume, urine flow

rate can be calculated by dividing the voided volume at the conclusion of the study by the time interval between voiding prior to and at the conclusion of the study.

Renal Function and Clearance Measurements

Because of inaccuracies associated with estimation of GFR based on serum creatinine or creatinine clearance, a more accurate measurement of renal function may be needed in patients at the extremes of age and body mass and in patients with severe malnutrition, grossly abnormal muscle mass (amputation, paralysis), high or low intake of creatinine or creatine (vegetarian diet, dietary supplements), rapidly changing renal function, prior to kidney donation, and prior to dosing with toxic drugs excreted by the kidney. Measurement of renal function at the time of the scan can aid in the interpretation of a radionuclide study, provide a measurement of renal function independent of serum creatinine, and serve as a baseline for monitoring changes. The two most widely used techniques to measure clearances are plasma sampling and camera-based techniques.

Multisample Plasma Clearances. The gold standard for measuring renal clearances is a constant infusion technique where the plasma concentration of the tracer remains constant.[112] A variant of this technique uses a subcutaneous injection; however, both of these methods are cumbersome, time consuming, expensive, and limited to research applications. An alternative approach that does not require urine collections is the plasma clearance obtained using the single injection, two-compartment model.[139] For tubular tracers, the plasma disappearance curve can be determined from multiple blood samples obtained over 90 minutes. Because GFR tracers have a much lower extraction fraction and a lower clearance, plasma samples typically need to be obtained for 4 hours to adequately characterize the curve.

Single and Dual Plasma Sample Clearances. Simplified techniques based on one or two plasma samples have been developed to estimate the multisample clearance.[112] The MAG3 clearance can be estimated from the dose injected and the amount of radioactivity in a single blood sample obtained approximately 45 minutes after injection[112,124,140] and the GFR can be estimated from the dose injected and the activity in one or two plasma samples obtained 1 to 4 hours after injection.[112,141–143] These techniques provide reliable results and can be performed at the time of a standard renal scan using MAG3 or DTPA.

Plasma Sample Techniques: Sources of Error and Availability. Plasma sampling techniques assume a normal volume of distribution. If a patient has ascites, marked edema, or a large effusion, the tracer can diffuse into these extra fluid spaces and the plasma clearance will not provide an accurate measure of renal function. Plasma sample clearances require meticulous technique and attention to detail. If the measurement is performed by a poorly trained or inexperienced individual, technical errors are often made and the results are spurious. Because of the need for specialized training, the necessity of handling plasma samples, extra effort, and lack of reimbursement, plasma sample clearances are not widely available in the United States.

Camera-Based Clearances. Camera clearance methods have been developed for DTPA, OIH, and MAG3 that do not require blood or urine samples.[141–145] The principle is based on the fact that the initial tracer accumulation by the kidneys is proportional to the clearance. Camera-based techniques determine the tracer accumulation (counts) in the kidneys at a defined period shortly after injection and divided by the counts injected to obtain a percent injected dose in the kidneys. The percent injected dose is converted to a clearance measurement using a validated nomogram.[145]

Camera-based clearances appear to be reproducible and have been reported to be superior to creatinine clearance for monitoring changes in renal function.[146] Although camera-based clearances are considered to be less accurate than plasma sample clearances,[112] they avoid sources of error (timing of plasma samples, correction for radioactive decay, dilution of standards, pipetting small volumes) inherent in plasma sample techniques.

Camera-based Clearances: Sources of Error. To obtain the percent injected dose in each kidney, kidney counts have to be corrected for background, infiltration, attenuation, and renal depth. Two common sources of error are background subtraction and the estimation of renal depth. Because MAG3 is extracted more than twice as efficiently as DTPA, the kidney-to-background ratio will be much higher for MAG3 than DTPA and any potential error introduced by background subtraction will be minimized.

Renal depth is usually estimated from a nomogram based on height and weight.[147,148] To the degree that a population-derived nomogram fails to fit a particular individual, the clearance measurement will vary from the true clearance. The sources of error due to background, self-attenuation, and renal depth tend to be reflected in a wider confidence interval associated with the accuracy of camera-based clearance compared to plasma sample clearances; however, these parameters tend to be constant on sequential studies and have less effect on reproducibility. Commercial camera-based techniques are currently available for measuring GFR (DTPA), effective renal plasma flow (OIH), and the MAG3 clearance. In evaluating the reliability of commercial software, it is important to confirm that the vendor has (1) incorporated the appropriate quality control features and (2) provided citable validation studies to confirm that the software is performing as claimed.

General Patient Preparation and Information

Patients appreciate knowing what to expect when they are referred for an unfamiliar test. The following information should be communicated to the patient.

Procedure and Time Required for the Study

The patient will receive an intravenous injection of the radiopharmaceutical and will lie quietly on an imaging table for 20 to 30 minutes. Depending on the protocol, there may be two imaging sessions. Unlike radiographic contrast, there is essentially no risk of an allergic or anaphylactic reaction.

Hydration

The patient should be told to arrive well hydrated because good hydration minimizes the radiation dose to the bladder and facilitates interpretation of the exam.

Diet and Medication

For a basic renogram, there are no medication or dietary restrictions. Medication and dietary restriction for angiotensin-converting enzyme (ACE) inhibition renography are discussed later.

Radiation Exposure

Depending on the radiopharmaceutical and the amount administered, the radiation exposure from a typical MAG3 or DTPA scan ranges from 5% to 70% of the background radiation a patient receives each year from cosmic rays and naturally occurring radioactive sources in the environment; it is less than 5% of the yearly radiation dose considered safe for doctors and technologists who work with radiation. In patients with normal kidney function, over 95% of the radiation leaves the body by 3 hours. Patients can go to public places and use a bathroom without risk to others (see later text for a more detailed discussion of radiation).

Pregnancy

If the patient is pregnant or thinks she may be pregnant, she should discuss this possibility with the nuclear medicine physician prior to arrival for the test.

Radiation Exposure to the Nuclear Medicine Patient

Radiopharmaceuticals are designed to target specific organs, tumors, or pathways and to avoid others; consequently, they do not distribute uniformly throughout the body. Different tissues receive different exposures depending on the isotope, its half-life, its tissue distribution, and its retention time. For example, ^{99m}Tc has a half-life of about 6 hours; even if none of a ^{99m}Tc tracer was eliminated from the body after intravenous administration, the amount remaining in the body 24 hours later (four half-lives) would be only about 6% of the administered dose.

The concept of effective radiation dose has been developed to define a single quantity that could express the overall potential deleterious effect of radiation exposures. This concept allows the risk of the different radiation doses to different tissues throughout the body to be expressed in a single measurement. The effective radiation dose equivalent is the whole-body radiation dose that would have to be given to produce a risk equivalent to the sum of the risks from the individual radiation doses to the various organs. The effective dose from a MAG3 or DTPA scan ranges from 15 to 20 mrem (0.15–0.2 mSv) per millicurie injected. The typical administered dose is 1 to 10 millicuries (37–370 MBq); consequently, the effective dose for a renal scan ranges from 15 to 200 mrem (0.15–2.0 mSv).[115] For comparison, background radiation is estimated to be approximately 300 mrem (3.0 mSv) per year.

Suspected Obstruction (Diuresis Renography)

Obstruction to urinary outflow may lead to obstructive uropathy (dilatation of the calices, pelvis, or ureters) and obstructive nephropathy (damage to the parenchyma). Urine outflow obstruction may be suspected based on clinical findings, the incidental detection of a dilated renal collecting system, or diagnosis of previous obstruction in a patient referred for follow-up. Diuresis renography is noninvasive, widely available, and can evaluate renal function and urodynamics in a single test. This noninvasive test is based on a high endogenous rate of urine flow stimulated by the administration of furosemide. Interpretation of the test is based on the washout of the radiopharmaceutical from the collecting system in the upper urinary tract.

Acquisition Protocols, Radiopharmaceutical Choice, and the Timing of Furosemide

The patient should arrive well hydrated and void immediately prior to the examination because a full bladder may affect upper tract emptying and give false-positive results.[120] Adult and pediatric consensus groups recommend tubular agents for diuresis renography because tubular tracers are much more efficiently extracted by the kidney than DTPA.[120,122,134,149] Several protocols are available for diuretic renography that differ mainly in the timing of furosemide administration and in the use of a single acquisition or a baseline scan followed by post-furosemide acquisitions if the baseline scan does not exclude obstruction.[120,122] Typical times for furosemide administration are the F – 15, F = 0, and F + 20 protocols where the furosemide is administered 15 minutes before, simultaneously with, or 20 minutes after the tracer administration. Each protocol has its advocates but all are acceptable and appear to give comparable results in the majority of patients.[134,150–153]

Dose of Furosemide

Furosemide is secreted by the proximal tubule and reaches its site of action in the tubular lumen of the thick ascending loop of Henle via the tubular fluid.[154] Secretion of

furosemide is reduced in patients with impaired renal function; consequently, the standard 40-mg adult dose may not be sufficient to induce an adequate diuretic response in a kidney with moderate or severely impaired renal function and a larger dose of furosemide may be required.[154,155]

Diagnostic Criteria, the T1/2, Gravity-Assisted Drainage, and Postvoid Images

Drainage is often assessed quantitatively by measurement of the T1/2 following furosemide administration. Although the T1/2 calculated from an ROI placed around retained activity in the collecting system rather than around the whole kidney provides a better assessment of drainage, T1/2 measurements are not standardized and they vary depending on timing, ROI assignment, and method of calculation.[120,122,156,157] There is general agreement that prompt clearance of the radiopharmaceutical from the renal collecting system with a T1/2 under 10 minutes excludes obstruction. On the other hand, a prolonged T1/2 should never be the sole criterion for determining the presence of obstruction and must be interpreted in the context of the whole set of images, curves, and quantitative indices as well as any clinical information or diagnostic studies that may be available. Techniques that consider renal function, utilize gravity-assisted drainage, and incorporate postvoid images appear to provide more robust alternatives to the T1/2.[131,133,134,136,158,159]

False-Positive and Indeterminate Studies

A poor diuretic response due to dehydration or impaired renal function may result in false-positive or indeterminate findings. Measuring the urine flow rate alerts the nuclear medicine physician to an inadequate diuresis.

Relative Renal Function

Unless obstruction is acute, it usually causes a loss of function in the affected kidney. If the relative renal function is approximately the same in both kidneys in a patient with suspected unilateral obstruction, the likelihood of obstruction is reduced even if the quantitative data such as the T1/2 are abnormal. In these cases, it may be appropriate to observe the patient and repeat the study at a later date or to combine the study with sonography to determine if the size of the renal pelvis is increasing.

Does a Patient Presenting with Flank Pain have Acute Renal Colic? If so, Can He be Managed Conservatively?

Knowledge of the size of the obstructing calculus is important because calculi less than 5 mm generally pass spontaneously; as the size of the calculus increases, spontaneous passage becomes less likely. Unenhanced (noncontrast) helical CT (UHCT) has rapidly gained acceptance as the procedure of choice for patients presenting with acute renal colic. UHCT avoids the risk of contrast, which is particularly important for patients with renal insufficiency, diabetes, dehydration, or allergy to iodinated contrast agents; moreover, stone size can be accurately ascertained, and the correct diagnosis can be made in approximately 50% of patients whose symptoms are not caused by a renal stone.

Many calculi between 3 to 8 mm in size are followed conservatively in the hope of spontaneous passage, and patients may be managed on an outpatient basis. In spite of its advantages, UHCT cannot determine the functional status of the kidney. Larger stones (5–8 mm) may not be associated with high-grade obstruction and can be managed conservatively, whereas some small stones (3–5 mm) do result in high-grade obstruction and may need more aggressive management. The addition of a diuretic renal scan can determine the presence or absence of obstruction and has been shown to direct patient management; in one study, the scan changed the decision to admit or discharge the patient in 30% of cases.[160–162] Data have not yet been collected to determine if the addition of the scan and resulting change in practice leads to better patient outcomes and/or reduced medical costs.

Ultrasound or CT Show a Dilated Collecting System. Is There Ureteral Obstruction?

Dilatation of the urinary tract with no apparent cause may be incidentally detected by ultrasound, CT, or MRI in a patient with no symptoms of acute obstruction. If the dilated collecting system represents chronic obstruction, an intervention may be required to preserve renal function; if there is simply dilatation of a nonobstructed collecting system, no further workup is required. Diuresis renography is preferred in the evaluation of the nonacute dilated collecting system because it is noninvasive, relatively inexpensive compared to CT or MR urography, and allows the clinician to quantitate the physiologic significance of the anatomic abnormality by measuring both the relative renal function and the diuretic stimulated washout of the tracer from the dilated system. Contrast is avoided, and the gonadal radiation dose is substantially reduced compared to CT urography.

A Patient with Previous Obstruction has Recurrent Symptoms. Has Obstruction Recurred? Has Surgery Successfully Relieved a Documented Obstruction?

A patient with previous documented and treated obstruction may present with symptoms suggesting recurrent obstruction; sonography is often not helpful in this setting because the urinary tract can be dilated secondary to the previous episode of obstruction. Diuresis renography is the preferred examination.

Antenatal Sonography Shows a Dilated Pelvis or Ureter. Is There Obstruction or Loss of Renal Function?

The significance of an abnormal antenatal renal sonogram can be readily evaluated by MAG3 diuresis renal scintigraphy in

the newborn. Relative function can be quantitated and drainage assessed. If the diagnosis of obstruction is uncertain, sequential studies can be obtained with sonography to determine if the renal pelvis is enlarging or with sequential MAG3 scans to evaluate drainage and to determine if function is decreasing in the affected kidney.

Suspected Renovascular Hypertension (ACE Inhibition Renography)

The diagnostic and therapeutic approach to patients with suspected renal artery stenosis (RAS) remains uncertain and controversial. Atherosclerotic renal artery stenosis (ARAS) is the most common cause of secondary hypertension[163]; however, it may be present in as many as 25% of normotensive patients over age 50[164] and is often present as an incidental or secondary finding in hypertensive patients.[164,165] ARAS is far more common than renovascular hypertension (RVH), whose classical definition is based on cure or amelioration of the hypertension after revascularization. Consequently, it comes as no surprise that the Scottish, EMMA, and DRASTIC studies, and the more recent STAR and ASTRAL trials, indicate that the indiscriminate revascularization of an atherosclerotic RAS appears to have little advantage over optimal medical therapy and is no longer justified.[166–170] These five trials, however, did not distinguish between the impact of revascularization in a hypertensive patient with RAS and the impact of revascularization in a hypertensive patient with a functionally significant stenosis. Although indiscriminate revascularization of a stenotic renal artery in hypertensive patients is no longer justified, more focused selection criteria that evaluate the functional significance of the stenosis may lead to improved outcomes.

Spiral computed tomography (CTA) and magnetic resonance angiography (MRA) provide detailed images of the aorta and renal arteries and have high sensitivity and specificity for detecting RAS.[163,171] The main limitation of CTA and MRA is the lack of information on renal blood flow or pressure distal to the stenosis.[171] In azotemic patients, CTA carries the risk of contrast nephrotoxicity, and the use of MR contrast in patients with a low GFR is associated with nephrogenic systemic fibrosis.[172] Doppler ultrasound is reported to provide reliable hemodynamic assessment of renal artery lesions in selected centers but others have found it to be time consuming, operator dependent, lacking diagnostic uniformity, and too unreliable in obese individuals to be an efficient tool to screen hypertensive patients for a functionally significant RAS.[171,173] This introduction underscores the need for diagnostic procedures that can accurately select those hypertensive patients with RAS most likely to be cured or improved after revascularization.

ACE Inhibition Renography and Scan Interpretation

A functionally significant stenosis leads to a decrease in the perfusion pressure distal to the stenosis resulting in a decrease in the transglomerular pressure gradient and a decrease in GFR. The reduction in perfusion pressure stimulates the release of renin and increased production of angiotensin I which is converted to angiotensin II by ACE. Angiotensin II preferentially constricts the efferent arteriole of the glomerulus and raises the transglomerular pressure gradient—a process that maintains GFR in the face of a moderate reduction in perfusion pressure.

In patients with a functionally significant renal artery stenosis, the blockade of angiotensin II production by ACE inhibition leads to a reduction in GFR that can be detected by renography. ACE inhibitors also inhibit kininase II, a dipeptidyl carboxy-peptidase that inactivates bradykinin, a potent vasodilator that causes selective efferent arteriolar dilation; this mechanism also contributes to the ACE-induced reduction in GFR.[174–176]

The reduction in GFR in patients with a functionally significant RAS following ACE inhibition can be detected by a decrease in renal uptake of DTPA by the affected kidney compared to the baseline scan; tubular tracers such as MAG3 demonstrate cortical retention (Fig. 10.38, right kidney)[135,137,159,177,178] which is also secondary to the decrease in GFR and results from a decreased flow of primitive urine through the renal tubules.[179]

Consensus panels have recommended that the test be interpreted as high, low, or indeterminate probability for renovascular hypertension.[135,177] A normal or near normal renogram that is unchanged or improves following ACE inhibition is low probability for renovascular hypertension and indicates that revascularization is unlikely to ameliorate the hypertension (Fig. 10.38, left kidney). Abnormal baseline renograms that are unchanged following ACE inhibition are indeterminate and are not predictive of the response to revascularization. Unilateral deterioration of the renogram curve and/or of the relative function following ACE inhibition compared to the baseline study represents a high probability scan for renovascular hypertension and indicates a high likelihood that blood pressure will be normalized or ameliorated by revascularization.

Sensitivity and Specificity of ACE Inhibition Renography

ACE inhibition renography in an appropriately screened hypertensive patient with preserved renal function can detect renovascular hypertension with a sensitivity approximating 90%.[137,175,178,180–188] Using the criterion of ACE inhibition-induced changes between baseline and ACE inhibition scans to define a positive test, the test has a specificity ≥90% and consequently has a high positive predictive value.[178,187] The sensitivity and specificity of ACE inhibition renography, however, are affected by several factors that have contributed to confusion in the literature.

1. Use of the anatomic presence of a renal artery stenosis as a surrogate for renovascular hypertension. ACE inhibition renography is a test to detect a functionally significant RAS, NOT a test to detect the presence of RAS.[135,177] Nevertheless, many investigators have used the angiographic

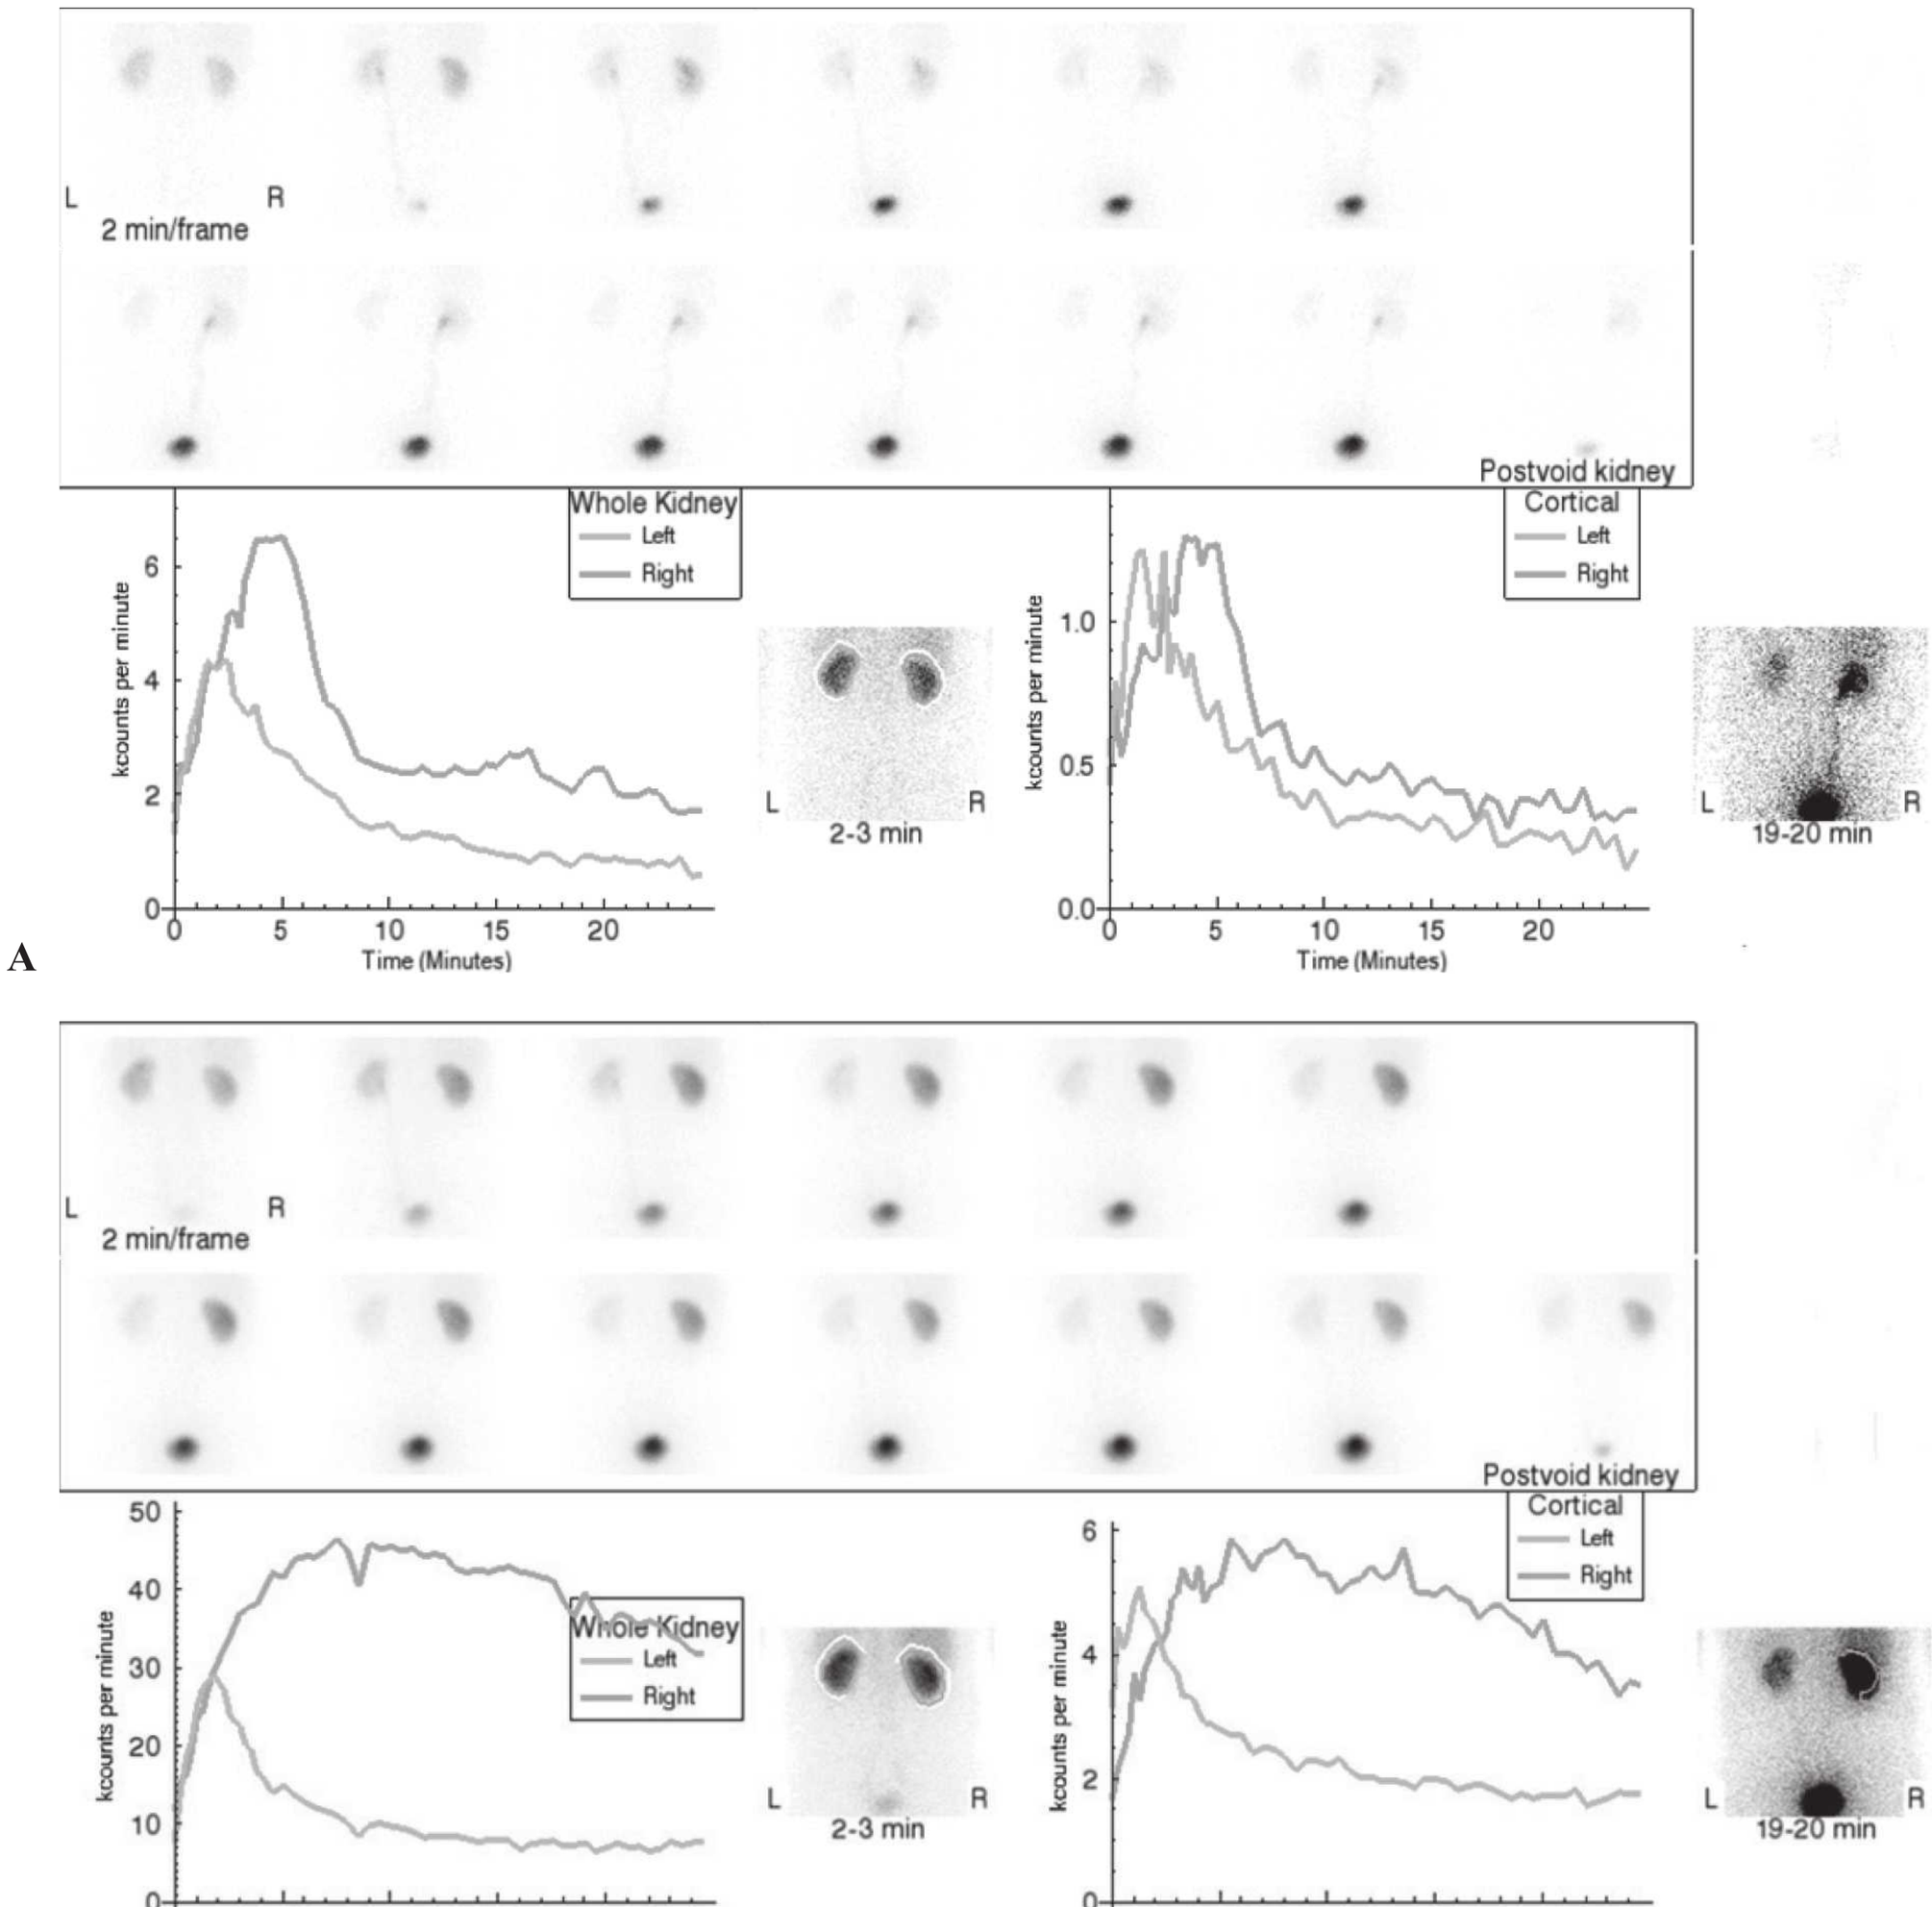

FIGURE 10.38 A 52-year-old patient with hypertension with a normal serum creatinine had a computed tomography (CT) scan for a possible incarcerated abdominal hernia. The CT scan revealed a heavily calcified right renal artery. A subsequent CT angiogram confirmed a renal artery stenosis and an angiotensin-converting enzyme (ACE) inhibition renal scan was requested to determine its functional significance. **A:** A baseline scan was obtained following the injection of 1.4 mCi of ^{99m}Tc MAG3 (52 MBq). The upper panel shows sequential 2-minute MAG3 images. The lower left panel shows the whole kidney renogram curves (*blue*, left kidney; *green*, right kidney); the lower right panel shows cortical renogram curves. The relative uptake was 51% (*left*) and 49% (*right*) with a MAG3 clearance of 295 mL/min/1.73 m^2. The images appear normal with time to maximum counts (T_{max}) and 20 min/max count ratios in the normal range for both kidneys although there was asymmetry with the T_{max} for the right kidney (4.8 min) more delayed than the T_{max} for the left kidney (1.8 minutes); in addition, the 20 min/max ratio for the right kidney, 0.30, was higher than that of the left (0.19). **B:** The patient received an intravenous injection of 2.5 mg of enalaprilat followed 20 minutes later with a second MAG3 injection of 9.0 mCi of MAG3 (333 MBq). The left kidney is normal. The relative function was essentially unchanged, 49% left, 51% right but the sequential 2-minute images show marked parenchymal retention of the tracer in the right kidney with a correspondingly abnormal whole kidney and cortical renogram curves. The marked change in the right kidney from the baseline to the ACE study indicates a high probability scan for renovascular hypertension. (See Color Plate.)

presence of a stenosis >50% as a surrogate for renovascular hypertension in spite of the fact that many of these stenotic lesions will not be hemodynamically significant.[106,177,178,189] In an attempt to circumvent this problem, other investigators have used the more stringent standard of >70% stenosis. Although good results have been obtained using RAS as the gold standard,[190] not surprisingly, the sensitivity and specificity of ACE inhibition renography is improved when the gold standard is the response to revascularization rather than the anatomic presence of RAS.[178,184,185,187,188]

2. Patient selection: test performance in azotemic and nonazotemic populations. Current data indicate that the test is not as accurate in azotemic patients with RAS. Although some studies report good results in azotemic patients,[183,191,192] most investigators have found ACE inhibition renography to be less accurate in azotemic patients.[135,137,177,178,181] In this population, a positive test retains a high specificity indicating a high likelihood that the hypertension will be ameliorated by revascularization,[193] but one study reported as many as 50% of tests in this population were intermediate probability.[137] Intermediate probability outcomes result from an abnormal baseline scan which is unchanged following ACE inhibition and are not predictive of the response to revascularization.
3. Analysis of the "intermediate probability" or indeterminate scan. To calculate sensitivity and specificity, indeterminate results must be placed with the high or low probability results. Intermediate probability studies placed in the "high probability" category increase sensitivity at the expense of specificity and, conversely, intermediate probability studies placed in the "low probability" category increase specificity at the expense of sensitivity.[194] The reported values for sensitivity and specificity vary depending on the frequency of azotemic patients in the study population and how intermediate probability results are handled in the data analysis.
4. Inconsistent use of recommended criteria for interpreting ACE inhibition renograms. Interpretative criteria for ACE inhibition renography have been published as an international consensus report in 1996; this report has subsequently been updated by the Society of Nuclear Medicine and published on its website.[135,177] Studies performed after 1996 should include an analysis based on these criteria especially because data show that strict adherence to these criteria improves the performance of ACE inhibition renography.[195]

Performance of the Examination

Detailed recommendations for performance of ACE inhibition renography are described in consensus reports[135,177] but several points should be emphasized.

1. Blood pressure must be monitored. Asymptomatic hypotension secondary to ACE inhibition can result in bilateral symmetrical abnormalities in the renogram curves.[194,196] This phenomenon is relatively uncommon but may occur in as many as 3% of patients referred for ACE inhibition renography, usually in patients who are volume or salt depleted.[196,197]
2. ACE inhibitors and angiotensin II receptor blockers (ARBs). The majority of ACE inhibition studies have been performed with captopril (25–50 mg) but enalaprilat (Vasotec, 40 μg per kg IV over 3–5 minutes, maximum dose of 2.5 mg) administered at least 15 minutes prior to tracer administration is an acceptable alternative.[177,183] Intravenous injection of enalaprilat avoids the possibility of a false-negative test due to delayed gastric emptying or poor absorption—a potential disadvantage is the possibility of a greater risk of a hypotensive response. Chronic ACE inhibition may reduce the sensitivity of the test[179,192] and, for this reason, guidelines recommend that captopril be discontinued for 4 days prior to the study and ACE inhibitors with a longer half-life be discontinued for 7 days. Data are limited regarding the impact of chronic ARB administration on the sensitivity and specificity of ACE inhibition renography.[175]
3. Diuretics. Chronic diuretic administration increases the likelihood of volume depletion which may lead to renal retention of the radiopharmaceutical, reduce the specificity of the test, and increase the risk of a hypotensive response. These concerns can be minimized if diuretics are discontinued for several days prior to the study.
4. Choice of radionuclide. In patients with azotemia, tubular agents such as MAG3 or I-123 are the agents of choice.[137,177] In patients with normal function, MAG3 and DTPA appear to give comparable results.
5. One-day versus two-day protocol. The traditional approach is a one-day protocol; a baseline study is performed, the ACE inhibitor is administered, and a second study is obtained allowing an immediate comparison between the baseline and ACE inhibition results. An alternative approach is to begin with ACE inhibition renography because a normal study is low probability for renovascular hypertension and obviates the need for a baseline study. If the ACE inhibition study is abnormal, the specificity can be improved by obtaining a baseline renogram; however, the patient will have to return for the baseline study on another day because of the earlier administration of the ACE inhibitor.

Does a Hypertensive Patient Have Renovascular Hypertension?

Risk factors for renovascular hypertension (RVH) include abrupt or severe hypertension, hypertension resistant to medical therapy, abdominal or flank bruits, unexplained azotemia in an elderly hypertensive patient, worsening renal function during ACE inhibition therapy, grade 3 or 4 hypertensive retinopathy, a history of heavy smoking, occlusive

disease in other vascular beds, and onset of hypertension under age 30 or over age 55. To determine the most appropriate test, patients need to be categorized into (1) those with low likelihood of RVH, (2) those with moderate to high likelihood of RVH and normal renal function, and (3) those with moderate to high likelihood of RVH and azotemia.

Technologies are evolving and multiple diagnostic imaging strategies have been proposed, but, to date, there is no generally accepted approach. Costs need to be considered in determining the clinical approach but costs are a moving target and hard to ascertain. Patients with a low likelihood of RVH can be treated medically without additional imaging studies. For the patient with one or more risk factors for RVH, normal renal function, and no known unilateral kidney disease, ACE inhibition renography provides a logical and cost-effective diagnostic approach. In this patient population, a recent analysis showed that ACE inhibition renogram as the first test was more cost effective than CT or MRA.[194]

The evaluation of the patient with azotemia or a patient known to have a small, poorly functioning kidney is more problematic. In this patient population, a positive ACE inhibition renogram still has a high predictive value for amelioration of the hypertension, but as many as half of the tests may be indeterminate for RVH, and the specificity of the test probably falls to about 80%. The advantages and disadvantages of other diagnostic approaches have been described, and test selection should be based on local expertise, cost, and how the test result will influence patient management.

Renal Transplant Scintigraphy

Donor Evaluation

Renal scintigraphy can evaluate global and individual renal function in potential donors as well as help determine which kidney to select for donation. Use of renal scintigraphy in donor evaluation, however, varies widely between centers.

Transplant Evaluation

Complications of renal transplantation can be divided into parenchymal failure (acute tubular necrosis [ATN], acute and chronic rejection, and calcineurin inhibitor toxicity) and mechanical failure (injury to the renal artery or vein, ureteral obstruction, and urine leak).[198] Sonography is usually the first approach for evaluation of renal graft dysfunction but a renal scan can provide complementary information. A normal scan immediately posttransplant excludes mechanical complications. Serial scans during the first 1 to 3 weeks posttransplantation may detect early rejection 24 to 48 hours before biochemical abnormalities occur and can be used to monitor recovery from posttransplantation ATN. Classically, ATN presents with relatively preserved perfusion accompanied by delayed uptake and excretion although severe ATN can also present with diminished flow. Rejection presents as diminished flow with delayed uptake and excretion of the tracer.[198]

Chronic transplant nephropathy represents cumulative and incremental damage to nephrons from both immunologic and nonimmunologic causes. Imaging studies are obtained if the clinician suspects complications relating to renal blood flow, urine leak, urinoma, obstruction, abscess, hematoma, or lymphoma. Sonography is typically the first approach. A renal scan may provide complementary information regarding obstruction or a urine leak and ACE inhibition renography can detect renovascular hypertension.[151,198] A renal scan cannot distinguish between rejection and calcineurin-inhibitor nephrotoxicity.

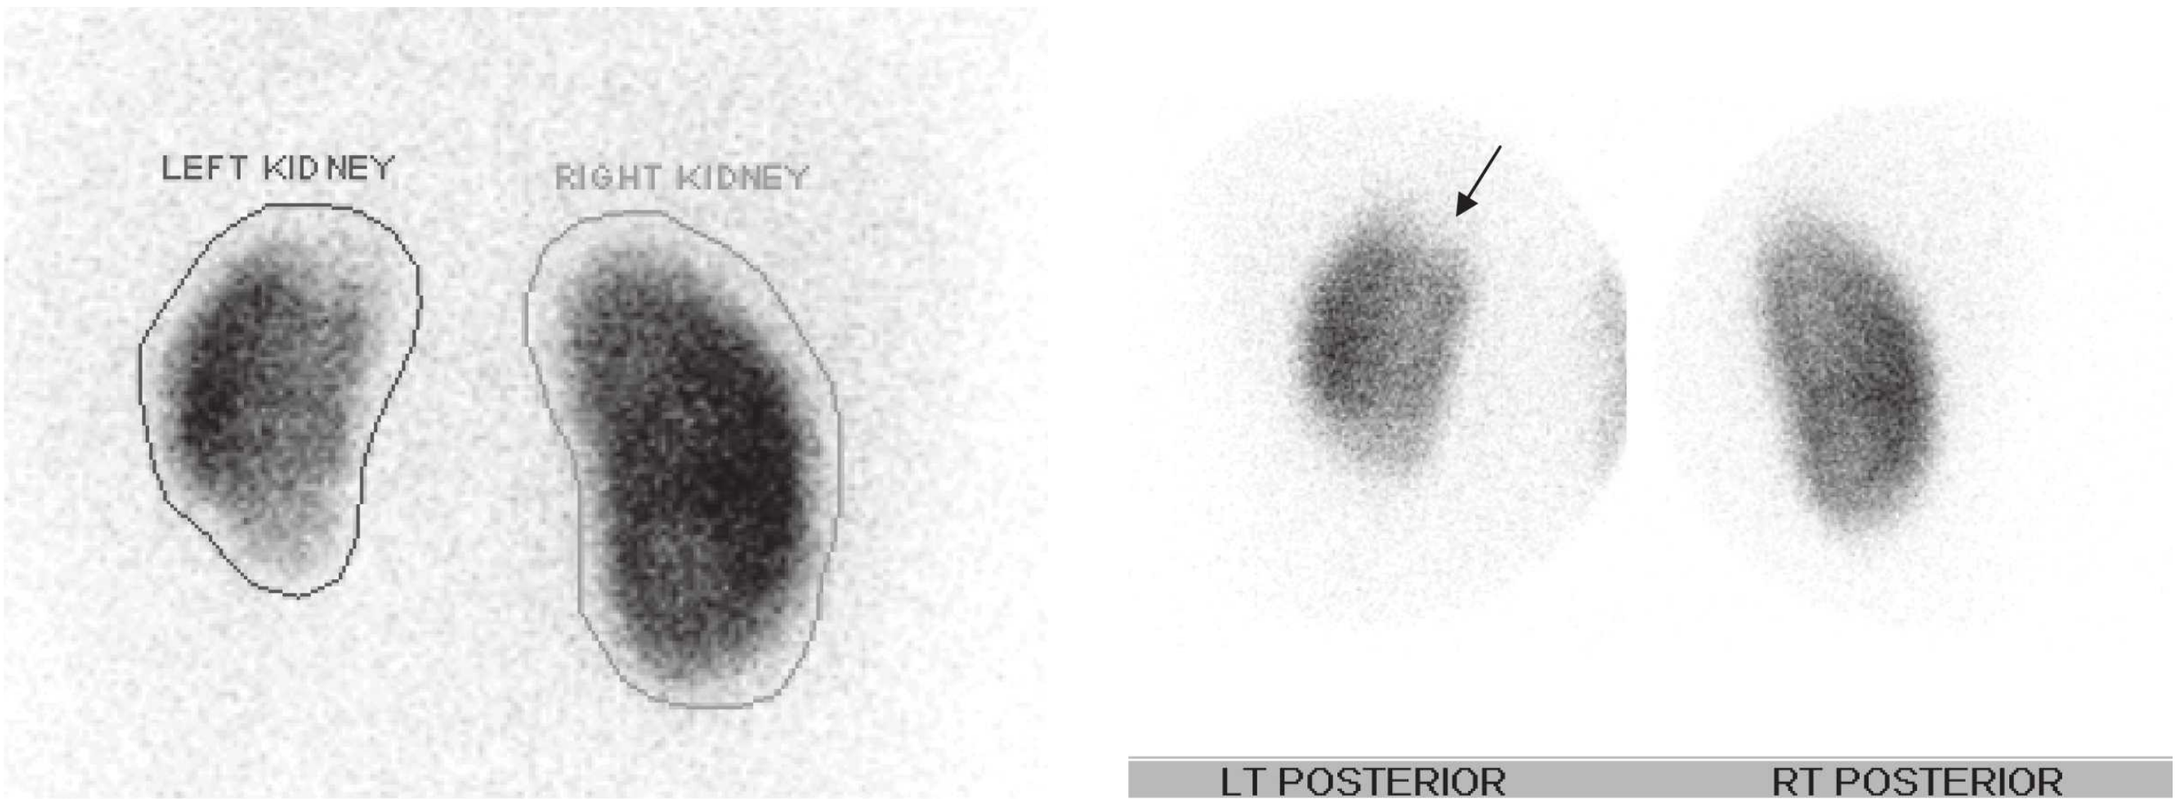
Renal Cortical Scintigraphy (Pyelonephritis and Scar)

DMSA is the radiopharmaceutical of choice for imaging the renal cortex.[128,129,151,199] Static images are obtained 2 to 4 hours after injection and sedation is rarely needed. A normal scan demonstrates homogeneous concentration of the radiotracer throughout the cortex except for a lower concentration in the region of the collecting system. DMSA scans can measure relative function and identify functioning renal tissue in patients with congenital abnormalities. The studies are most commonly obtained in patients with suspected pyelonephritis to distinguish upper from lower urinary tract infections and to detect the presence of scar following an episode of acute pyelonephritis. Pyelonephritis and scarring are recognized by focal areas of decreased DMSA uptake in the renal parenchyma; however, any process that replaces, injures, or destroys normal cortical parenchyma will result in an abnormal scan.

Does a Child Presenting with a Febrile Urinary Tract Infection Have Pyelonephritis?

Pyelonephritis is a serious illness in the pediatric population; renal scarring from recurring infection remains an important cause for substantial long-term morbidity.[200] Clinical and experimental studies have demonstrated that scarring can be prevented or diminished by early diagnosis and aggressive therapy. In infants and young children, pyelonephritis is not always accompanied by high fever, an elevated sedimentation rate, and leukocytosis. Furthermore, a normal voiding cystourethrogram does not exclude acute pyelonephritis, and it is increasingly recognized that sonography and excretory urography cannot be used to exclude acute pyelonephritis in infants and children. Renal cortical (DMSA) scintigraphy is more sensitive for the detection of pyelonephritis than sonography (Fig. 10.39), and many investigators recommend cortical scintigraphy in the initial evaluation of children with suspected pyelonephritis. MRI and CT with contrast are also sensitive tests for the detection of pyelonephritis, but MRI is expensive, and there is the possibility of an allergic reaction to iodinated contrast given during the CT scan.

There is no consensus on the use of DMSA scans in the evaluation and follow-up of patients with urinary tract infection. The diagnostic algorithm depends on how the clinician



A B

FIGURE 10.39. A 6-year-old boy presented with fever, vomiting, a urinary tract infection, and an erythrocyte sedimentation rate of 98. **A:** A dimercaptosuccinic acid (DMSA) scan obtained with a parallel hole collimator shows the left kidney to be smaller than the right kidney and also suggests an area of decreased DMSA activity in the left upper pole. **B:** Additional images of each kidney were obtained using a pinhole collimator which provides better resolution than the parallel hole collimator. Pinhole images clearly show an area of decreased DMSA uptake in the superior pole of the left kidney (*arrow*) consistent with pyelonephritis; the normal right kidney is shown for comparison.

will use the information. Some institutions treat pediatric patients with suspected pyelonephritis empirically and only pursue diagnostic studies if the patient does not respond. In other institutions, patients with pyelonephritis receive more aggressive therapy and/or follow-up in the hope of reducing the risk of scarring and recurrent infection and, thereby, avoiding the subsequent development of hypertension or renal failure.[128,129,151,199]

Radionuclide Cystography

Vesicoureteral reflux, urinary tract infections, and renal scarring can lead to hypertension and chronic kidney disease; however, a large percentage of patients with pyelonephritis do not have reflux. Furthermore, reflux often resolves spontaneously. Management of patients with urinary tract infection and/or reflux tends to be individualized and varies from center to center. Reflux may be suspected based on an antenatal ultrasound showing ureteral or calyceal dilatation, a urinary tract infection in infants or young children, acute pyelonephritis, or documented reflux in a sibling. A conventional voiding cystourethrogram (VCUG) with fluoroscopy is usually the first test to detect and grade the degree of reflux. If follow-up studies are required, the patient can be followed by radionuclide cystography. The technique is accurate for detecting reflux, and the radiation dose to the gonads is much less than with a VCUG.[128,129,151]

Direct Radionuclide Cystography

The bladder is catheterized, and the study is performed by instilling saline containing approximately 1 mCi (37 MBq) of a ^{99m}Tc radiopharmaceutical into the bladder. These radiopharmaceuticals are not absorbed into the blood from the urinary bladder. Images are continuously acquired during filling of the bladder and subsequent voiding. Reflux can be quantitated by analysis of data recorded on the computer during the study.

Indirect Radionuclide Cystography

Bladder catheterization is not required. The patient typically receives an intravenous injection of ^{99m}Tc-MAG3 for evaluation of individual kidney function, urine drainage, and reflux; dynamic images are obtained during bladder filling, voiding, and after voiding. This technique avoids catheterization, but it is not as sensitive as direct radionuclide cystography for detecting reflux.

CHAPTER

11 Computed Tomography and Magnetic Resonance Imaging

Kyongtae T. Bae • Sonal Krishan

Cross-sectional imaging is essential for the diagnosis and clinical management of a number of renal pathologies. Although ultrasound (US) represents a first-line imaging modality in the assessment of the kidney because of its cost effectiveness, portability, and availability, the images are highly operator dependent and are limited in anatomic coverage as compared to computed tomography (CT) scans and magnetic resonance imaging (MRI). CT scans and MRIs offer images of superb anatomic detail and permit the accurate and noninvasive assessment of a wide range of renal and urologic pathologies including: congenital anomalies, obstructive disease, inflammatory lesions, vascular insufficiency, benign and malignant tumors, and trauma. Although CT scans remain far more commonly used in clinical settings, the role of MRI is growing because of its superior intrinsic tissue contrast and the absence of radiation exposure. Additionally, MRIs can be used as the problem-solving modality when US or CT findings are nondiagnostic.

TECHNICAL CONSIDERATIONS FOR COMPUTED TOMOGRAPHY SCANS AND MAGNETIC RESONANCE IMAGING

Principles of Computed Tomography Scans

Similar to conventional X-ray radiographic images, the physical basis for a CT scan is the attenuation of X-ray photons passing through the body. The basic hardware of a CT scanner system consists of an X-ray gantry (which supports a rotating X-ray tube and a set of X-ray detectors); a patient table that moves in and out of the gantry; and a computer system integrated with the gantry, data-storage hardware, and image-display console. A precisely collimated narrow X-ray beam (a fan-shaped beam) is generated, then transmitted through the patient's body and received and identified by the detectors on the opposite side of the gantry. The use of a rotating X-ray beam and detector arrays permits the detection and measurement of the X-rays attenuated by tissues from many different projections. It is from these measurements that the CT images are mathematically reconstructed.[1] The CT scan is operated at various user-selectable voltages (e.g., 80, 100, 120, 140 kVp) and currents (milliampere second [mAs]) that closely determine radiation dose and image quality.

Computed Tomography Attenuation or Computed Tomography Number (Hounsfield unit)

The spatial resolution of a CT image typically achieves 0.3 to 0.5 mm with an imaging matrix size of 512 × 512 pixels. Each pixel (picture element) value of a CT image represents the tissues' X-ray attenuation coefficient at that pixel, which is expressed in Hounsfield units (HU). The data size of each pixel is typically 2 bytes. Because a CT image consists of 512 × 512 pixels, the data size of a CT image is approximately 0.5 MB (512 × 512 × 2). The attenuation value assigned to each pixel is based on a reference scale in which −1,000 HU is the value assigned to air and 0 HU is assigned to water.[2] Fat is typically −30 HU or less, whereas calcification, bone, and iodinated contrast are usually greater than 100 HU. User selection of the number of shades of gray (window width) in the image and the central hue of gray (window level) permits the modification of displayed image contrast. By adjusting the window width and level, the image can be optimized for evaluating a wide range of tissues with varying attenuations. For example, bone and a contrast-filled bladder are typically presented as bright (high attenuation) structures, whereas the lungs are typically presented as dark (low attenuation) structures. Subtle structures such as a solid tumor within a normal parenchyma may be displayed more conspicuously in a specifically designed window setting (e.g., liver window).

Computed Tomography Technical Advances

CT technology has advanced from the traditional single-row detector array to a multiple-row detector array. Multidetector-row CT (MDCT) scans, which are now the standard method for performing CT examinations, allow

multiple channels of data to be acquired simultaneously. As a result, MDCT scans covers a large volume of area in a short scan time with thinner slices and an improved spatial resolution along the patient's craniocaudal axis. Presently, 64-detector MDCT systems are most commonly in use; however, the 320-detector MDCT has been recently introduced into clinical practice. Using MDCT, the entire abdomen can be imaged in a few seconds. MDCT scans offer a greater speed of acquisition and higher resolution images than single-detector CT scans and thus greatly facilitate multiplanar imaging and three-dimensional (3D) reconstruction (Fig. 11.1).

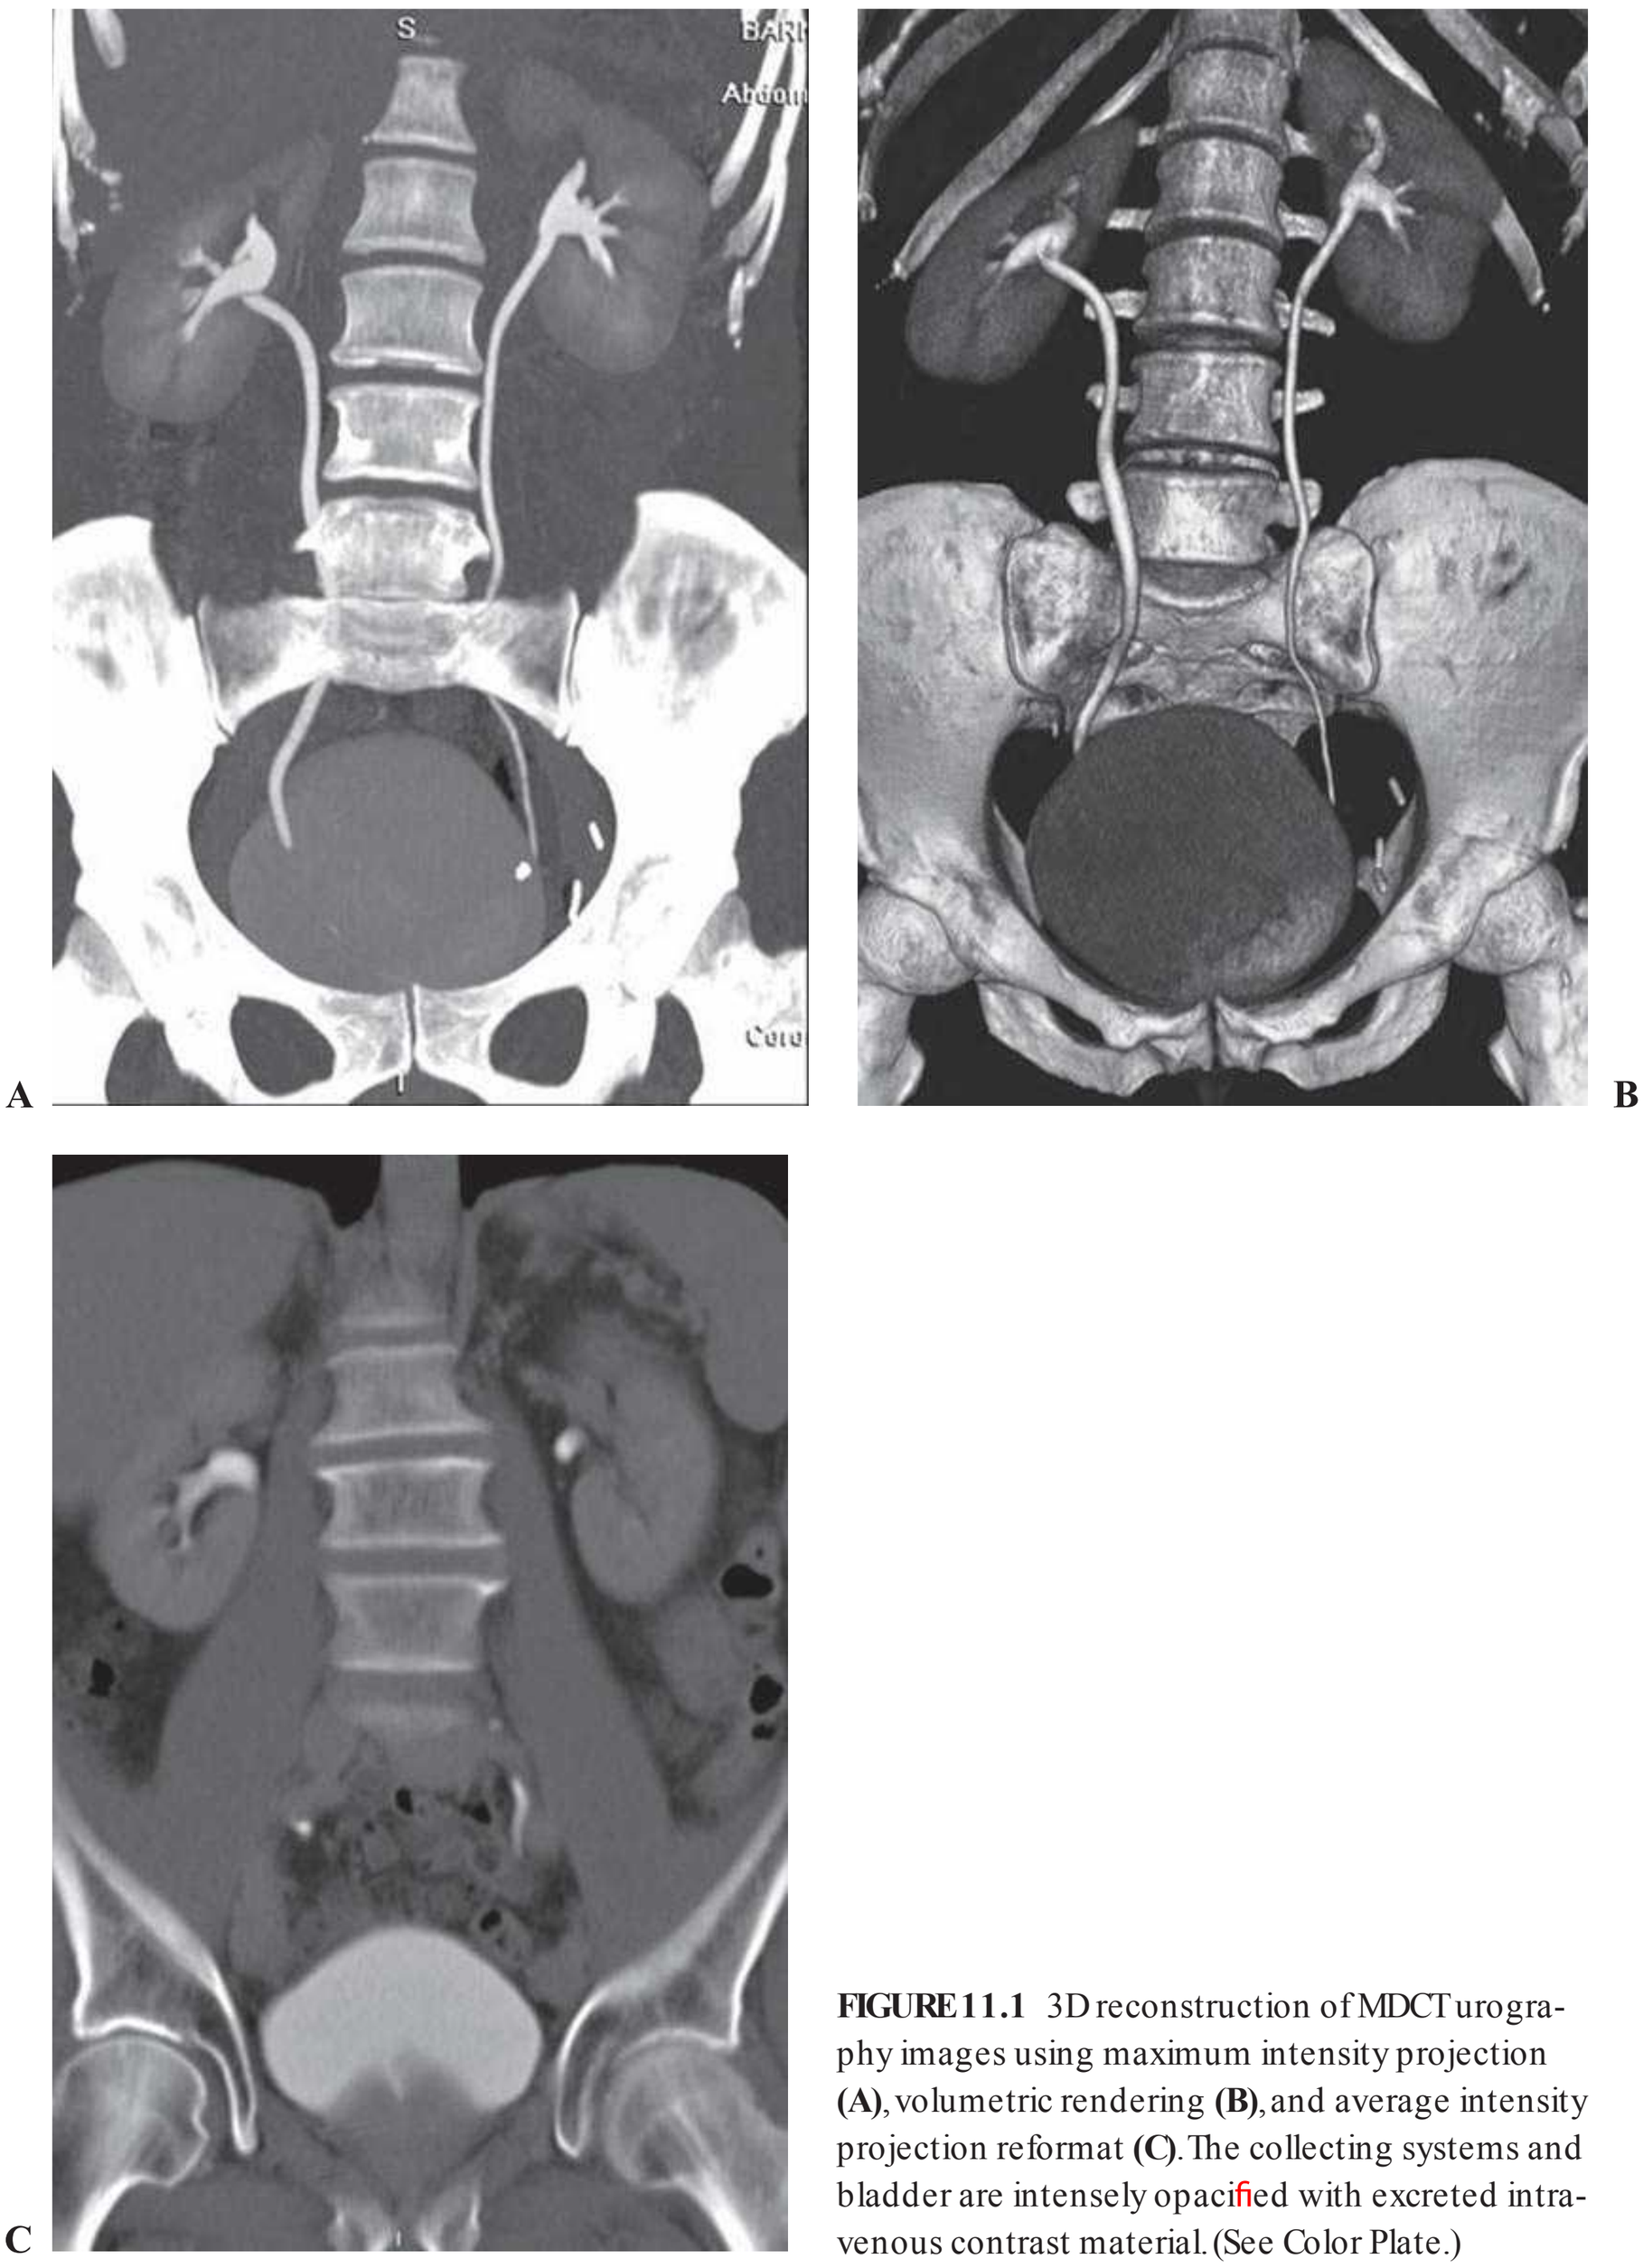

FIGURE 11.1 3D reconstruction of MDCT urography images using maximum intensity projection **(A)**, volumetric rendering **(B)**, and average intensity projection reformat **(C)**. The collecting systems and bladder are intensely opacified with excreted intravenous contrast material. (See Color Plate.)

The technical advances of MDCT scans have allowed highly technical and challenging clinical applications, such as CT angiography (CTA), to be practiced routinely. MDCT scans have essentially replaced the conventional catheter-based diagnostic renal angiography. In many institutions, MDCT urography is performed in place of the conventional intravenous urography.[3–5] MDCT renal imaging is widely used as the "one-stop shop" single imaging modality for the evaluation and surgical planning of many clinical conditions involving the kidney and urinary tract. In addition, the application of 3D techniques to CT scans allows for the accurate depiction of tumor depth, location, relationship of the tumor to adjacent structures, and the delineation of renal vascular anatomy as well as aid in preoperative planning (Fig. 11.2).

Recently, dual-energy MDCT scans were introduced, allowing the simultaneous acquisition of low- and high-voltage CT images during the same scanning phase. This technique has the potential to better characterize renal stone compositions and renal lesions through the assessment of their distinct CT attenuation profiles, thereby providing potentially improved physiologic and molecular information.[6]

Use of Contrast Media in Computed Tomography Scans

A CT evaluation of renal anatomy and pathology often requires the intravenous injection of iodinated contrast media. Intravenous contrast enhancement is useful for the depiction of small lesions by increasing their conspicuity, for the demonstration of vascular anatomy and vessel patency, and for the characterization of lesions through their patterns of contrast enhancement. On the other hand, an unenhanced CT scan is better suited to detect renal or urinary calcifications and intrarenal or perirenal hemorrhage because CT images obtained after the administration of contrast media may mask these abnormalities.[7–9] Unenhanced CT scans are also recommended for the quantification of tumor contrast enhancement on the postcontrast scans and for patients with poor renal function.

The commercially available radiographic contrast agents are tri-iodinated derivatives of benzoic acid. All currently available intravenous (IV) contrast media are excreted by the kidney through glomerular filtration, with no significant tubular excretion or resorption.[10,11] It is prudent that the physician inquire about the patient's history, particularly regarding the renal function and any history of allergies to the contrast material. A history of asthma and severe allergies increases the risk of subsequent reaction to contrast agent injection by a small percentage. The administration of corticosteroids, with or without antihistamines, 12 hours before a contrast injection to reduce the occurrence of adverse reactions in allergic patients has been well documented. Oral contrast is less critical in urologic imaging than in gastrointestinal imaging. In fact, the use of oral contrast media may be counterproductive for the evaluation of renal calculi or CTA.

A contrast-enhanced CT scan is typically performed with 100 to 150 mL of 300 to 370 mg per milliliter of contrast medium injected at 2 to 3 mL per second. The amount of contrast medium is adjusted for the patient's size, clinical indications, and the CT scanner type. For CTA, fast injection rates (4 to 5 mL per second) are recommended. CT scan delays are determined by fixed delay or bolus tracking techniques.[12]

After the administration of an IV contrast agent, contrast-enhanced CT scans can be acquired at different contrast enhancement phases: early arterial, corticomedullary, nephrographic, and excretory phases (in the order of increasing CT scan delays) (Fig. 11.3). Although the kidney is normally imaged in routine abdominal CT scans at a single (nephrographic) phase of contrast enhancement, dedicated renal imaging protocols consist of scanning of the kidney at multiphases of contrast enhancement. Imaging phases must be selected in accordance with clinical indications because it is important to minimize the number of scanning phases to reduce the radiation exposure for a patient.

The early arterial phase begins with the arrival of the contrast medium in the renal artery and ends prior to the occurrence of intense renal venous return. This phase is primarily useful in arterial CTA (i.e., surgical planning and renal artery stenosis evaluation) and is very limited for the diagnostic imaging of the kidney and urinary tract. The corticomedullary phase of the kidney corresponds to an intense enhancement of the renal cortex prior to a substantial enhancement in the medulla. The depiction of a hypervascular renal mass and renal artery anatomy is maximized during the corticomedullary phase. The nephrographic phase of the kidney corresponds to homogeneous enhancement throughout the renal parenchyma with a loss of corticomedullary differentiation. The depiction of renal lesions in the cortex or medulla is maximized during this phase. The degree of contrast enhancement in a renal mass is evaluated by noting the difference in the CT scan attenuation of the mass between this phase and in the unenhanced CT images. The onset of the excretory or urographic phase is about 2 minutes after the start of contrast medium injection. Maximal opacification of the renal calyces, pelvises, and ureters occurs later, about 5 to 10 minutes after the injection of the contrast medium. This is the best enhancement phase for the assessment of (benign and malignant) conditions affecting the urinary tract.

Magnetic Resonance Imaging Principles

An MRI scan begins with placing the patient in the central bore of an electromagnet, which generates a static magnetic field. Nuclei with odd numbers of protons or neutrons (of which hydrogen is the most abundant in biologic tissue) align themselves with their magnetic moments, either parallel or antiparallel to the external field. A net magnetization vector lies in a direction parallel to the static magnetic field of the magnet bore of the MRI (called the z-axis by convention). A radio frequency (RF) transmission coil transmits RF pulses through the patient and energizes the protons in the z-axis. When the RF pulse is turned off, the protons give off

the energy (relaxation) that was imparted to them by the RF pulse.[13,14] This emitted energy is received by a receiver RF coil, and it is from this energy that the MR image is created. MRI pulse sequences determine the patterns of repetitive RF pulsations and the sampling of MR signals emitted during the intervals between RF pulses. Each MR sequence takes advantage of the intrinsic property of the body's tissues to absorb and release this energy. How this energy is imparted through the physics of the pulse sequences and whether energy is released quickly or slowly determines the weighting of an image. In general, an image is either T1 or T2 weighted. An MRI possesses exquisite contrast resolution, even without the use of IV contrast. On T1-weighted images, the fluid is generally dark (also called low signal) and on T2-weighted images, the fluid is bright (also called high signal).[13,14]

In order to map the anatomic distribution of different tissue signals, magnetic field gradients are established within the MR scanner along the x-, y-, and z-axes. Because the protons' resonance frequency depends on the magnetic field strength, controlled applications of magnetic field gradients induce protons to precess at different frequencies and phases according to their spatial distributions. The pattern of a received signal from a selected tissue volume can be converted to an image in which digital information related to protons' spatial distribution is reconstructed into images displayed over a gray scale.[13,14] Unlike CT attenuation values (HU), MR signal intensities are not directly specific to tissue compositions. Therefore, MR signal intensities between tissues are frequently compared in relative scales, such as a ratio to reference signal intensity.

Technical Advances in Magnetic Resonance Imaging

Because the respiratory motion of the kidney may significantly decrease the image quality, it is critical to perform an MRI scan with fast sequences within a breath hold. A variety of fast T1-weighted and T2-weighted sequences are available with the development of advanced coil and parallel imaging techniques to improve both temporal and spatial resolutions of an MRI. An MR angiography (MRA) is routinely performed when a diagnostic evaluation of the renal vasculature is requested. Although noncontrast sequences are available for an MRA, the dominant technique is the 3D gadolinium-enhanced MRA. For an evaluation of the urinary tract, an MR urography (MRU) has been developed. An MRU may be performed on T2-weighted sequences, exploiting the

long T2 of urine without gadolinium or on T1-weighted sequences after the administration of gadolinium contrast during the excretory phase.

Recent advances have resulted in new MR techniques for evaluating renal function such as perfusion, diffusion, oxygenation, and sodium concentration. A functional MRI of the kidney has not yet found broad clinical application, but it has great potential. Through the ongoing development of functional MRI techniques, we may expect an increasing role for functional MRIs in the management of patients with renal disease.[9,15,16]

The Use of Contrast Media in Magnetic Resonance Imaging

Gadolinium chelates are almost exclusively used for IV contrast materials for MRIs. Gadolinium agents have been shown to produce comparably lower incidences of allergic reactions than the iodinated contrast agents used in CT scans. The gadolinium compounds are filtered at the glomerulus and are neither reabsorbed nor secreted. They parallel iodinated contrast material in their pattern of initial intravascular and subsequent extracellular space distribution and in their pattern of excretion. Gadolinium-based contrast agents demonstrate a similar pattern of contrast enhancement as iodine-based agents (see Fig 11.4).[17,18]

For many years, gadolinium-based contrast-enhanced MRIs were believed to be safer and they were the preferred method of contrast (instead of iodine-based contrast material) for patients with renal impairments. However, since early 2006, evidence has been mounting that some gadolinium-based contrast agents may potentially cause the fibrosing sclerodermalike condition called nephrogenic systemic fibrosis (NSF) in patients with renal failure.[19–21] Patients at the highest risk of NSF include: (1) patients who have severe acute or chronic renal impairment with glomerular

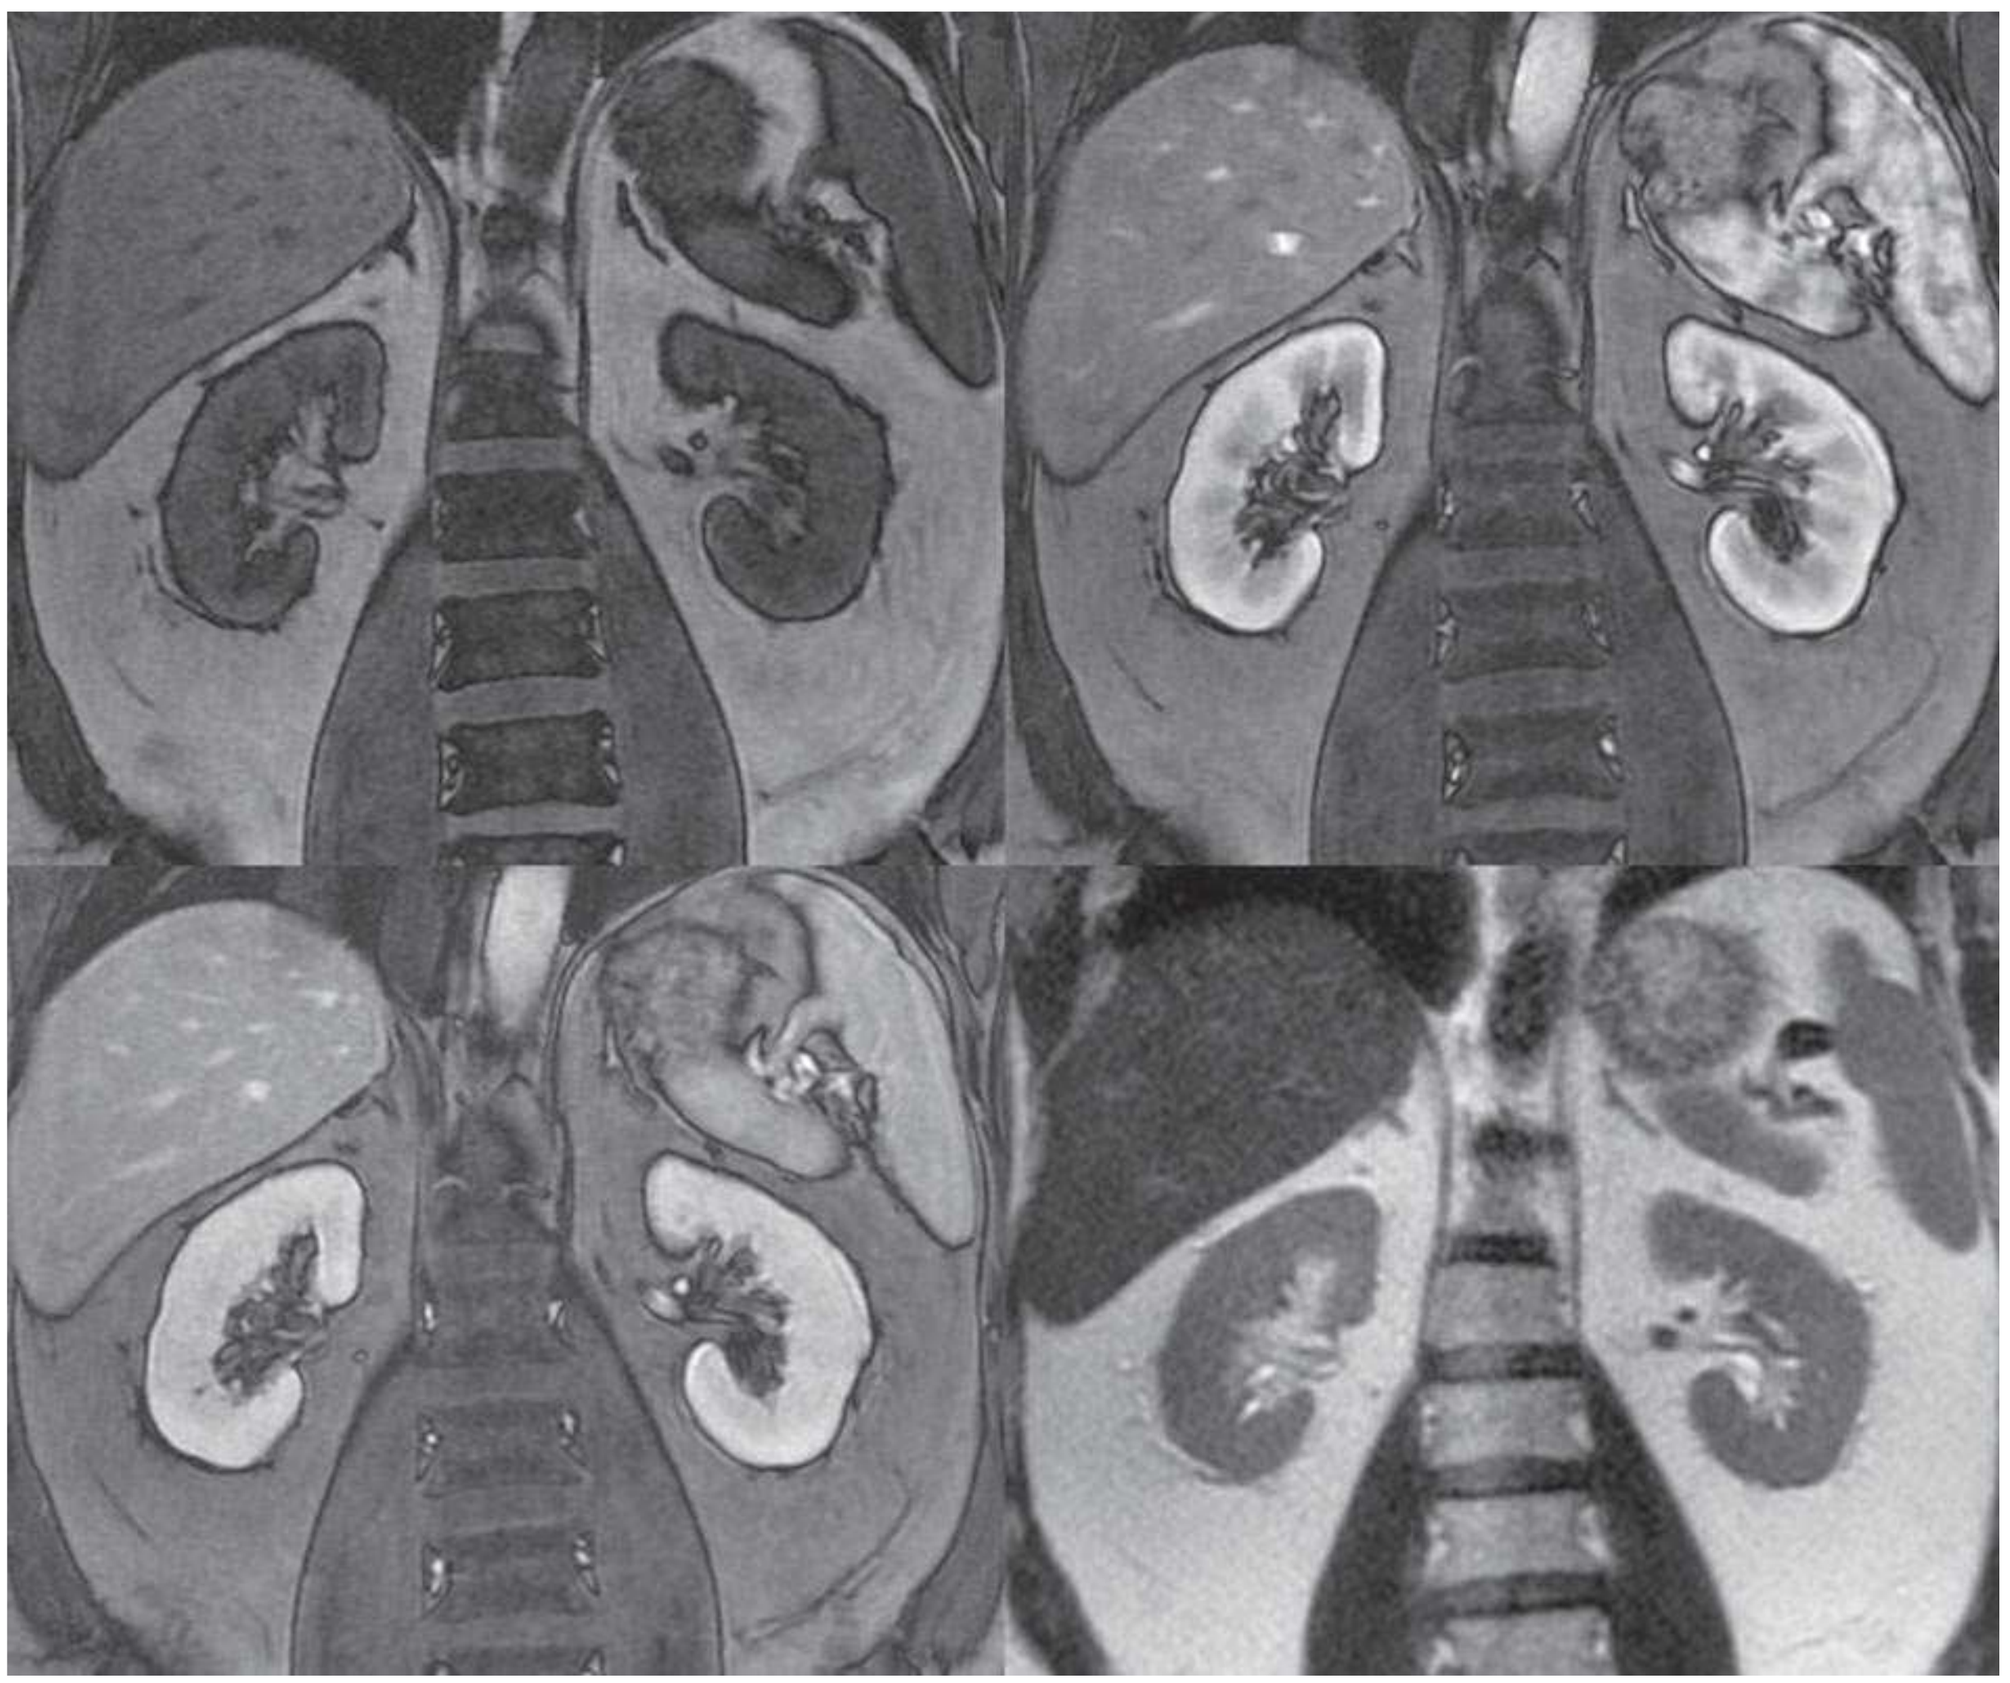

FIGURE 11.4 MR images of normal kidneys: T1-weighted without intravenous contrast (*left upper*), contrast-enhanced T1-weighted at corticomedullary phase (*right upper*), contrast-enhanced T1-weighted at nephrographic phase (*left lower*), and T2-weighted (*right lower*).

filtration rates (GFR) <30 mL per min/1.73m^2; (2) patients on dialysis (hemo or peritoneal); and (3) patients with reduced renal function awaiting liver transplantation. The recognition of this adverse reaction to gadolinium-based agents in renal-impaired patients emphasizes the need for an appropriate clinical indication for gadolinium-enhanced MRIs in this patient population. If an MRI is clearly indicated, the lowest dose of the agent that leaves the smallest amount of gadolinium in the body must be used and, in certain cases, immediate dialysis after the administration is recommended.[19–21]

MAGNETIC RESONANCE IMAGING VERSUS COMPUTED TOMOGRAPHY SCANS

CT scans and MRIs complement each other in providing diagnostic information for the detection and characterization of renal pathologies. Because CT scans are faster and easier to perform, it is more commonly used in the evaluation of renal and perirenal disease. The MRI remains primarily a problem solving modality adjunct to a CT scan or is used when a CT scan is contraindicated. The CT scan is superior for the reliable detection of calcified structures, whereas an MRI provides superb intrinsic tissue-contrast resolution and multiplanar imaging, which is particularly useful for the evaluation of renal vasculature.

If nephron sparing surgery is contemplated, an MRI is better able to differentiate a tumor from perinephric fat, the renal sinus, and the collecting system, thus helping the urologist decide if a partial nephrectomy is feasible. Staging renal lesions is more complete with an MRI than a CT scan, particularly when determining renal vein and inferior vena cava (IVC) involvement.[22,23] Patients who have genetic anomalies resulting in an increased risk for renal cell carcinoma (RCC) (e.g., von Hippel-Lindau), and those with conditions that produce other renal lesions that may mimic RCC (e.g., tuberous sclerosis), can be followed safely with a yearly MRI. This follow-up regimen will protect these high-risk patients from recurrent exposure to ionizing radiation from CT scans, with no loss in the ability to detect or characterize renal lesions.[24–37] Conversely, patients who are critically ill (e.g., intensive care unit patients) and those who have difficulty with the breath-holding requirements are not ideal candidates for renal MRIs. Patients unable to cooperate for other reasons (e.g., dementia, chronic obstructive pulmonary disease, morbidly obese) are also unsuitable for MRIs. Scanning these patients often results in a poor quality examination that may not be interpretable. Patients who have ferromagnetic implants (some neurovascular aneurysm clips, cochlear implants, pacemakers, defibrillators) are also contraindicated for MRIs. Furthermore, patients with claustrophobia may not be able to undergo MRIs.[24–37]

NORMAL ANATOMY

The kidneys lie within the retroperitoneum that is in turn divided by facial planes into three compartments centering the kidneys: the perirenal, the anterior pararenal, and the posterior pararenal spaces. The kidneys, the perirenal fat, and the adrenal gland are in the perirenal space enclosed by the anterior (Gerota) and posterior (Zuckerkandl) layers of the renal fascia. The perirenal space also includes the renal and adrenal vessels, the aorta, the inferior vena cava, and the perivascular lymph nodes. The kidneys lie lateral to and roughly parallel with the lateral border of the psoas muscle. The renal fossa is bounded medially by the psoas muscle, posteriorly by the quadratus lumborum muscle, laterally by the transversus abdominis muscles, and superiorly by the diaphragm. Anteromedially, the kidneys are covered by peritoneum; posteriorly, the 12th rib crosses the left kidney at a 45-degree angle, with approximately one-third or more of the left kidney superior to the inferior margin of the thoracic cage.[38–42] A fibrous envelope called the renal capsule covers the kidney and is firmly adherent to the renal substance. A potential space exists between the kidney and its capsule, which in abnormal situations (such as trauma and infection) may contain blood, pus, or urine.[38–42]

The renal sinus contains fat and fibrous tissue, renal vessels, nerves, and lymphatics. The sinus extends around the renal pelvis, the infundibula, and the calyces and is continuous with the perinephric fat. The renal arteries arise from the aorta and enter the renal hila. The renal veins lie anterior to the renal arteries, whereas the left renal vein usually runs between the aorta and the superior mesenteric artery.[38–42] The adrenal glands lie anterior and medial to the upper poles of kidneys and are bilobed V- or Y-shaped structures.

The anterior pararenal space contains the second and third parts of the duodenum, the pancreas, and the ascending and descending portions of the colon. It is limited anteriorly by the parietal peritoneum, and posteriorly by the renal fascia. The posterior pararenal space contains only fat and is bounded posteriorly by the transversalis fascia. The parietal peritoneum and transversalis fascia fuse laterally to form the lateroconal fascia. The anterior and posterior pararenal spaces communicate to a limited extent above and below the level of the renal vessels. Fascial planes are demonstrated as linear structures of soft tissue attenuation surrounded by low attenuation fat.[38–42] These fascial planes may unfuse and form a potential space between the perirenal and pararenal spaces to be filled with fluid; in particular, a sequelae of pancreatitis.

On unenhanced CT scans, the kidneys appear as oval structures with soft tissue (gray) attenuation surrounded by low attenuation (dark) perirenal fat (Fig. 11.3). They intensely (brightly) enhance with intravenous contrast. The appearance of the kidneys on MRIs depends on a number of factors, including the type of MR sequences, hydration, and contrast enhancement (Fig. 11.4). On T1-weighted images, the kidney presents with intermediate (gray) signal intensities similar to visceral organs and muscle. On T2-weighted images, the

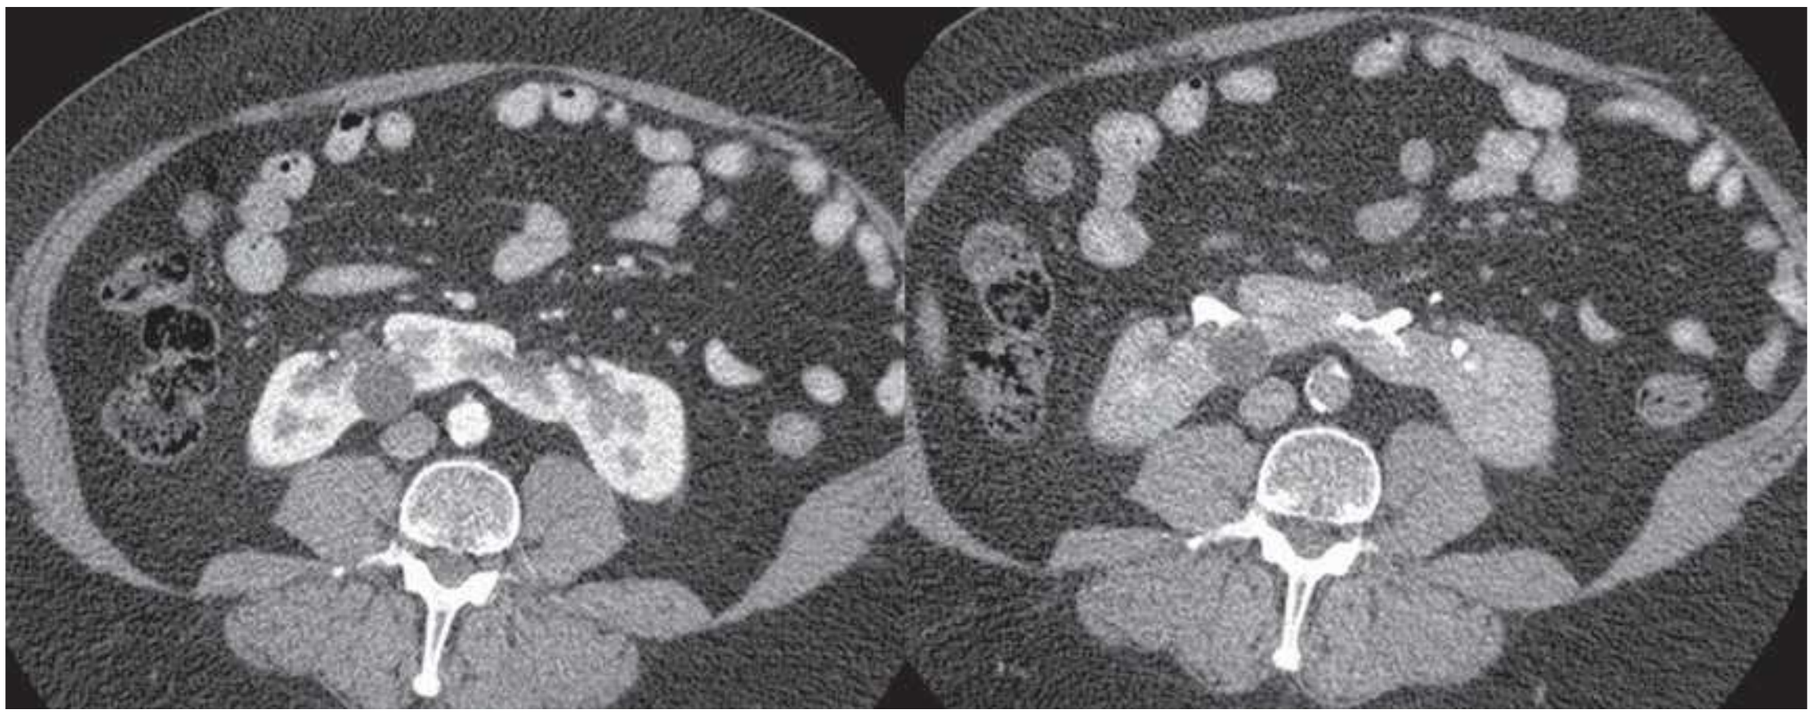

FIGURE 11.5 CT images of horseshoe kidney obtained at cortcomedullary (*left*) and delayed excretory phase (*right*). A small cyst is noted in the right kidney.

kidney is slightly hyperintense showing signal intensities similar to the spleen. The renal medulla is slighter darker on T1 images but is brighter on T2 images than the renal cortex. This is likely because of a greater unbound water (urine) content in the medulla.[25] Gadolinium contrast agents administered intravenously shorten T1 and enhance the renal parenchyma in T1-weighted images.[36,43–45] When lesion contrast enhancement is difficult to detect, a subtraction technique between unenhanced and enhanced T1-weighted images is required.

The calyces, renal pelvises, and ureters containing abundant water (urine) have low signals on T1-weighted images and high signals on T2-weighted images. The intraluminal signal intensities of the renal vessels vary widely depending on the MR sequences, imaging planes, and gadolinium contrast. The perirenal fat is bright on both T1- and T2-weighted images. The fat saturation technique suppresses the hyperintense perirenal fat signal and helps detect and characterize a renal lesion with fat, such as angiomyolipoma.

RENAL PATHOLOGIES

Congenital Variants of Renal Anatomy

Congenital and developmental variants of the kidney such as ectopic kidneys, horseshoe kidneys (Fig. 11.5), duplicated collecting systems, and various hypoplasia or dysplasia (Fig. 11.6) are routinely detected on cross-sectional imaging. An MRI is

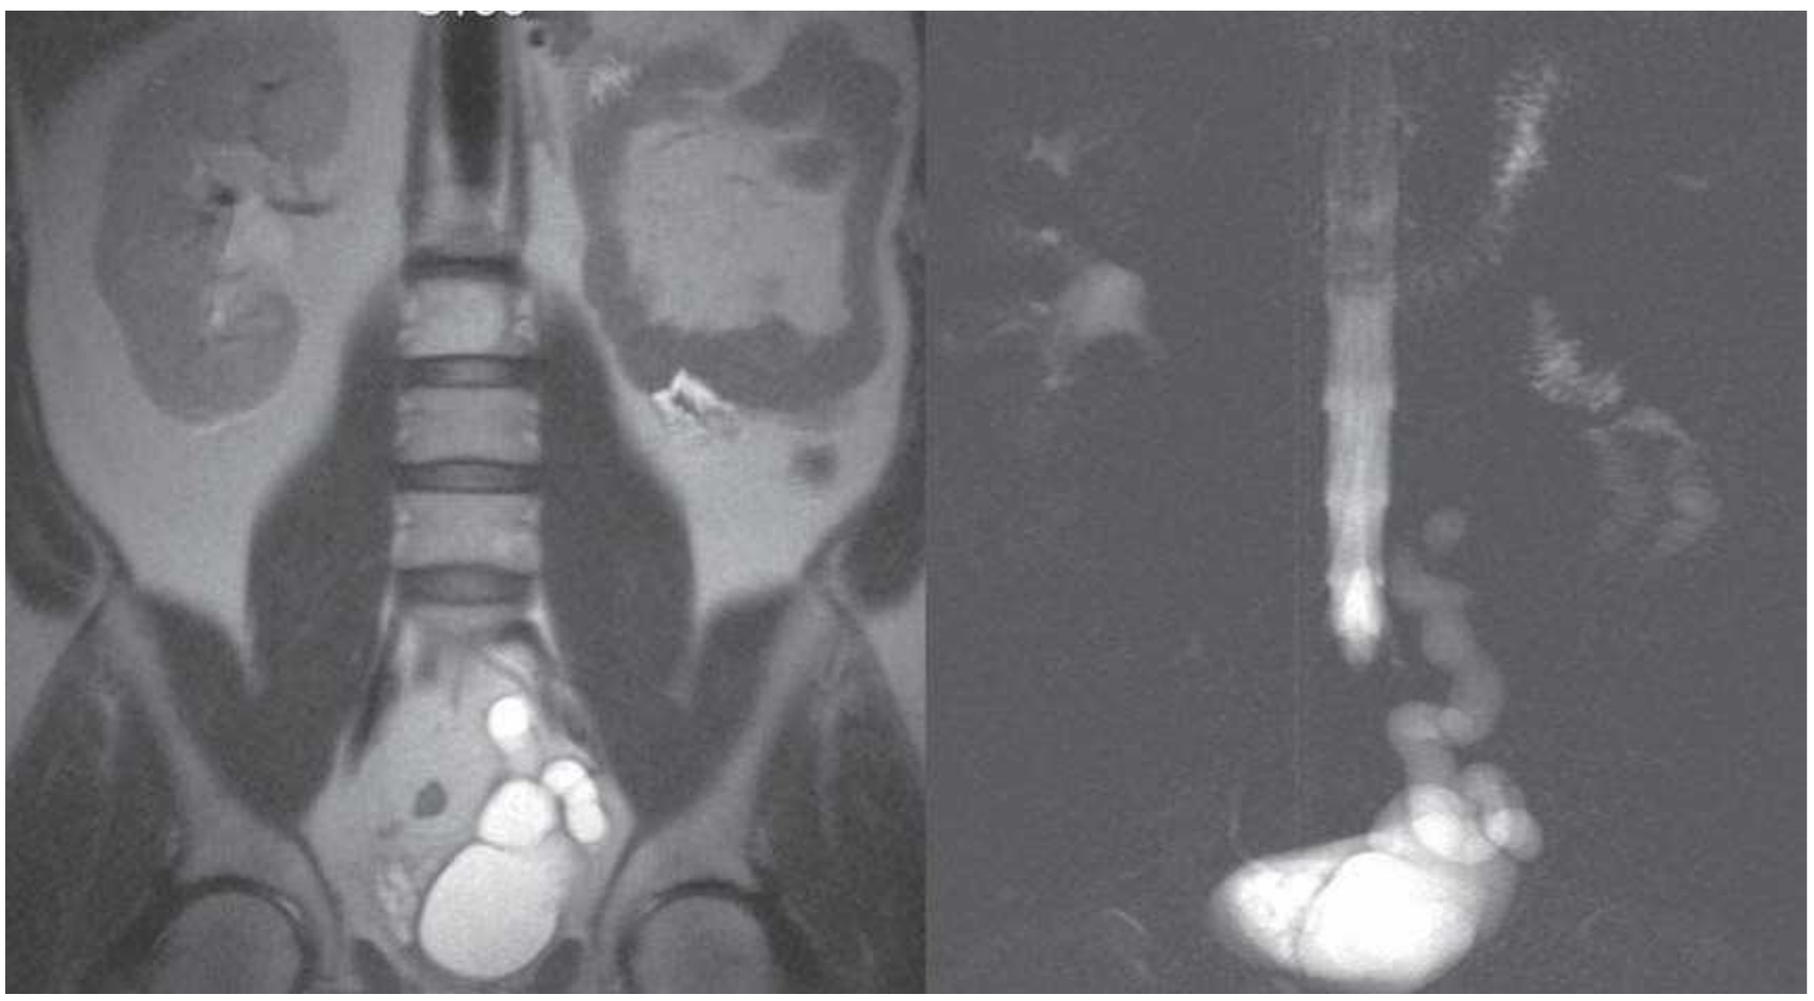

FIGURE 11.6 Left renal agenesis with dilated, tortuous ureteral remnant shown on T2-weighted MR (*left*) and MR urography (*right*). The right kidney shows compensatory hypertrophy.

FIGURE 11.7 CT images of kidneys obtained without intravenous contrast (*left upper*), at nephrographic phase with contrast (*right upper*), and at delayed excretory phase (*left lower*). Mild hydronephrosis in the left kidney caused by a distal ureteral calculus (*right lower*) is conspicuously demonstrated by excreted contrast filling the dilated collecting system.

particularly attractive as an imaging modality for the serial follow-up of pediatric patients with suspected renal anomalies because it requires no ionizing radiation and offers superb intrinsic contrast without exogenous contrast agents.[46,47]

Obstructive Disease

Unenhanced renal CT scans have emerged as an attractive alternative to intravenous urography (IVU) and ultrasound (US) imaging in patients with suspected renal colic. A CT scan allows us to evaluate the abdomen and the retroperitoneum for other disorders that mimic renal colic, including diverticulitis, appendicitis, an aortic aneurysm, and retroperitoneal fibrosis. The dilated, fluid-filled collecting system and ureter, along with the anatomic site, degree, and cause of obstruction can be evaluated on unenhanced images (Fig. 11.7). The acutely obstructed kidney may be enlarged and edematous. The renal execretion of contrast can be assessed on contrast-enhanced CT scans. With an acute obstruction, the usual transient, early cortical–medullary phase contrast enhancement is prolonged (persistent nephrogram) with a delayed excretion of contrast into the collecting system (Fig. 11.8).[3,6,27,28,36,43,48–56] Chronic obstruction may cause a marked distention of the fluid-filled collection system and an atrophy of the renal parenchyma.[3,6,27,28,36,43,48–56]

FIGURE 11.8 CT showing acute obstruction at the left uretero-pelvic junction with persistent cortico-medullary enhancement (compare the pattern of enhancement to the right kidney).

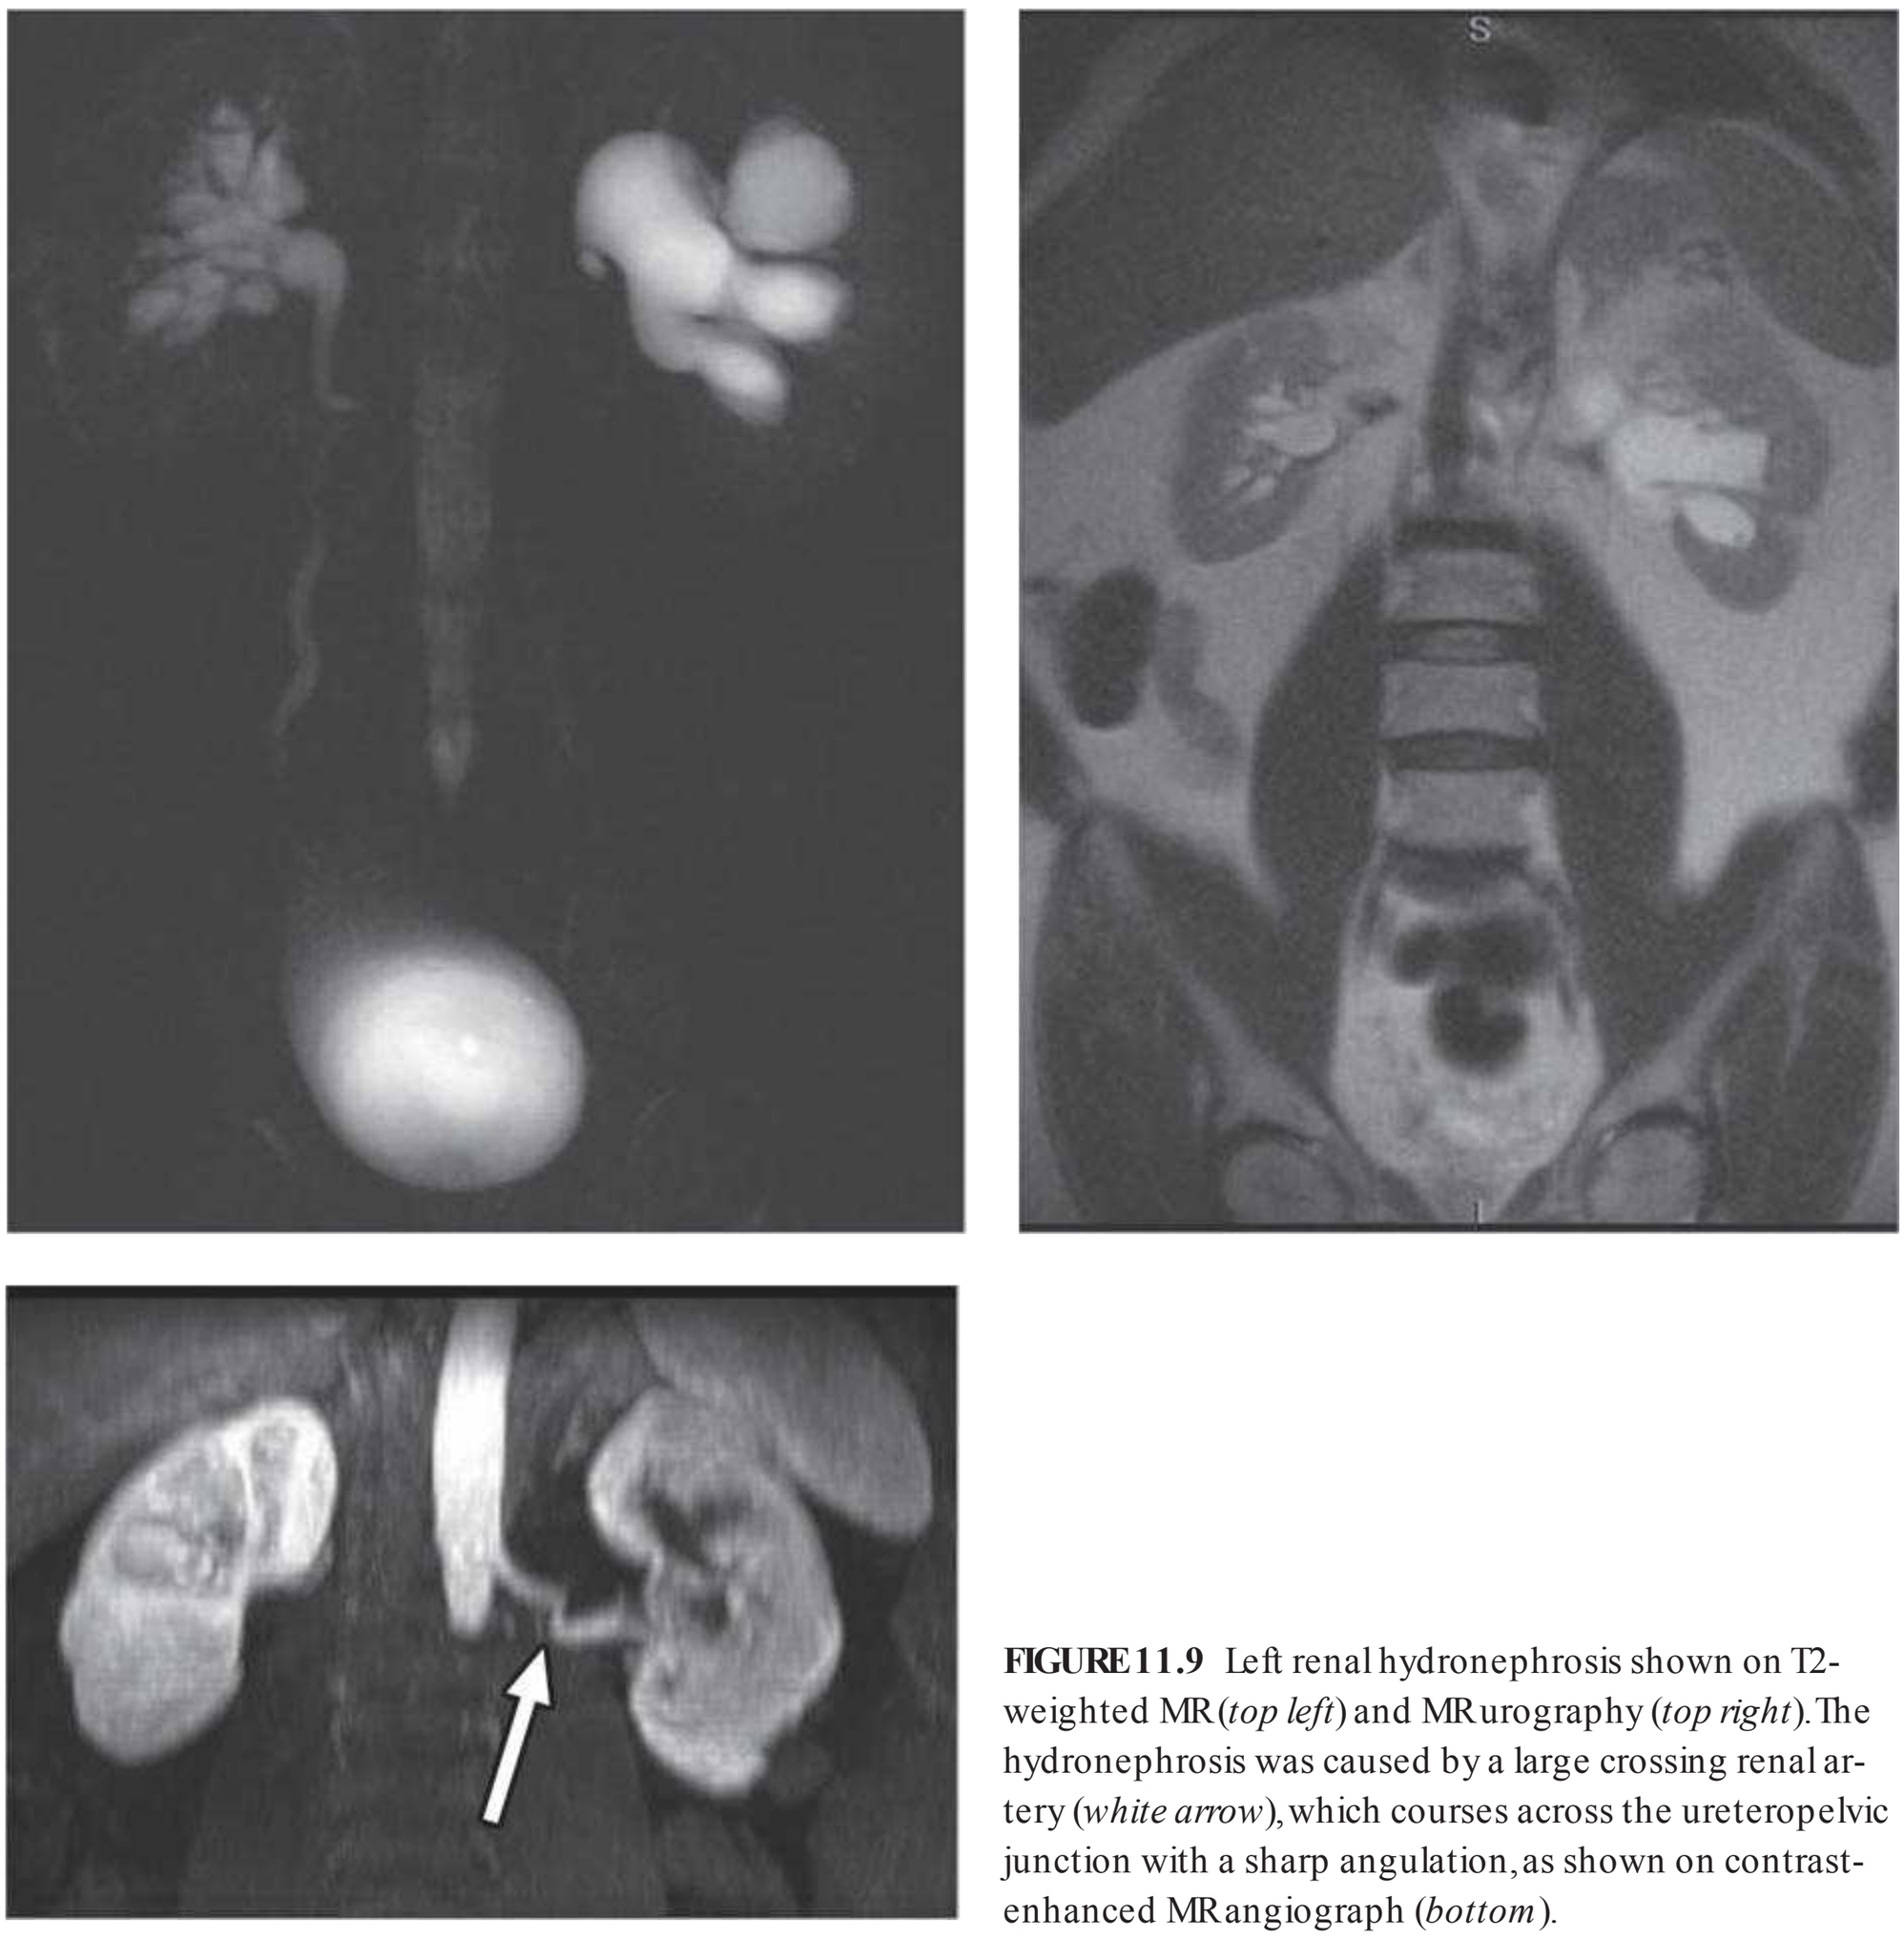

FIGURE 11.9 Left renal hydronephrosis shown on T2-weighted MR (*top left*) and MR urography (*top right*). The hydronephrosis was caused by a large crossing renal artery (*white arrow*), which courses across the ureteropelvic junction with a sharp angulation, as shown on contrast-enhanced MR angiograph (*bottom*).

Although an MRI is not commonly used as the first-line diagnostic imaging modality for the evaluation of suspected obstructive disease, the ureteral, pelvic, and calyceal dilatation caused by a distal obstruction can be readily delineated on transaxial, sagittal, or coronal MRIs. Gadolinium contrast is not necessary to determine the presence of an obstruction. In particular, an MRI that uses heavily T2-weighted images without gadolinium contrast has been shown to be accurate in detecting an obstruction (Fig. 11.9).[3,6,27,28,36,43,48–56]

Nephrolithiasis

Because CT scans provide an accurate, rapid, and safe evaluation of suspected renal calculi without contrast, it has replaced IVU for this application. Unenhanced CT scans have been reported to have sensitivities ranging from 96% to 100% and specificities ranging from 92% to 100% for the diagnosis of nephrolithiasis or urolithiasis.[57–63]

Regardless of the chemical composition, renal and ureteral calculi are generally radiodense on CT scans (with the rare exception of indinavir-induced stones). Thus, cystine and urate calculi that are difficult to detect on conventional abdominal radiographs can be readily diagnosed on unenhanced CT scans. Crixivan (indinavir sulfate), a protease inhibitor used to treat patients with HIV, can precipitate in the urinary system forming radiolucent stones that may not be directly visualized on CT scans. When nephrolithiasis is suspected, the initial CT scan should be obtained before the administration of contrast agents because the high-attenuation contrast excreted into the collecting system may obscure underlying calculi.

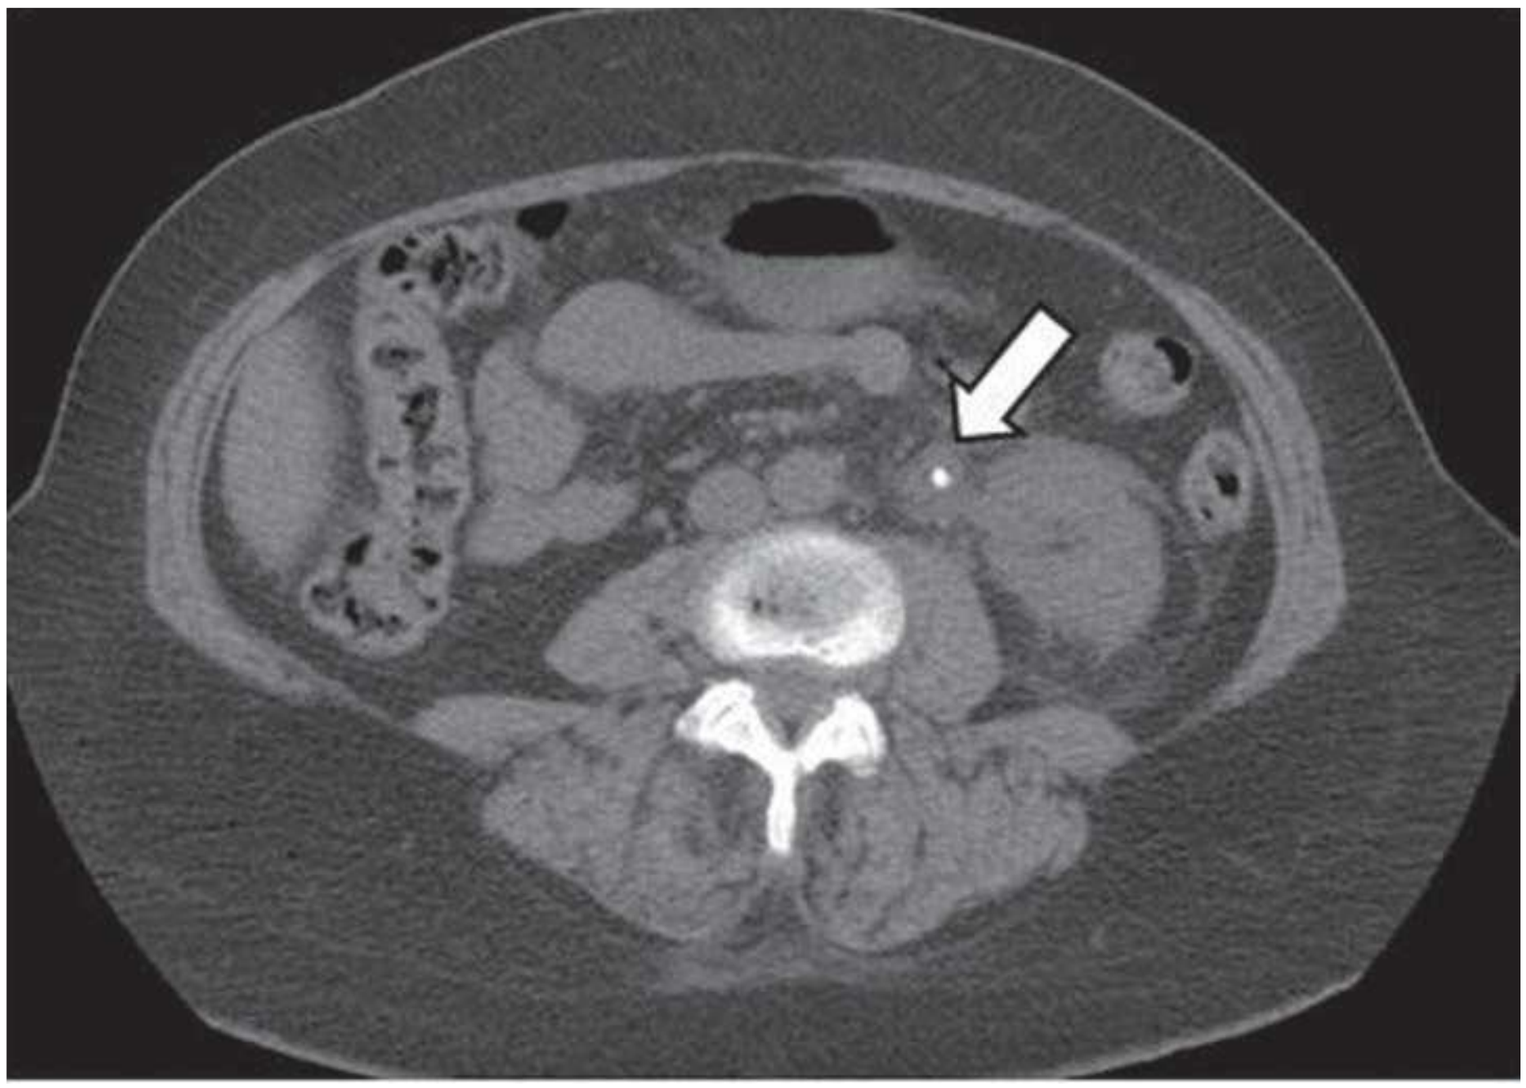

FIGURE 11.10 Unenhanced CT showing a hyperattenuating calculus at the left uretero-pelvic junction with peri-nephric and peri-ureteric soft tissue stranding consistent with acute left renal colic due to nephrolithiasis.

The most common locations for an obstruction by a stone are the natural anatomic points of narrowing: the ureteropelvic junction (Fig. 11.10), the pelvic brim where the ureter crosses the iliac vessels, and the ureterovesical junction. The most obvious sign of a ureteral stone on a CT scan is a focus of high attenuation (similar to bone) within the ureter.[57–63] Secondary signs of an obstruction include ureteral dilatation, asymmetric inflammatory change of the perinephric fat, hydronephrosis, and nephromegaly. An obstructing stone at the ureterovesical junction may be difficult to differentiate from a stone that recently passed into the bladder. In such a case, scan the patient in a prone position and the stone that falls to the anterior portion of the bladder is a stone that has passed.[57–63]

Renal or ureteral calculi are not directly visible on an MRI because they do not produce MR signals. They may be indirectly identified as foci of a signal void within the renal parenchyma, the collecting system, or ureters (Fig. 11.11). However, other objects including air, metal, and sutures also present as sites of signal void on an MRI.

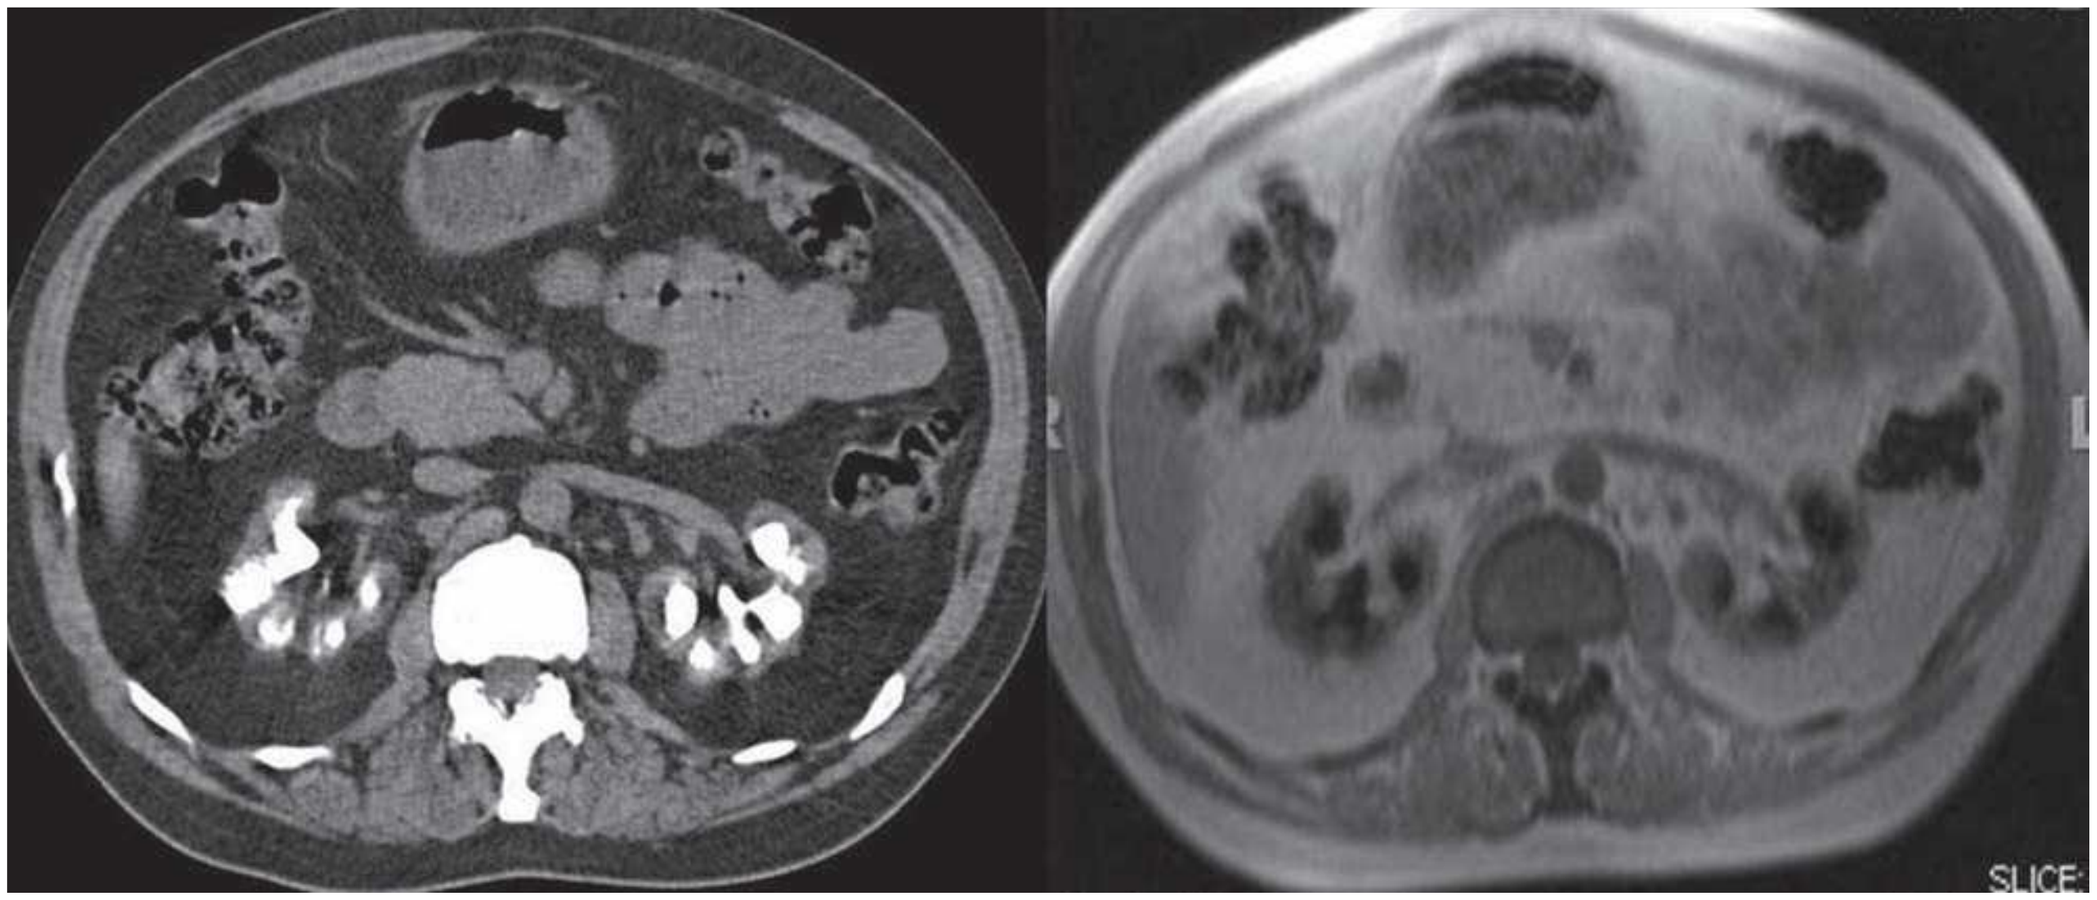

FIGURE 11.11 Extensive medullary calcinosis is shown as multiple hyperattenuating foci in the bilateral kidneys on unenhanced CT (*left*) but only as signal voids on T1-weighted MRI (*right*), undifferentiated from gas in the gastrointestinal tract.

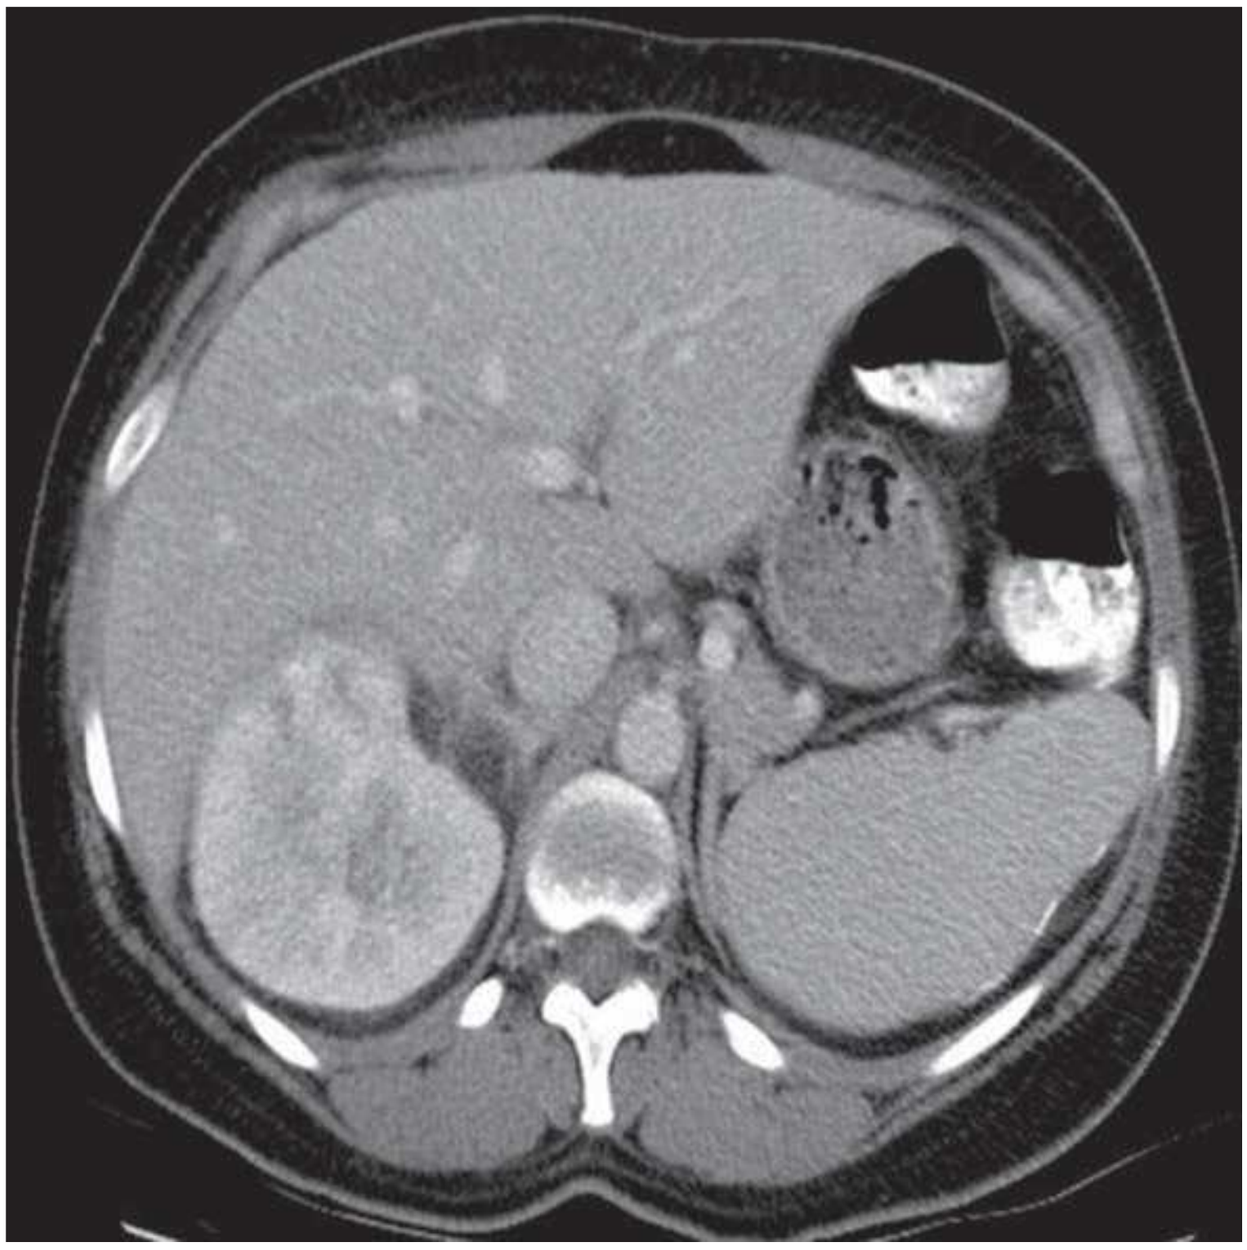

FIGURE 11.12 Contrast-enhanced CT in a patient with clinical symptoms of acute pyelonephritis showing striated nephrogram in an edematous right kidney with multiple linear non-enhancing areas.

Inflammatory Disease

Acute Pyelonephritis

Acutely inflamed kidneys may present with a range of findings on a CT scan. These include renal enlargement, heterogeneous patterns of contrast enhancement or striated nephrograms (Fig. 11.12), and pelvicaliceal air. Perirenal effusions and a thickening of the perirenal fascia may be seen with severe inflammation. A CT scan is also useful in depicting long-term sequelae of renal infections, renal parenchymal scarring and atrophy, and deformities of the collecting system (Fig. 11.13).[30,40,64–66] A CT scan is also superior to ultrasonography in detecting and delineating renal and perirenal abnormalities that are associated with pyelonephritis and abscesses.

Acute pyelonephritic kidneys may show loss of corticomedullary distinction on T1-weighted MRIs. Perirenal edemas may produce a decrease in the signal intensity of the surrounding fat and the thickening of renal fascia. Areas of inflammation and abscess cavity walls demonstrate contrast

Figure 11.13 Left kidney with recurrent acute pyelonephritis (*left*) resulting in atrophy shown in follow-up CT (*right*).

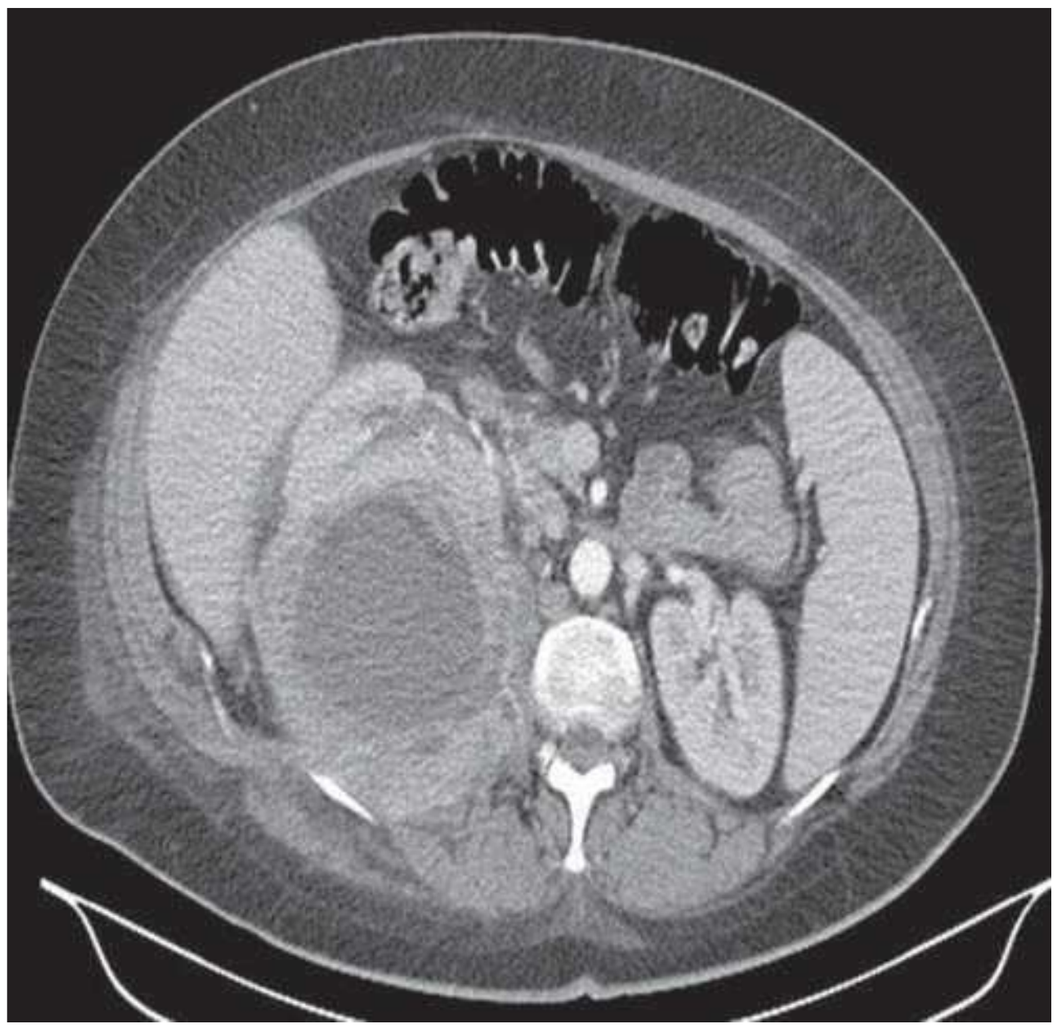

FIGURE 11.14 Contrast-enhanced CT showing a large, thick-walled abscess arising from the posterior cortex of the right kidney and extending into the adjacent posterior pararenal space.

enhancement after the administration of gadolinium contrast agents. On the T2-weighted images with fat saturation, edema and an inflammatory reaction may present with areas of an increased signal in the renal parenchyma and perirenal space.[30,41,66]

Renal Abscesses

Renal abscesses appear as well-defined collections of fluid in nonlobar distributions. An abscess may present with a thick wall that enhances after the administration of contrast agents in CT scans or MRIs and may contain air (Fig. 11.14). Abscesses may extend or rupture into the perirenal fat. A CT scan is superior to sonography in delineating abscesses and the pararenal extent of inflammation and is preferred when intervention is planned.[67,68] Abscesses may show varied signal intensity on MRIs depending on the content of fluid within the abscesses.

Fungal Infections

Fungal infections of the kidney are rare and are seen in immunocompromised patients. CT findings include a focal or global lack of contrast excretion, renal mass, renal enlargement, and filling defects of soft-tissue masses within the renal collecting system.[68]

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is an uncommon inflammatory condition that often follows chronic renal obstruction. It produces intrapelvic and intracalyceal collections of fluid or fatty material. The renal parenchyma is often atrophic and is replaced by accumulated fat, pus, and cellular debris and calcification.[69] Calcification in the collecting system and perirenal abscesses are frequently present.

Cystic Disease

Cysts in the kidneys are extremely common and an uncomplicated renal cyst can be diagnosed reliably by a CT scan or an MRI. Simple renal cysts are variable in size and number. On a CT scan, a simple cyst usually appears as a well-defined rounded mass of water attenuation (0 to 20 HU), with an imperceptible wall and no enhancement after the administration of contrast agents. The MRI appearance of a simple renal cyst is characterized by a sharply demarcated, homogeneous, and hypointense mass on T1-weighted images. The simple cyst becomes uniformly hyperintense on T2-weighted images and shows no enhancement following contrast medium administration.[70–73] Complex renal cysts may be irregular in shape and have thicker or calcified walls. Fluid within complex cysts may present with high attenuation (hyperdense cysts) on a CT scan or complex signal intensity on an MRI (bright T1 and dark T2 or bright T1 and T2 images); in fact, they may simulate solid tumors. Such lesions require a further diagnostic evaluation with a dedicated renal CT scan or an MRI protocol, including scanning before and after the administration of a contrast agent. The degree of contrast enhancement within a lesion is critical in the characterization of the renal lesion.

Cystic renal lesions are often characterized according to the Bosniak classification system.[71,72] Class I cysts are simple benign cysts. Class II cysts have one or more thin (<1 mm) septa running through them, thin areas of mural calcification, or fluid contents of increased attenuation; they do not enhance after the administration of contrast medium and are benign (Fig. 11.15). Class III cysts are more complicated and contain thickened septa, nodular areas of calcification, or solid nonenhancing areas. Such lesions are suggestive of malignancy and should be biopsied or surgically explored, although fewer than half will turn out to be malignant. Class IV cystic masses are clearly malignant, with solid enhancing nodules or irregular walls, and should be treated accordingly (Fig. 11.16). A subcategory, IIF, has been suggested for lesions with multiple class II features, and these require follow-up.[65,70,74–81]

Parapelvic Cysts

Extraparenchymal cysts commonly occur in the renal sinus (parapelvic or peripelvic cysts). These cysts are often discovered incidentally, are frequently multiloculated, and may be large enough to displace hilar fat and compress adjacent renal parenchymas.[65,70,74–81] Although they do not communicate with the collecting system, they may simulate hydronephrosis because of their proximity to

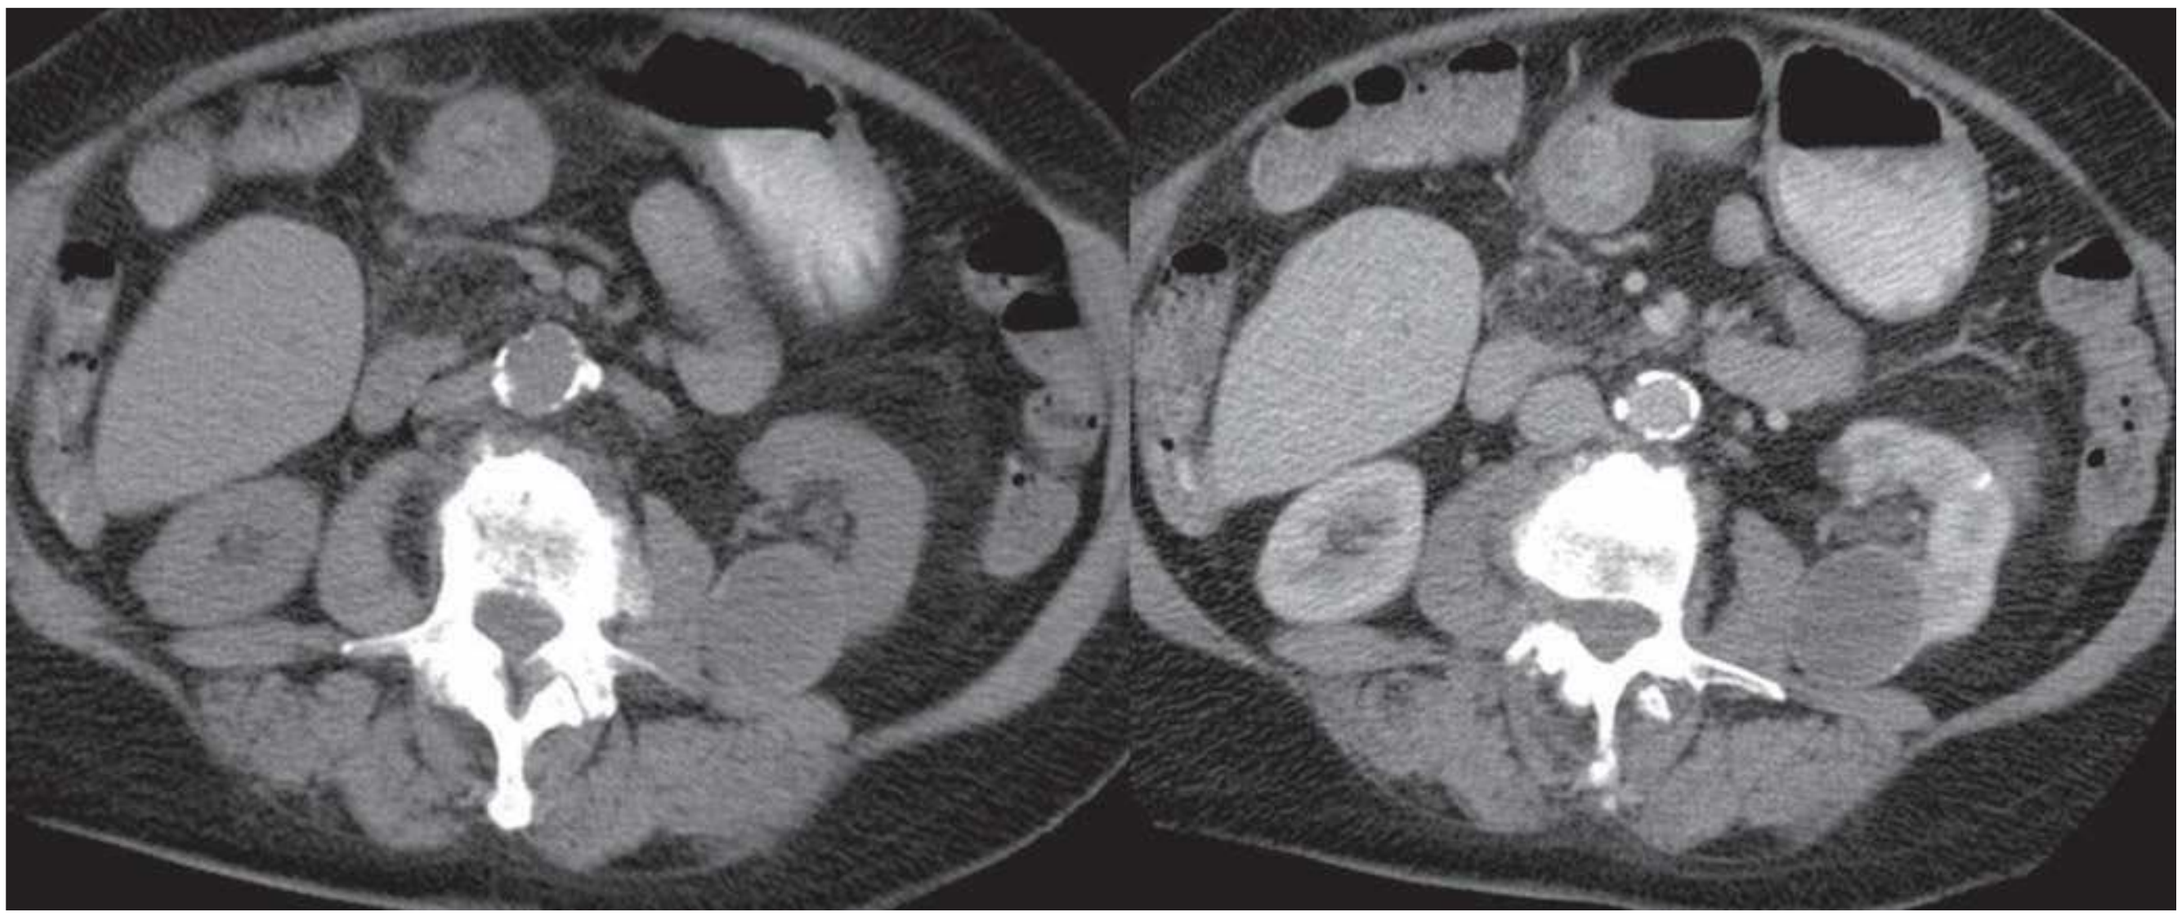

FIGURE 11.15 Bosniak class II cyst in the left kidney with slightly higher attenuation contents and subtle peripheral hyperdense rim on the pre-contrast CT but no contrast enhancement on the post-contrast CT.

the collecting system. When the diagnosis is uncertain, a delayed CT scan or an MRI after the administration of contrast agents can help differentiate unenhanced parapelvic cysts from a contrast-enhanced dilated collecting system (Fig. 11.17).

Autosomal Dominant Polycystic Kidney Disease

In individuals with a positive family history, the diagnosis of autosomal dominant polycystic kidney disease (ADPKD) can be established by radiologic imaging. The reported sonographic criteria[82] cannot be used with a CT scan or MRI because these imaging modalities have a higher sensitivity than US for the detection of renal cysts, particularly small cysts.[83,84] The kidneys are affected bilaterally in almost all instances, but may be quite asymmetric. Early in the disease, the kidney is close to normal in size with a substantial amount of normal renal parenchyma. However, with disease progression, the kidneys gradually enlarge as the cysts increase in number and size and replace normal parenchymas (Fig. 11.18).[85]

Most ADPKD renal cysts are simple cysts but increase with complex cysts as the disease progresses. The CT attenuation and MRI signal intensity of complex cysts affected by hemorrhage or infection may vary. ADPKD patients with

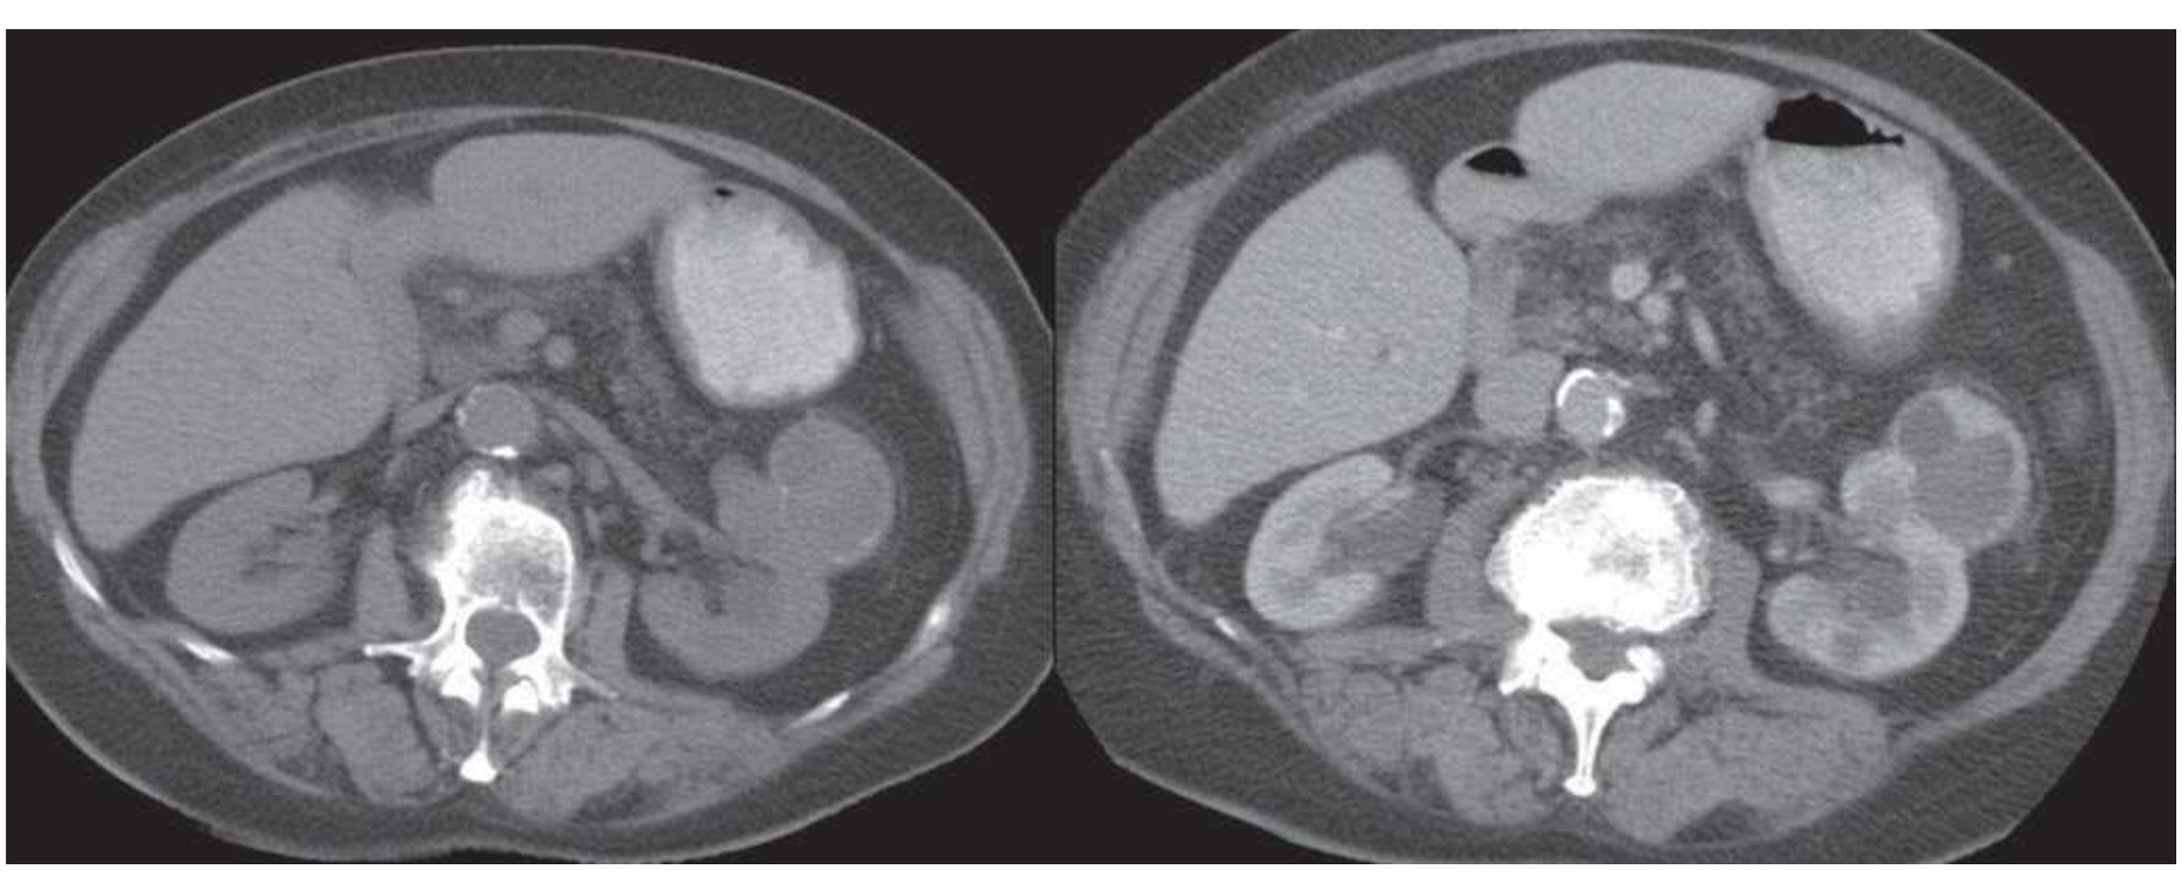

FIGURE 11.16 Pre- and post-contrast CT of Bosniak class IV cyst in the left kidney demonstrating peripheral nodular enhancement.

FIGURE 11.17 Bilateral parapelvic cysts are shown as bright structures on axial T2 MRI (*left*) and water-attenuation cystic structures on contrast-enhanced axial CT (*middle*) and coronal CT (*right*). The parapelvic cysts on axial CT do not enhance but are surrounded by delayed excretion of contrast medium within the collecting system. An incidental large abdominal aortic aneurysm is noted.

clinically suspected renal infection or pain are referred for a CT scan or an MRI evaluation of intracystic infection or hemorrhage.[65,70,74–81,85,86] But this is often difficult because the attenuation and signal intensity values of these cysts vary depending on the presence of blood products, proteinaceous mucoid material, or simple cyst fluid. Sequential studies allow for the evaluation of a fresh hemorrhage and the resolution of hematomas.

Acquired Cystic Disease Associated with Chronic Dialysis

Patients with acquired cystic disease associated with hemodialysis typically present with multiple bilateral cysts of varying size in small kidneys (Fig. 11.19). Although sonography is usually used for a diagnostic evaluation, small fibrotic end-stage kidneys may be difficult to image with sonography.[87] A contrast-enhanced CT scan or MRI is more sensitive

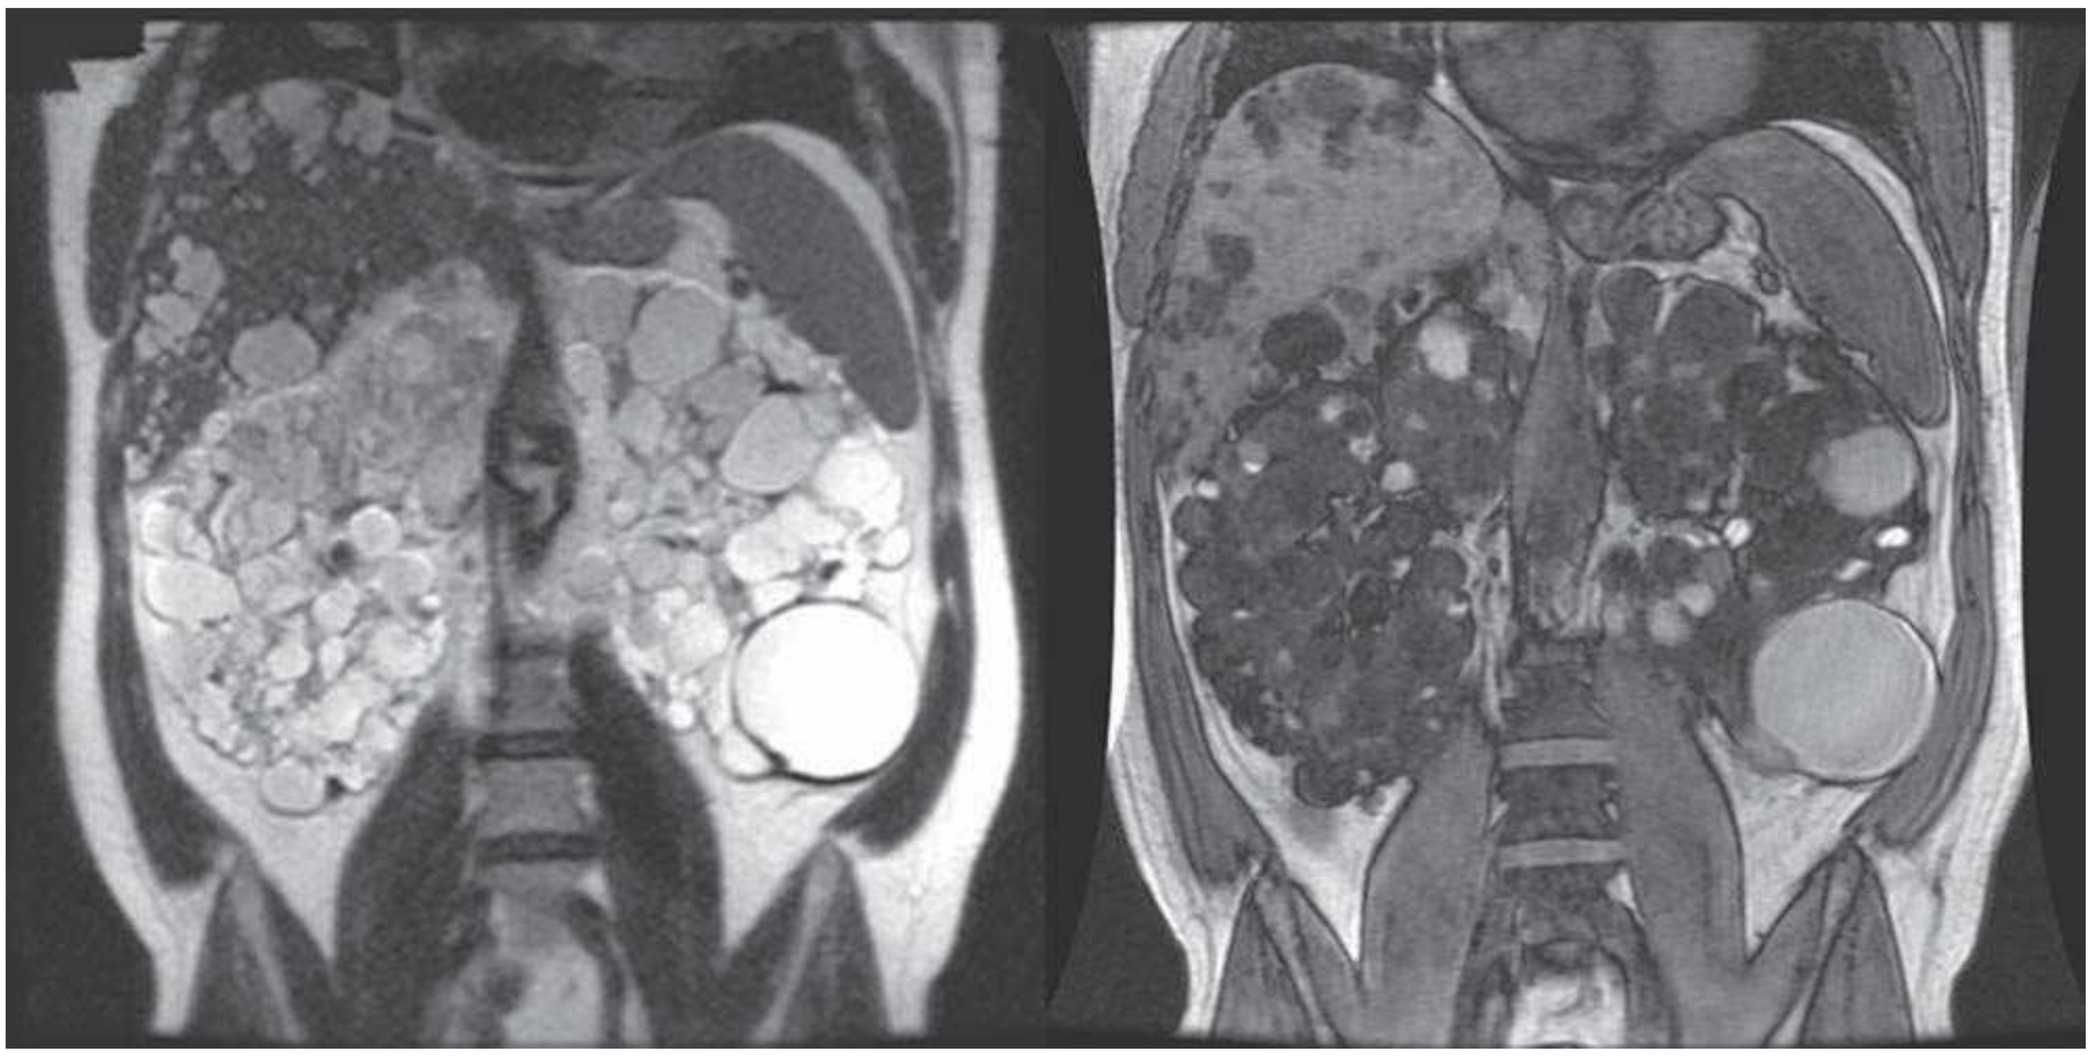

FIGURE 11.18 ADPKD on coronal MR images. Innumerable cysts occupying markedly enlarged bilateral kidneys on T2 (*left*) and T1 (*right*) MR images. Simple cysts are of bright T2 and dark T1 signal intensity, whereas complex cysts present with intermediate to bright T1 signal intensities. Extensive hepatic cysts are also present.

FIGURE 11.19 Contrast-enhanced CT showing multiple cysts of varying sizes in both kidneys that are markedly atrophied.

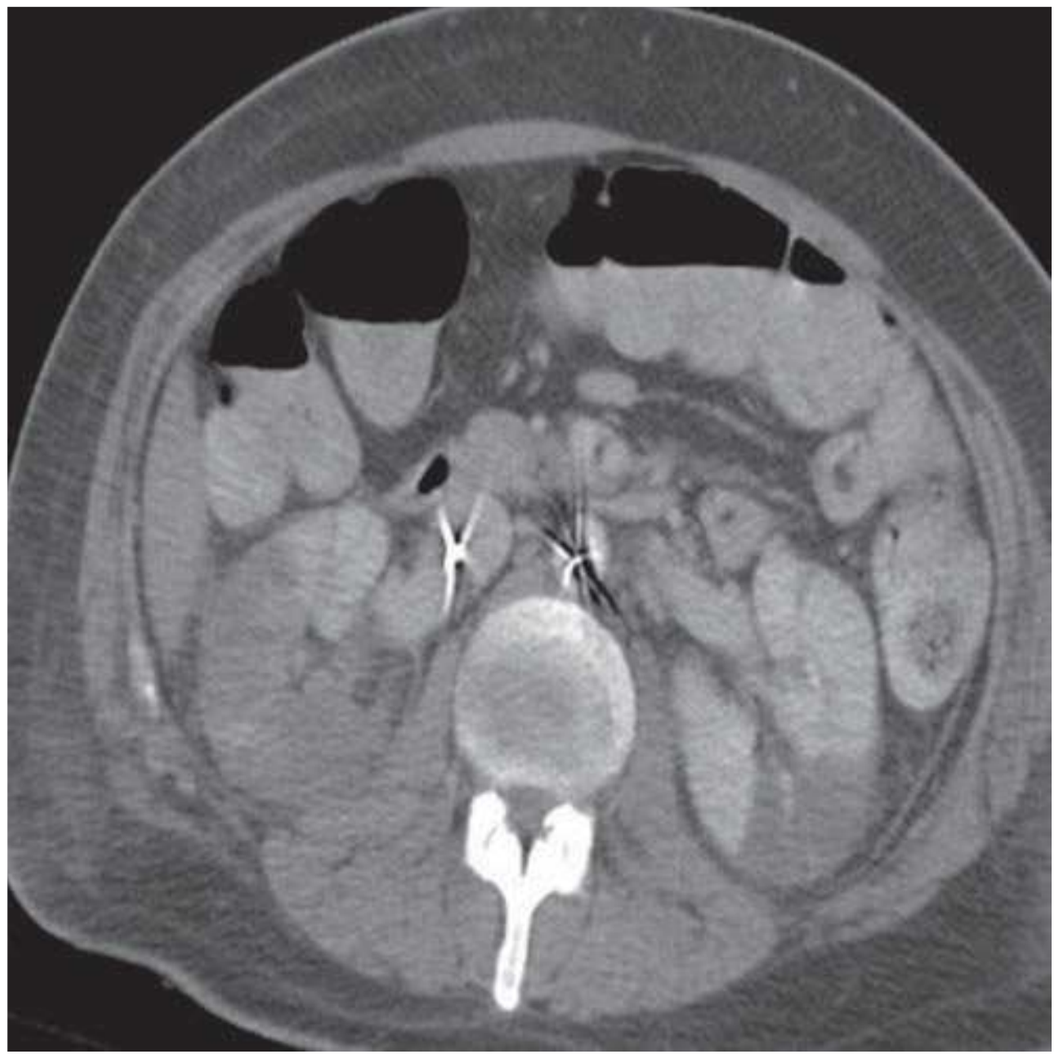

FIGURE 11.20 Contrast-enhanced CT demonstrating bilateral multiple renal infarcts as wedge-shaped nonenhancing low-attenuation areas.

to determine the extent of the disease, cyst complications, and renal carcinomas.[88–90] Because of limited or an absent renal function of these individuals and the presence of numerous simple and complex cysts, an MRI is the preferred modality for the evaluation of potential renal malignancies. Nevertheless, a contrast-enhanced CT scan may also be used if patients are receiving dialysis.[90]

Vascular Pathologies

Renal infarcts typically present as clearly marginated wedge-shaped peripheral areas of low attenuation on contrast-enhanced CT scan (Fig. 11.20) or low signal intensity on contrast-enhanced MRI. A parenchymal atrophy caused by chronic vascular insufficiency may be detected on a CT scan or MRI.

A CT scan or an MRA is used to assess the number and size of the renal arteries, which is crucial for the evaluation of a renal donor for transplant. A CTA and an MRA have largely replaced conventional catheter angiography for this application. A CTA and an MRA can also demonstrate renal artery aneurysms or stenosis (Fig. 11.21), arteriovenous malformations, and focal or diffuse stenoses caused by atherosclerosis, connective tissue disease, or fibromuscular dysplasia. Although the 3D gadolinium-enhanced protocol is the preferred technique for an MRA, new time of flight MR protocols have been introduced to image renal vessels without gadolinium for patients with a severely compromised renal function.

Renal vein thrombosis typically presents with intraluminal filling defects and vein enlargement (Fig. 11.22). Acute venous occlusion may result in renal enlargement and parenchymal edema and, occasionally, hemorrhagic infarction. A contrast-enhanced CT scan or an MRI may show a persistent nephrogram and delayed contrast excretion. A parenchymal atrophy and the development of venous collaterals may be followed with chronic renal vein thrombosis.[3,91–98]

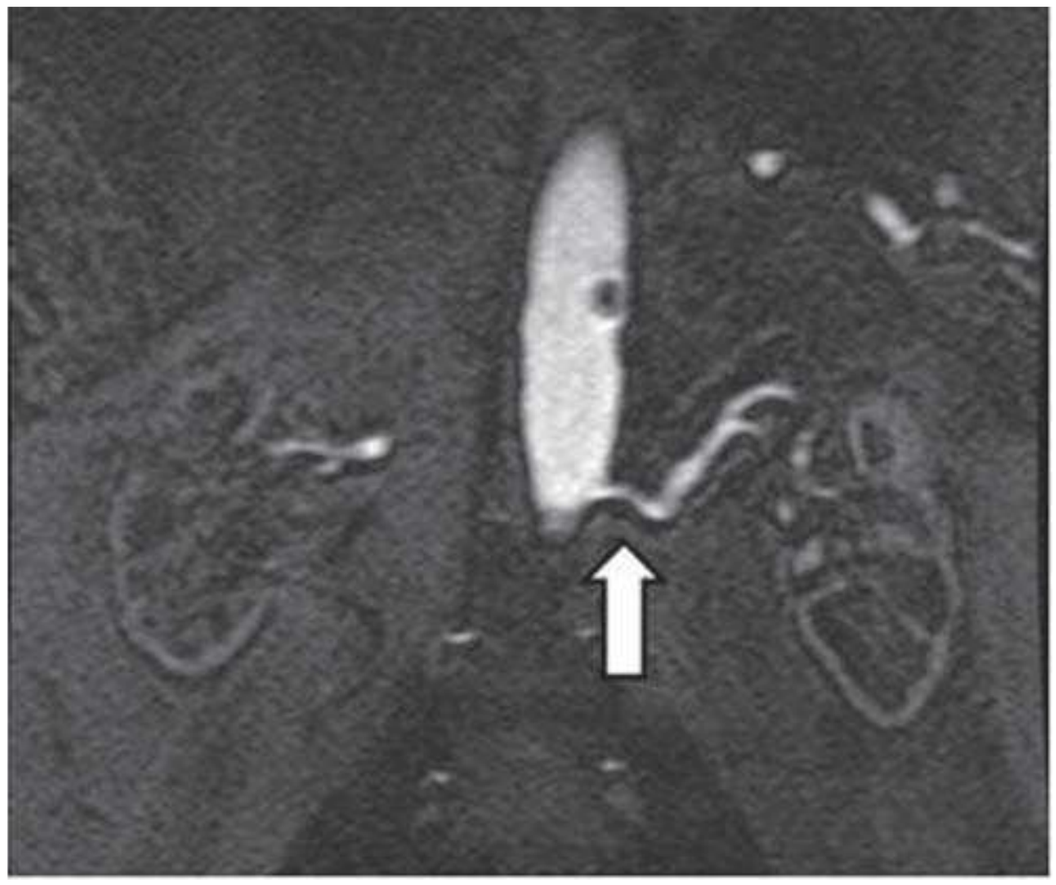

FIGURE 11.21 Contrast-enhanced coronal MR angiography showing a focal stenosis near the origin of left renal artery (*arrow*).

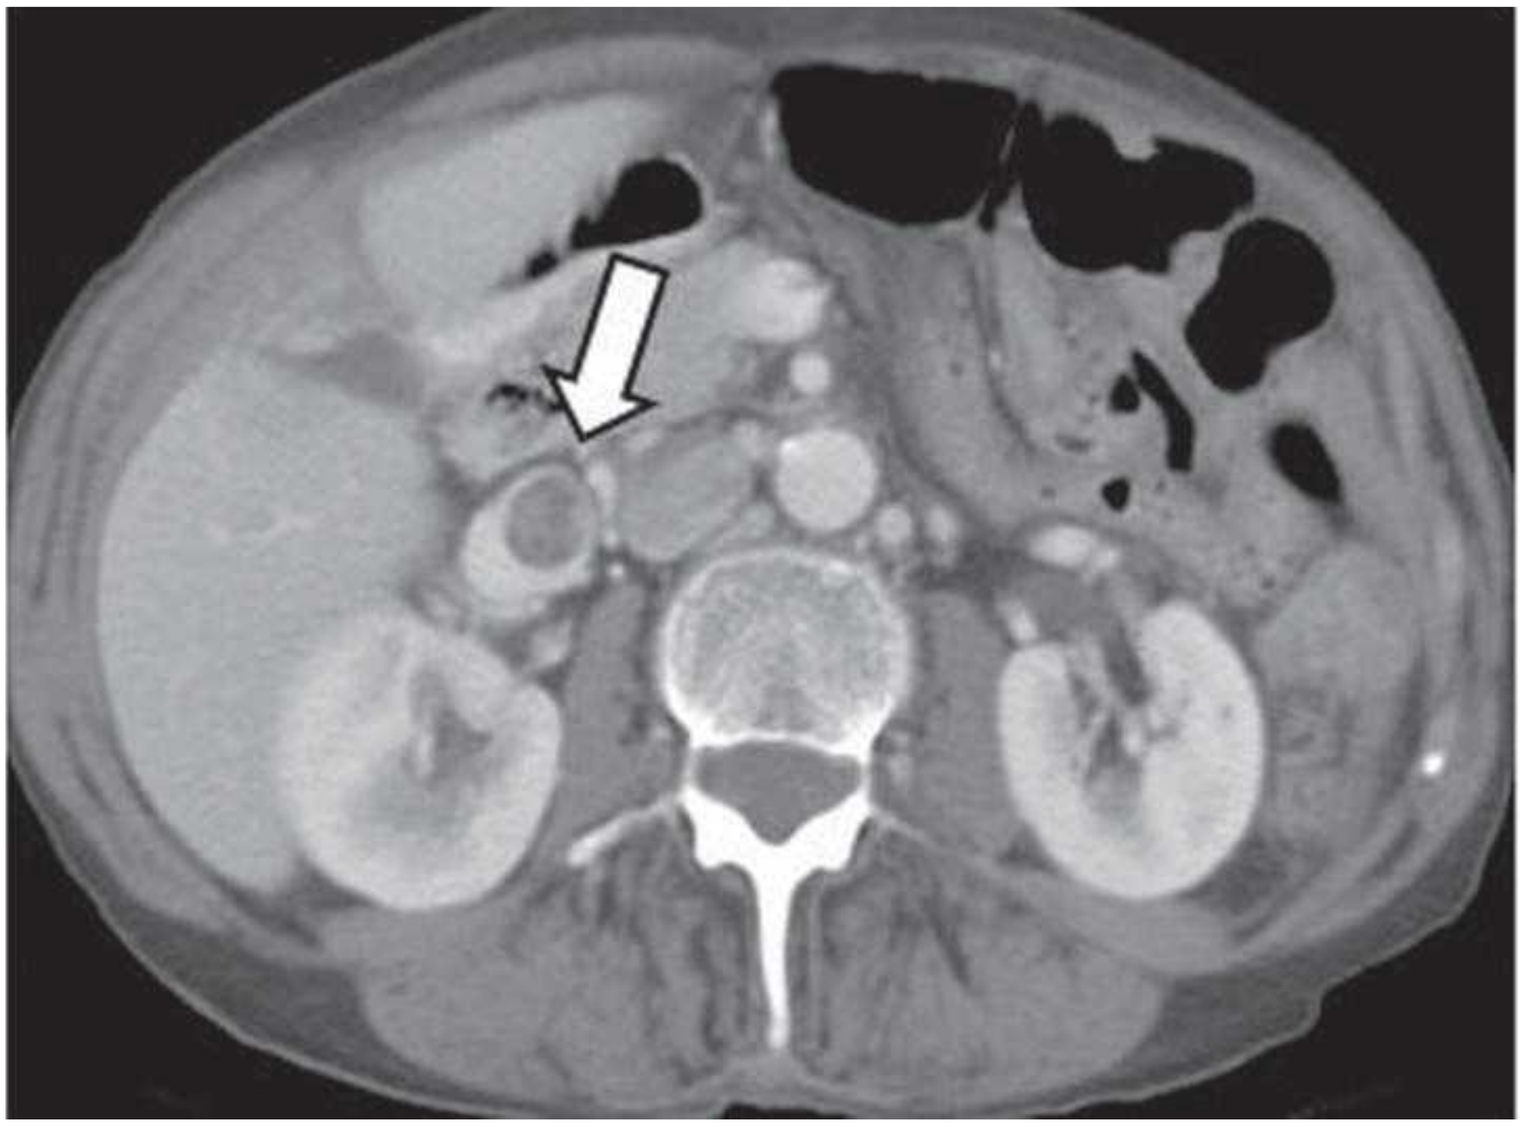

FIGURE 11.22 Contrast-enhanced CT showing a low-attenuation filling defect (*arrow*) in an expanded right renal vein consistent with renal vein thrombosis.

Renal Transplant Evaluation

The structural integrity of renal allografts and common peritransplant complications (hematomas, urinomas, lymphoceles, and abscesses) can be readily assessed with a CT scan or an MRI. However, the characterization of graft dysfunction, such as the differentiation of rejection and acute tubular necrosis (ATN), remains challenging by any radiologic imaging method. Recent applications of functional MRI techniques including diffusion, blood oxygen level dependent (BOLD), and sodium MRI are promising for the noninvasive evaluation of graft dysfunction[16] but are not ready for routine clinical application. A CTA or an MRA are very useful for the evaluation of the allograft vasculature including arterial or venous stenosis and aneurysm.[99,100]

Renal Tumors

The evaluation of hematuria is a common reason for a urology referral. Historically, the workup included IVU, urine cytology, and cystoscopy. Other imaging modalities available for hematuria workup include a CT scan, ultrasonography, an MRI, and a retrograde pyelography. In particular, MDCT is increasingly used as a single-imaging comprehensive evaluation of a patient with hematuria. The unenhanced phase of the CT scan is highly reliable for diagnosing urolithiasis. The enhanced nephrographic phase aids in the detection of renal parenchymal masses. The excretory phase with 3D reformation allows for the evaluation of the entire urothelium. MDCT has been shown to have high sensitivity in detecting upper tract urothelial cancers. Some investigators add a corticomedullary phase to characterize the renal artery and vascularity of parenchymal renal masses. One concern about this comprehensive CT technique is the radiation dose to the patient, and some investigators advocate not covering the entire abdomen and pelvis in all phases of the examination in order to limit the radiation dose.[32,37,52,56]

An MRI is equivalent to a CT scan in its ability to detect renal lesions of approximately 1 cm[56] and in detecting a lymphadenopathy.[56] An MRI detects polar lesions better than a CT scan and has up to 100% sensitivity in detecting a renal vein invasion. Most renal tumors, including benign lesions, enhance on CT scans and MRIs. T1-weighted chemical-shift MRIs are highly reliable for the detection of fat content within renal lesions. With fat saturation sequences, the fatty portions of a mass drop in signal, which is diagnostic of a fat-containing renal mass such as angiomyolipoma. After the exclusion of angiomyelolipomas and in the absence of lymphoma and metastatic disease, all other enhancing renal lesions represent surgical lesions. Unfortunately, neither CT scans nor MRIs can reliably differentiate some benign enhancing tumors such as oncocytomas from renal cell carcinomas.[32,37,56,65,71,94,101–109]

Benign Tumors

Angiomyolipoma

Angiomyolipomas are benign lesions composed of variable amounts of fat, smooth muscle, and abnormal blood vessels. They occur spontaneously in the general population, mainly in women in the fifth decade of life. In patients with tuberous sclerosis, they occur at a much younger age and are frequently multiple, with an incidence of 50% to 80%.[110,111] A confident diagnosis can be made with a CT scan if the fatty tissue predominates. The tumor may grow very large in size and may extend into the perinephric space. An intralesional hemorrhage often occurs. The MRI appearance of angiomyolipomas depends on the amount of fat, smooth muscle, and vessels within the lesion.

FIGURE 11.23 Angiomyolipoma (*arrow*) in the left kidney with bright signal intensity similar to the surrounding body fat on T1-weighted MRI without fat saturation (*left*) but showing a signal drop on T1-weighted with fat saturation (*right*).

Angiomyolipomas composed predominantly of fat present with signal intensity on T1- and T2-weighted images similar to the surrounding fatty structures and demonstrate a signal drop on the fat suppression sequences (Fig. 11.23).[65,102,110,112]

Renal Oncocytomas

Renal oncocytomas are rare tumors that typically appear as smoothly marginated, homogeneously enhancing solid masses. These masses may demonstrate a characteristic central linear area of lower attenuation (stellate central scar) on a contrast-enhanced CT scan. But, this appearance on CT is found in only a small proportion of these tumors and is not specific, and the diagnosis of these benign masses necessitates an operative biopsy/resection (Fig. 11.24).[7,65,76,105,107] A recent CT study reported that the segmental enhancement inversion between two phases of a contrast-enhanced CT scan was significantly more frequent in oncocytomas than in renal cell carcinomas and could be diagnostically useful in differentiating the two.[113]

Renal Adenomas

Renal adenomas are indistinguishable from other solid renal masses on CT scans or MRIs. They may show variable contrast enhancement and may present as a contour abnormality or distortion of intrarenal anatomy, necessitating further workup and intervention.[114]

Malignant Tumors

Renal Cell Carcinoma

Renal cell carcinomas are a relatively common malignancy. Their appearance on CT scans and MRIs varies with the size and tumor vascularity. Tumors may distort the renal contours or alter intrarenal architecture (Fig. 11.25). On a CT scan, their attenuations are similar to those of the surrounding renal parenchyma in unenhanced images. Tumors often enhance heterogeneously on enhanced CT scans, with central areas of low attenuation (Fig. 11.26). On an MRI, tumors demonstrate a variable signal on both T1- and T2-weighted images. The most common appearance is a heterogeneous mass of low-to-intermediate signal on T1-weighted images that increases in signal intensity on T2-weighted images. Dynamic CT scans or MR scanning after a bolus of contrast may demonstrate an intense enhancement of relatively vascular tumors and retroperitoneal feeding of collateral vessels.[93,115–117] An extension of the tumor into the perirenal

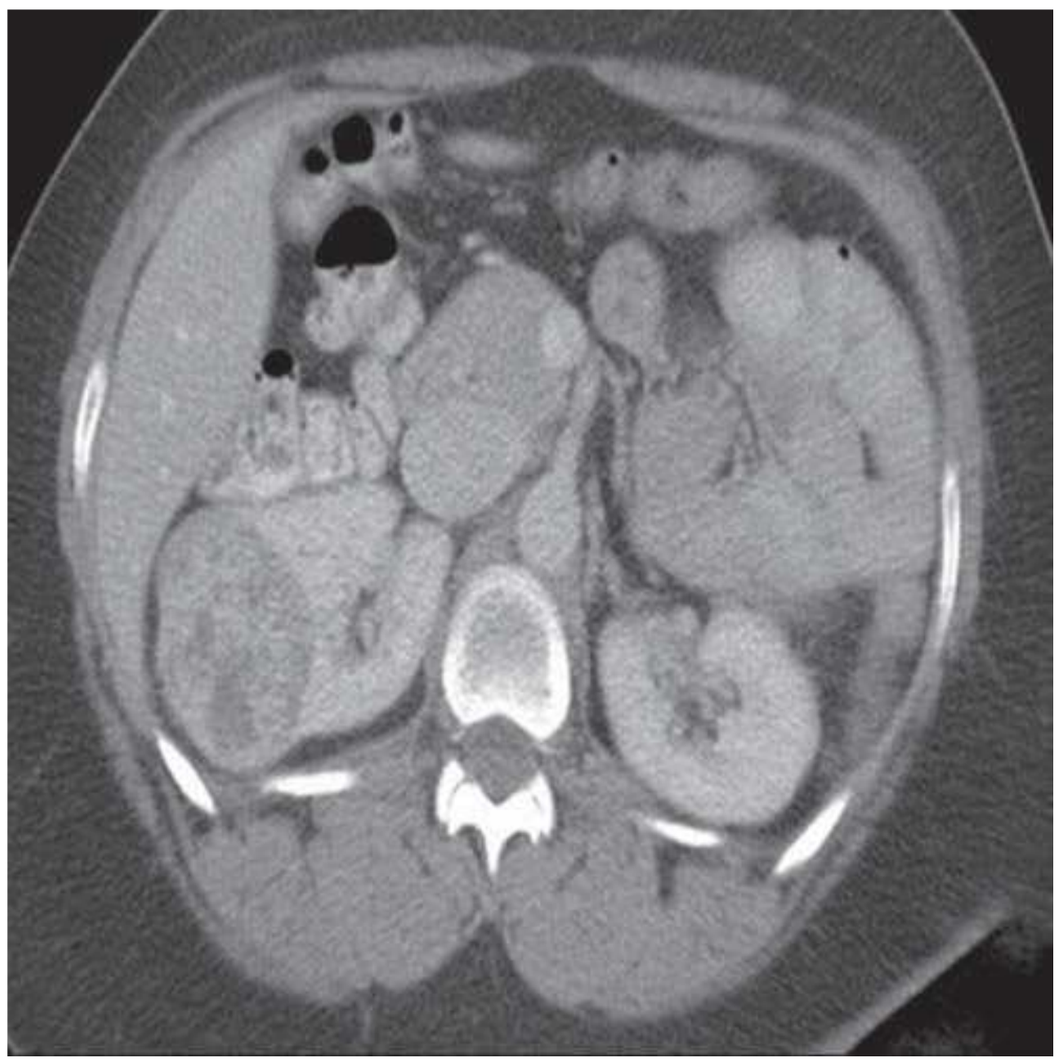

FIGURE 11.24 Contrast-enhanced CT showing an oncocytoma in the right kidney with mixed areas of enhancement and low attenuation. This is difficult to differentiate from renal cell cancer based on imaging alone.

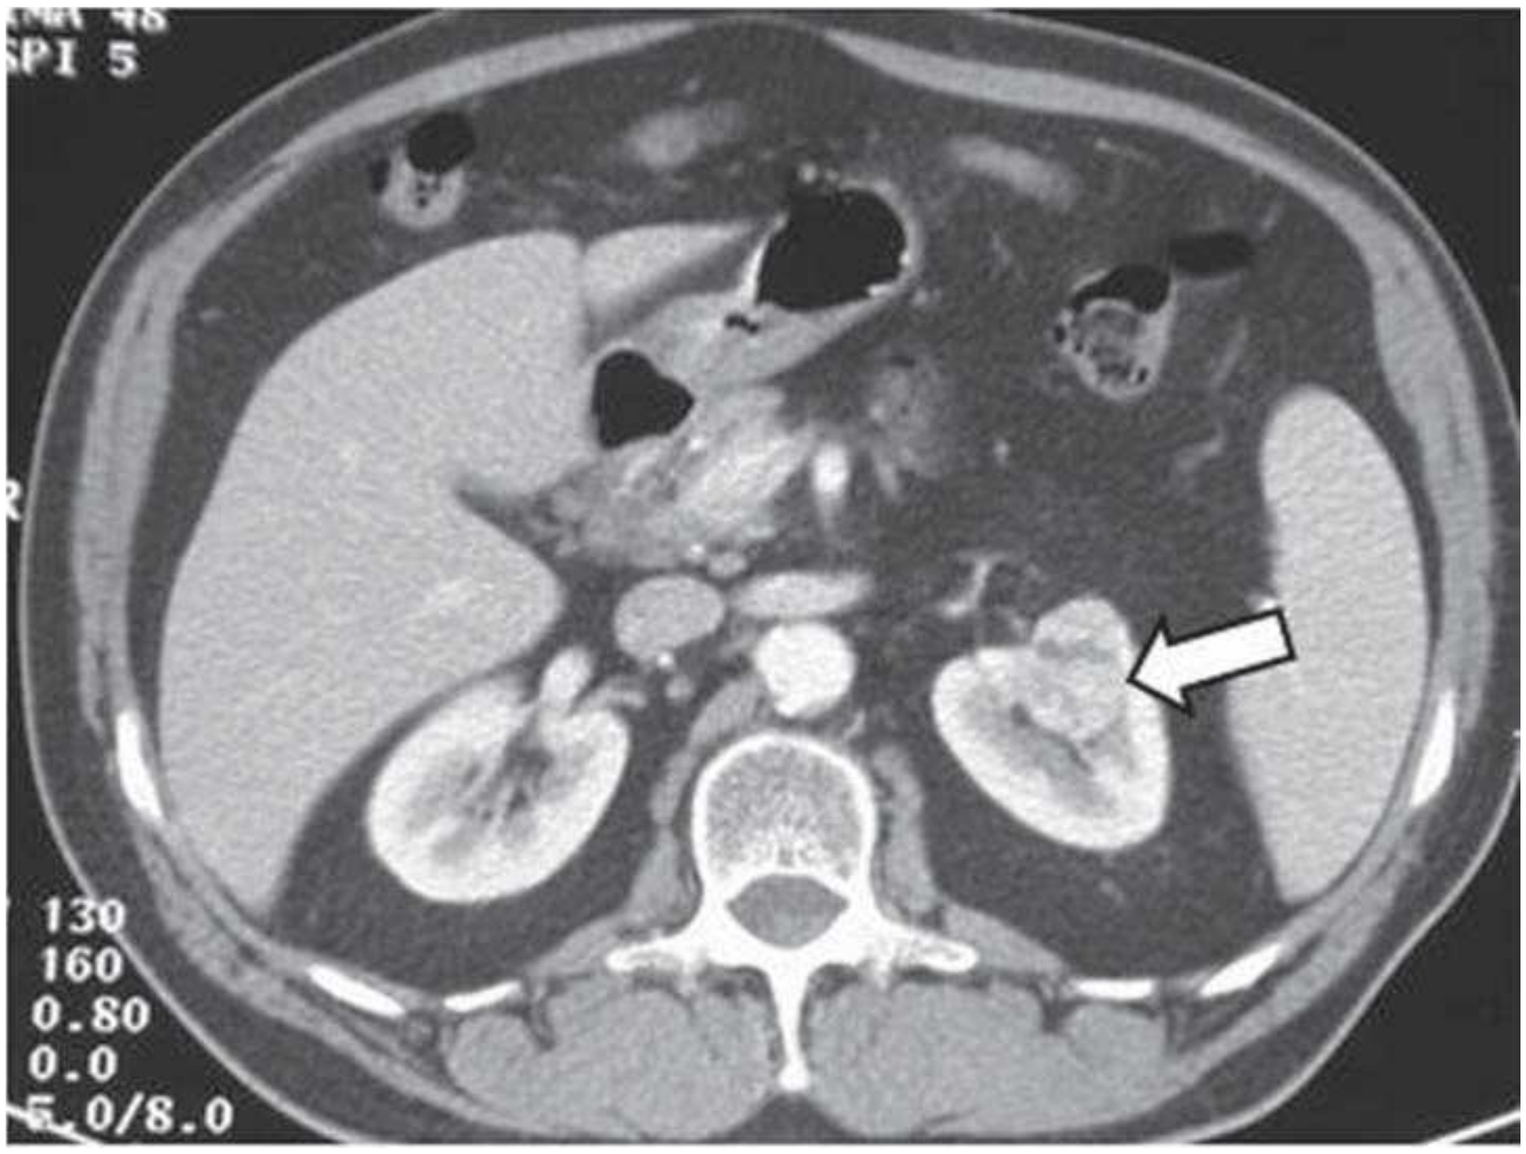

FIGURE 11.25 Contrast-enhanced CT showing a subtle left renal cell cancer replacing the left renal sinus fat.

fat or the adjacent liver, spleen, or paraspinous musculature; an interruption of the perirenal fascial planes, renal veins, and inferior vena cava; and perihilar and perivascular adenopathy can be assessed accurately by CT scans or MRIs. MRIs and CT scans have been shown to be comparable in the diagnosis and the staging of renal cell carcinomas. Because of greater spatial resolution, a CT scan is superior to an MRI in detecting small lesions, and an MRI has not been used as a screening tool in patients with hematuria. However, MRIs have been shown to be more accurate than CT scans in tumor staging. MRIs are particularly beneficial for the evaluation of the patency of the renal veins and inferior vena cava, the delineation of perivascular lymphadenopathy, and the extension of the tumor into adjacent organs.[93,115–117] Three-dimensional image reconstructions of renal tumors can be obtained with MDCT.[56,118] This information can help the surgeon, especially if a partial nephrectomy is being considered. CT-guided radiofrequency ablations of renal cell carcinomas are an alternative treatment option, particularly in patients that are not surgical candidates. CT scans are also used to follow these patients to assess for residual disease or recurrence.[9,40,56,93,102,106,108,119–124] In many institutions, a CT scan is the technique of choice for the diagnosis and staging of renal cell cancer; an MRI is used when a contrast-enhanced CT scan is contraindicated, or if frequent follow-up is required in high-risk patients.[93,115–117]

Renal Lymphoma or Leukemia

Primary lymphoma of the kidney is rare because there is no lymphatic tissue within the kidneys. Renal involvement may be due to hematogenous spread or contiguous invasion from an adjacent retroperitoneal lymphadenopathy. The kidneys are more commonly involved in non-Hodgkin lymphoma than in Hodgkin lymphoma, particularly when the disease has relapsed.[125–127]

Renal lymphoma has a variable radiologic appearance on CT scans and MRIs. The most common pattern is multiple masses that are of the same or slightly higher attenuations than normal renal parenchyma on an unenhanced CT scan and are low to intermediate in signal intensity on T1- and T2-weighted MRIs. Lymphomas are hypovascular tumors and demonstrate lower contrast enhancement than normal renal parenchymas[125–127] on contrast-enhanced CT scans or MRIs

FIGURE 11.26 Contrast-enhanced CT showing a large right renal carcinoma with heterogeneously enhancing solid areas and necrosis.

FIGURE 11.27 Contrast-enhanced CT showing a low-attenuation mass in the left kidney consistent with lymphoma.

(Fig 11.27). Other appearances include a direct invasion from adjacent retroperitoneal lymphadenopathy, an infiltrative pattern with renal enlargement, or a solitary mass.[125–127]

Leukemic renal infiltration is frequently seen at a postmortem examination and can be associated with renal impairment. It may present as unilateral or bilateral renal enlargement or focal mass or masses.[128]

Metastatic Disease

Primary tumors that may metastasize to the kidney include carcinomas of the lung, breast, adrenal gland, and colon; malignant melanoma; and non-Hodgkin lymphoma.[41,43] These tumors may present as either a solitary or multiple focal mass that demonstrates less enhancement than normal renal parenchyma on a contrast-enhanced CT scan or an MRI. The direct extension of extrarenal retroperitoneal tumors may lead to renal obstruction and a loss of function.[41,43]

Renal Sarcomas

Sarcomas of the kidney are rare. They present as solid masses that may grow very large in size and vary in their degree of vascularity.[129] Large tumors often contain central areas of necrosis. The imaging characteristics are nonspecific, making it difficult to distinguish a renal sarcoma from a renal cell carcinoma.

Transitional Cell Carcinoma

Transitional cell carcinomas of the renal collecting system and ureter present with three characteristic appearances on a CT scan or an MRI: sessile soft-tissue filling defects in the lumen of the enhanced collecting system (Fig. 11.28) or ureter; thickening of uroepithelial wall; or infiltrating nonenhancing renal masses (Fig. 11.29). Tumors may be smooth or papillary in contour and may cause ureteral obstruction and renal functional impairment. In addition to assessing the collecting system and ureter, CT urography allows us to detect and characterize renal lesions and extrarenal masses and is more sensitive in detecting renal calculi.[28,32,43,52,54,56,93,130] A CT urography is also the imaging of choice for tumor staging, demonstrating the invasion of perihilar fat and associated lymph node enlargement. Alternatively, an MR urography can be used to assess the collecting system in patients with a contraindication to iodinated contrast CT scans.

Renal Trauma

Renal injury is common, occurring in 8% to 10% of the cases of blunt and penetrating abdominal trauma. About 90% of renal injuries result from blunt force injury and 10% from penetrating

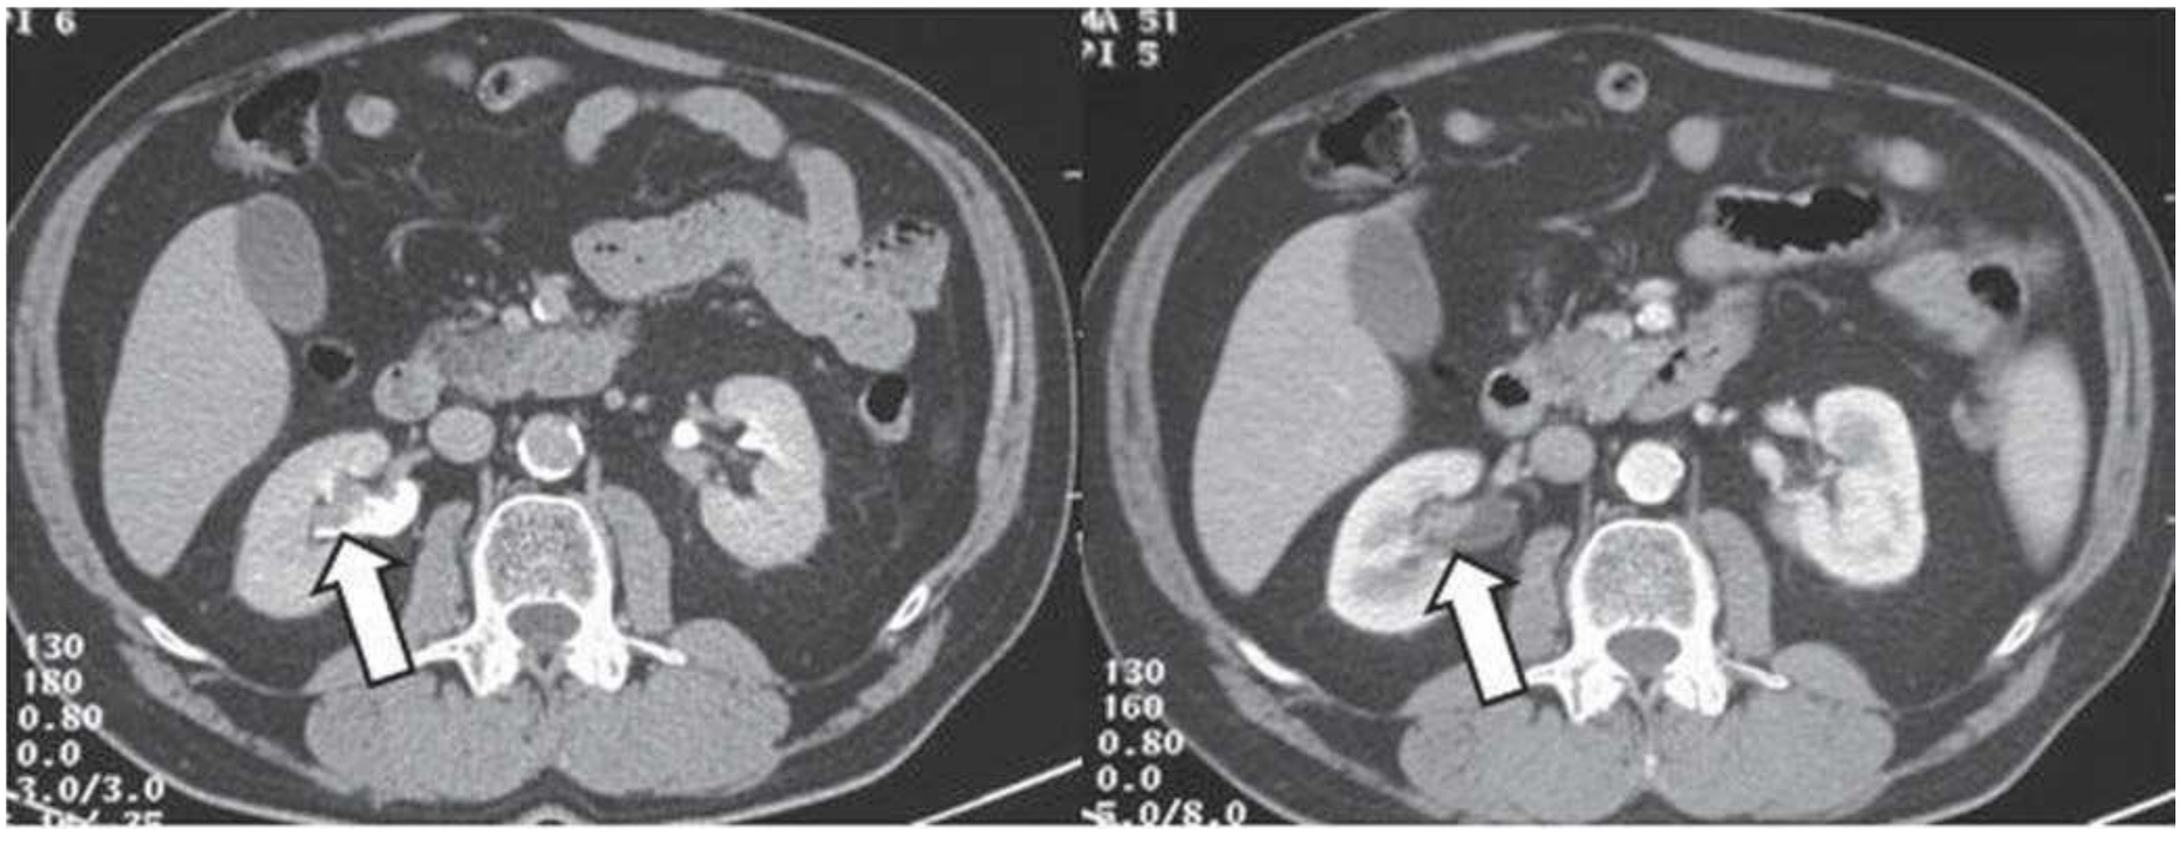

FIGURE 11.28 TCC in right kidney presenting as a filling defect on the excretory phase (*left*) and demonstrating subtle enhancement on an earlier enhancement phase (*right*).

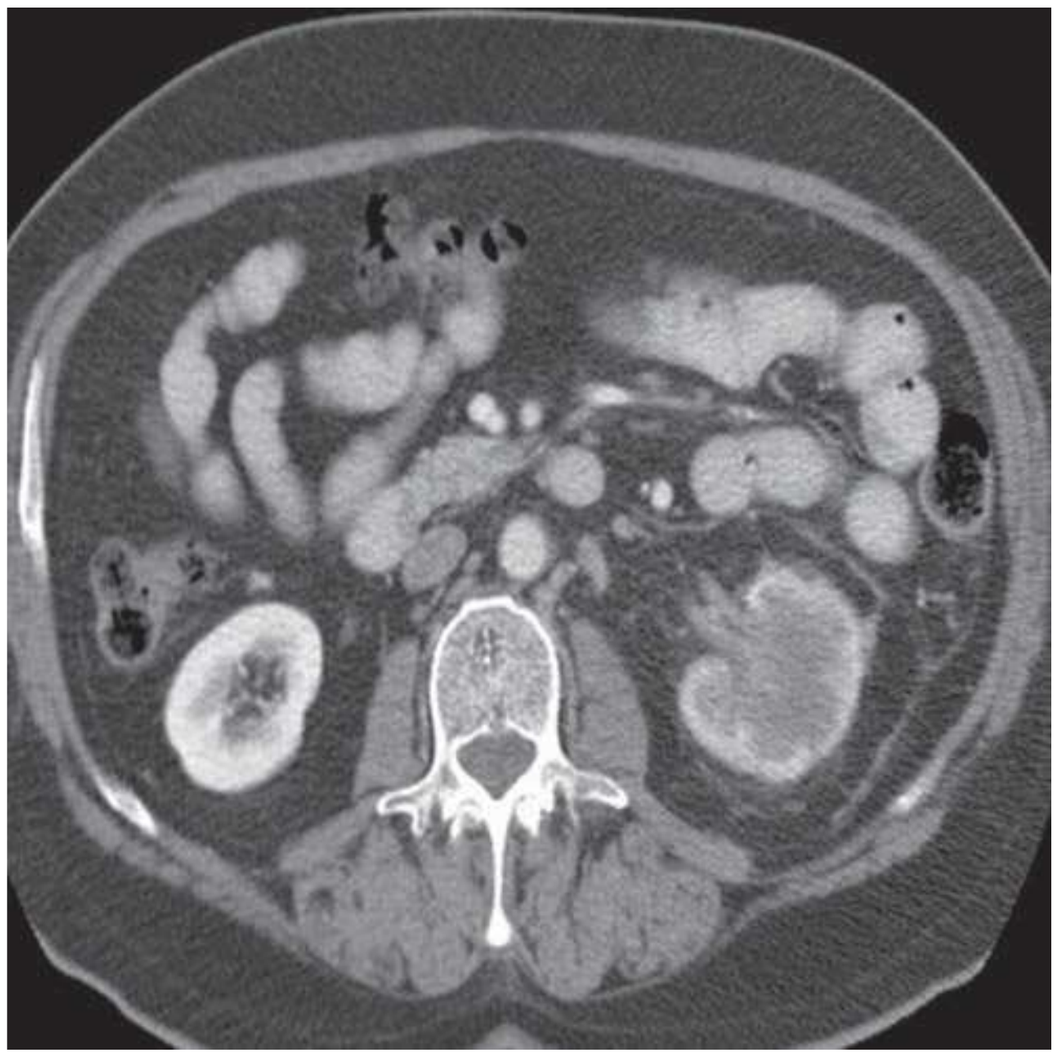

FIGURE 11.29 TCC in left kidney presenting as diffuse infiltrating mass that effaces the normal corticomedullary differentiation, resulting in a faceless kidney.

FIGURE 11.30 Unenhanced CT showing a focal hyperdense area in the right kidney consistent with contusion. Contrast in the collecting system is from contrast-enhanced CT performed a day prior.

trauma, but vary somewhat with location. The clinical indications for the imaging evaluation of the genitourinary system depend on several factors, including the overall hemodynamic status of the patient, other injuries sustained, the site of blunt or penetrating trauma, and the presence or absence of gross hematuria.[37,56,131] The American Association for the Surgery of Trauma (AAST) has devised a renal injury severity score based on surgical observations. A CT grading scale following the surgical management is classified as grade I, a minor contusion with or without concomitant subcapsular hematoma; grade II, a superficial laceration without the involvement of the collecting system; grade III, a deep parenchymal laceration with or without urinary extravasation; and grade IV, a renal pedicle injury.

The majority of blunt renal injuries are CT grades I and II and are managed conservatively without intervention.[37,56,131] Contusions are visualized as ill-defined low attenuation areas with irregular margins in the renal parenchyma. They may appear as regions with a striated nephrogram due to differential blood flow through the contused parenchyma or as focal areas of renal parenchymal extravasation on delayed CT studies (Fig. 11.30). These lesions usually resolve during follow-up imaging.[37,56,131] More significant renal trauma may or may not require intervention by angiography or surgery. Controversy exists over the management of grade III injury, with the most recent trend favoring conservative therapy. Grade IV and penetrating renal injuries are surgically explored.[132–134]

Patients with suspected renal injuries who are clinically stable can benefit greatly from a CT assessment. A contrast enhanced CT scan can detect renal contusions and lacerations. Lacerations present with irregular streaks of low attenuation within the contrast-enhanced renal parenchyma and are classified as incomplete lacerations (affecting the renal parenchyma without communicating with pelvicalyceal structures) and complete lacerations (interrupting the collecting system). Subcapsular hematomas are shown as a lower density intracapsular hemorrhage compressing the enhanced kidney (Fig. 11.31).

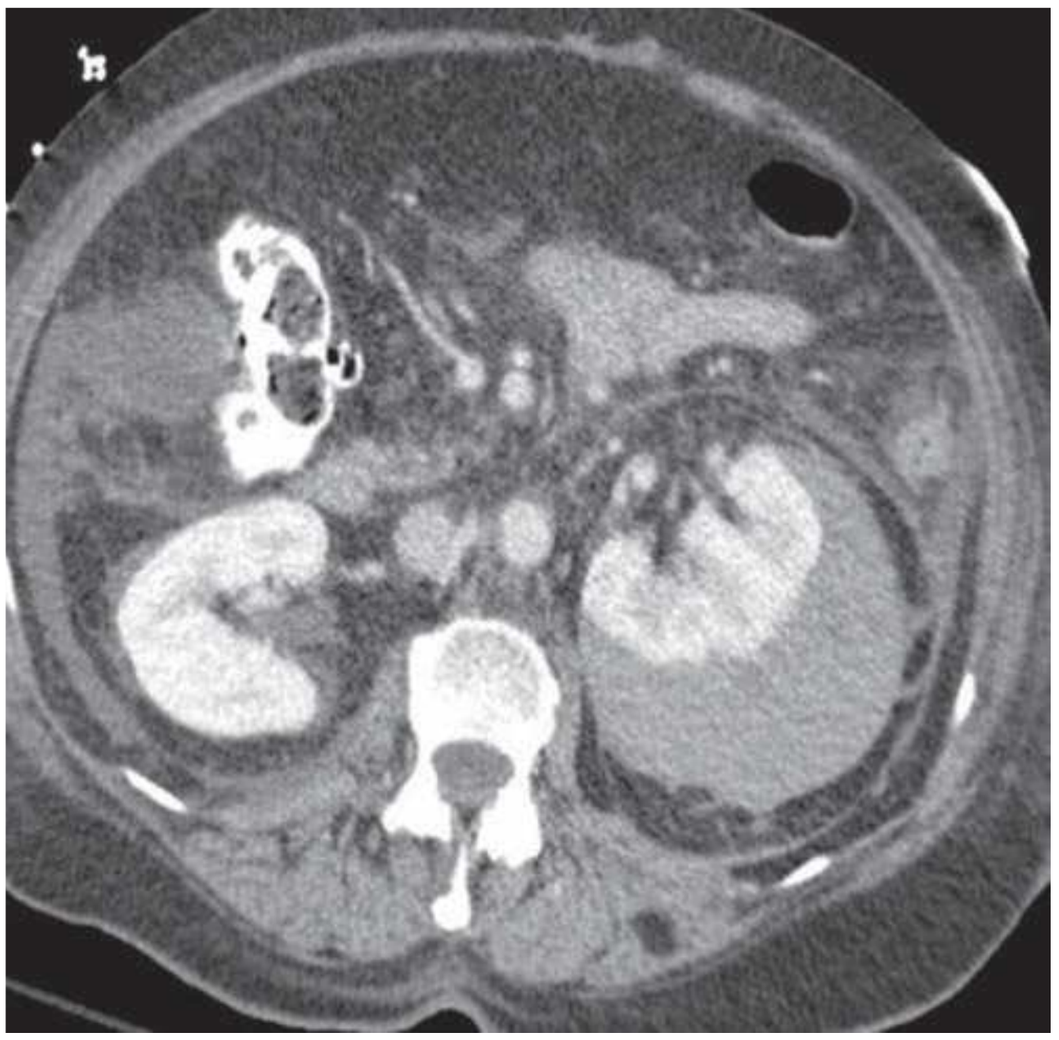

FIGURE 11.31 Contrast-enhanced CT showing a large left subcapsular hematoma displacing the left kidney.

FIGURE 11.32 Contrast-enhanced CT showing shattered left kidney with perirenal hematoma.

Extravasated blood varies in its CT scan attenuation value, depending on the age of the hematoma and the hemoglobin content. With fluid collections filling the perirenal or pararenal spaces and displacing the kidney, a perirenal hemorrhage or urine extravasation (best seen on delayed images) should be considered. Fresh blood may have a higher attenuation value than extravasated urine in an unenhanced CT scan. Renal infarction may occur with a segmental occlusion of polar arteries due to trauma.[132–134] On a CT scan, catastrophic renal injuries, such as shattered kidneys, can be easily detected (Fig. 11.32). Concomitant injuries to other visceral organs may be present.[132–134] When there are underlying renal abnormalities including renal cysts, tumors, and hydronephrosis, relatively minor trauma may result in major injuries to kidneys, thereby confounding the diagnosis.

CHAPTER

12 Diagnostic Angiography and Therapeutic Endovascular Intervention of the Renal Circulation

Alex Perino • Rajan Gupta • Ivan P. Casserly

The last decade has seen a dramatic paradigm shift in the diagnostic evaluation of pathology of the renal arterial and venous circulations. Noninvasive angiographic techniques, notably computed tomography (CT) and magnetic resonance (MR) angiography, have advanced to the degree that the diagnostic accuracy of these noninvasive imaging modalities rivals that of invasive angiography.[1,2] In fact, in the renal venous circulation, these modalities are typically superior to invasive angiography. Hence, invasive angiography of the renal circulation is now generally performed to confirm the findings of noninvasive studies of the renal artery for the purpose of vascular intervention. The result is a more targeted and individualized approach to angiography that answers a clinical question or helps direct an endovascular therapy.

In contemporary practice, the majority of pathologies involving the renal circulation that require intervention are treated using an endovascular as opposed to a surgical approach. The majority of procedures are performed in the renal artery, with the primary pathologies being treated including atherosclerosis and fibromuscular dysplasia (FMD). Novel endovascular treatments are also emerging for the treatment of resistant hypertension (HTN). Renal venous interventions are rare.

This chapter outlines the angiographic anatomy of the renal arterial and venous circulations, describes the technique of renal artery angiography, and provides an overview of the most commonly performed interventions in the renal circulation.

ANGIOGRAPHIC ANATOMY

Renal Artery

In most individuals, a single right and left renal artery arises from the abdominal aorta at the level of the L2 vertebra (Fig. 12.1). Although both renal arteries arise at a similar level from the abdominal aorta, the right renal artery typically has an anterior origin, whereas the left renal artery has a posterior origin (Fig. 12.2).[3] In addition, owing to the inferior location of the right kidney, the right renal artery has a downward course, whereas the left renal artery has a more horizontal course (Fig. 12.1B). Each renal artery divides at the hilum of the kidney into a posterior branch that runs posterior to the renal pelvis and supplies the majority of the posterior portion of the kidney and an anterior branch that typically divides into four segmental branches (apical, upper, middle, and lower) (Fig. 12.3).[4–6] The upper and lower poles of the kidney are supplied by the apical and lower anterior segmental branches, with the upper and middle segmental branches supplying the remainder of the anterior surface of the kidney. Each segmental branch divides into lobar and subsequently into interlobar branches that course between the renal pyramids. At the corticomedullary junction, each interlobar artery divides into two arcuate arteries that terminate in interlobular arteries, which supply the inflow to the afferent arterioles in the glomeruli.

Anomalous anatomy of the renal arteries is common. The most common variations include[4,6]:

1. Variation in number of renal arteries (Fig. 12.4): Multiple renal arteries are very common, with 30% of patients having multiple renal arteries to a single kidney, and 10% of patients with multiple renal arteries to both kidneys. Some authors divide these "extra" renal arteries into two groups based on the course of the artery: accessory arteries course along the route of the main renal artery and enter the kidney at the hilum, whereas aberrant renal arteries have a distinct course to the main renal artery and enter the kidney from the renal capsule away from the hilum. Accessory and aberrant renal arteries typically arise from the lower thoracic and abdominal aorta, or iliac arteries. Less common sites of origin include the lumbar or mesenteric vessels. Accessory or aberrant renal arteries most commonly supply the upper or lower poles of the kidney.
2. Variation in branching pattern (Fig. 12.5): Prehilar branching of the main renal artery is seen in approximately 12% of individuals. This anatomic variant may complicate efforts to provide embolic protection during interventional procedures at the ostium of the main renal artery.

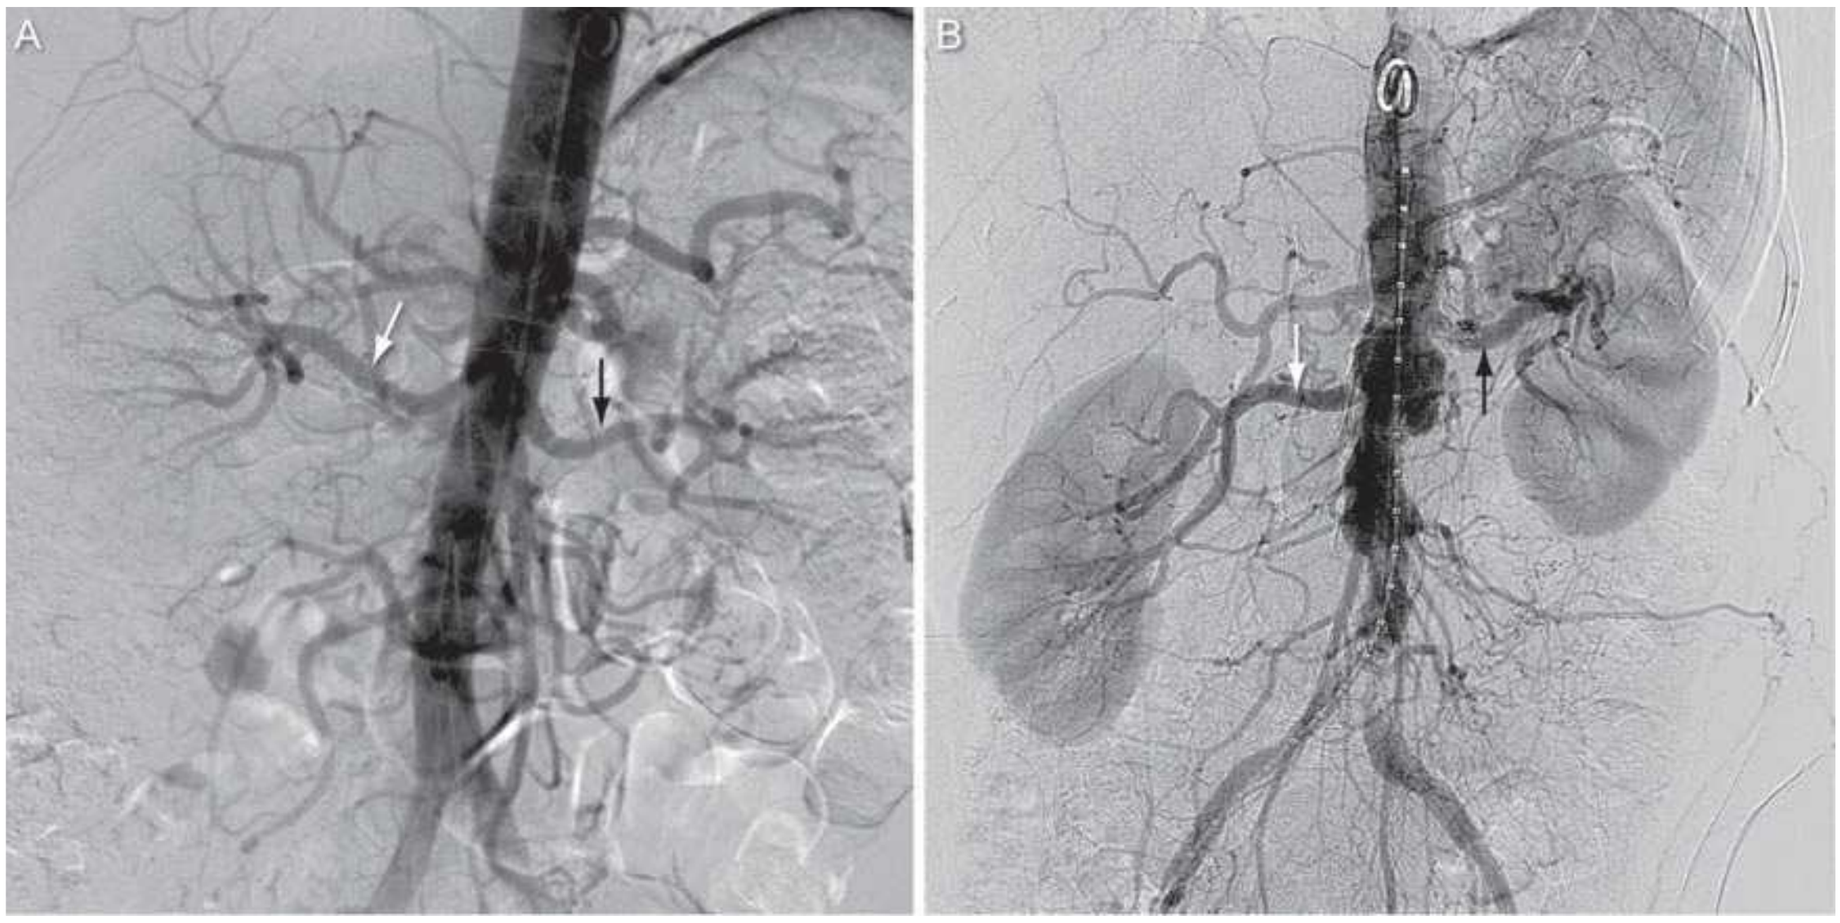

FIGURE 12.1 A,B: Abdominal aortograms from two separate patients showing origin of renal arteries from L2 level of abdominal aorta. Typical inferior course of right renal artery shown in Figure 12.1B. *White arrow*, right renal artery; *black arrow*, left renal artery.

Renal Vein

The venous drainage of each kidney generally parallels the arterial pattern. A single renal vein drains blood from each kidney in most individuals (Fig. 12.6). The renal vein lies anterior to the renal artery at the hilum and drains to the inferior vena cava (IVC), which is located to the right of the abdominal aorta. As a result, the length of the left renal vein is significantly longer than the right renal vein (6–10 cm versus 2–4 cm). In addition, the left renal vein must course between the superior mesenteric artery and the abdominal aorta in order to reach the IVC (Fig. 12.6). In contrast to the right renal vein, the left renal vein receives several tributaries, including the adrenal, gonadal, and lumbar veins.

FIGURE 12.2 Axial (i.e., cross-sectional) computed tomography image at level of L2 showing anterior (ventral) origin of right renal artery (*white arrow*) relative to the left renal artery (*black arrow*). *Interrupted black arrow*, superior mesenteric artery; *interrupted white arrow*, left renal vein; *Ao*, aorta; *LK*, left kidney.

Anomalous anatomy of the renal veins is common. The most common variations include:

1. Variation in number of renal veins: Multiple right renal veins have been reported in 15% to 30% of individuals.
2. Variation in course of renal veins: This variation is typically seen in the left renal vein. The most common variation is a circumaortic course, where the left renal vein divides into anterior and posterior limbs that encircle the abdominal aorta, and is estimated to occur in ~15% of individuals. Less commonly, the left renal vein has a completely retroaortic course, which is seen in 3% of individuals.

INVASIVE ANGIOGRAPHY OF THE RENAL CIRCULATION

Prior to reviewing the specifics of the technique of renal artery angiography, it is worth discussing the essential elements that are common to all renal angiographic procedures including the use of contrast agents and contemporary imaging systems for peripheral angiography.

Contrast Agents

The contrast agent most commonly used in current practice for renal artery angiography is Iodixanol (Visipaque, GE Healthcare). This agent has an osmolality that is similar to that of blood

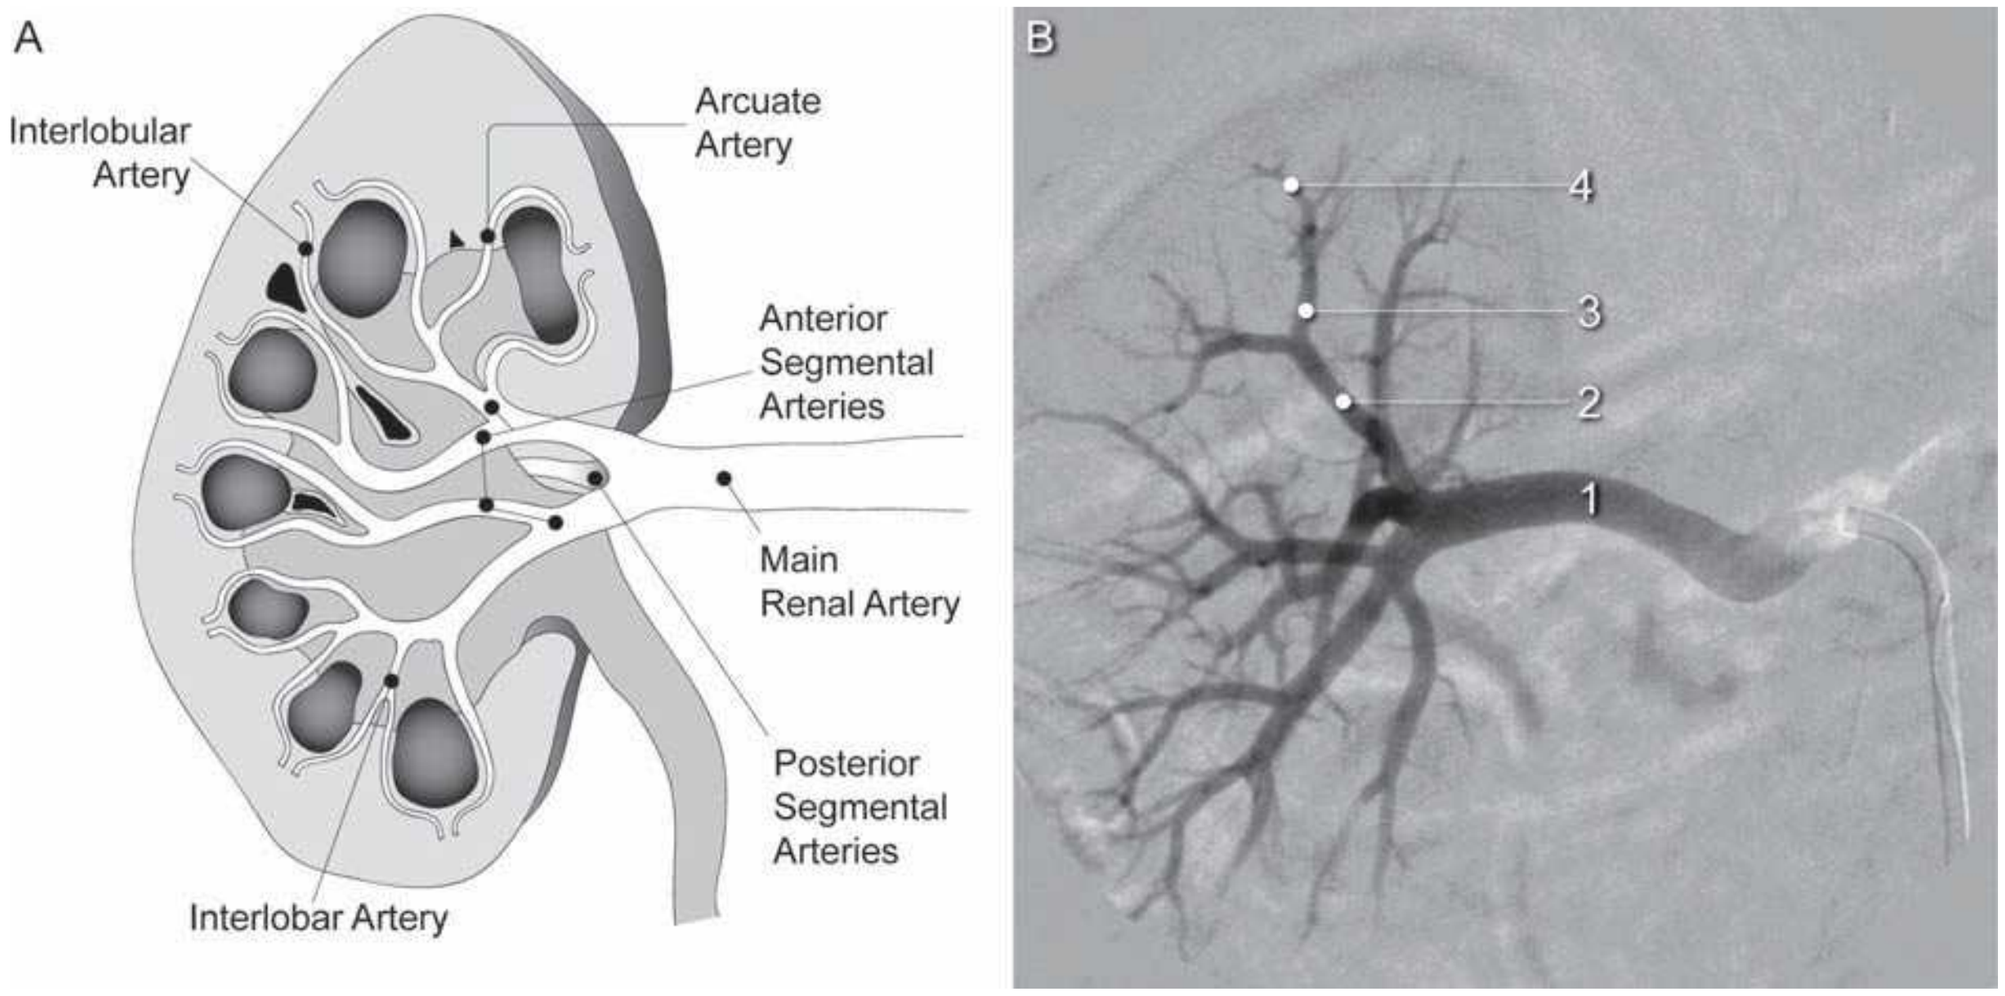

FIGURE 12.3 Renal artery anatomy. **A:** Schematic diagram of renal artery and its named subdivisions. **B:** Angiographic image of right renal artery. *1*, Main renal artery; *2*, segmental artery; *3*, interlobar artery; *4*, arcuate artery.

(i.e., 300 mOsm per kg H_2O), which differentiates it from low (620–790 mOsm per kg H_2O) and high (>1,700 mOsm per kg H_2O) osmolar agents and results in significantly improved tolerance by patients.[7] Although Iodixanol has a lower iodine concentration compared to low and high osmolar contrast agents, the impact on the imaging characteristics achieved with this agent is negligible, especially when contemporary imaging equipment is utilized. Iodixanol has the highest viscosity of all the available contrast agents which can make intravascular injections difficult, especially when performing hand injections using small caliber catheters. This impact can be minimized by warming the agent to 37°C prior to injection, which is standard practice in most angiographic laboratories, and using automated systems for contrast injection

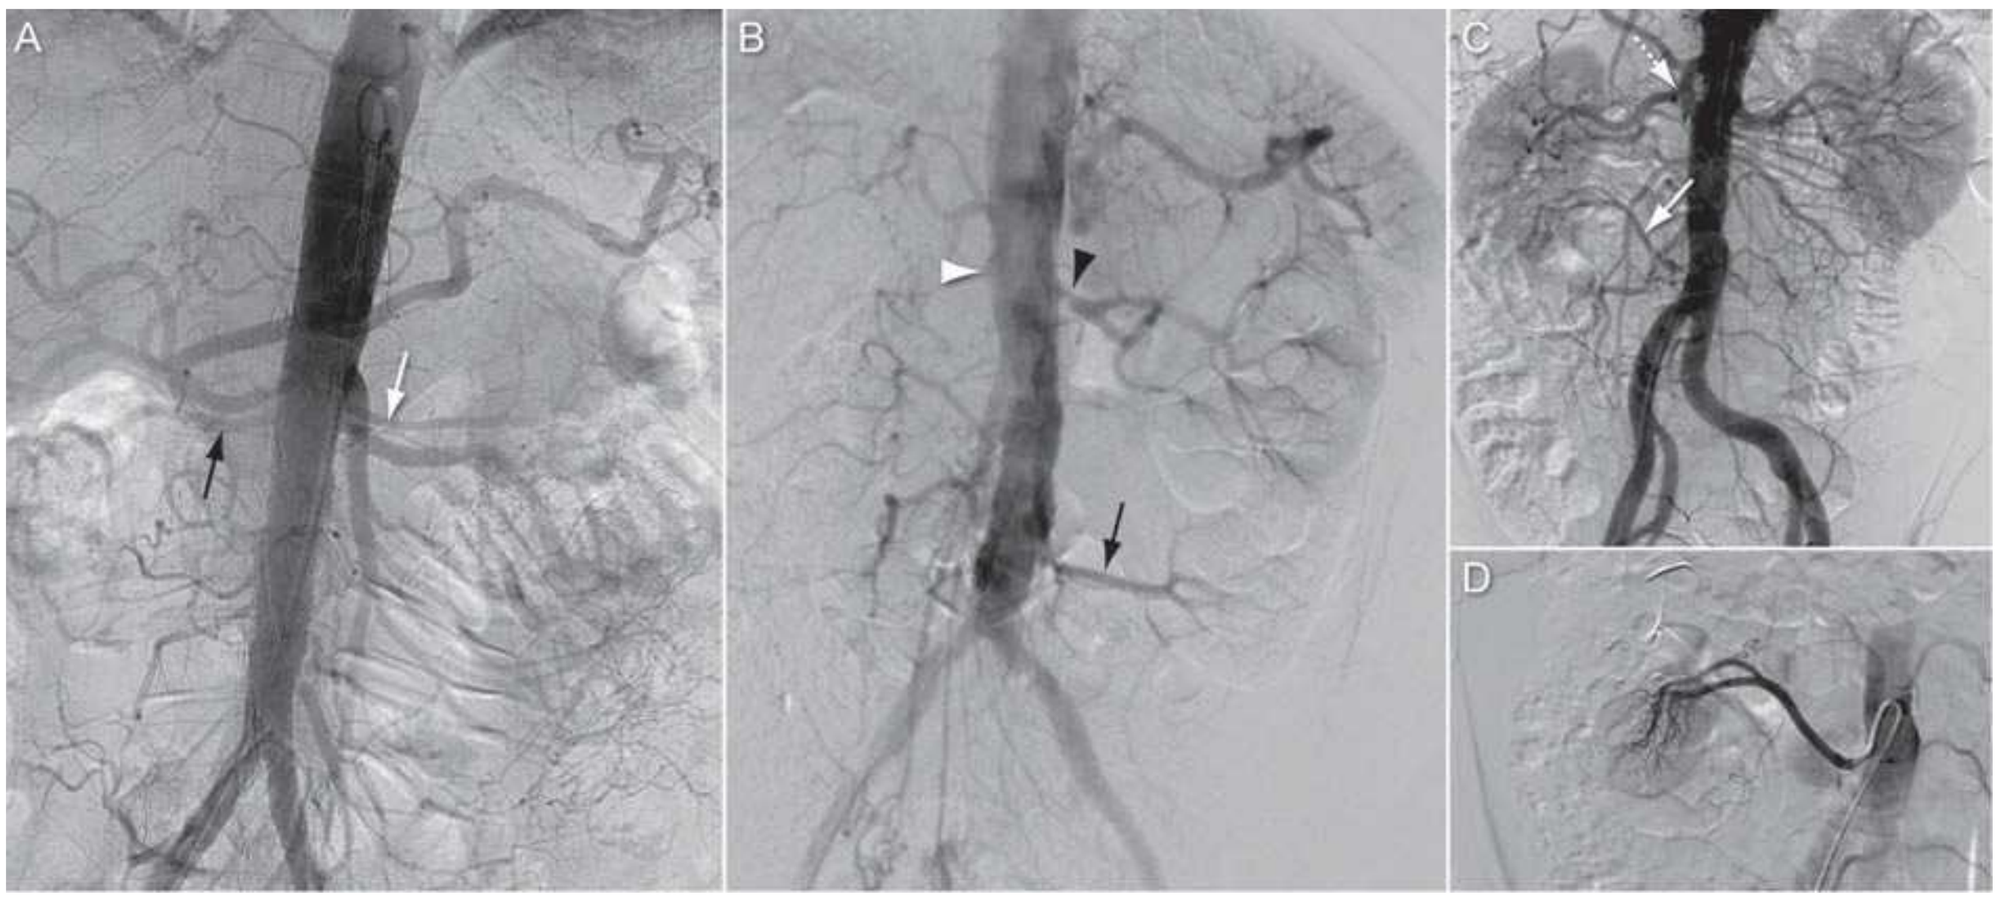

FIGURE 12.4 Multiple renal arteries. **A:** Abdominal aortogram from patient with bilateral accessory renal arteries. *Black arrow*, right lower accessory renal artery; *white arrow*, left upper accessory renal artery. **B:** Abdominal aortogram from patient with aberrant left renal artery arising from lower segment of abdominal aorta just above the aortoiliac bifurcation (*black arrow*). *White arrowhead*, occluded right renal artery; *black arrowhead*, severe stenosis at origin of left main renal artery. **C:** Abdominal aortogram from patient with aberrant right renal artery arising from lower segment of abdominal aorta just above the aortoiliac bifurcation (*white arrow*). *Interrupted white arrow*, right main renal artery. **D:** Selective angiogram of aberrant right renal artery from patient shown in Figure 12.4C.

(e.g., ACIST CVi, ACIST Medical Systems, Eden Prairie, MN; and Avanta, MEDRAD Inc., Warrendale, PA).

Alternate contrast agents have been used for patients with severe renal insufficiency in whom the risk of contrast-induced nephropathy is significant and in those with an allergy to iodinated contrast agents, Carbon dioxide (CO_2) has been used as an intra-arterial contrast agent since the early 1970s. However, it wasn't until the introduction of digital subtraction angiography (DSA) (see later text) in 1980 that CO_2 angiography became a useful diagnostic tool (Fig. 12.7).[8] In general, CO_2 angiography is well suited to imaging of large caliber vessels below the level of the diaphragm such as the abdominal aorta, aortoiliac segment, and proximal segments of major branches from the abdominal aorta (including renal arteries).[9] Imaging of smaller caliber vessels is problematic, and images must be acquired at a high frame rate to ensure acquisition of the image before dissipation of the gas.

The use of gadolinium-based contrast agents for intra-arterial angiography has largely been abandoned in current practice due to the emergence of nephrogenic systemic fibrosis as a potential complication of exposure to this agent in patients with significant renal insufficiency.[10–12] Similar to CO_2 angiography, angiography with gadolinium provides reasonable diagnostic data in larger caliber vessels and requires a high frame rate for image acquisition.

Imaging Systems

The basic image equipment requirements for acquisition of angiographic images of the peripheral circulation (including renal circulation) includes an image chain that consists of a generator and X-ray tube located beneath the table on which the patient is positioned, and an image intensifier, optical distributor, and camera located above the patient (Fig. 12.8). Real-time presentation of the angiographic image is generated on a monitor located within view of the operator. Over the last decade, a number of advancements in the imaging chain, most notably the introduction of flat panel technology in image intensifiers and the digitization of image processing, have enhanced the quality of the images generated.

In addition to this basic imaging chain, the technology of digital subtraction angiography (DSA) is fundamental to imaging of the cardiovascular system. Although this technique was developed in the 1970s, continued refinement of the technology used to generate DSA imaging has occurred providing additional improvements in image quality and functionality. In essence, the technique of DSA involves the acquisition of X-ray images before the administration of the contrast agent and during opacification of the vessel of interest following the intra-arterial injection of contrast proximal to the vessel segment of interest.[9,13] Processing of the images is then performed that involves subtracting the background X-ray image (referred to as the "mask" image) that displays bony and soft tissue structures from the X-ray image during vessel opacification, resulting in an image that displays vessel opacification alone (Fig. 12.9). The technique requires that no significant motion (e.g., patient motion, respiratory motion, peristalsis) occurs between the acquisition of the background image and vessel opacification. DSA represents the gold standard for imaging of the vascular tree, including the renal circulation.

Renal Artery Angiography Technique

With the advances in CT and MR angiography, diagnostic angiography of the renal arteries is typically performed to confirm the diagnostic findings of these noninvasive anatomic imaging modalities prior to planned interventional procedures.[1,2] However, in clinical practice, there remains a subset of patients with significant renal insufficiency who require

invasive angiography for diagnostic purposes due to thresholds of serum creatinine (Cr) and eGFR (i.e., Cr > 1.5 mg per dl, eGRF <60 mL per min) utilized by most radiology departments for exposure of patients to iodinated contrast and gadolinium-based contrast agents that are used for CT and MR angiography, respectively.

A necessary preamble to renal artery angiography is the establishment of arterial access. In most circumstances, this is obtained in the right or left common femoral artery (CFA). Less commonly, the brachial or radial artery may be used. The advantages and disadvantages to these various access sites are outlined in Table 12.1.

Depending on the clinical situation (e.g., preprocedural imaging, baseline renal function, procedural indication), abdominal aortography may be performed prior to selective renal artery angiography. This is achieved by placing a flush catheter with multiple side holes at the level of the T12 vertebra and injecting contrast at 20 mL per sec for a total of 40 mL (Fig. 12.10). The abdominal aortogram provides information about the location of the renal artery ostia and the condition of the abdominal aorta (e.g., presence of atherosclerosis) and its major branches.

Selective angiography of the renal arteries is performed by using catheters with preformed shapes to facilitate selective engagement of the renal artery ostia (Fig. 12.11). A variety of catheters are available for this purpose. The choice of a specific catheter is determined by the anatomy of the abdominal aorta, the location of the renal artery ostium, the course of the proximal segment of the renal artery, the arterial access site used, and the experience of the operator. In the authors' practice, the most commonly used catheters when approaching the renal artery from the CFA access site are the

12.1 Advantages and Disadvantages of Various Arterial Access Sites for Renal Artery Angiography and Intervention

Access Site	Advantages	Disadvantages
Femoral	• Large caliber vessel with low risk of ischemic complication	• Greatest risk of bleeding complication • Difficult engagement of renal artery with prominent inferior course of proximal segment
Brachial	• Medium caliber vessel. Easier to access than radial and accomodates larger caliber sheath	• Moderate risk of both bleeding and ischemic complications
Radial	• Lowest risk of significant bleeding complications • No risk of ischemic complication in presence of negative Allen's test • Well suited for engagement of renal artery with inferior course of proximal segment	• Small caliber typically limits use of sheath sizes of no greater than 6-French which may limit ability to deliver certain interventional devices

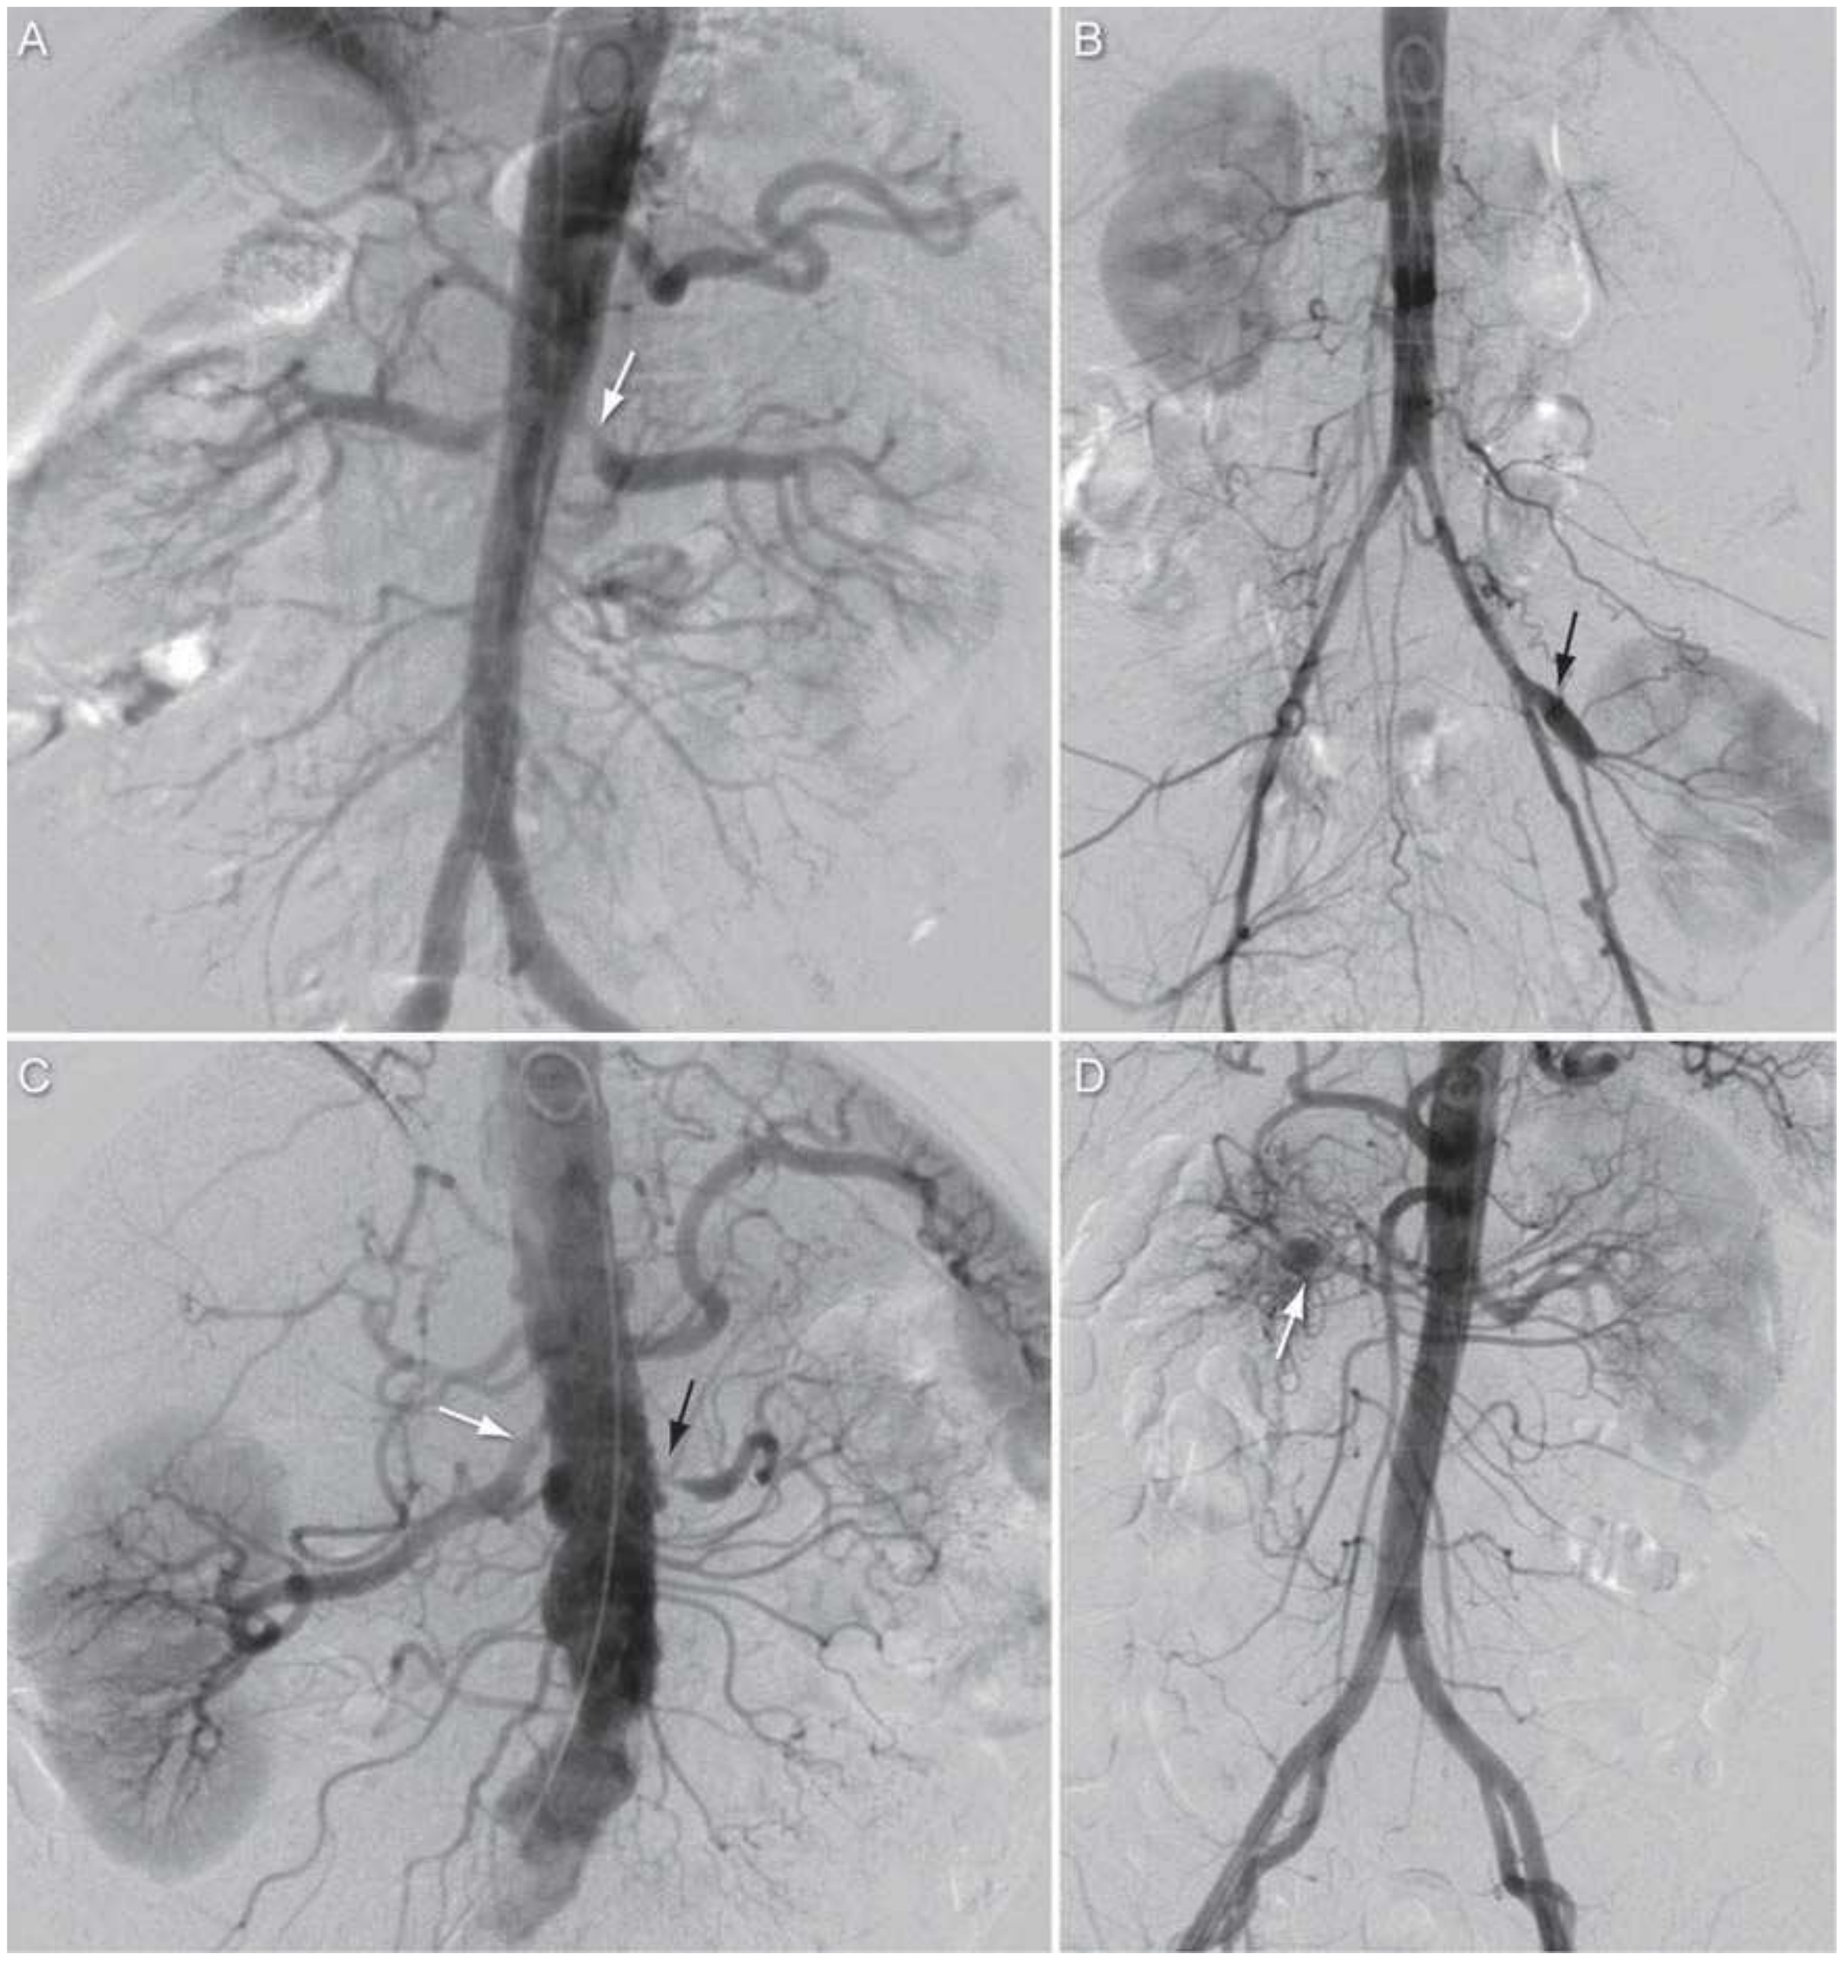

FIGURE 12.10 Examples of abdominal aortograms performed prior to selective renal artery angiography. **A:** Severe stenosis at origin of left main renal artery (*arrow*). **B:** Transplanted kidney with vascular origin from left external iliac artery (*arrow*). Native left renal artery presumed to be occluded based on absence of left renal nephrogam. **C:** Severe atherosclerosis is evident in the abdominal aorta. Critical stenosis noted at origin of left renal artery (*black arrow*). Right renal artery indicated by *white arrow*. **D:** Normal abdominal aorta and left renal artery. Aneurysm of right renal artery noted (*arrow*) with poor opacification of the right renal nephrogram.

Sos, Simmons, Cobra, and JR4 catheters. When approaching from the upper extremity access sites, the most commonly used catheter is the multipurpose catheter (Fig. 12.12).

Images are acquired using DSA. Typically, adequate imaging of the renal arteries is achieved by injecting contrast at 4 mL per sec for total of 8 mL through the catheter. Due to the anterior and posterior location of the right and left renal ostia, respectively, the ostia and proximal segments of both renal arteries are best visualized with the image intensifier in the left anterior oblique projection.[3] Delayed imaging is generally performed to allow visualization of the nephrogram, which provides an estimate of the renal size and the contour of the kidney (Fig. 12.13). In certain clinical situations (e.g., aneurysmal disease), imaging in multiple planes or rotational angiography may be required to elucidate the precise relationship of the pathology to branch points, which can influence treatment decisions.

RENAL ARTERY INTERVENTION

In current practice, the majority of renal artery intervention is performed for the treatment of atherosclerotic disease, and to a lesser extent FMD, and will thus constitute the major

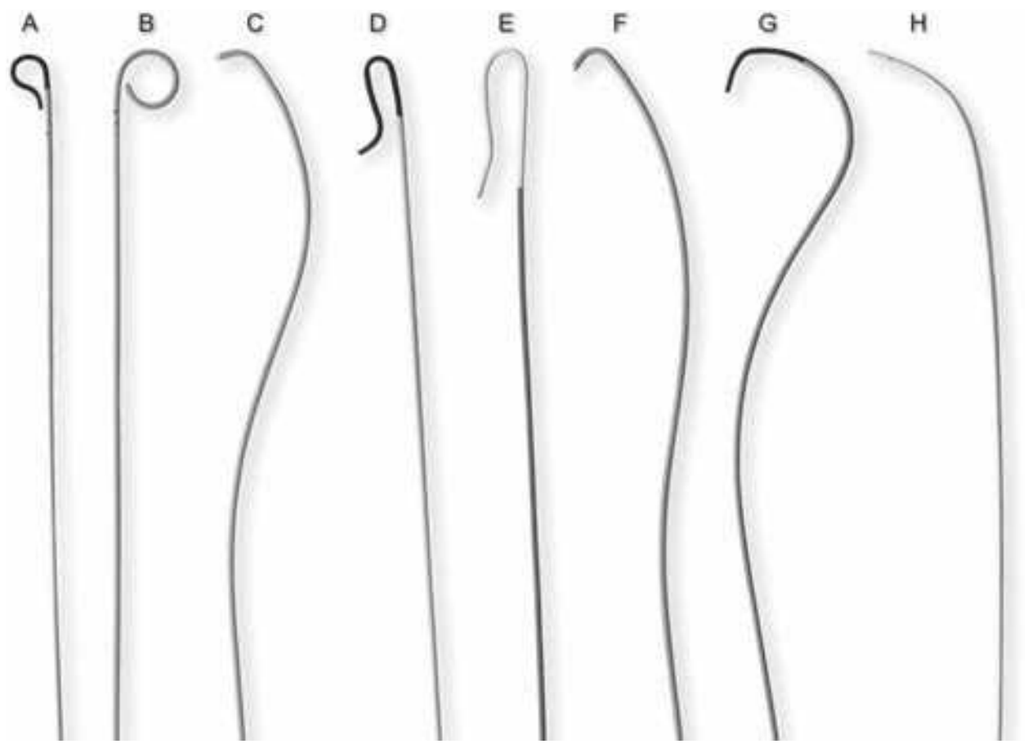

FIGURE 12.11 Catheters used to perform abdominal aortography **(A,B)** and selective renal artery angiography **(C–H)**. **A:** Omni flush, **(B)** pigtail, **(C)** JR4, **(D)** Sos, **(E)** Simmons, **(F)** internal mammary, **(G)** Cobra, and **(H)** multipurpose.

focus of this section. Less commonly treated pathologies are briefly discussed. Finally, the emerging therapy of renal artery denervation is outlined as there is considerable excitement about the potential of this therapy in the treatment of an array of medical renal disorders.

Atherosclerotic Disease

Atherosclerotic disease of the renal arteries is a common entity, particularly in patients with HTN (prevalence of 1% to 5%) and in those with documented atherosclerotic disease in other vascular territories (prevalence of 30% to 40%). Roughly 90% of all cases of renal artery stenosis (RAS) are due to atherosclerotic disease, which is characterized by a typical location at the renal artery ostium or proximal segment of the main renal artery (Fig. 12.14). This is due to the fact that renal artery atherosclerosis typically reflects an extension of atherosclerosis involving the abdominal aorta (Fig. 12.15).

The most challenging component of renal artery intervention for atherosclerotic RAS is case selection, rather than the execution of the intervention itself. Ischemic nephropathy is a complex entity, and considerable controversy exists over the appropriateness of renal revascularization for this disease.[14–16] Unfortunately, randomized trials comparing medical therapy with renal artery intervention have not proved to be particularly helpful in defining the patient populations that benefit from revascularization. In the absence of such guidance, the authors attempt to identify those patients who are most likely to benefit from revascularization for atherosclerotic RAS by asking two fundamental questions:

1. Is the patient's clinical condition being caused by atherosclerotic RAS?
2. If so, is there a reasonable chance that revascularization will have a meaningful clinical benefit?

The answer to the first question is typically answered by the nephrologist taking care of the patient and is provided by matching the patient's clinical presentation (e.g., resistant HTN, acute renal failure with initiation of angiotensin converting enzyme inhibitor, flash pulmonary edema in the setting of uncontrolled HTN, acute or subacute renal failure) with the anatomy of the RAS (unilateral vs. bilateral, severity of stenosis) and anatomic and functional data regarding the parenchymal function and perfusion of each kidney.

The second question is typically arrived at following a discussion between the nephrologist and interventionalist. In general, it is felt that the more severe the RAS, and the less severe the parenchymal disease in the affected kidney, the more likely that revascularization of the main renal artery is likely to have a clinical impact on the patient. The variables that are used to help make this determination and their impact on clinical outcomes following renal revascularization are summarized in Table 12.2. It should be accepted that these variables are most useful when the goal of intervention is to preserve renal function. When the goal of intervention is to improve the control of HTN,

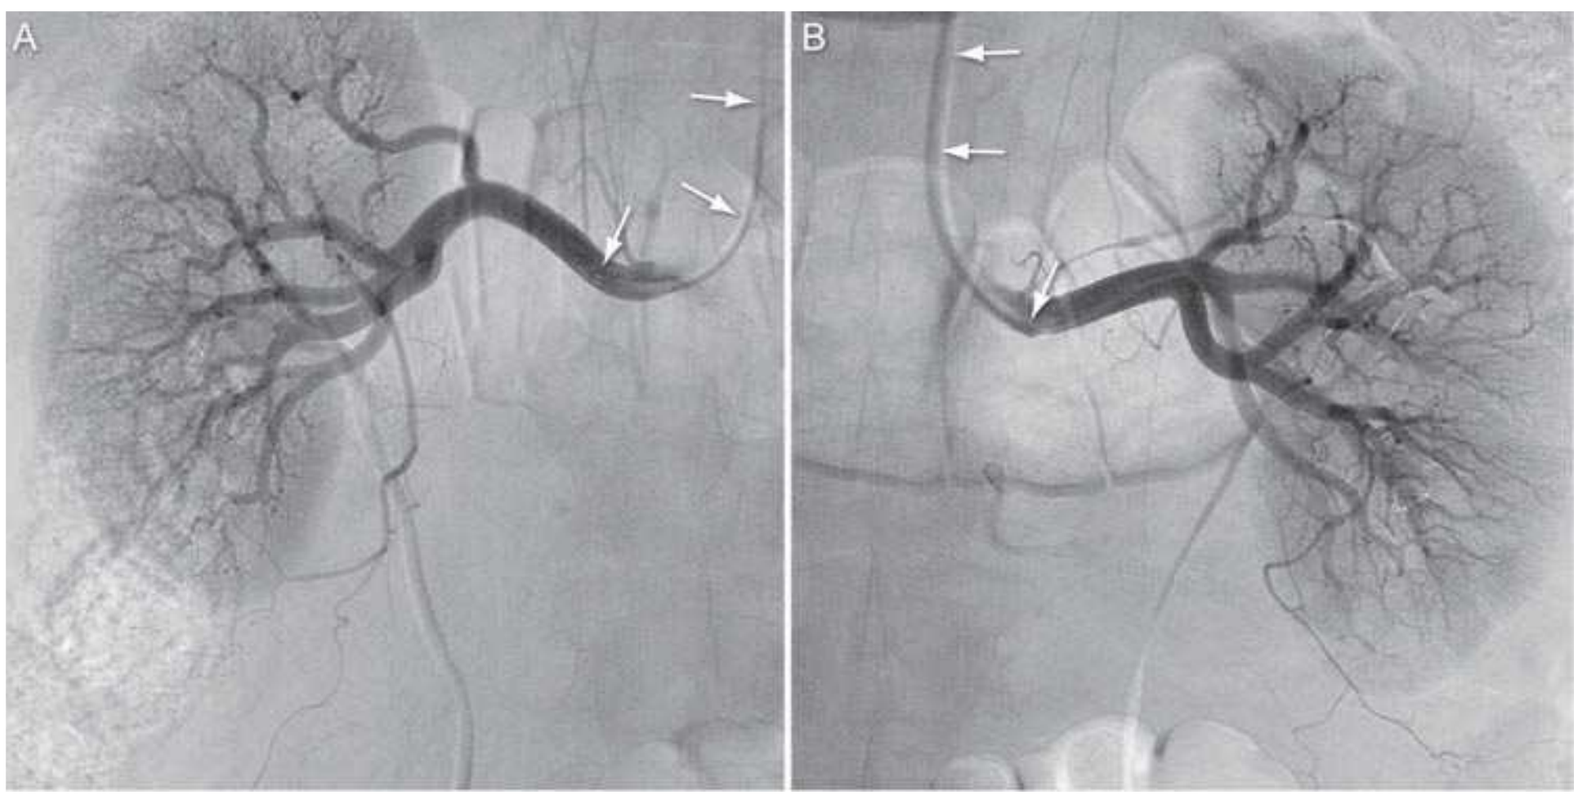

FIGURE 12.12 Selective angiography of the right and left renal arteries using upper extremity access and multipurpose catheter (*white arrows*).

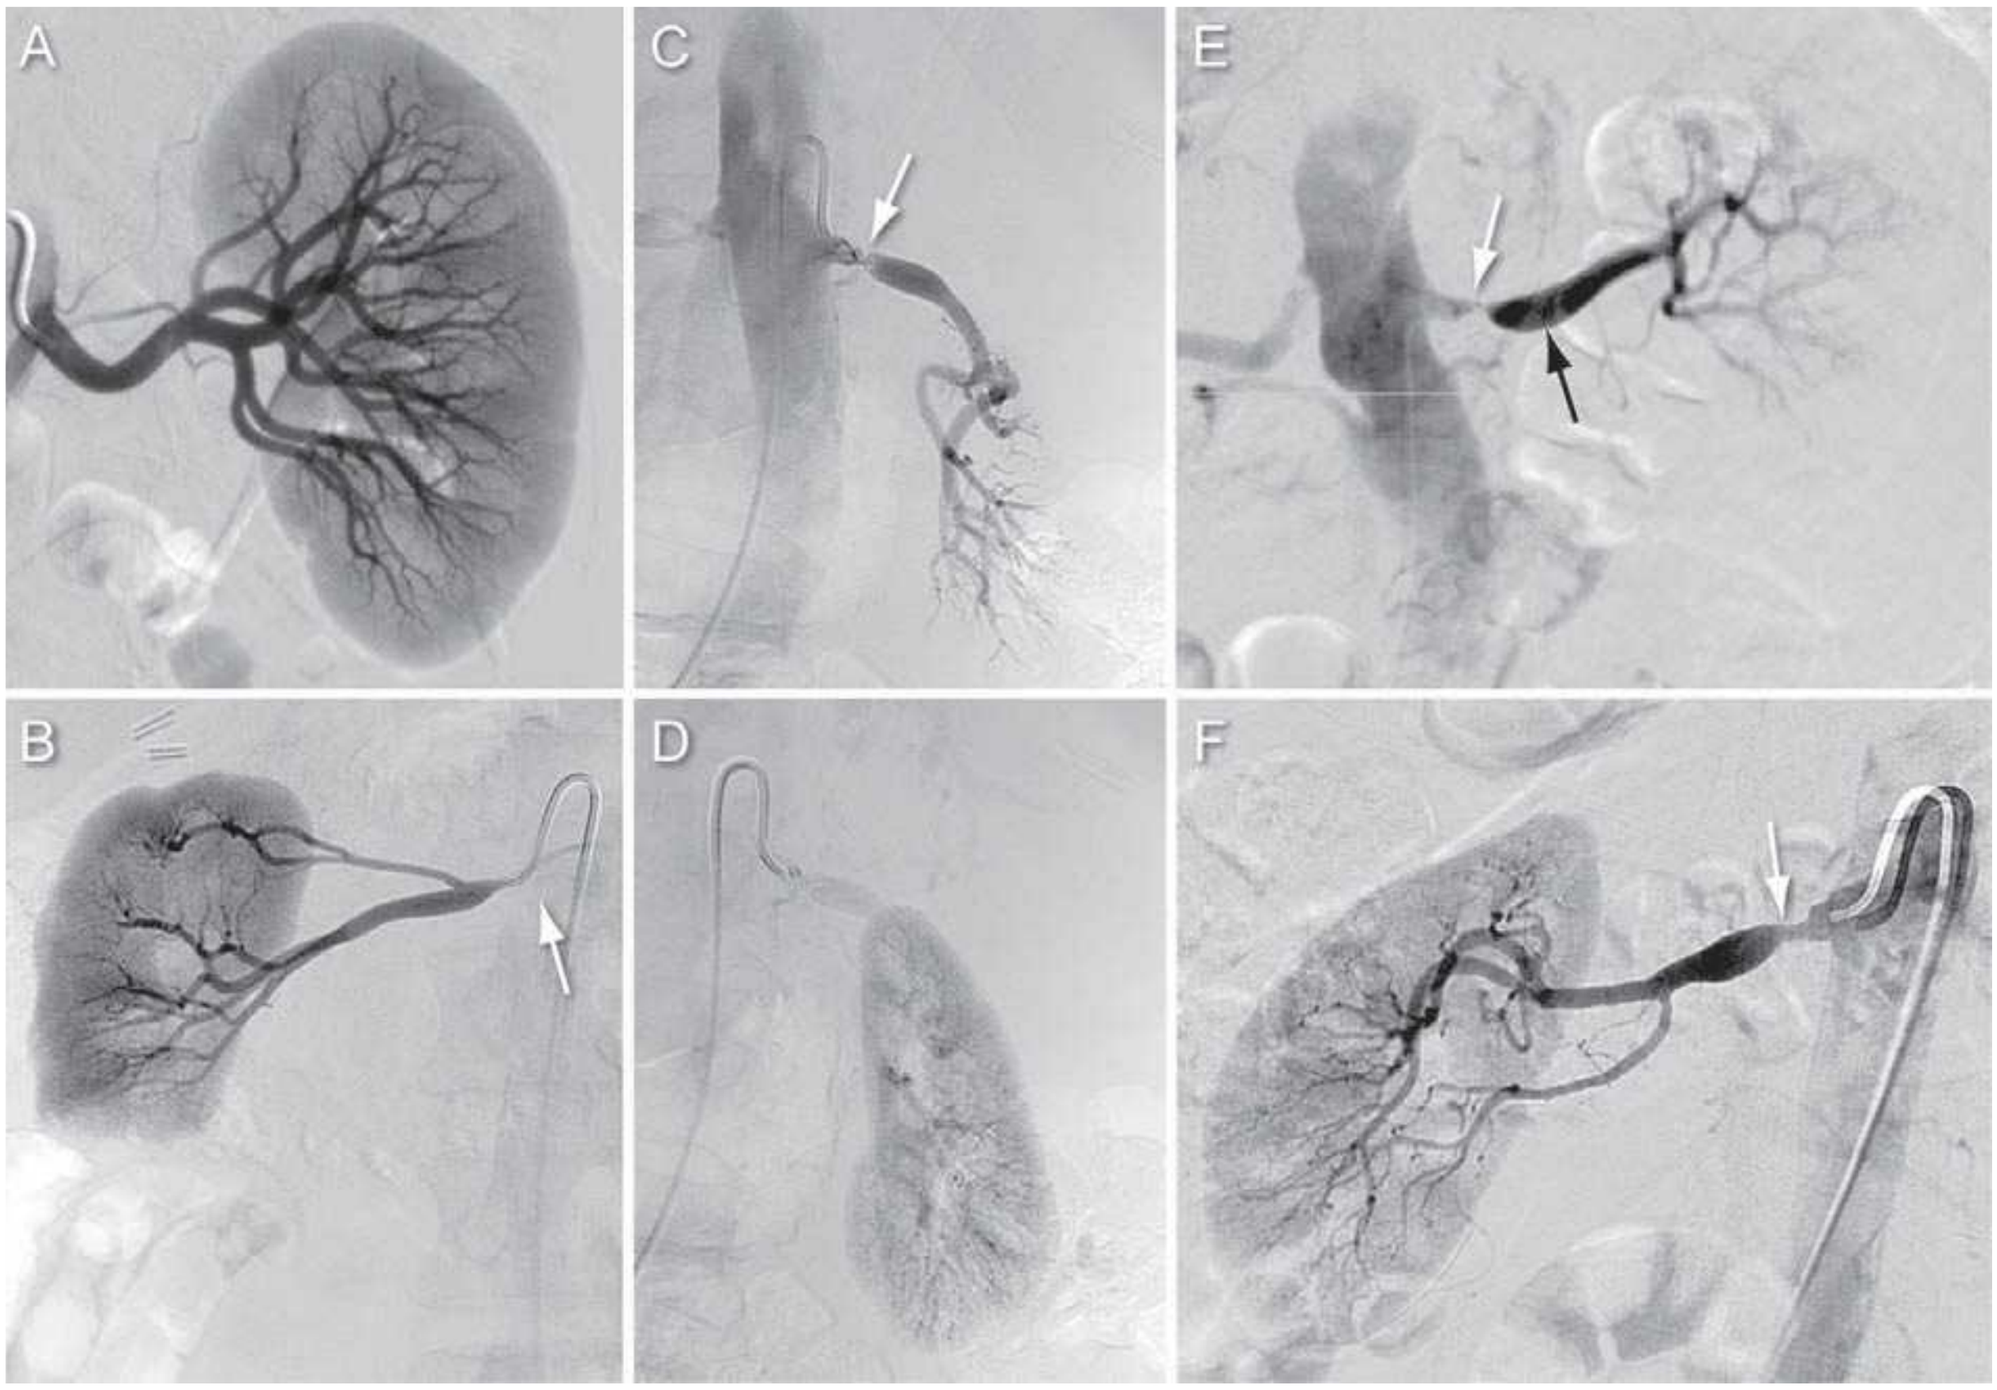

FIGURE 12.13 Spectrum of angiographic findings on renal artery angiography in patients with renal artery atherosclerosis. **A:** Angiogram of left renal artery in a 35-year-old woman without renal artery atherosclerosis to serve as comparison. decision-making is more complicated, as it can be very difficult to predict the effect of revascularization on renin output from a severely ischemic kidney that may have little parenchymal function.

Execution of Intervention for Atherosclerotic RAS

Arterial access is obtained in the common femoral artery (CFA) or upper extremity artery. A guide catheter is used to engage the ostium of the culprit renal artery (Fig. 12.16). Guide catheters are significantly stiffer than diagnostic catheters and have a greater potential for causing injury to the aorta or renal artery ostium. Because atherosclerotic disease of the renal artery is typically a manifestation of aortic atherosclerosis that encroaches on the renal artery, great care with manipulation of guide catheters in the abdominal aorta is warranted in order to prevent atheroembolism to the lower extremity, mesenteric, and/or renal arteries. A variety of techniques (e.g., no-touch technique) have been described that minimize this manipulation.[17]

Once the guide is engaged at the ostium of the renal artery, an interventional wire is advanced into one of the segmental vessels. In current practice, 0.014-inch wires with atraumatic coil tips are typically used.[18] The stenosis is dilated with an angioplasty balloon with a balloon-artery ratio of ~0.8. Regardless of the initial result with angioplasty, the lesion is then typically stented using a balloon-expandable stent (Fig. 12.17). This is based on two considerations: (1) stenting achieves a highly predictable acute result by overcoming the issue of elastic recoil and treatment of any dissections that can lead to subsequent abrupt vessel occlusion, and (2) stenting reduces the high rate of restenosis that is seen with angioplasty alone.[19] Most of these stents are composed of stainless steel, but a small minority are of composed of cobalt-chromium. Balloon-expandable stents are

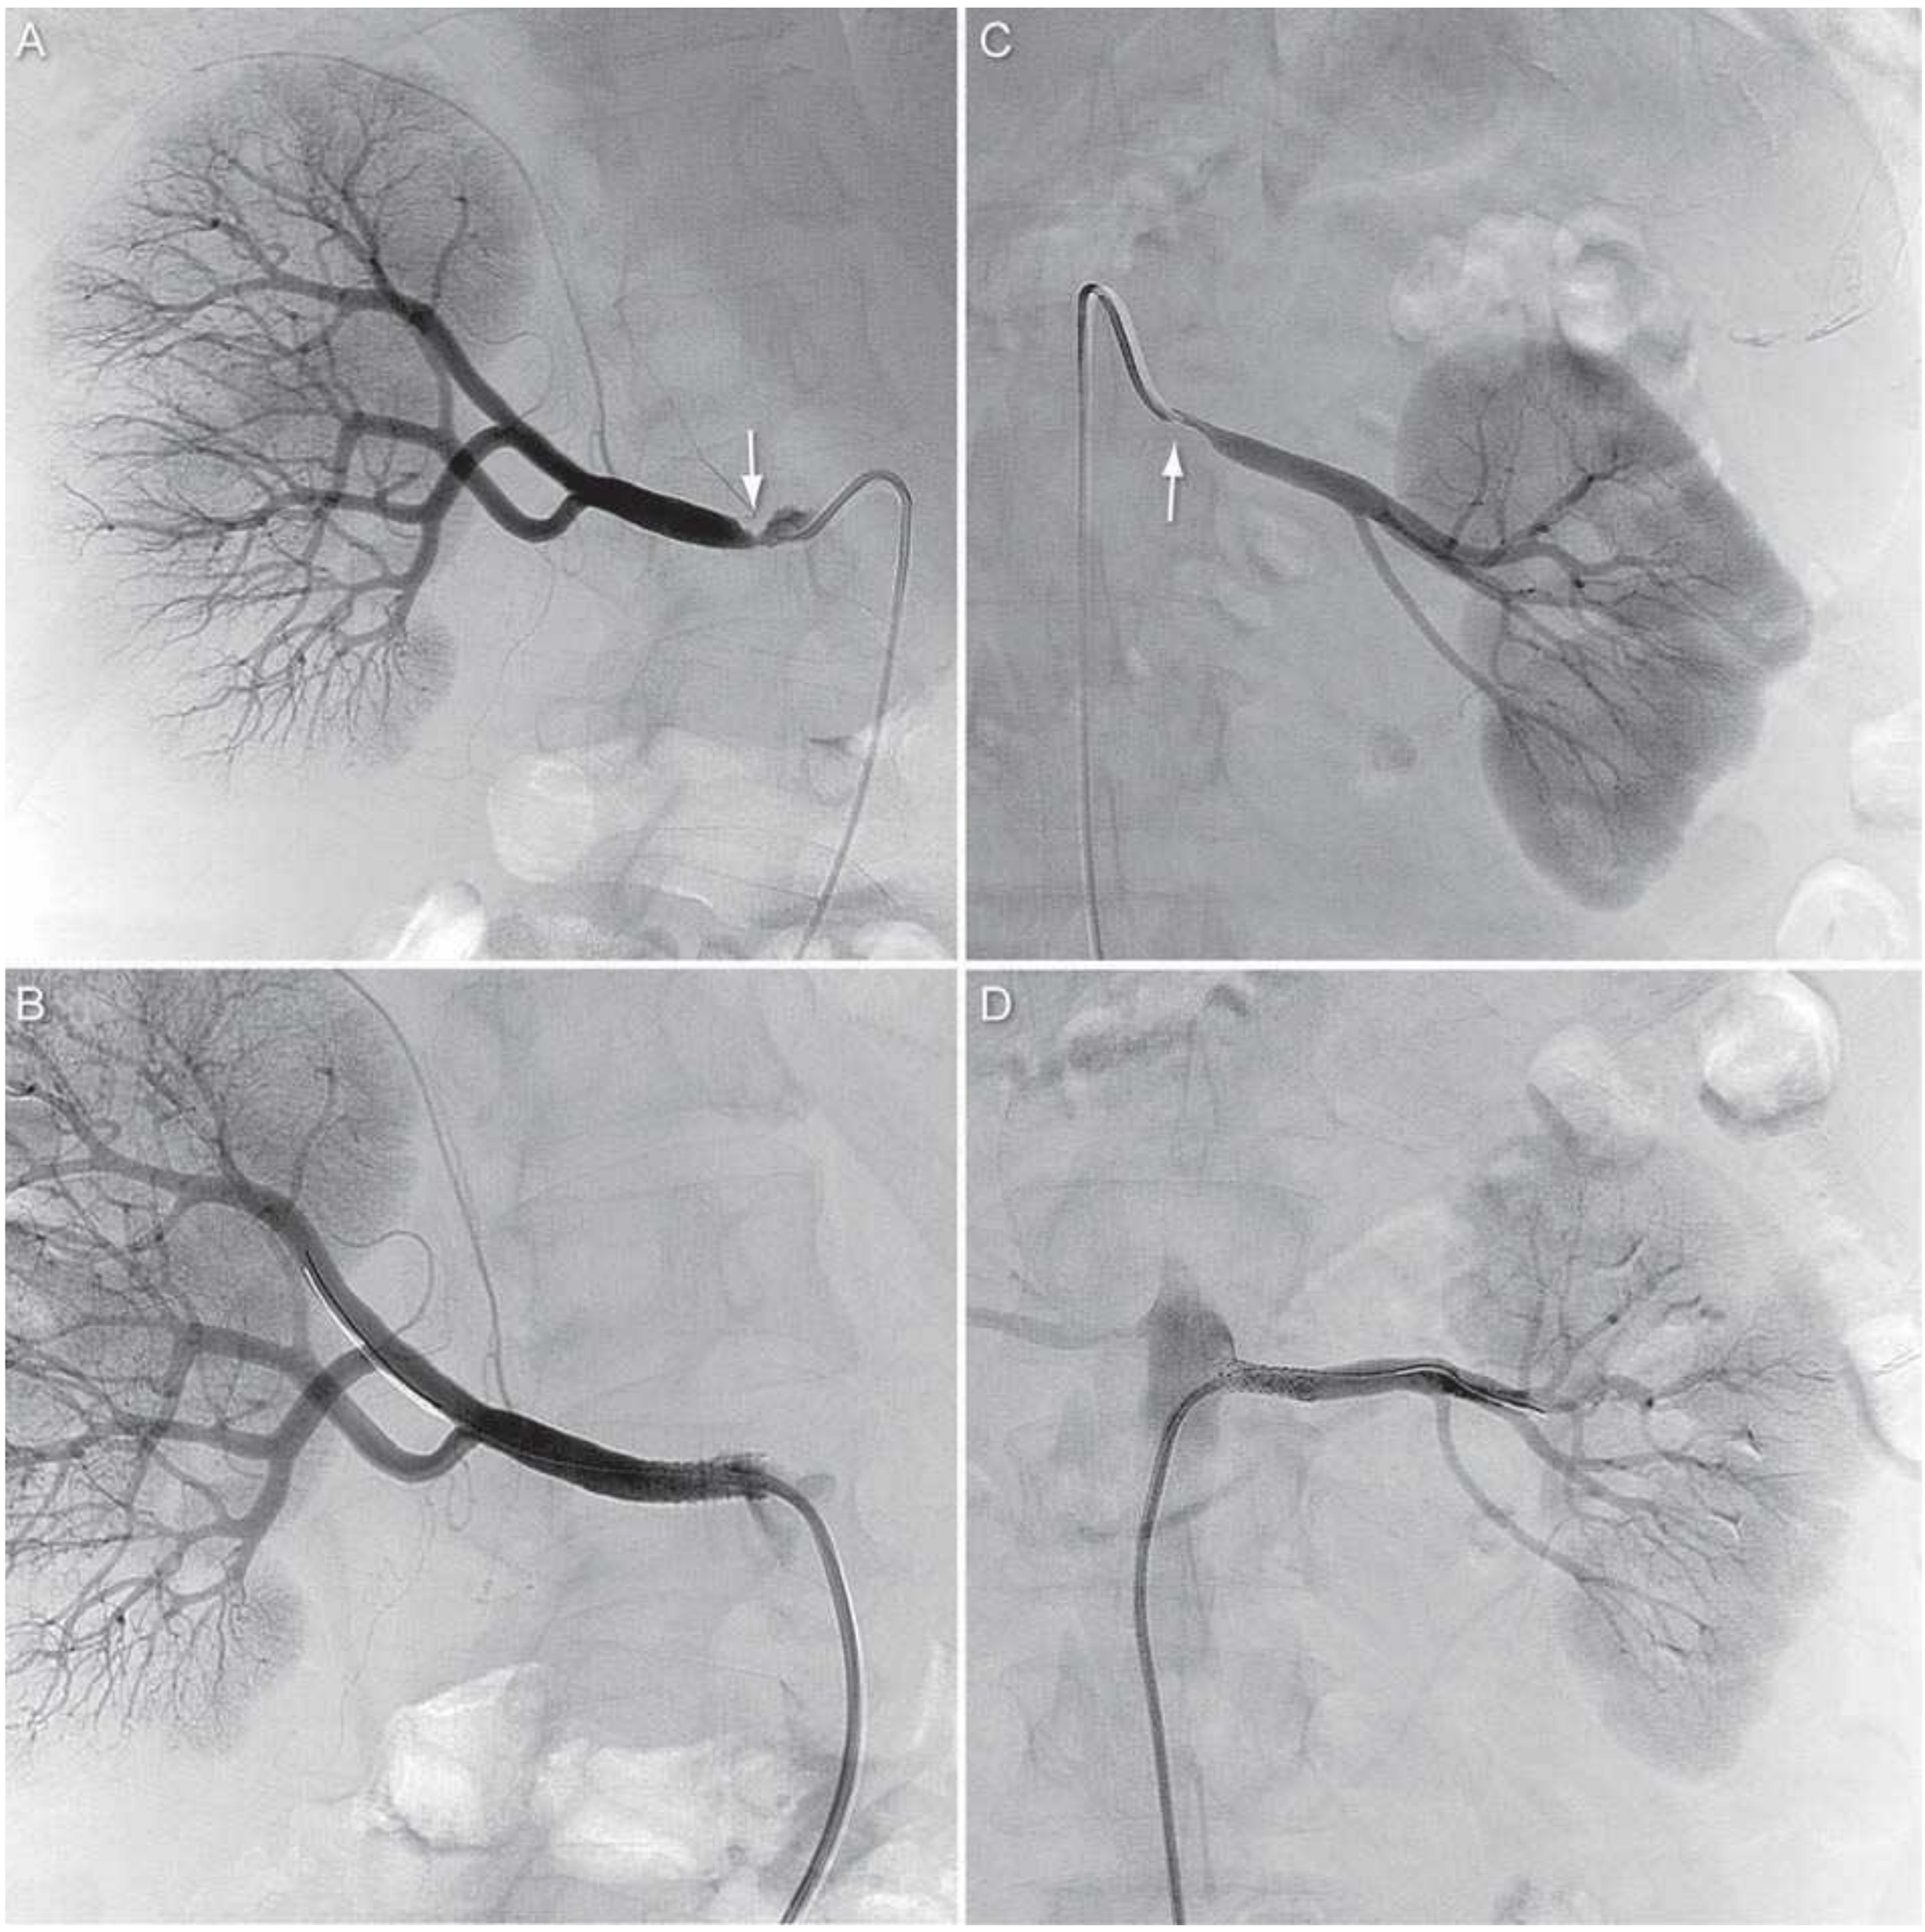

FIGURE 12.14 Examples of renal artery atherosclerotic lesions treated with balloon-expandable stents. **A,B:** Baseline and poststenting angiograms, respectively. **C,D:** Baseline and poststenting angiograms, respectively.

used in this location because of their high radial strength, which is an important consideration at the ostial location. Positioning the stent such that the ostium of the renal artery is covered by stent is a critical component of renal artery stenting. This will generally result in 1 to 2 mm of the stent projecting out into the abdominal aorta. Failure to achieve this objective is associated with high rates of restenosis. The stent is typically postdilated using a noncompliant balloon with a balloon–artery ratio of ~1.0.

The use of embolic protection during renal artery intervention is inconsistent in current practice. In theory, these devices should help prevent atheroembolism to the kidney as a result of angioplasty and stenting, and thus improve the safety of renal artery intervention by minimizing any adverse impact on renal function. Filter-type embolic protection devices have been used with good clinical success.[20–22] A broad range of these devices are available for use, based on U.S. Food and Drug Administration (FDA)-approved indications for use in saphenous vein graft intervention in the coronary circulation,[23–25] and during stenting of the carotid artery (Fig. 12.18).[26,27] Technical challenges associated with their use in the renal artery include the absence of a sufficient landing zone for placement of filter, the presence of early branching of the renal artery preventing embolic protection of both branches, renal artery diameters that exceed the recommended diameter recommendations

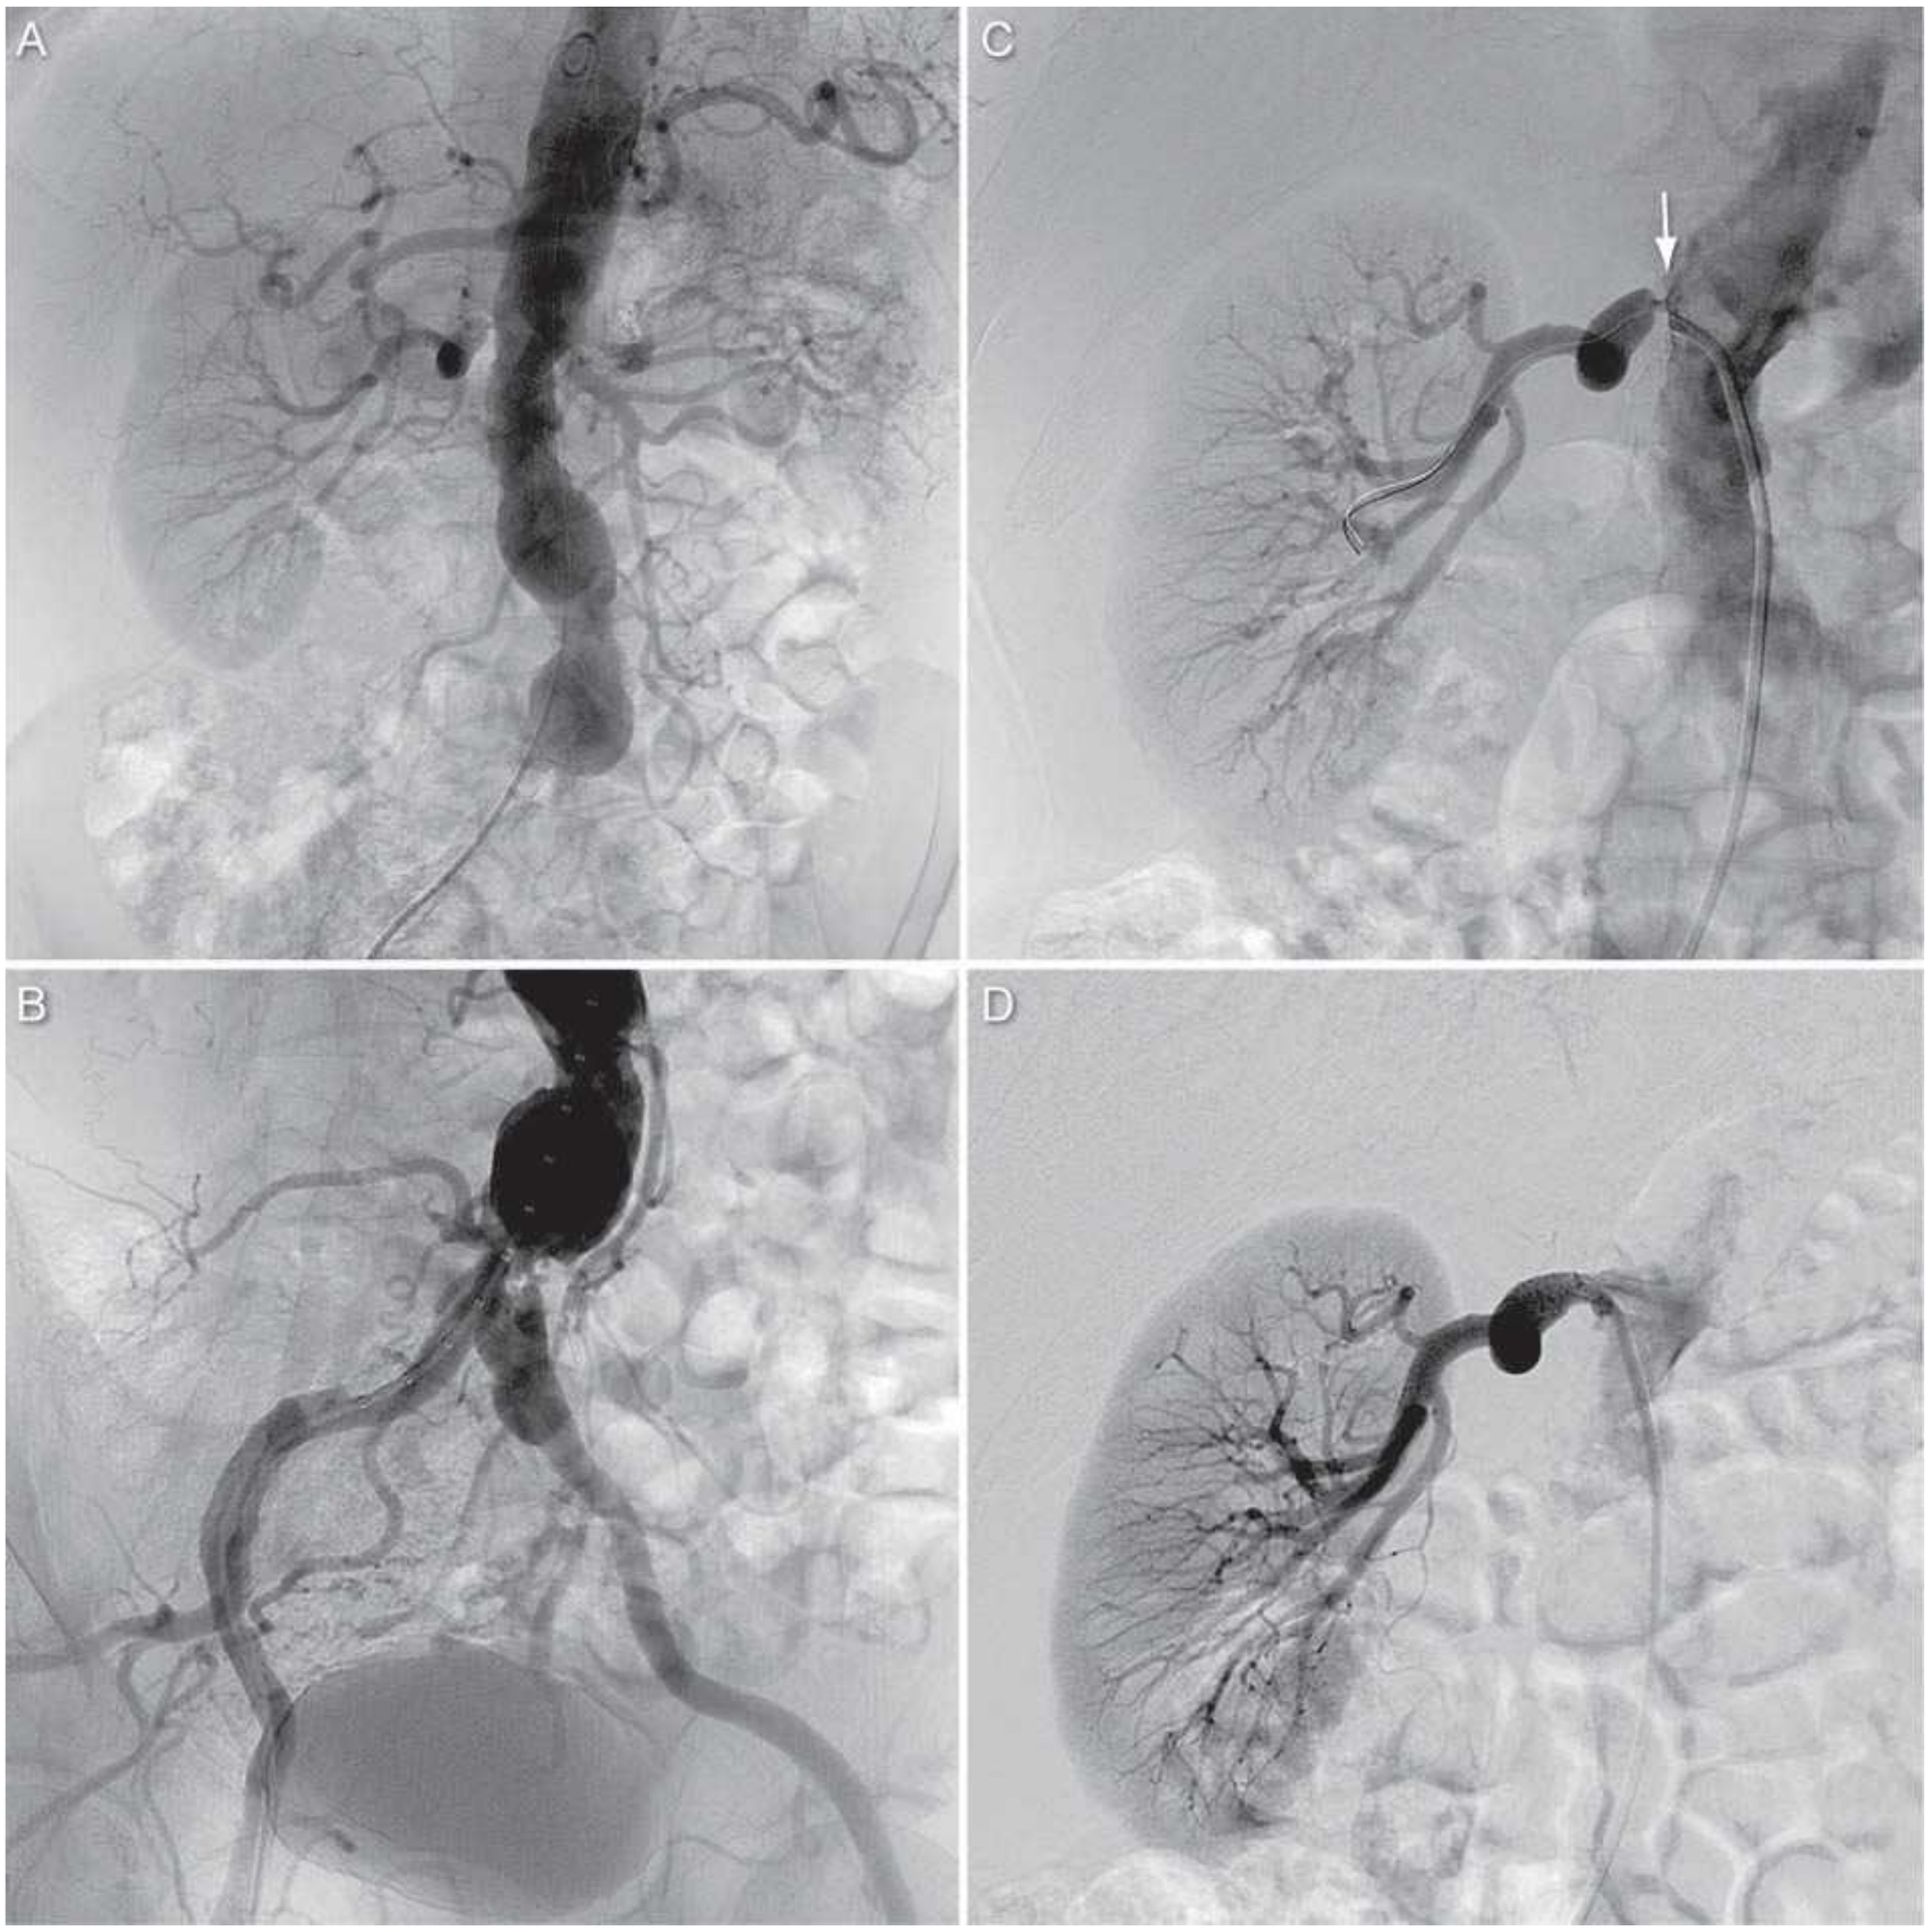

FIGURE 12.15 Clinical case reinforcing concept that renal artery atherosclerosis represents extension of atherosclerosis in the abdominal aorta. **A:** Abdominal aortogram showing extensive atherosclerosis and areas of ectasia. **B:** Pelvic angiogram showing severe stenosis at the aortoiliac bifurcation. **C:** Selective angiogram of right renal artery showing critical stenosis at ostium of right renal artery. **D:** Selective right renal artery angiogram following placement of balloon-expandable stent.

for filter use, and difficulty in delivering the filter through critical stenoses without prior angioplasty. Assuming the absence of these technical issues, it seems reasonable to recommend the use of these devices during renal artery intervention for atherosclerotic RAS, particularly when treating patients with a single functioning kidney, and when baseline renal function is impaired to a degree that even small amounts of atheroembolism would be poorly tolerated.

All renal artery interventions for atherosclerotic RAS are performed using anticoagulation (e.g., unfractionated heparin, bivalirudin) to prevent device-related thrombosis during the procedure. Following the procedure, all patients receive lifelong aspirin (81–162 mg daily) and statin therapy (based on the diagnosis of atherosclerotic disease) and our practice is to recommend clopidogrel 75 mg daily for 1 month. The latter recommendation is based on an extrapolation of data from the coronary circulation where the use of dual antiplatelet therapy with clopidogrel and aspirin was the most effective regimen in preventing acute (<24 hours) and subacute (24 hours to 30 days) stent thrombosis.[28]

12.2 Summary of Variables Used to Predict Favorable or Unfavorable Response to Revascularization for Treatment of Atherosclerotic Renal Artery Stenosis

Variable	Favorable	Unfavorable
Renal function		
Serum Cr	Elevated (but <3 mg/dl)	Normal
Trajectory of serum Cr prior to intervention	Steep increase	Flat or frequent fluctuations
Duration of renal failure	Acute, subacute (<6 months)	Chronic
Urinary protein	<1 gm/24 hours	≥1 gm/24 hours
Kidney size	>10 cm	<8 cm
Renal contour	Smooth, bean-shaped	Lobulated
Resistive index	<0.8	≥0.8
Severity of renal stenosis	Severe (≥70%–90%), critical (≥90%)	Mild (≤50%), moderate (50%–70%)

Cr, creatinine.

Clinical Outcomes following Percutaneous Revascularization of Atherosclerotic RAS

The interpretation of clinical outcomes of percutaneous revascularization for atherosclerotic RAS is a controversial topic with remarkably disparate interpretations of the same data, often based on the inherent biases of the observer. A significant body of data exists. However, given the controversial nature of this topic and the inherent limitations of single center observational data, only data from prospective randomized trials and prospective registries with core-lab adjudication of events will be discussed.

There have been three randomized trials comparing angioplasty with medical therapy that are summarized in Table 12.3.[29–31] In general, these trials enrolled patients with HTN with preserved renal function. The threshold level of ≥50% RAS for inclusion into the trials likely resulted in the

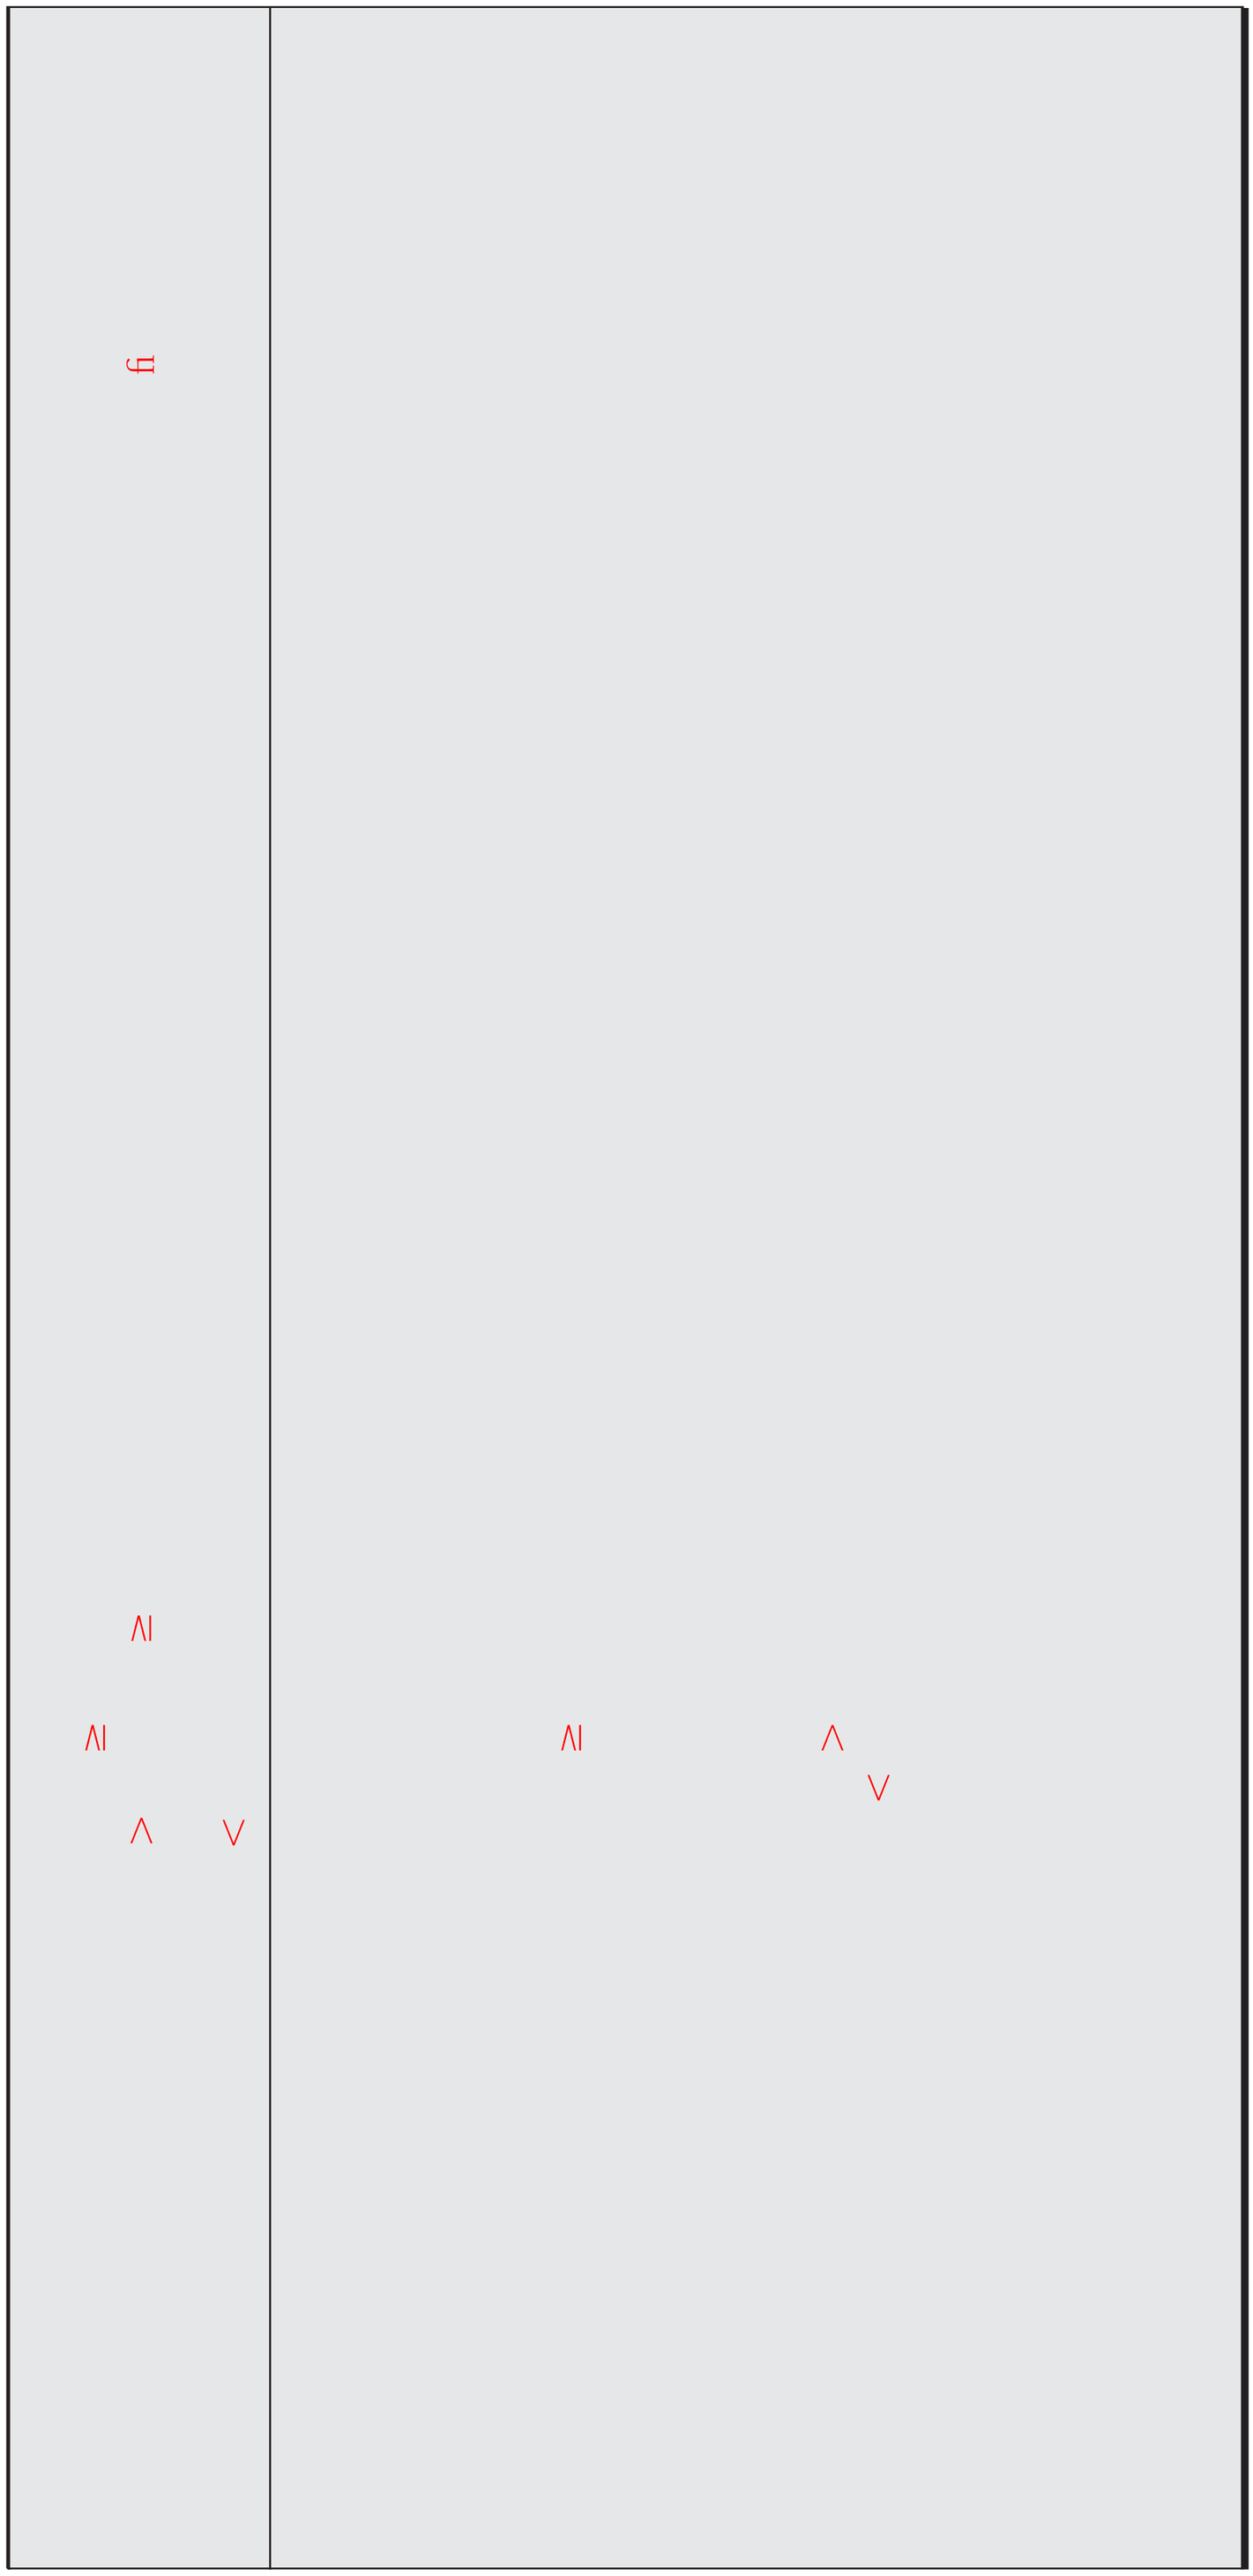
treatment of renal stenoses that were not hemodynamically significant, and may have attenuated any possible treatment effect of renal revascularization. Thus, based on the nature of the patient populations that were included in these studies, it could have been predicted that it would have been difficult to show a benefit of renal revascularization. This was further compounded by the very small size of the patient cohorts in each of these trials (n = 49, 55, and 106) and the high rate of crossover from the medical arm to the angioplasty arm in two of the three studies. With such a high crossover rate, the use of an intention-to-treat method of analysis that was uniformly applied greatly underestimates the potential benefit of any intervention. Accepting these limitations, the conclusion of these trials was that angioplasty was associated with a modest improvement in blood pressure control that manifested itself in the use of less antihypertensive medications when compared to medical treatment alone.

There have been two notable large nonrandomized prospective registries of renal artery stenting that are distinguished from other nonrandomized studies by their prospective nature and the use of independent core laboratory monitoring of angiographic and ultrasound data.[32,33] As a result, there is greater confidence about the reliability of the data reported. These studies enrolled a largely hypertensive population who had an inadequate response to angioplasty for treatment of a severe stenosis (≥70%) of the renal artery. The acute procedural success achieved with stenting was very high (>93%). Significant complications occurred in 5% to 8% of cases, with the majority of these being related to complications at the arterial access site. Restenosis, as determined by duplex ultrasound, occurred in 12% to 17% of patients. Significant improvements in blood pressure control with less use of antihypertensive medication were observed, and renal function was stable over a 24 to 36 month period of follow-up. The major contribution of these studies is in the assessment of the safety profile of the procedure of renal artery stenting.

Two randomized trials comparing renal artery stenting with medical therapy have been completed (summarized in Table 12.3).[34,35] Neither of these studies demonstrated a benefit of renal revascularization. The study by Bax et al. had a number of significant shortcomings, most notably a small sample size (n = 140) that make it difficult to assess the usefulness of the data.[34] By contrast, the ASTRAL trial was the largest randomized trial of renal artery intervention ever performed (n = 806).[35] However, the design and execution of this study were flawed in a number of respects.[36] Only patients in whom the physician was uncertain about the likely benefit of renal artery revascularization were included. This immediately resulted in the selection of a low-risk population who were less likely to benefit from renal revascularization. The use of a threshold of ≥50% stenosis in the renal artery for inclusion in the study resulted in ~40% of patients with stenoses between 50% and 70% being enrolled. Such a degree of stenosis would not be anticipated to be



hemodynamically significant, and therefore would not be associated with clinical benefit from revascularization. In fact, the absence of a core lab to adjudicate the severity of RAS from the renal angiograms in this study makes it likely that a higher percentage of patients with <70% stenosis were included, given the propensity for operators at primary study sites to overestimate the degree of stenosis using visual estimates. The quality of the operators performing the renal stenting procedures is called into question by the alarming rate of major complications reported in this trial (9%). Events such as renal artery occlusion and perforation, and lower extremity gangrene occurred in this trial, but were not observed in either of the large prospective registries performed in the United States, where access site complications were the most common events. The ASTRAL trial was performed in the United Kingdom, raising the possibility that there are possible differences in outcomes with renal artery stenting in different continents, an hypothesis that has gained some traction based on data from carotid artery stent trials based in Europe and the United States.[37–39]

In summary, the ASTRAL trial confirmed that there is no benefit from renal artery revascularization in the setting of an incidental finding of RAS or a RAS of uncertain clinical significance. The trial failed to answer the question of the role of renal artery revascularization in clinical situations where the treating physician is confident that renal artery revascularization is of benefit. Unfortunately, there has been a tendency by several authors, including the primary authors of the ASTRAL trial, to oversimplify and misinterpret the findings of the ASTRAL by concluding that there is no benefit of revascularization in all patients with atherosclerotic RAS. This has contributed to an inappropriate nihilism toward renal revascularization for atherosclerotic RAS and the failure to offer this therapy in patients for whom renal revascularization has a real clinical benefit.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a nonatherosclerotic, noninflammatory disorder of small and medium sized arteries that results in the development of stenoses, aneurysms, and dissections in the affected arteries.[40,41] Pathologically, the disorder is classified according to the layer of the arterial wall affected (i.e., intima, media, adventitia) and the pathology observed in that layer (e.g., fibroplasia [accumulation of collagen], hyperplasia [smooth muscle hyperplasia without collagen accumulation]).[42,43] Medial and perimedial fibroplasia account for the vast majority of cases, and have a characteristic "string of beads" appearance on angiography (Fig. 12.19). The remaining pathologic types are difficult to distinguish by angiography, and are often grouped together. Both concentric and long smooth stenoses are felt to be the typical angiographic appearance associated with these nonmedial fibrodysplasias. The renal arteries are involved in 60% to 75% of patients with FMD, with bilateral involvement in ~35% of patients. In contrast to atherosclerotic RAS, the most common location of renal artery involvement by FMD is in the mid- and distal segments of the main renal artery and the branch vessels. It is estimated that ~10% of all cases of RAS can be attributed to FMD.

Interventional Treatment of FMD in Renal Arteries

The dominant indication for the interventional treatment of renovascular FMD is the treatment of HTN in the following clinical circumstances[40,41]:

1. New onset of HTN where the goal of revascularization is to achieve cure of HTN
2. Patients with poorly controlled HTN despite medical therapy
3. Patients who are intolerant of antihypertensive medications
4. Patients who are noncompliant with antihypertensive medications
5. Documentation of loss of renal volume due to ischemia

Fortunately, renal dysfunction due to renovascular FMD is uncommon, and renal failure is rare.

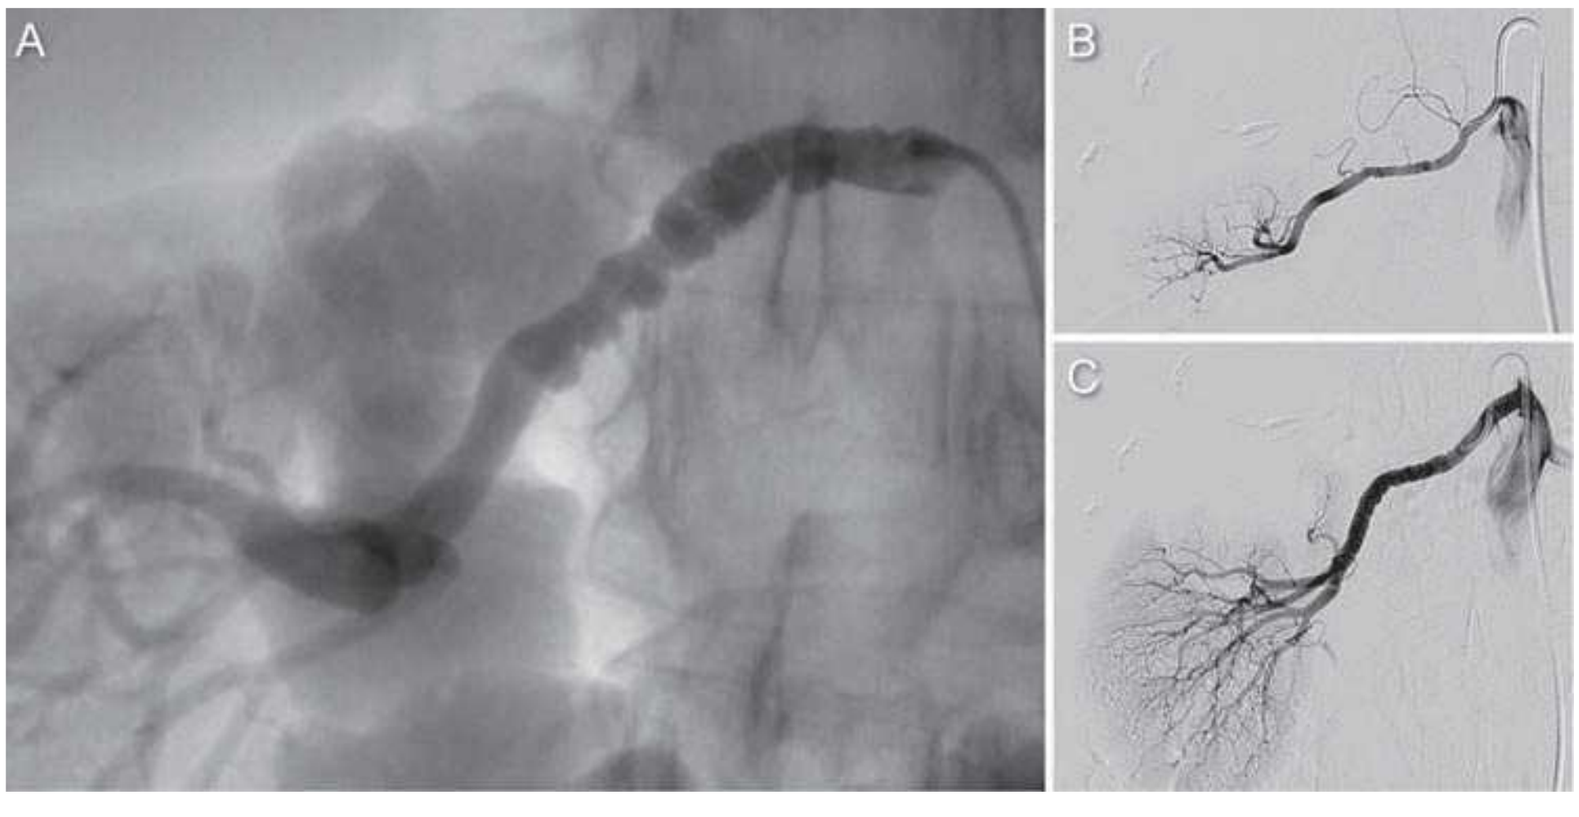


FIGURE 12.19 Typical angiographic apperance of fibromuscular dyplasia involving the renal arteries. **A:** Prominent "string of beads" appearance of right renal artery. **B:** More subtle string of beads appearance in main right renal artery and accessory right renal artery.

Much of the data regarding the interventional treatment of renovascular FMD are derived single center observational series, with no prospective randomized studies (summarized in Table 12.4).[44–52] Accepting the limitations of such studies, the following generalizations regarding the interventional treatment of renovascular FMD are accepted by most experts in the field. In contrast to atherosclerotic RAS, angioplasty is established as the gold standard for treatment of stenotic renovascular FMD. This is based on acute procedural success rates of >90% in most series, and acceptable rates of restenosis that are significantly lower than those observed in the treatment of atherosclerotic RAS (i.e., 7% to 27% at 3-year follow-up). The clinical outcome in terms of blood pressure control varies significantly across studies, likely due to disparities in the spectrum of the disease in these relatively small patient groups. However, a lack of any response is uncommon with a reported frequency of <20% in most series. Variables that have been associated with an increased likelihood of complete cure or improvement in blood pressure control include younger patient age, shorter duration of HTN, less severe baseline HTN, absence of extrarenal arterial involvement, and smaller kidney size.[44,47,50] The true predictive value of these variables derived from small series needs to be interpreted with caution, but do argue in favor of an attempt at angioplasty in the newly diagnosed younger patient with FMD complicated by HTN due to an increased likelihood of complete cure.

The interventional technique of angioplasty for renovascular FMD is similar to that described above for atherosclerotic RAS.[53] One of the significant differences, however, is that it can be difficult and sometimes impossible to assess the precise site of stenosis along a length of a diseased segment of vessel. The location of the stenosis can be most accurately ascertained by using a 0.014-inch pressure wire introduced into the renal artery or branch vessel (e.g., PrimeWire Guidewire, Volcano Therapeutics Inc,

12.4 List of Studies Reporting Procedural and Clinical Outcomes of Angioplasty for Treatment of Fibromuscular Dysplasia of the Renal Arteries

Study	Year	Patients (n)	Success rate (%)	Effects on Blood Pressure[a]			Mean Follow-up (months)	Complications (%)
				Cured (%)	Improved (%)	Unimproved (%)	Mean (range)

San Diego, CA; and PressureWire Certus, St. Jude Medical, St. Paul, MN). In the presence of a significant stenosis, a pressure gradient between the transducer located near the tip of wire and the guide catheter located at the ostium of the renal artery is observed. By slowly withdrawing the pressure wire, the location of the stenosis can be determined, which guides the location of the angioplasty. It is important to confirm the absence of any pressure gradient at the completion of the procedure. Imaging tools such as intravascular ultrasound may assist in this process, but in the authors' experience do not have the same fidelity for localizing the precise site of the hemodynamically significant stenosis or stenoses.

RENAL ARTERY ANEURYSM

The true incidence of aneurysms of the renal artery is difficult to estimate. Among patients undergoing angiography, an incidence of 0.6% to 1% has been reported.[54] In the current era, the majority of patients have single, small (i.e., <2 cm) aneurysm that is asymptomatic. However, renal artery aneurysms that are bilateral, multiple, and up to 8 cm in size have been reported. In most series, the dominant underlying etiology for renal artery aneurysmal disease includes FMD and atherosclerosis, with a small number being attributed to renal artery dissection, arteritis (giant cell and Takayasu) and trauma, and connective tissue diseases (i.e., Marfan syndrome, Ehlers Danlos syndrome).[55] The majority of renal artery aneurysms are located in the body of the main renal artery (usually near the junction with the branch vessels), with the remainder in the branch vessels within the parenchyma of the kidney. Aneurysmal disease in accessory renal arteries is rare.

Renal artery aneurysms may manifest following rupture or renal infarction due to embolization of thrombus within the aneurysm. Treatment in such circumstances where the aneurysm is symptomatic is clearly indicated. However, the management of asymptomatic patients is more controversial. In such patients, the major risk is felt to be spontaneous rupture. As such, parameters that are felt to be associated with an increased risk of rupture are used to guide the decision to intervene. Although no large epidemiologic studies exist, there appears to be some consensus that larger aneurysms (i.e., >2 cm), enlarging aneurysms, and aneurysms in pregnant women or in those with a potential for pregnancy should be treated. The latter opinion is based on multiple case reports of ruptured renal artery aneurysms in pregnant women.[56,57]

The decision to offer surgical versus endovascular treatment of a renal artery aneurysm is dependent on the morphology of the aneurysm and the anatomic relationship between the aneurysm and the main renal artery and its branches. High quality three-dimensional (3D) reconstructions of the renal artery and aneurysm using either CT angiography or invasive rotational angiography are of paramount importance in this regard.

A variety of surgical techniques have been described (Fig. 12.20), including tailoring (i.e., partial resection of aneurysm followed by reconstruction of a vessel of normal caliber from the remaining arterial wall), use of saphenous vein or polytetrafluoroethylene (PTFE) graft, and aneurysm resection followed by direct reanastomosis of the renal artery.[58] Frequently, a combination of these techniques may be required.

In terms of the endovascular treatment of renal artery aneurysms, a number of techniques have been described (Fig. 12.21).[59–62] These include embolization techniques using coils or liquid embolic agents. Occasionally, a balloon is inflated or a stent is implanted across the neck of the aneurysm to facilitate these embolization procedures in patients with wider aneurysm necks. Stent grafts (i.e., stents with a PTFE covering) have been used but are limited by their inflexibility and high profile, making delivery through smaller and tortuous vessels difficult. In addition, side branches that are covered by the stent graft are obstructed. The complexity of the decision-making in these procedures underscores the need for interventionalists with significant experience with management of aneurysms and renal arterial intervention to lead such cases.

RENAL ARTERY EMBOLIZATION AND ABLATION

In addition to the treatment of renal artery aneurysms, renal artery embolization may be performed for a variety of other clinical indications including the control of active hemorrhage, obliteration of arteriovenous malformations (Fig. 12.22) or fistulae, treatment of renal artery pseudoaneurysms, devascularization of renal and adrenal tumors, and the treatment of conditions in which ablation of the parenchyma of the kidney is desired (i.e., medical nephrectomy [e.g., hyperreninemia-related HTN, severe nephrotic syndrome, chronic ureteric fistulae in high risk surgical patients, irreversible transplant rejection]).[63,64]

There are three categories of embolic agents that may be used to achieve renal artery embolization: solids, particulates, and liquids (sclerosants). The particular agent(s) used depend largely on the clinical indication and the specific anatomy of the renal artery and its branches (Figs. 12.23 and 12.24). For example, for the clinical indication of medical nephrectomy, embolization of the entire kidney is typically achieved by embolization of the small vessel branches with injection of liquid and particulate agents, followed by deployment of metallic coils in the main renal artery.

Success rates of over 90% are generally reported for renal artery embolization, although highly complex cases where preservation of renal function is paramount are likely to have lower rates. By definition, all patients will suffer a renal infarct following renal artery embolization, which is typically manifest by flank pain and fever that begins 1 to 3 days following the procedure. The impact on renal function will be determined by the size of the renal infarct, the function of the infarcted territory, and the baseline renal function. In addition to loss of renal function, the most feared complication is inadvertent non-target embolization of the arterial supply to the spinal cord, bowel, or lower extremity. Careful attention to technique should minimize these risks.

PERCUTANEOUS RENAL SYMPATHETIC DENERVATION

Since the early 1970s, a considerable body of data has emerged demonstrating a significant role of the afferent and efferent nerves of the renal sympathetic system in the initiation and maintenance of systemic HTN.[65–67] These nerves run in the adventitia of the wall of the main renal arteries and have long been investigated as a potential target for therapeutic intervention. In fact, surgical methods of sympathetic denervation were practiced prior to the availability of modern pharmacologic antihypertensive agents, but were abandoned due to high rates of perioperative mortality and morbidity. With the recognition that nearly half of all patients

with HTN do not achieve optimal blood pressure control, a search for a nonsurgical approach to renal sympathetic denervation was explored. At present, one commercial product has been developed and tested in clinical trials (Simplicity Catheter System, Ardian, Palo Alto, CA, recently acquired by Medtronic Inc., Minneapolis, MN) with several other companies and investigators exploring other technologies and techniques to achieve renal sympathetic denervation.

Technique of Renal Sympathetic Denervation

The current commercial product (Simplicity Catheter System) achieves renal sympathetic denervation by applying low power radiofrequency (RF) treatment (i.e., <8 watts) to the length and circumference of the proximal segment of both main renal arteries. This is performed by engaging the main renal artery with a guide catheter through which the radiofrequency catheter is directly inserted into the main renal artery. A total of four to six RF treatments, each lasting 2 minutes, are applied longitudinally and circumferentially in the proximal segment of each renal artery. The RF treatments are typically associated with diffuse visceral abdominal pain that does not persist beyond the duration of the treatment and is managed with usual narcotic and sedative medications (e.g., fentanyl and midazolam). Technically, these procedures are straightforward and much less challenging than stenting of atherosclerotic RAS.

Clinical Outcome Data for Percutaneous Renal Sympathetic Denervation

To date, one proof of principle registry and one randomized trial have been completed using the Simplicity Catheter System.[68,69] The registry study treated 45 patients with resistant HTN (i.e., systolic blood pressure [SBP] >160 mm Hg and on three antihypertensive medications) and a glomerular filtration rate (GFR) of 45 mL/min/1.73 m^2 at five European and Australian sites.[69] In terms of safety, there were two procedure-related complications: one was an arterial access site complication, and the second was a renal artery dissection due to manipulation of the guide catheter that did not have a clinical consequence. Among the treated patients, there was a significant and sustained reduction in the mean systolic and diastolic pressures out to 12 months (27/17 mm Hg at 12 months). In fact, the reductions in blood pressure increased over the 12 month period, suggesting that the effects of denervation are durable.

Using the same enrollment criteria, the Symplicity HTN-2 Trial randomized 106 patients to renal denervation versus medical therapy.[68] At 6-month follow-up, there was a significant reduction in office-based blood pressure measurements in the renal denervation group (32/12 mm Hg) and no significant change in the medical treatment group (1/0 mm Hg). There were no major device- or procedure-related complications, underscoring the straightforward

nature of the technique and the safety of the procedure. Renal function was stable in both groups, indicating no adverse effect on the kidney parenchyma.

Given the positive results from these studies, considerable excitement about this technology has been generated. Further studies in the United States are planned to achieve FDA-approval. In addition, trials of this therapy in other disease entities in which renal sympathetic activation is thought to play a key pathogenic role (e.g., chronic kidney disease, congestive heart failure, hepatorenal syndrome, cirrhosis with ascites) are at various stages of planning.

CHAPTER

13 Renal Biopsy: Indications and Evaluation

I. David Weiner • C. Craig Tisher • Byron P. Croker

This chapter discusses the indications for performing a renal biopsy, describes the procedure and methods of tissue preparation, and demonstrates the manner in which biopsy specimens are interpreted using a combination of light microscopy, electron microscopy, and immunohistologic microscopy. The technique of percutaneous renal biopsy was introduced clinically in the early 1950s. Iversen and Brun[1] are generally credited with describing its initial use. They believed the technique would be quite useful in obtaining more information about diseases that caused acute kidney injury. At that time, the diseases were referred to as lower nephron nephrosis. The renal biopsy technique was used with increasing frequency during the 1950s, and it has enjoyed wide usage throughout the world since the early 1960s. The technique has provided a wealth of information about the histopathology, pathogenesis, and classification of renal disease that could not have been obtained by any other means.

Proponents of the biopsy procedure employ this technique to diagnose kidney disease, to assess prognosis, to monitor disease progress, and to aid in the selection of a rational approach to therapy. It is used extensively both in younger[2–7] and older patients.[8–14] However, the procedure is not without morbidity and, occasionally, mortality. Therefore, the risk/benefit ratio must be considered carefully in each patient who is being evaluated for a biopsy.

As originally described, the biopsy was performed with the patient in the sitting position, and the procedure involved aspiration of the tissue sample. Brun and Raaschou[15] used the Iversen-Rohlm cannula and syringe, which yielded a cylinder of tissue approximately 1.5 mm in diameter and of variable length. Kark and Muehrcke[16] chose to place the patient in the prone position and initiated the use of the Franklin modification of the Vim-Silverman cutting needle (Popper & Sons, Inc., New Hyde Park, NY) in place of the aspiration technique. Today, most nephrologists position the patient in the prone position and use a spring-loaded, semiautomatic biopsy device. The use of either ultrasonography (US) or computed tomography (CT) to locate the kidneys and to aid in positioning the biopsy needle has greatly simplified the technique and improved its safety.

Adequate tissue samples are obtained in greater than 95% of procedures. In a retrospective study, Bolton and Vaughn[17] reported that renal tissue was obtained in 97% of their patients with the use of image-amplification fluoroscopy, compared with 81% without the use of fluoroscopy. Percutaneous renal biopsies performed with renal imaging using either US or CT were successful in ~98% of patients in several series.[18–21]

The percutaneous renal biopsy is a safe and reliable technique in the hands of the experienced operator. The most common complication is bleeding, which occurs in the majority of patients if they are studied carefully after biopsy using ultrasonography[22] or CT.[23,24] However, the bleeding is self-limited and rarely requires an operative intervention or a blood transfusion. In a survey[25] of the results of over 5,500 percutaneous renal biopsies, the rate of complications, including the need for a blood transfusion or a nephrectomy, the puncture of other organs, or the presence of a clinically evident perinephric hematoma, was 2.1%. The overall mortality is approximately 0.1% to 0.2%,[25–27] which is comparable to that reported for percutaneous liver biopsy or coronary angiography.[25] In a study from a single institution[28] in which 1,000 consecutive percutaneous renal biopsies were analyzed, a total of 94 complications were observed in 81 patients. Gross hematuria, including the passage of blood clots, represented 73% of the complications. Two patients underwent exploration for the evacuation of perirenal hematomas, but no kidneys were lost. One patient died of multiple complications after biopsy.

Multiple factors are associated with an increased risk of complications from the renal biopsy procedure. In one study, the presence of a serum creatinine of at least 5.0 mg per deciliter was associated with a 2.3-fold increase in the risk of a complication.[29] Other studies have identified uncontrolled hypertension, thrombocytopenia, and anemia as predictors of increased risk for complications.[30–32] The simultaneous presence of both hepatitis C and HIV infection is associated with as much as a 5.7-fold increase in complications,[31] but the presence of amyloidosis or monoclonal gammopathy is not.[33,34]

The timing of postprocedure complications has important implications regarding how long patients should be observed prior to discharge. Most studies have shown that the great majority of complications can be identified in the initial 6 to 8 hours after the procedure,[32,35] suggesting that a renal biopsy can be performed safely as an outpatient procedure. However, some studies report that as many as 33% of complications are not identified after 8 hours of observation.[29] Screening tests such as the presence or absence of a postprocedure perirenal hematoma may be helpful in assessing the risk of a clinically significant complication.[36,37]

TECHNIQUES

Prior to an elective renal biopsy, it is important to screen the patient for the presence of bleeding disorders. A careful history should be obtained to determine whether abnormal bleeding occurred during previous surgical procedures. A history of severe menorrhagia, if female, and other evidence of abnormal bleeding, as well as a family history of bleeding disorders should be sought. Screening laboratory studies may include an assessment of the platelet count and bleeding time. In addition, it is advisable to obtain the hematocrit and hemoglobin levels within 24 hours prior to the procedure. Renal imaging, typically by ultrasonography, should be performed prior to a biopsy to assess for the presence of anatomic abnormalities, including solitary kidney, horseshoe kidney, hydronephrosis, small kidneys, or other anatomically abnormal kidneys, which may adversely affect the risk of a renal biopsy. Currently, most percutaneous biopsies are performed with the guidance of US or CT to permit an accurate localization of the kidney. The use of a premedication, such as midazolam (Versed), to help alleviate patient anxiety may make the procedure less unpleasant for the patient. We routinely place an intravenous access in the patient.

Most operators prefer to biopsy the lower pole of the left kidney to reduce the risk of inadvertently passing the biopsy needle through a major renal artery or vein. After the completion of the biopsy, patients are instructed to remain at bed rest for 6 to 8 hours. In our institution, we screen with US or CT in the immediate postprocedure period for the presence or absence of a perirenal hematoma and its size, if present. We assess the blood pressure and pulse every 15 minutes for 1 hour, every 30 minutes for 1 hour, then hourly for the next 4 to 6 hours. The patient is asked to save an aliquot of each voided urine in a separate clear plastic specimen jar labeled with the date and time, which is kept at the patient's bedside for inspection. This provides a visual check for evidence of bleeding into the intrarenal collecting system. The hemoglobin and hematocrit are determined 6 to 8 hours after the biopsy, or earlier if hemodynamic instability or gross hematuria is observed. If the hemoglobin and hematocrit are stable, the patient is relatively pain free and there is no hemodynamic instability or gross hematuria, we discharge the patient home with instructions to call immediately should there be a change in his or her clinical condition. If the patient does not meet these criteria, we admit the patient overnight for further observation.

An outpatient renal biopsy, as described in the previous paragraph, is a component of an ongoing trend to identify approaches to optimize the use of health care resources. An ample amount of literature demonstrates the safety of this approach in both native and transplanted kidney biopsies in both children and adults.[38–40] Ultrasonographic evidence suggests that most episodes of major bleeding occur within the initial 6 hours after a renal biopsy and that the size of perirenal hematomas actually decreases thereafter.[39] These data confirm an earlier report by Carvajal et al.[2] who found only three significant bleeding episodes in 890 consecutive percutaneous biopsies performed in pediatric patients. These data, when linked with the experience in the outpatient setting thus far, suggest that in carefully selected patients in whom the procedure is performed without difficulty, the use of ambulatory percutaneous renal biopsy can be justified. If patients are free of pain at the site of biopsy, have clear urine, and have stable cardiovascular signs for a minimum of 4 to 6 hours after the procedure, they can be safely discharged.[40] Activity should be restricted for at least 24 hours, and patients should be cautioned to seek medical attention immediately if there is macroscopic hematuria or pain over the biopsy site.

Several types of spring-loaded automatic or semiautomatic biopsy guns are employed to perform percutaneous biopsies of both transplanted[21,39–50] and native kidneys.[21,49–63] Based on a sample of almost 2,000 percutaneous biopsy procedures, the rate of complications, including a clinically evident hematoma, nephrectomy, blood transfusion, acute urinary tract obstruction, or biopsy of another organ, was 1%. Adequate samples of tissue were obtained 94% of the time on the initial attempt at biopsy. These data compare very favorably with the published experience with either the Franklin modification of the Vim-Silverman needle or the Travenol Tru-Cut disposable needle (Travenol Laboratories, Deerfield, IL).[17,25] Furthermore, when direct comparisons have been made, the results obtained with the biopsy gun were easily comparable to those achieved with the Travenol disposable needle.[44,48,54,55,60,61] In another study,[21] 1,090 percutaneous kidney biopsies were performed using US guidance and an automated spring-loaded biopsy device. A total of 114 (10.4%) were performed on renal allografts and 976 (89.6%) were performed on orthotopic kidneys. No serious complications, including the loss of kidney, life-threatening hemorrhage, or a persisting hemodynamically relevant arteriovenous (AV) fistula, were encountered. In 98.8% of the patients, sufficient tissue was obtained to make a reliable histopathologic diagnosis.

When combined with real-time US technology, there are several advantages to using the fully automatic biopsy guns. For example, the depth of the biopsy is controlled precisely and can be selected for a particular clinical situation. In the case of one of the most commonly used instruments

(Biopty, Bard Urological Division, C.R. Bard, Covington, GA), the long-throw device has a depth of 2.3 cm, yielding a specimen with a potential length of up to 1.7 cm. The short-throw device has a depth of 1.15 cm and a potential specimen length of 0.9 cm.[64] Fully automatic biopsy guns can be triggered with one hand, thus leaving the operator with a free hand to control the US probe if necessary. Instruction in the use of the biopsy gun is also easier. Many also believe that there is less discomfort with use of the biopsy gun.[21,53,54,60] Some studies have found decreased bleeding with automated biopsy devices,[65] whereas others have not.[60] The use of automated renal biopsy devices has almost completely replaced the use of manual devices.

Currently, there is no universal agreement on the optimum size of the needle that should be used with the various biopsy guns. Many favor the 18-gauge needle, which retrieves almost as many glomeruli per specimen as larger gauge needles.[41–54] This is due, in part, to the fact that the individual specimens have cleaner, sharper edges with less crush artifact. Certainly, in pediatric patients, the 18-gauge needle has been found to be quite adequate.[49,50,52,63] We favor use of a 15- or 16-gauge needle for biopsies in adult patients.

An alternative technique for performing the renal biopsy involves the transjugular approach. In this technique, a guide wire is inserted through the right internal jugular vein, through the vena cava, into the right renal vein, and is then wedged into the lower pole of the right kidney. A transvenous biopsy needle, similar to those used for transjugular hepatic biopsies, is then inserted over the guide wire, advanced into the kidney, and samples are taken. The first description of the procedure is generally attributed to Mal et al.,[66] who reported its use in 50 consecutive patients. All were patients in whom conventional percutaneous renal biopsy was felt to be clinically contraindicated, because of a need for simultaneous hepatic and renal biopsies, severe clotting disorders, respiratory insufficiency, uncontrolled hypertension, morbid obesity, or a solitary kidney. Renal tissue was obtained in 88% of patients, and glomeruli were present in 76% of the samples. Since this initial description, the procedure has become available and is used in a large number of centers. Typically, because of the increased technical difficulty and the cost of the procedure, the transjugular renal biopsy is reserved for patients with contraindications to a percutaneous renal biopsy. Subsequent studies that followed this initial report have confirmed its usefulness in patients in whom a conventional percutaneous approach is contraindicated. In general, adequate tissue is obtained in 85% to 95% of procedures.[67–72] The reported complications include capsular perforation, collecting system puncture, hematuria or loin pain, sufficient bleeding that blood transfusion is necessary, and hypovolemic hemorrhagic shock.[67–71,73,74] Because of the risk of postprocedure complications, most patients should be observed overnight after the procedure. The presence of an underlying clotting disorder is associated with an increased risk of complications,[74] but morbid obesity is not.[70] Thus, the transjugular renal biopsy provides an approach to the renal biopsy in patients in whom a conventional percutaneous approach is contraindicated. The risk of complications, although not inconsequential, is generally considered acceptable if the result of a renal biopsy is important in the patient's management.

Because decreased glomerular filtration rate can lead to platelet dysfunction, which may increase the risk of bleeding, efforts have been made to determine whether specific prebiopsy testing can decrease the risk of clinically significant postrenal biopsy bleeding. Traditional coagulation tests, such as partial thromboplastin time (PTT), prothrombin time (PT), and the International Normalized Ratio (INR), assess coagulation factor-mediated clotting, which is not altered with renal disease. Therefore, such tests are not good predictors of bleeding after a renal biopsy. The bleeding time, sometimes termed the template bleeding time, is more specific for assessing platelet function. Many authors feel that the bleeding time should be a routine component of the pretransplant evaluation,[75,76] whereas others disagree and have instead suggested that failing to measure the bleeding time does not expose the patient to an increased risk of bleeding.[77] Our personal practice is to assess the bleeding time, particularly in individuals with an increased blood urea nitrogen (BUN), in whom the risk of uremic platelet dysfunction is greater.

There are a number of treatment options in patients with uremic platelet dysfunction. Desmopressin (deamino-8-D-arginine vasopressin) rapidly decreases the bleeding time in patients with uremic platelet dysfunction,[78] and can be used to treat patients with a prolonged bleeding time.[75] A recent prospective, randomized clinical trial suggested that the routine use of desmopressin in patients with a serum creatinine less than 1.6 mg per deciliter and normal coagulation parameters, irrespective of bleeding time, decreases both the likelihood of postbiopsy bleeding (treated, 13.7% versus control, 30.5%) and, in those with bleeding, decreases both the size of the hematoma and the duration of hospital stay.[79] Although very intriguing, it is our current belief that confirmatory studies are necessary before adopting routine desmopressin treatment for all renal biopsies. Uremic platelet dysfunction can also be treated either with renal replacement therapy, such as hemodialysis,[80] or with oral estrogen therapy.[81,82] These alternative therapies take longer to improve the bleeding time than is required for desmopressin, and therefore are not routinely used.

INDICATIONS

There is no universal agreement on the precise indications for use of the percutaneous renal biopsy despite almost 60 years of experience with the technique by the nephrology community. The present section describes several clinical situations in which this technique is either routinely or frequently employed to aid in the evaluation and management of a patient with undiagnosed kidney disease.

Acute Kidney Injury

There are many occasions when the etiology of acute kidney injury secondary to intrinsic renal disease is not evident despite a carefully performed history and physical examination and the availability of information gained from various laboratory studies. A biopsy can be very useful in establishing the diagnosis, determining the approach to management, and defining the prognosis in this clinical setting. Retrospective studies from several centers have revealed that the diagnosis of acute tubular necrosis (ATN) cannot be established clinically[76,83–85] in 10% to 25% of patients who present with acute kidney injury. A biopsy in this population can be important because other causes of acute kidney injury are revealed, such as crescentic proliferative glomerulonephritis, interstitial nephritis, Wegener granulomatosis, polyarteritis nodosa, multiple myeloma, amyloidosis, endocapillary proliferative glomerulonephritis, cortical necrosis, hemolytic-uremic syndrome (HUS), systemic lupus erythematosus (SLE), and thrombotic thrombocytopenic purpura, to list just a few. These diseases usually require an approach to management that is different than that normally employed in uncomplicated cases of ATN.

Occasionally, a biopsy can provide helpful clinical information in patients who appear to have ATN on clinical grounds at initial presentation, but who do not regain renal function after 2 to 3 weeks of supportive therapy, including dialysis. The diagnostic possibilities generally are the same as those listed in the preceding paragraph. A careful evaluation of the clinical situation is deemed prudent before a renal biopsy is initiated because this procedure carries a higher risk in the patient with acute uremia.[86]

Nephrotic Syndrome

A renal biopsy in the clinical setting of an acute nephrotic syndrome not associated with systemic disease is influenced greatly by the age of the patient. It is common practice to treat children initially with high-dose corticosteroids, because most younger children have minimal change nephrotic syndrome (MCNS) on a biopsy. The presence of a selective proteinuria and normal renal function and the absence of hypertension strengthen the clinical diagnosis. In children, a biopsy is usually reserved for patients with no response to corticosteroid therapy or in whom the clinical and laboratory features of the illness at the time of initial presentation are distinctly atypical for MCNS. These features would include hypertension, azotemia in the absence of volume depletion, nonselective proteinuria, a highly active urine sediment including red cell casts, and involvement of other organ systems.

Most nephrologists believe that the adult nephrotic patient without signs of systemic disease should undergo a biopsy before therapy is initiated because the majority of these patients, including elderly persons,[87] have a renal disease other than MCNS.[10] The most frequent cause of the nephrotic syndrome in adults is idiopathic membranous glomerulonephritis[10,88]; other frequent causes include focal segmental glomerular sclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN), proliferative glomerulonephritis, immunoglobulin A (IgA) nephropathy, and amyloidosis. Because the optimal treatment differs in different conditions, a renal biopsy can provide helpful clinical information. Moreover, fewer than one-third of adult patients have MCNS. Thus, if the physician elects to administer a short course of high-dose corticosteroid therapy equivalent to that employed in pediatric patients, approximately two-thirds of the patients would not be expected to respond favorably. Despite suggestions to the contrary, [25] we believe the risks associated with the use of corticosteroids or other immunosuppressive agents, such as azathioprine, chlorambucil, cyclosporine A, mycophenolate mofetil, and cyclophosphamide, in this population are too great to justify their use in the absence of a specific histologic diagnosis.

Isolated Proteinuria

Isolated nonnephrotic proteinuria of 1 g or less per 24 hours without hematuria or pyuria in an otherwise asymptomatic patient who does not have diabetes mellitus is a relatively common clinical problem. Often, the proteinuria is first detected during a routine physical examination required for participation in school athletics, during a preemployment examination, or at the time of application for life insurance. In young adults, orthostatic proteinuria is commonly identified in this presentation, carries a benign prognosis, and does not require a renal biopsy.[89] Otherwise, unless the patient requests a kidney biopsy for purposes of reassurance, it is currently our policy to merely monitor the clinical course of such patients at periodic intervals of 6 months to 1 year. There is little evidence to suggest that these patients will progress to renal failure or that they are candidates for any type of specific medical therapy in the absence of impaired renal function.[90] If there is any evidence during follow-up of functional deterioration or the development of additional clinical signs or symptoms suggesting the presence of a primary renal disease or kidney involvement secondary to systemic disease, the patient is thoroughly reevaluated and is often advised to undergo a kidney biopsy for diagnosis and possible therapeutic intervention.

In asymptomatic patients who do not have diabetes mellitus and who remain nonnephrotic but persistently excrete more than 1 g of protein per 24 hours, we advise a renal biopsy. It is this group of patients who are more likely to have an underlying renal abnormality. Some of the more common diagnostic possibilities include early idiopathic membranous glomerulonephritis, FSGS, and IgA nephropathy. Patients with urinary abnormalities such as hyaline and granular casts are even more likely to have an underlying glomerular abnormality.[91]

Hematuria with or without Proteinuria

Asymptomatic hematuria, especially in children and young adults, is a frequent cause of referral to nephrologists. It is important that causes of hematuria due to neoplasms in either

the upper or lower collecting system or due to either cystitis or pyelonephritis be excluded before one considers a renal biopsy. In general, the diagnostic value of a renal biopsy in the setting of idiopathic microscopic hematuria relates directly to the extent of associated clinical and laboratory findings. For example, in a series of 76 pediatric patients with isolated hematuria, Trachtman et al.[92] found that almost three-quarters of all biopsy specimens obtained in patients who had either a first-degree relative with hematuria or a history of at least one episode of gross hematuria were abnormal histologically. IgA nephropathy and Alport syndrome were the two most common findings. Schröder et al.[93] performed renal biopsies in 65 children with isolated hematuria of at least a 1-year duration. Of the group, 95% had histologic abnormalities that included IgA nephropathy (16 patients), Alport syndrome (8 patients), thin glomerular basement membrane (33 patients), and nonspecific mesangial abnormalities (5 patients). In a later report, Topham et al.[94] evaluated 165 children and adults with isolated hematuria using cystourethroscopy and renal biopsy. All had a normal intravenous pyelogram, were normotensive with a normal serum creatinine, and were free of both proteinuria and a urinary tract infection. In this group, 47% had significant histologic findings, including IgA nephropathy in 49 patients, whereas only 5 abnormalities were identified on a cystourethroscopy. Renal biopsy abnormalities were most common among patients under 20 years of age (69%), prompting these investigators to conclude that a renal biopsy should replace a cystoscopy in younger patients as the next step in evaluation if renal imaging yielded normal results. Furthermore, because renal histologic abnormalities are quite frequent in the clinical setting of isolated hematuria, these investigators recommended a kidney biopsy in patients over 45 years of age in whom findings at renal imaging and cystoscopy are normal.

The likelihood of identifying significant glomerular pathology is considerably higher when hematuria is accompanied by proteinuria, with or without an abnormal urine sediment that includes red blood cell, granular, hyaline, or white blood cell casts. We believe it is important to establish the histologic diagnosis of the renal lesion in this clinical setting; although admittedly, a biopsy is not required to identify the source of hematuria. Primary renal diseases that can be seen include IgA nephropathy, acute or resolving postinfectious glomerulonephritis, MPGN, and an occasional example of interstitial nephritis. Heredofamilial and multisystem diseases that may be seen include Fabry disease, sickle cell trait and disease, polyarteritis nodosa, Wegener granulomatosis, diabetes mellitus, SLE, and Henoch-Schönlein disease. Many of these systemic diseases may be evident on clinical grounds if a careful prebiopsy evaluation is undertaken, as discussed in the next section.

Systemic Disease

There are many systemic diseases that involve the kidney, although the extent and frequency of involvement varies considerably in different conditions. Patients often undergo a renal biopsy for diagnosis and management on the basis of either the frequency or severity of the renal lesion. These diseases include SLE, Henoch-Schönlein purpura, polyarteritis nodosa, Goodpasture syndrome, Wegener granulomatosis, and various gammopathies.

In approximately 40% to 50% of all patients with type I insulin-requiring diabetes mellitus and comparable percentages with type II adult-onset diabetes mellitus, renal failure develops during the course of the disease.[95,96] The natural history of renal disease in both types of diabetes mellitus has been well studied and is reasonably predictable[96]; thus, in most patients, a renal biopsy is seldom indicated for a diagnosis or management. However, a biopsy can be helpful in patients whose course may be complicated by the sudden development of renal failure, proteinuria, or nephrotic syndrome, or who have serologic evidence of other causes of renal disease.

Although nephrotic syndrome is observed in approximately 10% of all patients with diabetes, its sudden appearance, especially in the young diabetic without previous evidence of functional renal impairment, should not be ascribed automatically to diabetic nephropathy. This point is well illustrated by the experience of Urizar et al.[97] who described five young diabetic patients with nephrotic syndrome in whom the renal disease was not distinguishable histologically from MCNS. Nephrotic syndrome appeared either simultaneously or shortly after the recognized onset of diabetes in three of the children. Treatment with corticosteroids in four patients resulted in a prompt response, with loss of edema, cessation of proteinuria, and normalization of all serum abnormalities. No patient had abnormalities suggestive of diabetic nephropathy. Other investigators have reported similar experiences.[98,99]

Other types of renal disease also can be seen in association with diabetes mellitus, often in the clinical setting of the nephrotic syndrome. Couser et al.[100] reported the coexistence of dense deposits within the glomerular and tubular basement membranes, resembling those seen in type 2 MPGN and lesions typical of diabetic nephropathy in a 24-year-old nephrotic man with type I diabetes mellitus. Other examples of well recognized renal diseases that have been reported to occur in patients with diabetes mellitus in either the presence or absence of diabetic nephropathy include acute postinfectious proliferative glomerulonephritis,[101,102] crescentic proliferative glomerulonephritis,[101] and membranous glomerulonephritis.[103–105]

The renal biopsy is central to the management of SLE with renal involvement (i.e., lupus nephritis). At present, it is our practice to biopsy all patients who present with clinical evidence of active lupus nephritis unless a medical contraindication exists. Border[106] has suggested that patients with more than six red blood cells (RBCs)/high-power field, a urine protein excretion greater than 200 mg per 24 hours, or an abnormal serum creatinine value are candidates for a biopsy. There is no other way to establish the type of renal lesion that is present, and the management of lupus nephritis varies considerably depending on the specific histologic lesion.

The value of renal biopsy in predicting a prognosis has been debated. The results of earlier studies suggested that the biopsy classification of lupus nephritis was useful in predicting the clinical course[107,108] and this issue was challenged[109–111] from a prognostic standpoint but reaffirmed subsequently.[112–116] Correspondingly, we believe it is important to establish as precise a histologic diagnosis as possible because, in general, patients with diffuse proliferative lupus nephritis with signs of disease activity, such as increased cellularity, segmental necrosis, fibrinoid deposits, and crescents in the glomeruli, have a poorer prognosis than individuals with mesangiopathic, focal proliferative, or membranous lupus nephritis.

Controversy also exists concerning the value of renal biopsy in patients with clinically silent lupus nephritis. In 1977, Mahajan et al.[117] described 12 patients with diffuse lupus nephritis but without clinical or laboratory evidence of renal involvement at the time of renal biopsy. A later report, in which 10 of the original 12 patients were followed from 5 to 11 years, revealed deterioration of renal function in 3 years, with one death as the result of renal failure.[118] All patients received prednisone alone or in combination with azathioprine. These investigators concluded that the prognosis for the preservation of renal function appeared better in patients with clinically silent diffuse proliferative nephropathy as opposed to those with clinically active disease, and recommended a biopsy in patients with SLE even in the absence of overt clinical renal involvement.[118] Woolf et al.[119] described eight patients ranging in age from 6 to 26 years, with clinically silent lupus nephritis, who on biopsy had a variety of histologic lesions indicative of active renal involvement. Although no consensus exists regarding the use of a renal biopsy in patients with SLE who are without clinical evidence of renal involvement, it is currently our policy to withhold a biopsy in this group of patients.

Renal biopsy can often aid the clinician in selecting an appropriate therapy for the treatment of vasculitis when renal involvement is present. Polyarteritis nodosa and Wegener granulomatosis require aggressive combination therapy with cyclophosphamide and prednisone. The prognostic value of crescents in antiglomerular basement membrane (GBM) disease and other conditions is discussed in later paragraphs. Other systemic diseases that often exhibit renal involvement and, therefore, can be diagnosed with the aid of a renal biopsy when other diagnostic tests have failed or have not been employed include multiple myelomas, kappa light-chain disease,[120] amyloidosis,[121] fibrillary glomerulonephritis, and mixed cryoglobulinemia with renal failure.[85,122]

Transplant Kidney

Renal biopsies are a valuable diagnostic tool in the management of the transplant recipient. A biopsy of an allograft represents the major clinical exception to avoidance of a percutaneous biopsy of a single functioning kidney. Numerous studies confirm the value and relative safety of a renal biopsy in this setting.[41,42–48,123,124] A biopsy is the most accurate means of determining the presence of lesions, such as cellular or humoral rejection, ATN, drug-induced or viral (especially BK virus) interstitial nephritis, hemorrhagic infarction, calcineurin inhibitor toxicity, and de novo or recurrent glomerulonephritis in the allograft. There are several clinical settings in which a biopsy of the allograft is often indicated. These include failure of the graft to function within the initial 7 to 10 days after surgery, a rapid deterioration in function of unknown etiology after the initial good function, an absence of a response to an adequate antirejection therapy within a reasonable period of time, and an unexplained nephrotic syndrome or nephrotic-range proteinuria.

A large number of cadaveric kidneys are engrafted, and ischemia-reperfusion injury is a frequent complication. Failure to achieve improved renal function within 7 to 10 days after surgery raises the possibility of a more severe form of renal injury, such as an infarction or a superimposed episode of acute rejection. A biopsy is often invaluable in determining the etiology of the renal failure, in guiding subsequent therapy, and in establishing a prognosis. For example, Kiaer et al.[125] reported a 100% graft loss when infarction, capillary thrombosis, and arterial or arteriolar thrombosis were found either singly or in combination on a biopsy. Thus, the presence of these lesions in the clinical setting of an acute kidney injury would obviate the necessity for the continued use of antirejection therapy.

The incidence of acute rejection, characterized by a sudden decrease in renal function, is greatest during the first 6 months after transplantation. In most instances, the suspicion of acute rejection can be made on clinical grounds. However, acute rejection often occurs in the absence of clinical features, such as graft tenderness or fever, and a patient believed to have acute rejection may not respond to a reasonable course of antirejection therapy. It may be desired to tailor the antirejection therapy to vascular versus tubulointerstitial rejection or antibody versus cellular rejection. A biopsy can be extremely helpful at this juncture in the patient's therapy. In particular, the presence of peritubular C4d deposition suggests the presence of acute humoral rejection, whereas its absence is typical in cell-mediated rejection.[126,127] A confirmation of acute humoral rejection involves the demonstration of morphologic evidence of acute tissue injury in combination with circulating antibodies to either donor human leukocyte antigen (HLA) or to other antidonor endothelial antigens.[128] Other complications, such as ATN, drug-induced nephrotoxicity, or overt renal infarction may be diagnosed.

As noted previously, C4d staining of biopsies has been a valuable tool. C4d is produced by the activation of the classic and lectin complement pathways. Thus, ischemia reperfusion (I/R), necrosis, lupus nephritis, and other conditions may exhibit C4d staining and must be considered in a biopsy interpretation.[129–133] Current guidelines recommend the exclusion of loci of I/R, necrosis, and fibrosis when using C4d staining to evaluate for possible humoral rejection.[128,134,135]

The occurrence of the nephrotic syndrome or nephrotic-range proteinuria in a transplant recipient suggests the possibility of either recurrent or de novo glomerulonephritis.[136,137] Those forms of disease that are most likely to recur in the transplant kidney include MPGN, FSGS, diabetic nephropathy, and IgA nephropathy.[136,137] To date, the most common de novo disease reported is membranous glomerulonephritis.[136] Although some would take exception, we believe it is worthwhile to establish the lesion that is responsible for proteinuria, especially if the proteinuria is associated with a decrease in renal function.

Renal Mass or Neoplasm

In addition to a percutaneous kidney biopsy for traditional medical indications, as introduced previously, the past decade has seen renewed interest in percutaneous (core) biopsies for renal masses and other neoplasms. The technique fell into disfavor in previous decades because of bleeding, false-negative results, and other less common complications.[138] Regardless, there is a driving force for tissue diagnosis because 50% of renal neoplasms are now identified as incidental to abnormal imaging for other reasons. A percutaneous renal mass biopsy is often performed to evaluate for a possible lymphoma, a renal abscess, or metastatic disease due to a known extrarenal malignancy. It may also be performed to confirm the diagnosis of a primary renal neoplasm in a patient with known disseminated disease or an unresectable retroperitoneal tumor in whom surgical treatment is contraindicated.[138–144] Although there was initial concern regarding the potential for seeding the biopsy tract with malignant cells, only a total of six cases have been reported, and multiple case series published since 1999 have reported no such events.[145]

CONTRAINDICATIONS

Both the relative and the absolute contraindications for a renal biopsy vary among nephrologists. However, most agree that the risk of complications increases in the presence of severe uncontrolled hypertension, sepsis, known or suspected renal parenchymal infection, a hemorrhagic diathesis, a solitary ectopic or horseshoe kidney (except in the case of a transplanted kidney), or when the patient is unable to cooperate during the procedure.

In 1958, Kark et al.[146] published the results from their initial 500 percutaneous renal biopsies and listed 11 contraindications. These included an uncooperative patient, large cysts, a renal neoplasm, a renal artery aneurysm, marked calcific arteriosclerosis, a hemorrhagic diathesis, a single kidney, a perinephric abscess, hydronephrosis or pyonephrosis, a terminal state of illness, and a rising blood nonprotein nitrogen level greater than 100 mg per deciliter. Hypertension was viewed as a relative contraindication, depending on the importance of the biopsy and the skill of the operator.

Certainly, the presence of a single kidney (except a renal allograft), including a horseshoe kidney, sepsis, or a hemorrhagic diathesis, remain important contraindications to percutaneous renal biopsy.[147] However, in some patients, an open or laparoscopic biopsy may well be justified if the clinical situation warrants the risk. This also holds true for the patient with a renal artery aneurysm or calcific arteriosclerosis and an undiagnosed parenchymal renal disease. Many times, a coagulation disorder can be corrected, thus allowing the biopsy to be performed. In most clinical situations, there is little or no reason to perform a biopsy if the patient has large multiple cysts or a terminal illness. The same is true in the presence of a perinephric abscess, acute pyelonephritis, hydronephrosis, or pyonephrosis. Today, a rising BUN or a BUN greater than 100 mg per deciliter is not considered a contraindication if the rise is sudden or unexplained and quite likely due to an acute and potentially reversible process, as discussed earlier in this chapter. The presence of normal-sized or large kidneys increases the likelihood that an acute rather than a chronic form of renal failure is present.

When a patient is hypertensive, we delay the biopsy until the blood pressure is brought under adequate control. Thus, the presence of hypertension should be considered, at most, a relative contraindication. It is important that blood pressure control is obtained because it is well documented that hypertensive patients are more prone to bleeding after a percutaneous renal biopsy.[17,28] Diaz-Buxo and Donadio[28] not only found a significantly greater incidence of complications in hypertensive patients (11.6%) as compared with normotensive subjects (7.1%) undergoing percutaneous renal biopsy, but the higher incidence also correlated positively with both the severity and the duration of the hypertension.

GROSS INSPECTION AND TISSUE PROCESSING

An evaluation of a kidney biopsy includes both a gross and a histologic examination of the specimen. A standard histologic examination includes light microscopy, immunohistology, and transmission electron microscopy. Other less frequently used techniques include scanning electron microscopy, microbiologic cultures, tissue and cell cultures, quantitative or qualitative chemical analyses, enzyme assays, and molecular pathology. Most of the remainder of this chapter is concerned with the preparation, histologic examination, and actual evaluation of the biopsy specimen for clinicopathologic interpretation.

Gross Examination

The general purpose of a gross examination is to determine adequacy and to divide the specimen into the appropriate portions for subsequent processing. The overall dimensions, color, and consistency should be noted. In particular, the area of viable cortex should be identified and delineated from the medulla, which is generally paler. Areas of infarction, other necrosis, or pyogenic inflammation that are often pale and highlighted by a hyperemic border may be evident by a gross examination. Ischemia with reflow also may be

hyperemic throughout. In general, if the specimen contains both the cortex and the medulla, the medulla is the deeper tissue as it is removed from the needle, although there are several exceptions. If the needle is thrust deeply into the kidney before the core is taken, the cortex may be missed altogether, or if the direction of the needle is obtuse to the pelvis, the needle may pick up the medulla first and then the cortex as it passes completely through the medulla. We have observed specimens that contain the cortex, the medulla, and then more of the cortex. Chronic disease will make it more difficult to delineate the cortex.

Allografts have additional notable characteristics. First, in older grafts, a thick rind of fibrous tissue surrounds the graft. This area may be quite pale and should not be confused with the cortex. In newer grafts, the surface may be deeply colored from a hemorrhage or the presence of granulation tissue. Second, the outermost rim of the cortex may be pale from ischemic atrophy or necrosis. The deeper cortex is of interest for the diagnosis of an additional disease. Many laboratories employ a dissecting microscope or hand lens to identify glomeruli in the cortex and to guide division of the specimen at the time of the biopsy.

Processing for Histologic Examination

Despite considerable effort, it has not been possible to develop a single method of tissue fixation and processing that is optimal for light, immunofluorescence, and electron microscopy. Therefore, it is customary to divide the cortical portion of the biopsy into three parts (Fig. 13.1). We prefer to divide the tissue core along its short axis, as illustrated, to minimize tissue damage. For longer cores, the largest part is taken for light microscopy, a smaller portion is taken for immunofluorescence microscopy, and the smallest portion is taken for electron microscopy. The exact proportions of this division are variable and depend on the total amount of cortex and the clinical setting (e.g., native versus allograft biopsy). The basic consideration in the division of the specimen depends on the definition of an adequate sample for each type of histologic examination. Six glomeruli generally are considered an adequate number in a native kidney for light microscopic evaluation. However, in exceptional circumstances, the limits are broad. For example, in the evaluation of a patient with nephrotic syndrome, a disease that is diffuse and generalized such as uncomplicated idiopathic membranous glomerulonephritis may be diagnosed with a single glomerulus. On the other hand, in the early stages of a focal proliferative disease or with the variable pattern of involvement often observed in lupus nephritis, the diagnosis may not be appreciated with six or more glomeruli. We prefer a core of tissue sufficient in length to provide 12 glomeruli for light microscopic examination. The extent or degree of severity of chronic atrophy also is determined best on larger specimens and is especially important for the assessment of permanent nephron loss.

The factors that determine the adequacy of a sample for immunohistology are somewhat different. The principal role of immunohistochemistry is to evaluate the type, location, and distribution of serum proteins, particularly those commonly identified in immune complexes or directed against a specific antigen, such as seen in anti-GBM disease. The biology of these immune diseases is such that the distribution of immune mediators is more diffuse and generalized, even though the light microscopic pattern may be focal and segmental; therefore, sections containing four to six glomeruli usually are adequate.

Electron microscopy is most useful in diffuse and generalized diseases. It is preferable to examine two or three glomeruli as well as tubules and small vessels whenever possible. After the viable cortex has been divided, any remaining tissue such as the medulla is also processed for light microscopy.

When only a few millimeters of cortex are obtained, we process the entire specimen for electron microscopy. During the examination for electron microscopy, the tissue also is evaluated by light microscopy so that the maximum amount of information can be obtained. In addition, electron microscopic processing is technically most suited for handling small pieces of tissue, and the overall preservation of the tissue is much better. If the core of the cortex is 4 to 8 mm in length, we process equal parts for the electron microscopy and the immunofluorescence microscopy (Fig. 13.1).

Two tissue cores are recommended for allograft biopsies because of the variable nature of rejection.[148] We also modify the division of tissue from transplant biopsies. This is done to expedite the diagnosis when rejection is suspected. Approximately half the cortex is submitted for frozen sections. Most of the remainder is processed for routine light microscopy. Small (1-mm) portions are saved for electron microscopy. Frozen sections are taken immediately for light microscopy stains, hematoxylin and eosin (H&E) and periodic acid-Schiff (PAS), and immunohistology microscopy. These procedures can be completed within 1 to 2 hours. Rejection can be determined from the frozen sections in many patients. The final evaluation has to wait

for routine processing in subtle or complex situations, but rapid processing produces permanent sections in 4 hours.

There is a diversity of opinion regarding the optimal tissue fixation for light microscopy. In part, this is because several fixatives are available that yield generally acceptable results. The fixative for use in general pathology has a formaldehyde base; a 4% solution of formaldehyde in neutral phosphate buffer is acceptable in most situations. Other common fixatives include Zenker, Van de Grift, Helly, and Bouin solutions.[149] Variations in fixation and other processing steps make less and less difference with time and experience.

There are circumstances when a standard fixation and tissue processing should be supplemented with special handling of the tissue. Urate, uric acid, other water-soluble crystals, and glycogen may be dissolved from the tissue during processing in aqueous solutions. Ethanol is the fixative of choice for preservation when the presence of urates and uric acid are suspected. Lipids are extracted from the tissue during the later stages of processing for routine paraffin sections; therefore, frozen sections are preferable for the demonstration of lipids. Some fixatives degrade antibody binding and nucleic acid hybridization to tissue or tissue extracts; therefore, processing must be appropriate for these tests. Because special handling is required in only a few cases, it is important to have a high index of suspicion when these situations arise and to alert the pathologist and the laboratory before the biopsy is actually performed.

After fixation, the tissue is dehydrated and embedded using one of several techniques. We prefer wax embedding because it is automated and permits the use of the greatest variety of special stains. We normally prepare seven slides with 2-μm thick sections. The first, fourth, and seventh slides are stained with H&E, the second and fifth are stained with PAS, and the third and sixth are stained with periodic acid-methenamine silver (PAMS).[149] Additional stains, such as Congo red, are used as necessary. Some laboratories use plastic materials for embedding, which produce very clean, thin, crisp sections that also can be stained with the H&E, PAS, and PAMS procedures. Specimens processed in this manner require separate handling and, in our experience, additional special stains often demonstrate poor contrast.

Many types of fixatives are available for electron microscopy, and several are acceptable for the evaluation of a kidney biopsy within certain limits. We recommend either of two initial fixatives for electron microscopy. The first is buffered formaldehyde. In its early use, formalin solution was maligned as a fixative for electron microscopy because of poor tissue preservation. This was not because formaldehyde is actually a poor fixative, but because formaldehyde produces a highly acidic solution in water and the increased acidity produces many artifacts. Buffered formaldehyde (pH 7) is a good fixative, is inexpensive, and is readily available. It has a long shelf life, and tissue can remain in the fixative for months if necessary before additional processing.

Glutaraldehyde is commonly employed to preserve kidney biopsy specimens for an electron microscopy and is our choice as a primary fixative for ultrastructural preservation, although it may be less readily available in routine histology laboratories. Regardless of the fixative, it is important that the tissue to be processed for electron microscopy is divided into pieces less than 1 mm in any dimension to ensure good penetration of the fixative and all other solutions used in subsequent processing. This is not a problem with needle biopsies, but wedge biopsies must be divided accordingly. After the primary fixation, the tissue is ready for additional processing, which should be performed in a dedicated electron microscopy laboratory.

Tissue for immunohistology can be handled in several ways. For frozen sections, the tissue is placed between gauze sponges, moistened with saline, and taken directly to the laboratory. It is important that the tissue not be allowed to float in saline because tissue specimens left in aqueous solutions absorb water, which distorts the architecture. Ideally, the transit time to the laboratory should be less than 30 minutes. If transport is delayed, the tissue should be kept on ice, but should not be frozen. Alternatively, a second method can be employed. Michel et al.[150] developed a holding solution composed of buffered ammonium sulfate and N-ethylmaleimide, which is used at room temperature for the preservation of biopsy specimens for immunofluorescence microscopy. The original solution has been modified slightly and is even more broadly applicable than originally described.[151] Michel's medium remains valuable for holding the tissue at room temperature or for shipping kidney specimens without refrigeration, provided certain guidelines are followed. First, the tissue pieces should be 2 mm or less in thickness. Second, the tissue should not be kept in the solution for longer than 1 week before it is rinsed and frozen as described for fresh tissue. We block the tissue in gelatin, as described by Burkholder et al.,[152] or routine cryomicrotomy solution, after which it is snap frozen in isopentane or Freon cooled with liquid nitrogen or an electrical refrigeration unit, or in a slurry of dry ice and acetone. Rapid freezing is important to reduce the formation of large ice crystals because they result in tissue distortion and sectioning artifacts. Tissue that is stored frozen before and after sectioning should be protected to prevent desiccation and denaturation artifacts.

Frozen sections are cut and stained according to any of several immunohistologic procedures. Direct immunofluorescence staining for serum proteins with fluoresceinated heteroantisera or monoclonal antibodies remains the standard procedure. Antibodies to IgG, IgM, IgA, C1q, C3, and albumin are used most frequently. With the appropriate interpretation, this panel of antisera allows for the successful identification of most clinical diseases. Staining for selected amyloid proteins and κ and λ light chains is helpful or necessary in many adult cases. A variety of other antigens have been used in special or experimental situations; however, most are not necessary in everyday clinical practice. After staining, the slides are cover-slipped with buffered glycerol at pH 8.2 in preparation for viewing.

A fluorescence microscope equipped with epifluorescence is convenient to use and should be outfitted with adequate illumination, a primary interference filter, and an appropriate secondary filter.

A number of methods employing other fixatives or embedding procedures for the immunohistochemical demonstration of serum proteins in kidney biopsies have been described, including the use of wax sections. Some of these alternative procedures are unreliable, but others[153] are suitable for the demonstration of antibodies and some complement proteins in paraffin sections.

Several other tests are occasionally required that can be performed only on frozen sections. These include neutral fat stains and most enzyme histochemistry. The use of immunohistochemistry, combined with a host of specific monoclonal antibodies, has produced a highly specific and sensitive system for the identification of cell and tissue antigens. The impact of this methodology has been most noticeable in our ability to identify lymphohistiocytic cell infiltrates and to classify cellular immune responses in the kidney such as cellular rejection, interstitial nephritis, and posttransplant lymphoproliferative disease (PTLD). We have found that the avidin biotin complex (ABC) procedure yields the best combination of sensitivity, specificity, quality control, and time for the completion of the test.[154] There are excellent monoclonal antibodies commercially available for the identification of B cells, T-cell subsets, and monocytes. Many of these may be used in tissues following the fixation in buffered formalin.

Immunoperoxidase staining of frozen sections can also be used in addition to or instead of immunofluorescence staining. The advantage of immunoperoxidase techniques over immunofluorescence microscopy includes a greater sensitivity and permanence of the staining when diaminobenzidine is used as the substrate for color development. The disadvantages of immunoenzyme staining for immunoglobulin localization include the increase in preparation time and the added expense. Endogenous peroxidase and endogenous biotin may produce a bothersome high background and should be blocked.[155]

Molecular Biology

In situ hybridization has been a powerful tool for a host of investigational studies.[156,157] A variety of molecular probes have been used to study gene expression at the level of messenger RNA (mRNA)[158–160] and for the detection of viral sequences.[161,162] For example, Epstein-Barr virus (EBV) probes may be useful in the diagnosis of PTLD. Renal biopsy specimens also can be used as a source of DNA or RNA for extraction and nucleic acid blotting or for polymerase chain reaction (PCR)-based techniques.[161,164–167] Although the potential for molecular diagnosis of renal disease by microarray analysis and other techniques is near at hand, there are few standard applications for clinical renal biopsy diagnosis at the present time.[168] Proteomic studies (e.g., mass spectroscopy) have been used in the subclassification of amyloids in tissue blocks[169,170] and have additional potential.

THE HISTOLOGIC EVALUATION

Light Microscopy

The purpose of this section is to present a systematic approach to the histologic interpretation of a kidney biopsy. The discussion also includes the role of several special stains in a biopsy diagnosis. The evaluation should begin with a review of all tissue that is present on the light microscopic sections at a relatively low magnification to assess the adequacy of the specimen and to identify any major abnormalities. This is followed by a systematic evaluation of the glomeruli, tubules, the interstitium, and the vasculature. It is preferable to establish the histopathologic findings before the clinical history is known to avoid a bias in the final biopsy interpretation. Nevertheless, the biopsy findings must ultimately be reconciled with the clinical presentation, course, and prognosis.

It is important that certain terms be carefully defined before continuing. There are four principal definitions that have evolved largely from light microscopic evaluation of kidney biopsies to describe glomerular disease. Focal denotes a process in which only some of the glomeruli are altered histologically. The majority of glomeruli are spared. Generalized indicates the majority of glomeruli on the biopsy are altered by some process; for instance, proliferation or sclerosis. A local, or segmental, lesion is one in which only a portion of a glomerulus exhibits an alteration. A segmental sclerotic process involves only a portion of a glomerulus. The opposite of a segmental process is one that is global in nature and generally affects the entire glomerulus. The term diffuse has been used ambiguously in the literature. Sometimes it has meant global and other times it has meant generalized; therefore, care must be taken when interpreting this term. We will avoid the term diffuse for these reasons. Glomerular lesions are generally focal and segmental or are generalized and global, but important exceptions exist (e.g., generalized and segmental in lupus nephritis).

The initial evaluation of the specimen is intended to determine the specific regions of the renal parenchyma that are present on the section, which might include the cortex and the outer and inner medulla. If only the cortex is seen, the presence of the renal capsule can aid in the orientation of the specimen. The glomeruli should be counted to provide a rough estimate of the sample size. This is generally accomplished best with the PAS-stained sections, in which the glomeruli (including those that are globally sclerotic) can be identified readily. All the tissue on each slide should be evaluated because certain features may not be present in all sections. Next, the overall condition of the renal architecture is evaluated to differentiate between

chronic or irreversible nephron loss and acute or reversible nephron damage. The type, distribution, and intensity of cellular infiltration are accurately established on the H&E and PAS sections. The PAS and PAMS stains are well suited to evaluate the degree of interstitial fibrosis, tubular atrophy, and glomerulosclerosis. In general, the degree of tubular and interstitial injury relates to the reduction in creatinine clearance when the sample size is adequate and the process producing the injury is uniform. The latter feature is important because, with approximately 1 million nephrons in each kidney, a needle biopsy specimen that contains 10 glomeruli only provides a sample of 1 in 100,000. As a first approximation, we employ a simple procedure to estimate the extent of chronic nephron loss in a biopsy. Using a PAS-stained section, the total number of glomeruli is counted and the percentage that is sclerotic is determined. Sclerotic glomeruli are generally shrunken in appearance because of the complete collapse of the capillary bed and the paucity of cells. In a study of chronic glomerulonephritis, we have shown that global glomerular sclerosis of up to 50% is associated with the maintenance of the serum creatinine near the normal range.[171] However, an increase in glomerular sclerosis of the global type above 50% to 60% is associated with increases in the serum creatinine. This estimate of chronic nephron loss is based on an interpretation of the intact nephron hypothesis.[172] When one portion of the nephron is lost to disease or injury, the remainder of the nephron undergoes atrophy. Thus, the accompanying tubule undergoes atrophy in the presence of global sclerosis. The converse also is true. Tubular atrophy is characterized by a decrease in the outer diameter of the tubule, thickening and wrinkling of the tubular basement membrane, simplification and a decrease in thickness of the tubular epithelium, and an increase in the interstitial connective tissue that surrounds the tubule. However, it is also true that one part of the nephron may take longer than another to atrophy. It is also important to estimate the percentage of atrophic tubules in the specimen because there may be significant tubular atrophy in the absence of glomerular sclerosis. These changes all lead to disruption of the normal architecture of the renal parenchyma. Because some nephrons are destroyed or atrophy, the remaining nephrons may hypertrophy, showing tubules with larger diameters and cells with increased cytoplasm. This picture of atrophy and hypertrophy is visualized in Figure 13.2. In this setting, hyperfiltration is associated with glomerular changes of increased size and mesangial matrix and segmental sclerosis.[173–177] These features are the harbingers of the point of no return or of continued deterioration in renal function.[178] The normal architecture also can be disrupted by more acute changes, such as edema and inflammation. In this setting, there is separation without evidence of atrophy of the renal tubules. Depending on the etiology of the injury, these latter changes may be reversible, as seen in ATN, or occasionally they may progress to the loss of the entire nephron.

Glomeruli

The next step in the interpretation of the biopsy is a detailed evaluation of the glomeruli, which includes a careful assessment of the various structures that comprise the glomerulus or renal corpuscle. The glomerulus is composed of the visceral epithelial cells, the endothelial cells, the mesangial cells with the mesangial matrix and the basement membranes of the capillary loops, the Bowman capsule and the

overlying parietal epithelial cells, the extraglomerular mesangium, and the afferent and efferent arterioles (Fig. 13.3). The first assessment is a determination of the overall glomerular cellularity, which is evaluated using H&E-stained sections (Fig. 13.4A). The cell type should be established if the glomeruli are hypercellular. This includes an estimate of the number of cells normally present in the glomerulus, including the mesangial, endothelial, visceral epithelial, and parietal epithelial cells; and the inflammatory cells that migrate into the glomerulus, including neutrophils, lymphocytes, and monocytes (Fig. 13.5). Most pathologists principally rely on a qualitative assessment of the cellular composition in sections 2- to 3-μm thick and stained with H&E. There are several guidelines for this assessment. Under normal conditions, a typical cross-section through the mesangium contains one to three mesangial cell nuclei. An entire glomerulus may contain one to two neutrophils, but more than two is abnormal. There are also a small number (1%) of mononuclear cells (monocytes) in the normal glomerular mesangium,[179] but these cells cannot be identified with certainty on routine H&E sections. Similarly, it may not be possible to distinguish monocytes from large lymphocytes or even epithelial cells without immunohistochemistry or electron microscopy. Some cells within the glomerulus may contain inclusions, inspissated material, or numerous vacuoles, such as those that are present in foam cells.

Next, the glomerular capillaries are examined to determine whether they are patent, collapsed, or obstructed with fibrin, platelets, or cells. The PAS and PAMS stains are important in the evaluation of the capillary walls (Fig. 13.4B,C). Both stains will label normal as well as have an abnormally thickened basement membrane. If the basement membrane is thickened, it is important to establish the nature of the changes. Both the epithelial and endothelial surfaces are smooth under normal conditions. If one surface is shaggy or irregular or exhibits projections, often referred to as spikes when present on the epithelial surface, it is distinctly abnormal (Fig. 13.4C). Occasionally, both surfaces of the basement membrane are irregular in configuration. In necrotizing glomerulonephritis owing to virtually any cause, the capillary wall, including the basement membrane, may be ruptured, discontinuous, or completely lost (Fig. 13.6). This histologic picture usually is associated with fibrin deposition. Fibrin deposition associated with necrosis should be distinguished from fibrin deposits that distend the capillary in the presence of an intact basement membrane. Larger immune complexes can be seen on Masson or PAS stains. These deposits can also be identified on 1-μm thick plastic sections stained

with toluidine blue[180] that are cut from tissue that has been prepared for electron microscopy (Fig. 13.7). The capillary (visceral) epithelial cells may exhibit hypertrophy, atrophy, or hyperplasia.

In addition to the mesangial cellularity, there may be an increase in mesangial matrix material with or without an increase in cells. This is evaluated best with the PAS and PAMS stains (Fig. 13.4B). Mesangial expansion may be global and may involve the entire glomerular tuft; it may be segmental (Fig. 13.8); or it may involve only the stalk region, which is designated the extraglomerular mesangium and forms part of the juxtaglomerular apparatus. Mesangial matrix expansion may extend into the capillary or may be observed in association with subendothelial capillary basement membrane thickening, so-called mesangial interposition.

Mesangiolysis is an alteration of the mesangium that is characteristic of thrombotic microangiopathies, but can be observed in patients with diabetes and other conditions.[181] The lesion appears as a relaxation or a disruption of the attachment of the capillary basement membrane to the mesangium. The basement membrane balloons outward in early lesions. The potential space is filled with disrupted mesangial matrix material, fibrin or platelet thrombi, fragmented erythrocytes, and other material (Fig. 13.9). Eventually, the mesangiolytic lesions sclerose and sclerosis is associated with worsening renal function.

The basement membrane of Bowman's capsule is thicker than the capillary basement membrane in the normal state and, like the capillary basement membrane, may increase in thickness with injury. The parietal epithelium lining the Bowman capsule can respond to injury with hypertrophy or hyperplasia or can exhibit infiltration with monocytes, resulting in the formation of crescents.[182]

The arterioles of the juxtaglomerular apparatus may be markedly abnormal because of the presence of glassy eosinophilic hyaline material (Fig. 13.10), edema, fibrin, other inflammatory changes; hypertrophy; or sclerosis. They may

contain fibrin thrombi (Fig. 13.11) or may exhibit segmental fibrinoid necrosis. The pericytes surrounding the arterioles should be examined carefully for evidence of hypercellularity and increased granularity. The PAMS stain is used to screen for the latter feature.

Tubules

Next, the tubules are examined in detail. The proximal tubule epithelium should be tall, columnar, and should possess a PAS-positive brush border and display a deeply eosinophilic cytoplasm. Acute signs of ischemic or toxic injury include swelling of the cell cytoplasm and disruption of the brush border. Cytoplasmic vacuolization is followed by cell necrosis. Later stages include the flattening of the remaining cells with irregular staining of nuclei, and evidence of early regeneration (Fig. 13.12). Apoptosis[183,184] follows a variety of stimuli, including cell-mediated cytotoxicity[185–187] with pyknosis of the nucleus, condensation of the cytoplasm, and extrusion of the tubular cells into the lumen. Characteristic PAS-positive droplets that represent lysosomes are present in increased numbers with proteinuria. Additional findings include lipid droplets and cytoplasmic vacuoles. Large irregular vacuoles are seen with severe hypokalemia (Fig. 13.13); whereas fine, diffuse cytoplasmic vacuoles are observed with exposure to osmotic agents, such as mannitol (Fig. 13.14). Vacuoles are observed in calcineurin inhibitor toxicity (Fig. 13.15). Inflammatory cells may infiltrate the tubule and, if present, the type of inflammatory cell should be characterized (Fig. 13.4F). The lumen may contain extracellular material, such as casts or white or red blood cells. The basement membrane may be thickened by atrophy or the presence of immune deposits, or it may exhibit breaks.

Interstitium

Normally, the tubules are separated by an inconspicuous interstitium, which contains peritubular capillaries and a few interstitial cells. The interstitium may be abnormally thickened or expanded by a variety of extracellular materials, including collagen, other proteins, crystals, or edema. The type of inflammatory cells should be characterized if inflammation is present. Inflammatory cells may display a specific distribution, such as perivascular or periglomerular, marginated in peritubular capillaries, or scattered uniformly throughout the biopsy. Monocytes may aggregate and assume an epithelioid appearance, giving rise to granulomas. Normally, the interstitium is more prominent in the medulla and around the muscular arteries.

Vasculature

Finally, the larger vessels should be examined. The medium-sized renal arteries have a histology typical of arteries elsewhere; however, intrarenal veins have minimal smooth muscle compared to veins of similar caliber in other organs. The most common arterial change is intimal thickening in association with irregular reduplication of the internal elastic lamina, a finding that is seen best with the PAMS stain. The lumen may contain fibrin thrombi, embolized material, or inflammatory cells (Fig. 13.4E). The walls of the arteries

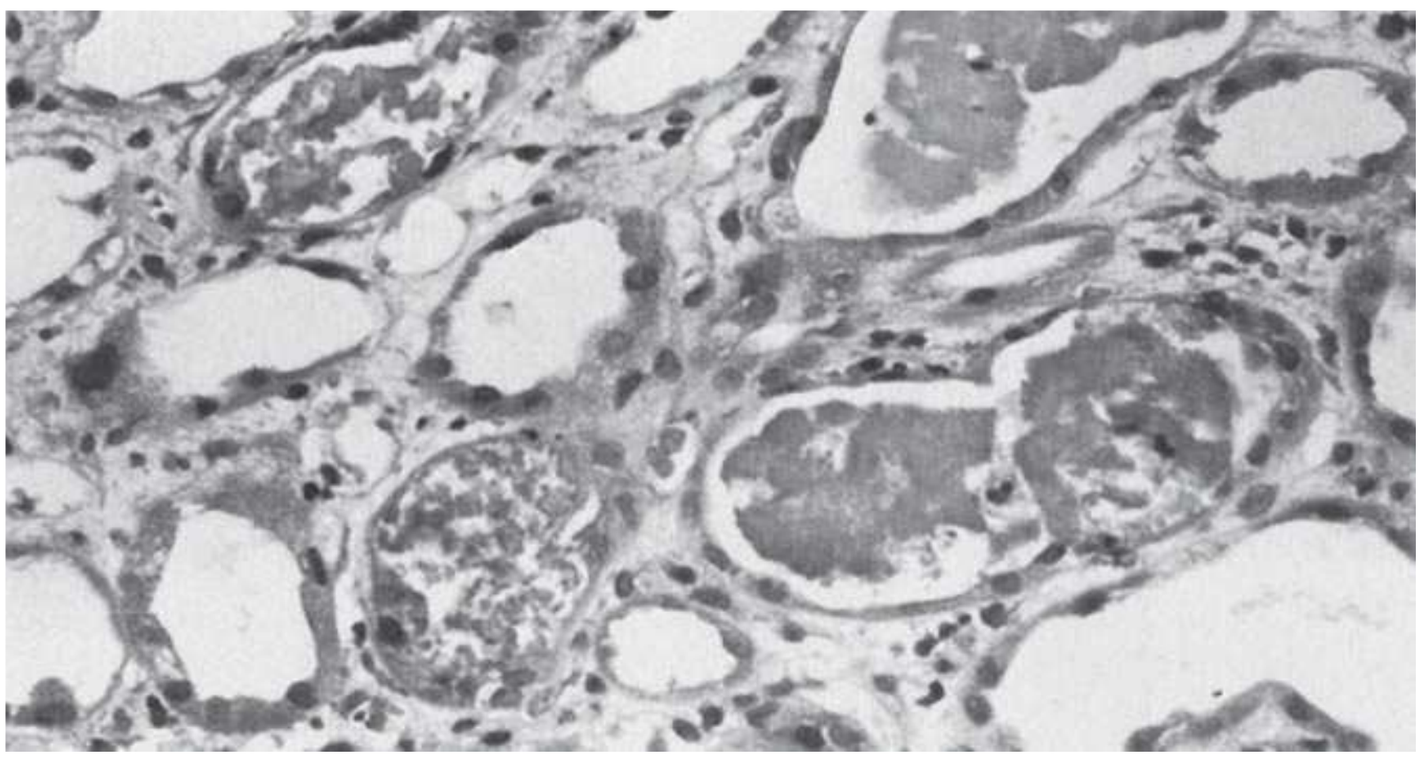

FIGURE 13.12 A photomicrograph depicting acute tubular necrosis (H&E; magnification ×440).

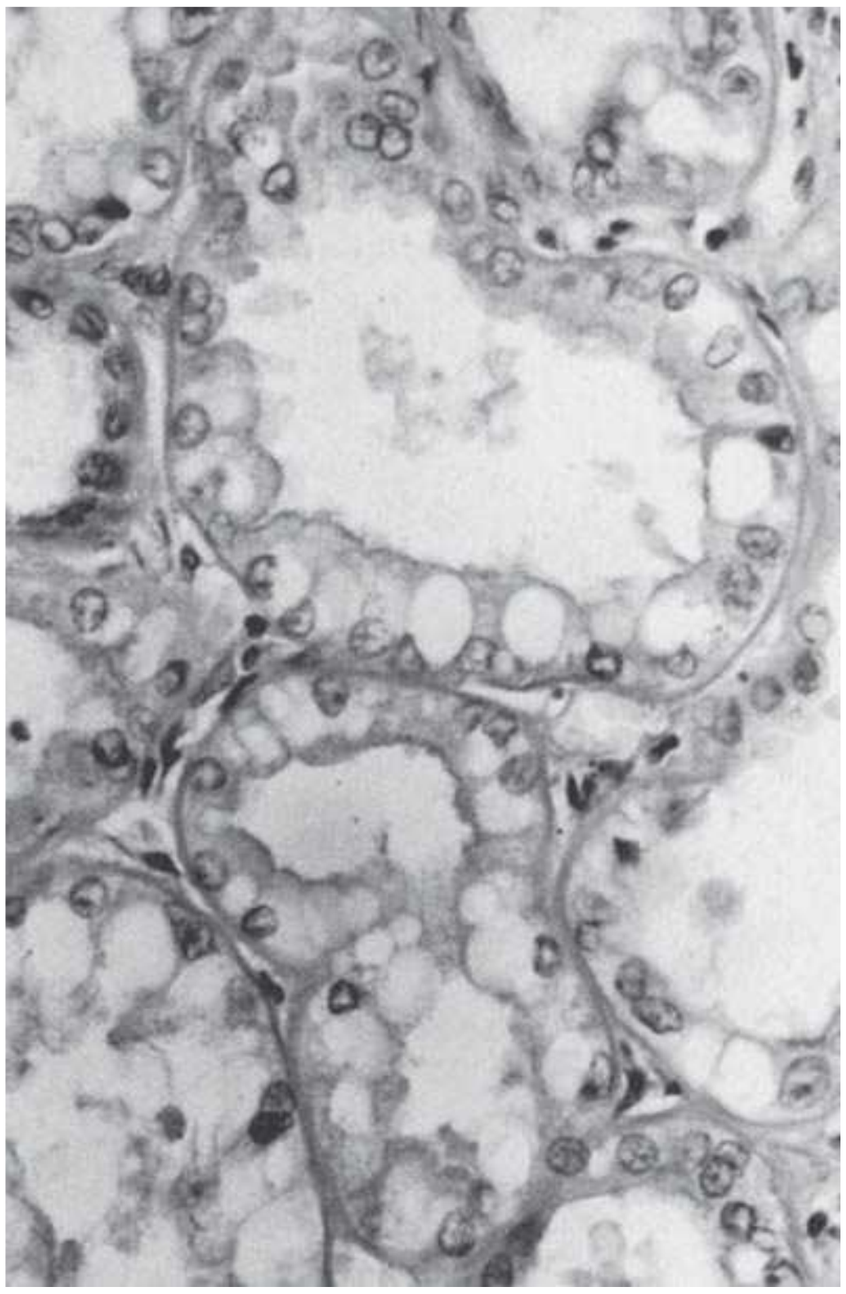

FIGURE 13.13 An example of severe hypokalemic nephropathy. Large irregular vacuoles are evident in the proximal tubule epithelium (H&E; magnification ×460).

also may be thickened as the result of edema, fibrin, other exogenous material, or inflammation. Similar, although less extensive, changes may be observed in the renal veins.

At this point, it is useful to compare the relative degree and type of involvement of each of the cortical structures. As discussed in the preceding text, when one portion of the nephron is diseased, the remainder of the nephron eventually is affected. The site of the initial insult usually demonstrates the earliest and most severe changes. Thus, in glomerulonephritis, the glomeruli usually exhibit the most

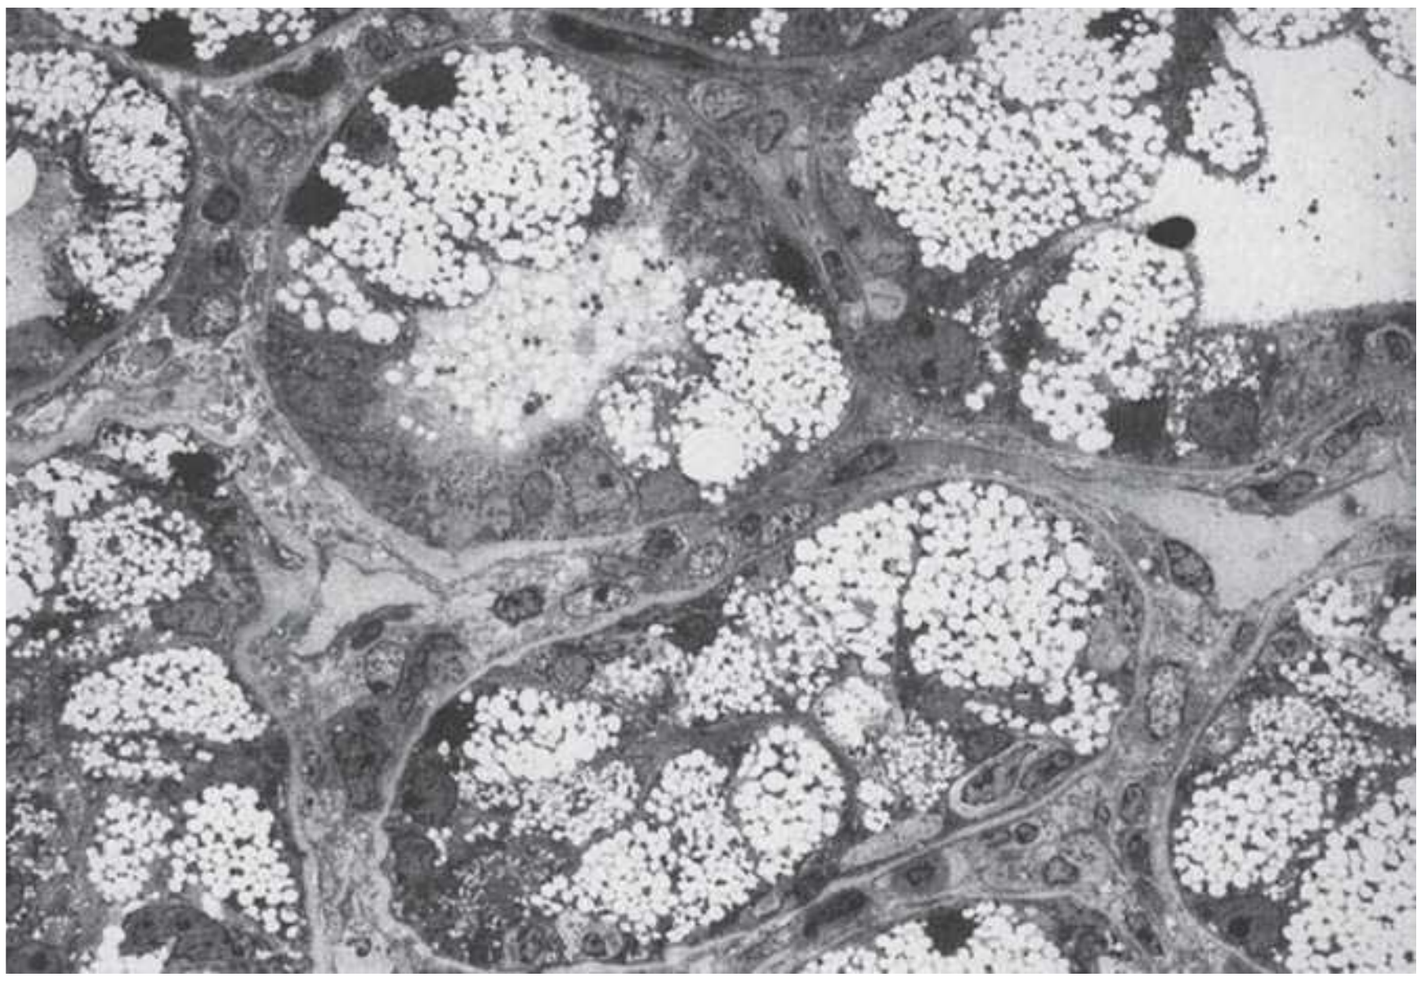

FIGURE 13.15 An electron micrograph illustrating severe tubular vacuolization secondary to calcineurin inhibitor toxicity. The nuclei are pyknotic, and the brush border is often disrupted or lost (magnification ×4,900). (From Tisher CC, Brenner BM, eds. *Renal Pathology with Clinical and Functional Correlations*. Philadelphia: Lippincott; 1989, with permission.)

striking changes, whereas less severe alterations in the form of interstitial inflammation and tubular injury accompany the primary lesion. The interstitium shows the most inflammation in interstitial nephritis, whereas the glomeruli may exhibit secondary involvement. If a process is severe enough and of a sufficient duration, all structures will atrophy and sometimes leave few clues to the etiology of the original disease. One is then left with a diagnosis of end-stage renal disease.

Electron Microscopy

The major advantage of electron microscopy is its greater resolving power when compared with light microscopy. In a kidney biopsy interpretation, electron microscopy is most useful in the examination of glomerular lesions. Immune complexes can be identified by electron microscopy when they are too small to be evident on light microscopy or when the immunofluorescence findings lack specificity. Electron microscopy gives the most definitive localization of immune complex deposits, thus making it possible to subcategorize their location as mesangial, subendothelial, subepithelial, or intramembranous. Some deposits have a characteristic substructure, such as those observed in light-chain disease,[188] amyloidosis,[121] cryoglobulinemic glomerulonephritis (Figs. 13.16A, B),[122] immunotactoid glomerulopathy,[189] or fibrillary glomerulonephritis (Fig. 13.17A, B).[190]

The basement membrane of the glomerular capillary loops may be uniformly thickened, as seen in diabetes mellitus,[191] or may be thin or irregular in appearance, as in Alport hereditary nephritis (Fig. 13.18)[192] or thin basement membrane disease.

Metabolic abnormalities may be identified by the presence of characteristic accumulations of lipids, such as seen in Gaucher disease.[193] Tubuloreticular arrays may be present in the endoplasmic reticulum of endothelial cells and are characteristic of lupus nephritis when seen in large numbers (Fig. 13.19), although they may be observed in other conditions, such as in HIV-associated nephropathy (Fig. 13.20). Endothelial cell injury is characteristic of thrombotic microangiopathy and vascular allograft rejection. Immune deposits can also be identified along the tubular basement membrane (TBM) in lupus nephritis (Fig. 13.21) and light chain deposition disease.[194]

Recently, the importance of electron microscopy in the evaluation of native kidney biopsies was reaffirmed. In a series of 233 biopsies, Haas[195] found that electron microscopy was necessary to arrive at a final diagnosis in 50 biopsies, representing 21% of the total cases. In another 48 cases, the

ultrastructural data were felt to provide important confirmatory information.

One disadvantage of electron microscopy is the limitation in the size of the sample; therefore, ultrastructural findings must be interpreted in the context of other histologic features. In addition, tissue processing for electron microscopy generally takes longer than that for light microscopy. Although rapid processing methods are available, they require special handling and therefore are more costly. Scanning electron microscopy has been used for biopsy investigation, but it is not incorporated into the processing of kidney biopsy specimens for routine clinical evaluation.

Immunohistology

Immunofluorescence and immunoenzyme staining have overlapping but different uses, as discussed previously. Standard immunofluorescence microscopy (as compared to confocal microscopy) is a more rapid but less sensitive technique. It is ideally suited for the detection of immune complex deposits. The major advantages of the immunoperoxidase technique are the greater sensitivity and the ability to examine the tissue with the light microscope, which makes the spatial relationships between tissue structures easier to identify.

There are four major immunoglobulin-staining patterns in glomeruli, which may occur singly or in various combinations (Fig. 13.22). They include linear staining along the basement membrane, granular subepithelial capillary wall staining, granular subendothelial capillary wall staining, and mesangial staining. Paramesangial deposits also may be seen alone, but as a rule, they are observed in association with one of the other granular patterns. Intramembranous deposits also are observed, but their exact location is difficult to determine. The granular deposits may be large and coarse (Fig. 13.22B) or fine (Fig. 13.22C). This difference is readily appreciated when comparing the coarse

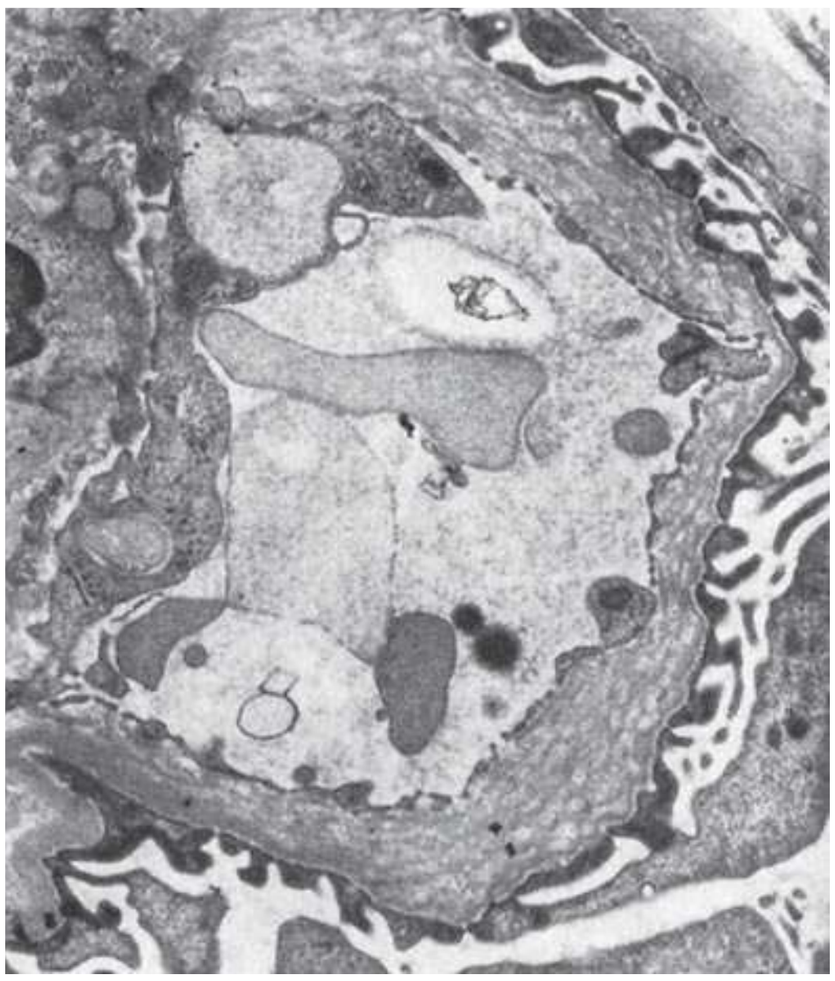

FIGURE 13.18 An electron micrograph of a portion of a glomerular capillary loop from a patient with Alport hereditary nephritis. The typical multilaminated appearance of the thickened basement membrane is evident (magnification ×3,800). (Illustration from Silva F, with permission.)

subepithelial deposits of poststreptococcal glomerulonephritis (Fig. 13.22B) with the subepithelial deposits of an early idiopathic membranous glomerulonephritis (Fig. 13.22C). Immune complex deposits may contain IgG, IgM, or IgA in any combination. C1q or C3 staining may be present in any of the same patterns as seen with immunoglobulins, or they may be observed separately. Linear staining requires careful interpretation. First, finely granular capillary wall staining can appear as a confluence of granules yielding a pseudolinear pattern. Electron microscopy resolves any doubt in this situation. Second, diseases such as diabetes mellitus and most other chronic renal diseases, including chronic allograft nephropathy, cause a thickening of the basement membrane. This is associated with increased staining of the capillary wall for serum proteins, particularly IgG4 and albumin, owing to electrostatic attraction.[196] These situations must be distinguished from the linear capillary basement membrane staining that is specific for IgG as observed in anti-GBM disease (Fig. 13.22A). In anti-GBM disease, the IgG staining clearly exceeds the albumin staining in intensity.

Epithelial cells, especially in the glomerulus and the proximal tubule, commonly have cytoplasmic droplets of protein in proteinuric conditions. Immune complexes also may be seen in the vessels, the interstitium, or along the tubular basement membranes. Vascular or tubular basement membrane staining for C3 in the absence of immunoglobulin is a common and often nonspecific sign of injury.

The use of immunoperoxidase staining with monoclonal antibodies directed against different antigens has made it possible to identify cell populations in tissue sections with great clarity and discrimination.[197] Immunofluorescence microscopy also can be used,[198] but the spatial discrimination is not as good. Most nonspecific inflammatory infiltrates are an approximately equal mixture of B and T cells, with a predominance of T-helper cells (CD4) over T-suppressor or cytotoxic (CD8) cells.[197–199] These cells form nodular aggregates in interstitial areas. Cellular allograft rejection predominantly has T cells (Fig. 13.4F)[197–199] and monocytes (macrophages).

In some cases, a viral cytopathic effect may be seen by standard histology (e.g., nuclear inclusions) and the viral pathogen inferred from the clinical situation or serologic tests. However, the virus can be specifically identified by immunohistochemistry or in situ nucleic acid hybridization. Common examples in the transplant setting are BK virus, cytomegalic virus (CMV), and EBV.

Other enzyme systems can be used to replace peroxidase in immunoenzyme staining. However, immunostaining

using horseradish peroxidase and diaminobenzidine as the substrate is the best combination currently available because the staining is crisp and the slides are permanent. Diaminobenzidine is a carcinogen and must be handled with caution. Immunohistochemistry has great diagnostic potential, which is limited primarily by the antibody specificity.

The vision of gene expression in kidney disease has progressed in two paradigms for kidney transplant pathology. The first is in "for cause" biopsies where the microarray transcriptiosome signature may help clarify the ambiguous Banff subclassification of "Borderline (Suspicious) for rejection" and various chronic renal allograft pathology states[200] known as chronic rejection, chronic allograft nephropathy, or interstitial fibrosis/tubular atrophy (IFTA).[201,202] The second paradigm is to monitor gene expression in biopsies to evaluate the adequacy of immunosuppresion in terms of determining which gene signature profiles are predictive of chronic progression.[203] Biopsy studies are supplemented by minimally invasive peripheral blood profiles.[204–206]

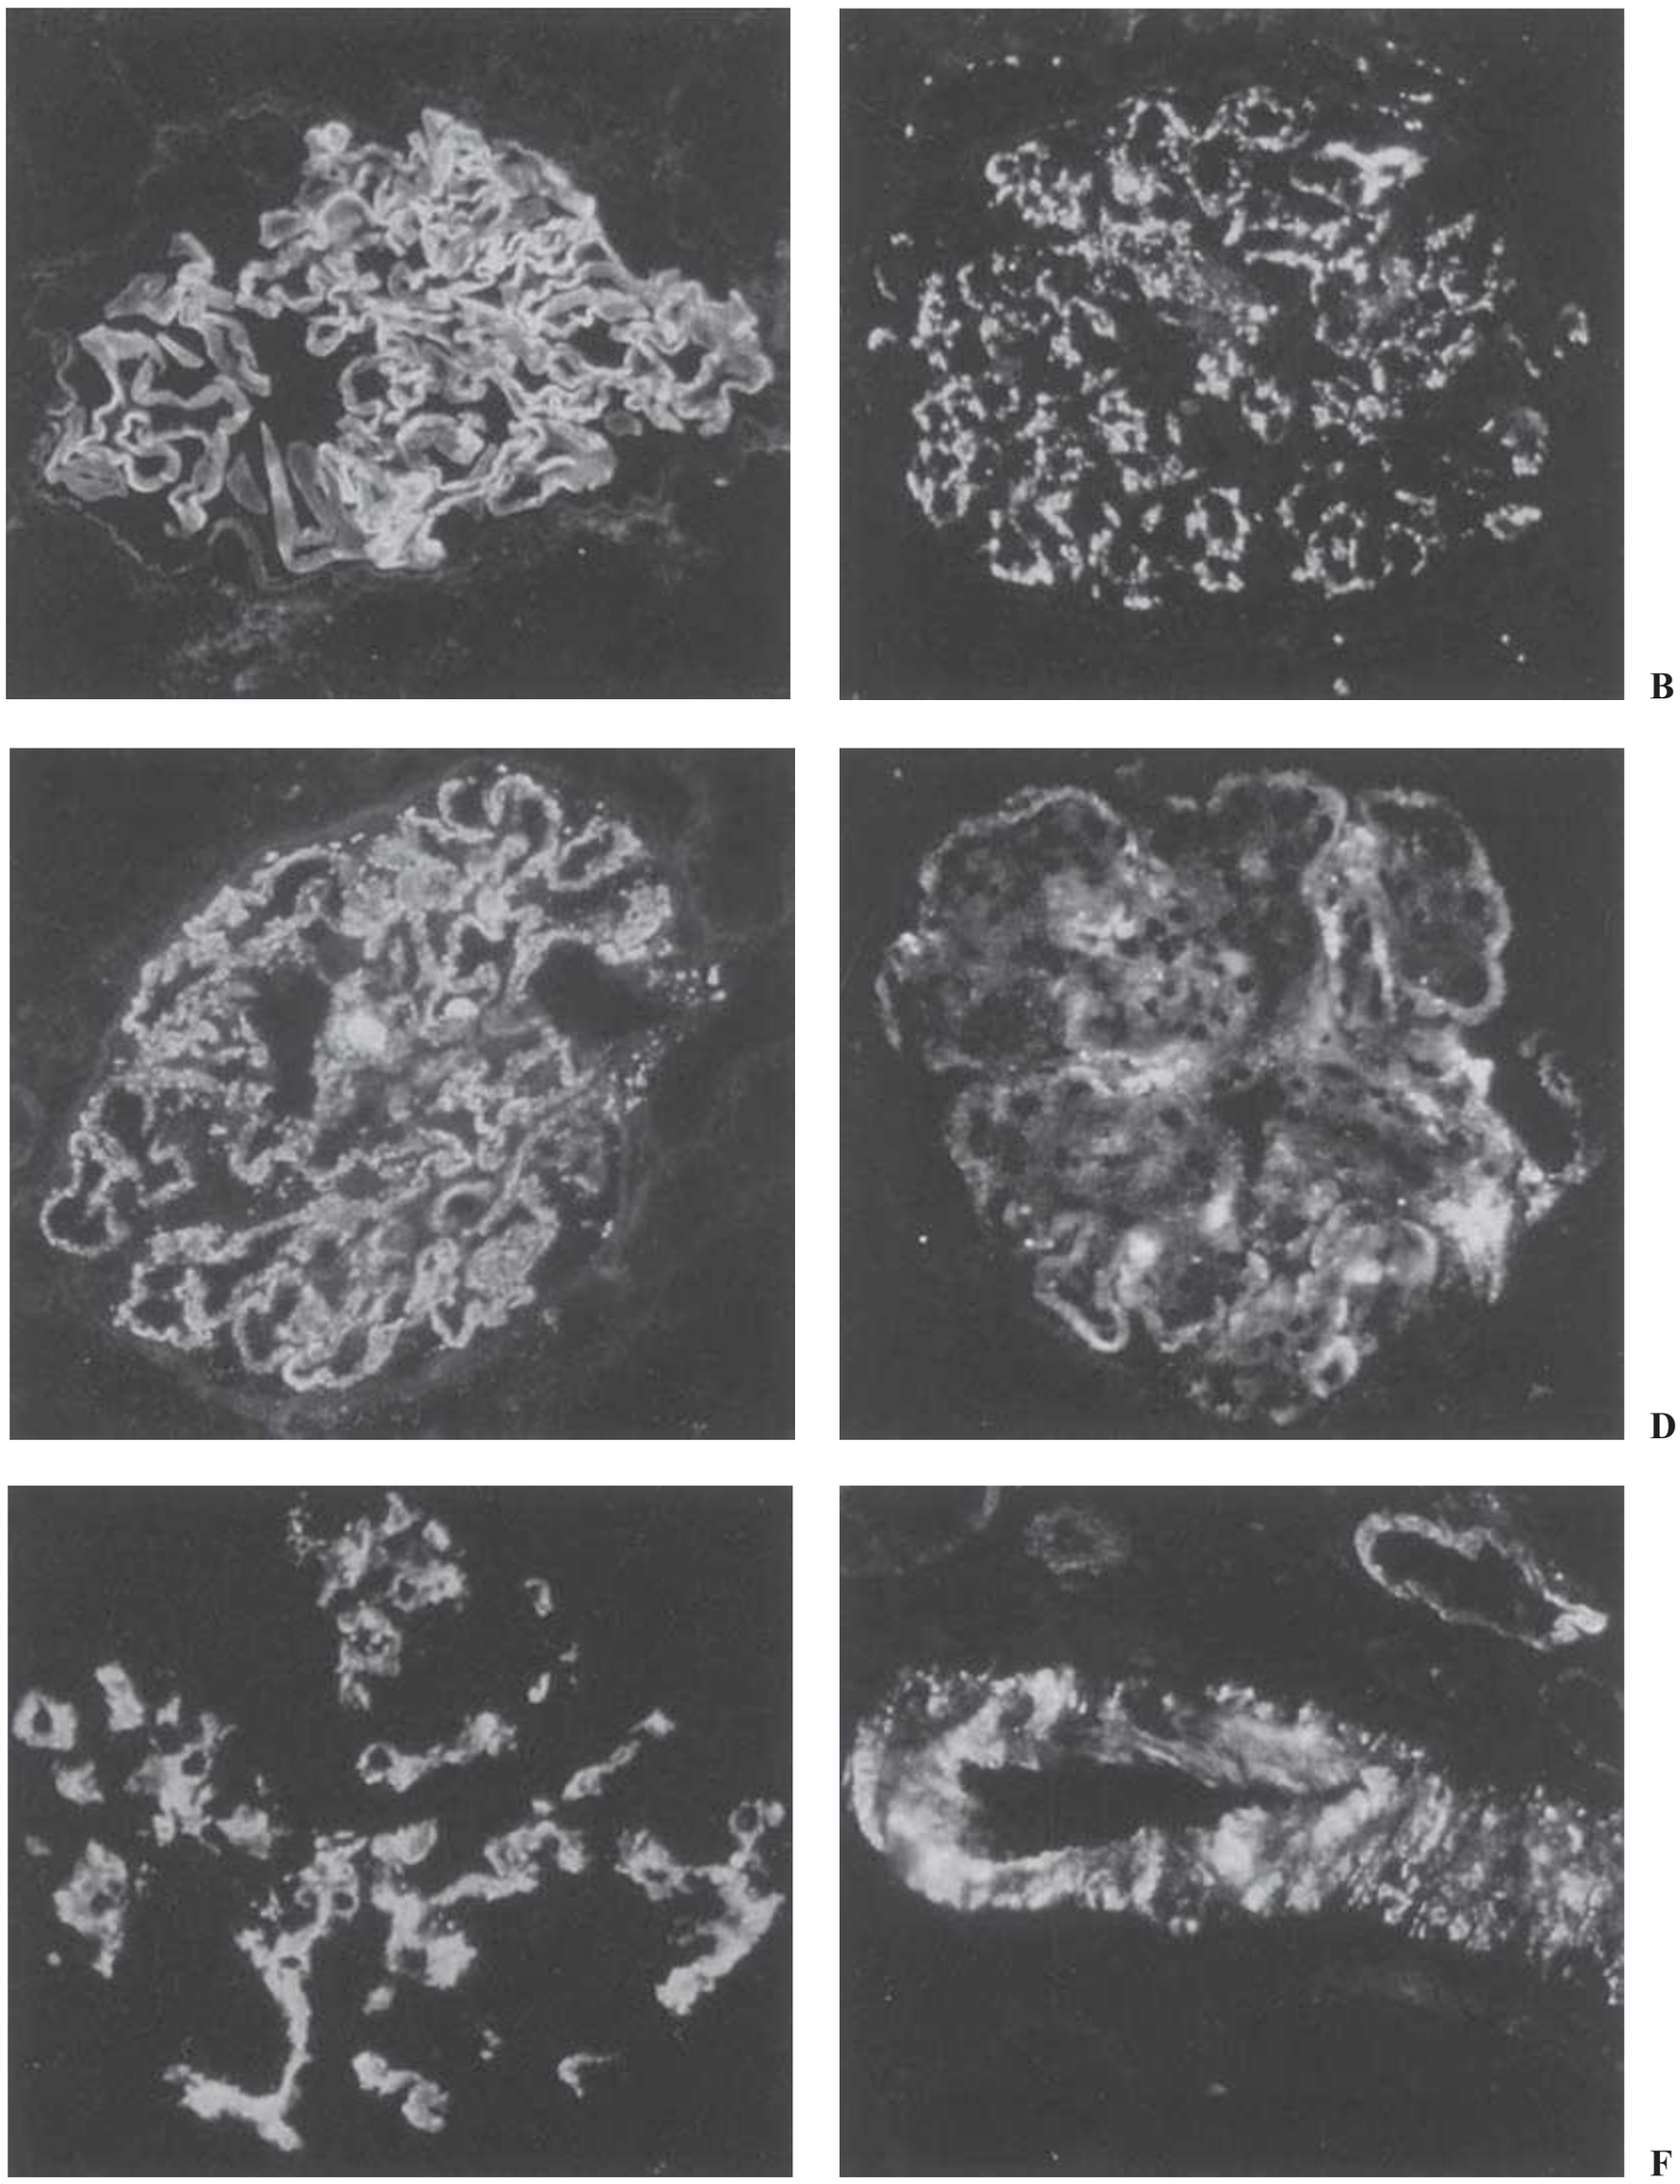

FIGURE 13.22 **A:** A glomerulus with fine, ribbonlike basement membrane staining with IgG indicative of anti-glomerular basement membrane disease (magnification ×200). **B:** A glomerulus exhibiting coarse granular deposits of IgG distributed irregularly along the glomerular basement membranes. This pattern is typical of poststreptococcal glomerulonephritis. C3 is usually present in the same pattern (magnification ×200). **C:** A glomerulus with fine IgG granules evenly deposited along the glomerular basement membrane. This pattern is typical of the subepithelial deposits of idiopathic membranous glomerulonephritis (magnification ×200). **D:** A glomerulus demonstrating the typical pattern of subendothelial immune complex deposits. The outer edge of the deposits abuts the inner surface of the glomerular basement membrane and is relatively smooth. The inner aspect of the deposits is shaggy and irregular and may merge with the mesangium, which is expanded. This pattern is characteristic of membranoproliferative glomerulonephritis (IgM; magnification ×200). **E:** A glomerulus exhibiting the typical pattern of IgA mesangial immune deposits. Note the absence of basement membrane localization. The dark spaces in the midst of the deposits represent mesangial cells, not capillary lumina. This pattern is typical of IgA nephrology, Henoch-Schönlein purpura, and mesangiopathic lupus nephritis (magnification ×200). **F:** An arteriole with transmural staining for IgM. This pattern is characteristic of relatively mild, acute vascular lesions of vascular rejection. In more severe lesions, there is a greater disruption of the vessel wall, which also can be seen by light microscopy. This pattern should be distinguished from the subintimal glossy deposits of hyaline that are seen in chronic vascular disease (magnification ×400). (See Color Plate.)

CLINICOPATHOLOGIC CORRELATIONS

Once the light, immunohistologic, and electron microscopic findings are completed, they should be integrated to derive a histologic diagnosis that is indicative of the disease process. The histologic diagnosis then is related to the clinical findings to give a clinicopathologic diagnosis that can be used to plan a course of therapy, establish the prognosis, or both. We do not try to describe all of the many histologic patterns of kidney disease in this section, because they are discussed in considerable detail in other chapters of this book. Instead, we briefly discuss selected examples in which the approach we have outlined is used.

Several renal diseases fail to reveal significant changes or only nonspecific changes on a histologic examination. For instance, in MCNS, the findings are principally the result of proteinuria and include foot-process simplification in the glomerulus and evidence of increased protein resorption by the proximal tubule. The only abnormality in benign recurrent hematuria may be the presence of red blood cells in the tubules. The differential diagnosis should include Alport disease early in its course and thin basement membrane disease. Differentiation requires a thorough electron microscopic examination of the specimen and the appropriate clinical studies.

Mesangial Expansion

In many conditions, mesangial expansion may be the only abnormality observed on light microscopy. The immunofluorescence findings separate a group of immune complex diseases that exhibit mesangial involvement. For instance, if IgA is the predominant immunoglobulin that localizes to the mesangium (Fig. 13.22E), the differential diagnosis should include IgA nephropathy and Henoch-Schönlein disease. If IgG is the principal immunoglobulin, then lupus nephritis should be considered and a careful search should be made by electron microscopy for subendothelial and subepithelial deposits or fibrillary glomerulonephritis. If the predominant immunoglobulin is IgM, then the differential diagnosis should include IgM nephropathy and the mesangiopathic form of lupus nephritis. Mesangial localization of C3 in the absence of immunoglobulins may represent a resolving immune complex disease. Evidence of resolving immune complexes may be seen by electron microscopy. The mesangial expansion may represent early diabetic nephropathy, arteriolonephrosclerosis, or FSGS if no complexes are noted on electron microscopy. If the material responsible for the mesangial expansion is negative or only weakly positive with the PAMS and PAS stains, it is important to examine additional sections after staining with Congo red in search of evidence of amyloid. On light microscopy, the most specific indication of amyloid is a green birefringence that occurs when the Congo red stain is viewed under polarized light (Fig. 13.4D). Occasionally, electron microscopy may be necessary to establish the diagnosis because it is the most sensitive technique to detect amyloid. Other, less common immune deposits that are also demonstrated easily with electron microscopy include κ light-chain disease, cryoglobulinemic glomerulonephritis, fibrillary glomerulonephritis, and immunotactoid glomerulopathy (Figs. 13.16A,B and 13.17A,B).

Neutrophilic Exudates

A neutrophilic exudate may be observed in a variety of renal diseases. The most prominent neutrophilic exudate is typically seen in poststreptococcal glomerulonephritis (Fig. 13.5),[207] a disease that does not usually require a biopsy for diagnosis. Occasionally, the typical clinical features are obscured, however, and a kidney biopsy is required. The patient may not seek medical attention until later in the disease course, when the light microscopic and immunofluorescence microscopic findings of coarse granular IgG deposits (Fig. 13.22B) may not be present. Often, however, C3 deposits remain. Again, electron microscopy may demonstrate typical large humplike subepithelial deposits that are in various stages of resolution. Numerous neutrophils also may be seen in other forms of postinfectious glomerulonephritis, in MPGN (Fig. 13.23),

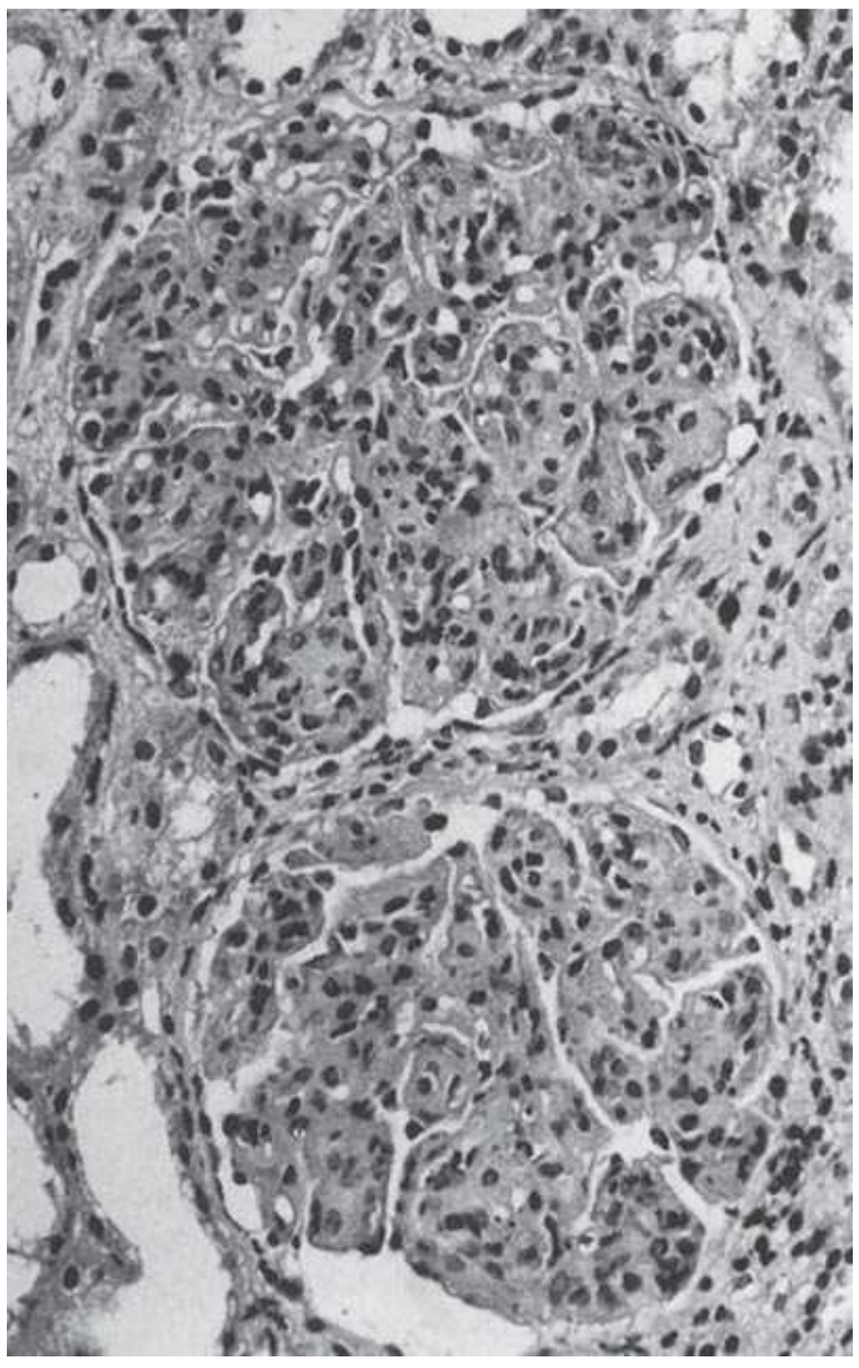

FIGURE 13.23 A photomicrograph demonstrating a mesangial hypercellularity and neutrophilic infiltrates in two glomeruli from a patient with type II membranoproliferative glomerulonephritis (H&E; magnification ×300). (From Lamb V, Tisher CC, McCoy RC, et al. Membranoproliferative glomerulonephritis with dense intramembranous alterations. A clinicopathologic study. *Lab Invest* 1977;36:607, with permission.)

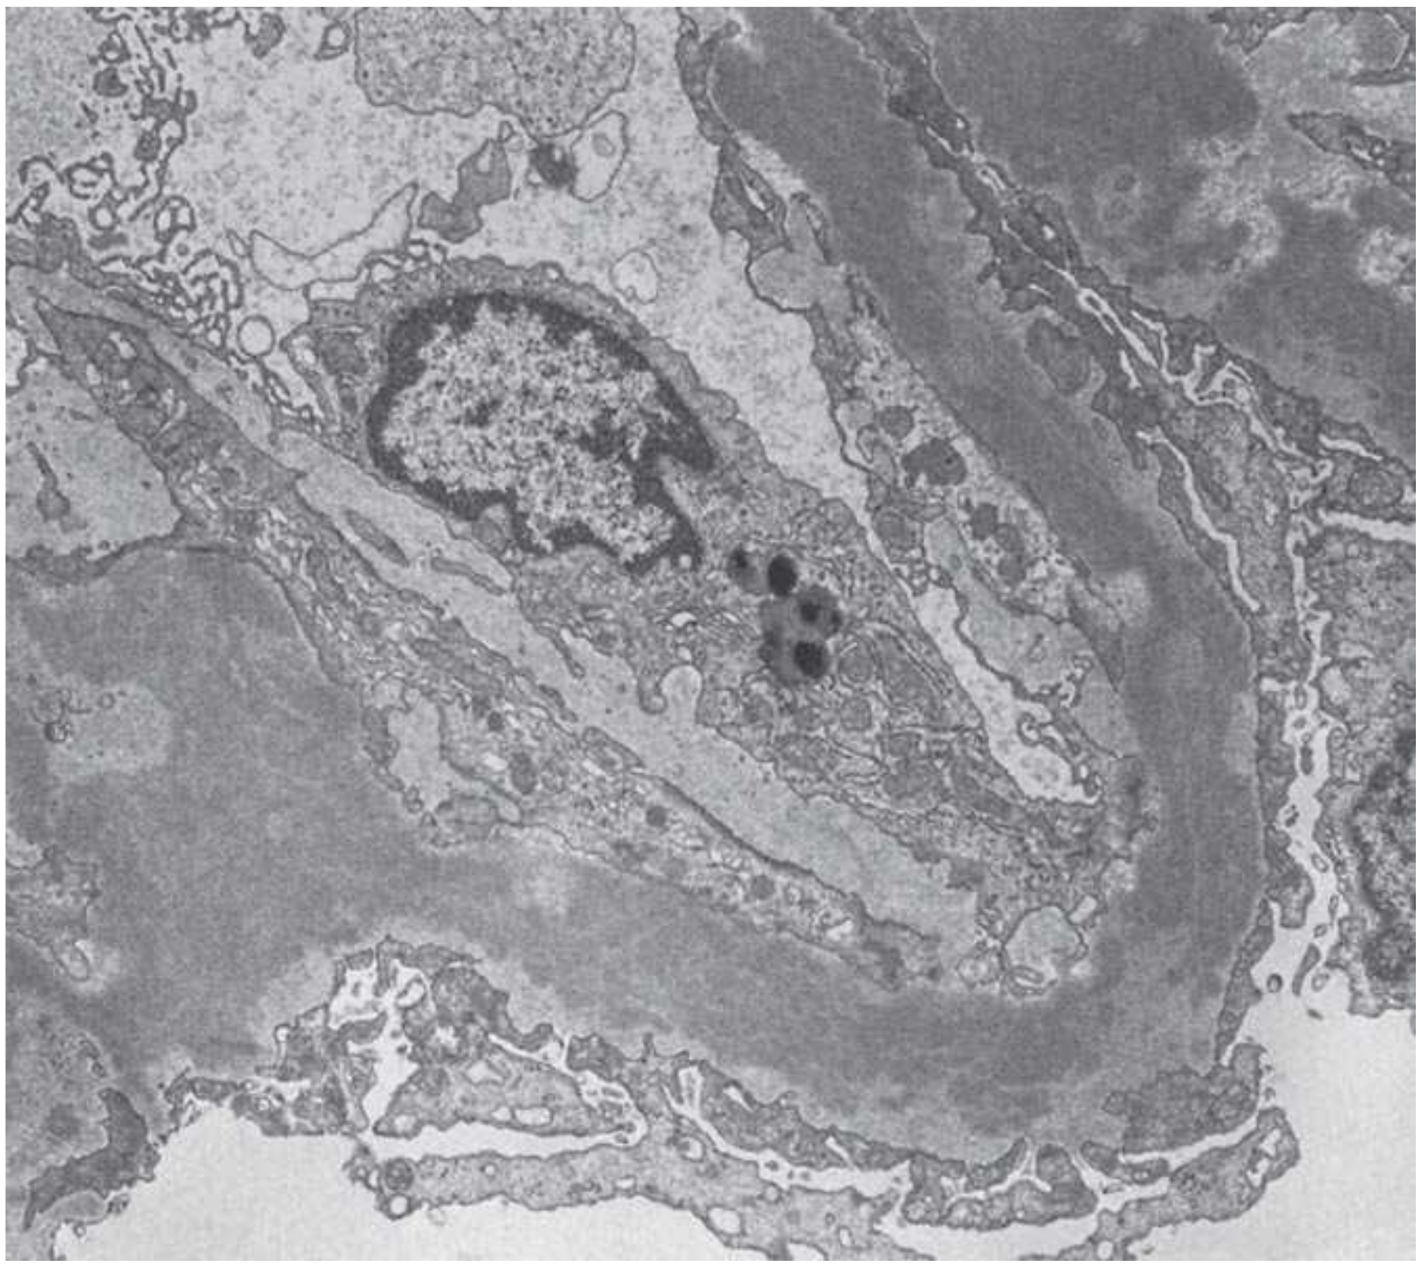

FIGURE 13.24 An electron micrograph of a peripheral capillary loop from the glomerulus of a patient with type II membranoproliferative glomerulonephritis. Intramembranous electron-dense deposits are present throughout the widened basement membrane (magnification ×9,650). (From Lamb V, Tisher CC, McCoy RC, et al. Membranoproliferative glomerulonephritis with dense intramembranous alterations. A clinicopathologic study. *Lab Invest* 1977;36:607, with permission.)

and in the proliferative forms of lupus nephritis. Membranoproliferative glomerulonephritis may be identified by its characteristic pattern of mesangial interposition and the electron-dense deposits that are primarily subendothelial in location in type I disease and intramembranous in location in type II disease (Fig. 13.24) when observed by electron microscopy. The proliferative forms of lupus nephritis are often characterized by the prominent variability in their histologic appearance from one part of a glomerular tuft to another and from one glomerulus to another.

Crescents

Crescents may be present in every type of immune-mediated glomerulonephritis; therefore, they are not diagnostic. Most types of glomerulonephritis associated with crescents can be identified by their characteristic patterns of immunoglobulin localization with immunofluorescence microscopy. These include the more severe forms of IgA nephropathy and Henoch-Schönlein purpura (IgA deposits), lupus nephritis, anti-GBM disease, and MPGN. Serologic studies for antineutrophil cytoplasmic antibodies (ANCA) have helped clarify the diseases with sparse immune deposits (pauci-immune glomerulonephritis) and fibrinoid necrosis or crescents.[208] These glomerular changes are indistinguishable from the glomerular involvement observed in the microscopic form of polyarteritis nodosa or Wegener granulomatosis. In the absence of a vasculitis involving the muscular arteries in the biopsy specimen, these conditions can be separated by the presence or absence of other systemic organ involvement.[209]

The association of crescents and the clinical outcome is typified by the findings in anti-GBM disease. Several authors have noted the generally benign course of anti-GBM disease in those few patients who do not develop crescents over the course of their disease even with minimal therapy.[210–212] A close follow-up is prudent in this group because, rarely, a patient has been shown to progress from noncrescentic to crescentic glomerulonephritis.[211] A graded response in renal and patient survival is dependent on the percentage of crescents. Five studies in the literature[210,212–215] had comparable results that could be combined to evaluate the relationship between the percentage of crescents in the biopsy and renal survival in a total of 133 patients. If the percentage of crescents was less than 85%, most patients (48 of 61) had independent renal function, that is, did not require renal replacement therapy, at follow-up (78%). If the percentage of crescents was 85% or greater, most patients (61 of 72) progressed to renal failure (85%) (Table 13.1). Similar results are found correlating serum creatinine values at presentation with renal survival in anti-GBM disease (Table 13.1).[210,212,214–216] There also is a correlation between serum creatinine and the percentage of crescents at presentation.[212]

In general, the presence of crescents in glomeruli is associated with a worse prognosis. Exceptions include poststreptococcal glomerulonephritis in children where the crescents may resolve without adverse sequelae.[217,218] ANCA-associated glomerulonephritis does not have as clear an association between crescents and renal survival.[208] Therefore, it is preferable to separate the various causes of crescentic glomerulonephritis for the determination of prognosis and treatment.

13.1 Survival in Anti-GBM Disease[241]

	Patient Survival		Renal Survival[a]	
	1 year	5 year	1 year	5 year
Initial creatinine < 5.66 mg/dL (500 μmol/L)	100%	94%	95%	94%
Creatinine > 5.66 mg/dL (500 μmol/L) but no dialysis	85%	80%	69%	50%
Dialysis dependent	67%	44%	5%	13%

[a]Renal survival is defined as the absence of the need for dialysis or renal transplantation.

Glomerulosclerosis

Glomerulosclerosis may be the result of scarring from a prior proliferative or immune complex lesion, or it can be primary in nature.[219] Two common examples of the latter are diabetes mellitus and FSGS. FSGS is commonly associated with hyalinosis and foam cells within the glomerular tuft and hyperplasia of the parietal epithelium in the area adjacent to the sclerosis (Fig. 13.8); however, these features may be absent in a given biopsy specimen. In the early stages of FSGS, only a few glomeruli are affected and these are usually located deep in the cortex.[220] Not infrequently, a biopsy may miss glomeruli with segmental lesions and the histology will resemble MCNS. With time, the segmental sclerosis progresses to global sclerosis and involves a greater number of glomeruli throughout the cortex. Although diabetic nephropathy and FSGS are not considered immune complex diseases, the globally or segmentally sclerotic glomeruli usually have staining for IgM and C3. Segmental glomerulosclerosis may also be the end result of any disease that progresses toward chronic renal failure. Therefore, FSGS as a primary disease must be differentiated from the end-stage process of focal glomerulosclerosis. To make a diagnosis of FSGS, one must exclude other causes of segmental sclerosis that produce hyperfiltration and secondary changes of glomerular sclerosis. The diagnosis cannot be made with certainty in the presence of advanced nephron destruction or severe vascular disease.

Capillary Wall Thickening

Thickening of the glomerular capillary walls can be seen in a variety of renal diseases. In its early stages, diabetes is characterized by thickening of the lamina densa, which may be visualized by electron microscopy. It may occur as a consequence of glomerulosclerosis and take on a wrinkled, ribbonlike appearance in association with other evidence of glomerular tuft ischemia or atrophy. Localized thickening can be seen in postinfectious proliferative glomerulonephritis because of the presence of subepithelial, humplike, immune-complex deposits. In idiopathic membranous glomerulonephritis, discrete granular immune-complex deposits are localized to the subepithelial surface of the capillary wall and are associated with subepithelial extensions of basement membrane material, referred to as spikes (Fig. 13.4C). These progress to form bridges to completely enclose the subepithelial deposits, yielding a tram-track configuration. In type I MPGN, subendothelial immune-complex deposits are often seen in association with a reduplication of the peripheral glomerular basement membrane (mesangial interposition, Fig. 13.25). Similar changes can be seen in type II MPGN, in which electron-dense material expands the original basement membrane of the peripheral capillary loop and is also associated with mesangial interposition (Fig. 13.24). In both type I and II MPGN, this combination of histologic changes can give rise to a double contouring of the peripheral portion of the glomerular capillary wall.

Regardless of the particular glomerular alteration, it is often important for a diagnostic and prognostic evaluation to note whether the lesion is segmental versus global or focal versus generalized. An example of this distinction is emphasized in the most recent classification of lupus nephritis,[221] which divided the World Health Organization class IV into segmental (class IV-S, Fig. 13.26) and global (class IV-G) subdivisions. There is a presumption or hypothesis that the segmental subclass may have a different pathogenesis, and one published study[222] shows a difference in outcome when compared with the global subclass.

Interstitial Inflammation

The differential diagnosis of interstitial inflammatory infiltrates poses some interesting diagnostic problems for the nephropathologist. Kidneys with nephron atrophy may have fibrosis and associated dense nodular lymphocytic infiltrates composed of mixtures of B cells and T cells. Interstitial infiltrates in the absence of nephron atrophy or acute glomerulonephritis suggest a primary interstitial

FIGURE 13.25 An electron micrograph illustrating typical mesangial interposition (*arrowheads*) in type I membranoproliferative glomerulonephritis (magnification ×3,200). (Illustration from Silva F, with permission.)

nephritis. The presence of large numbers of neutrophils in the tubules (neutrophilic tubulitis), the Bowman space, and the interstitium suggests a diagnosis of acute bacterial interstitial nephritis, whereas an occasional tubule with neutrophils may be seen in ATN. Cellular infiltrates composed of lymphocytes and plasma cells, with or without eosinophilia, commonly are the result of a drug allergy or are idiopathic in nature. Urinary outflow obstruction and renal vein thrombosis may cause interstitial edema and mild inflammation, but these changes are relatively nonspecific. Acute tubular necrosis is also associated with mild interstitial infiltrates in the region of the straight portion of the proximal tubule. A more chronic interstitial nephritis can result from an adverse response to nonsteroidal anti-inflammatory drugs. A pattern of nephron atrophy that affects the tubules before the glomeruli and vessels is consistent with, but is not pathognomonic of, chronic interstitial nephritis. Rarely, a lymphocytic lymphoma or leukemia may be seen on a kidney biopsy.

Vascular Lesions

Arteriosclerosis is the most common vascular lesion observed in kidney biopsies. It may represent a primary vascular disease such as that seen with long-standing hypertension, or it may be observed in association with progressive nephron loss that occurs with end-stage renal disease of any etiology. Extensive hyaline arteriolosclerosis suggests the presence of diabetes mellitus (Fig. 13.10). Milder hyaline lesions are seen in FSGS and, sporadically, in hypertension and other conditions. Necrotizing vasculitis is rarely seen in kidney biopsies in the absence of the glomerular lesions of polyarteritis, lupus nephritis, or Henoch-Schönlein purpura. Thrombotic microangiopathy is a distinctive lesion of small arteries and glomerular capillaries. It is characterized by an insudation of fibrin and RBCs, the latter of which is often in the form of schistocytes, into the walls of the small arteries and glomerular capillaries. The latter may appear as mesangiolysis. These acute changes often progress to renal ischemia and atrophy. This lesion can be seen in varying degrees of severity in several clinical settings, including the hemolytic–uremic syndrome, malignant hypertension, progressive systemic sclerosis, lupus nephritis, and anti-GBM disease.

Renal Allograft Pathology

Percutaneous biopsies of renal allografts introduce another set of diagnostic challenges for the pathologist. Virtually any lesion that occurs in the native kidney also can be found in the allograft in addition to the histologic picture of rejection.[137] An absence of function in the immediate postoperative period, especially in a cadaveric kidney, is usually due to ischemic tubular damage or rejection. A pathogenetic classification of rejection is given in Table 13.2, which incorporates features of immunologic mechanisms and the clinical setting. A hyperacute rejection may occur in a small percentage of patients and has a very distinctive morphology

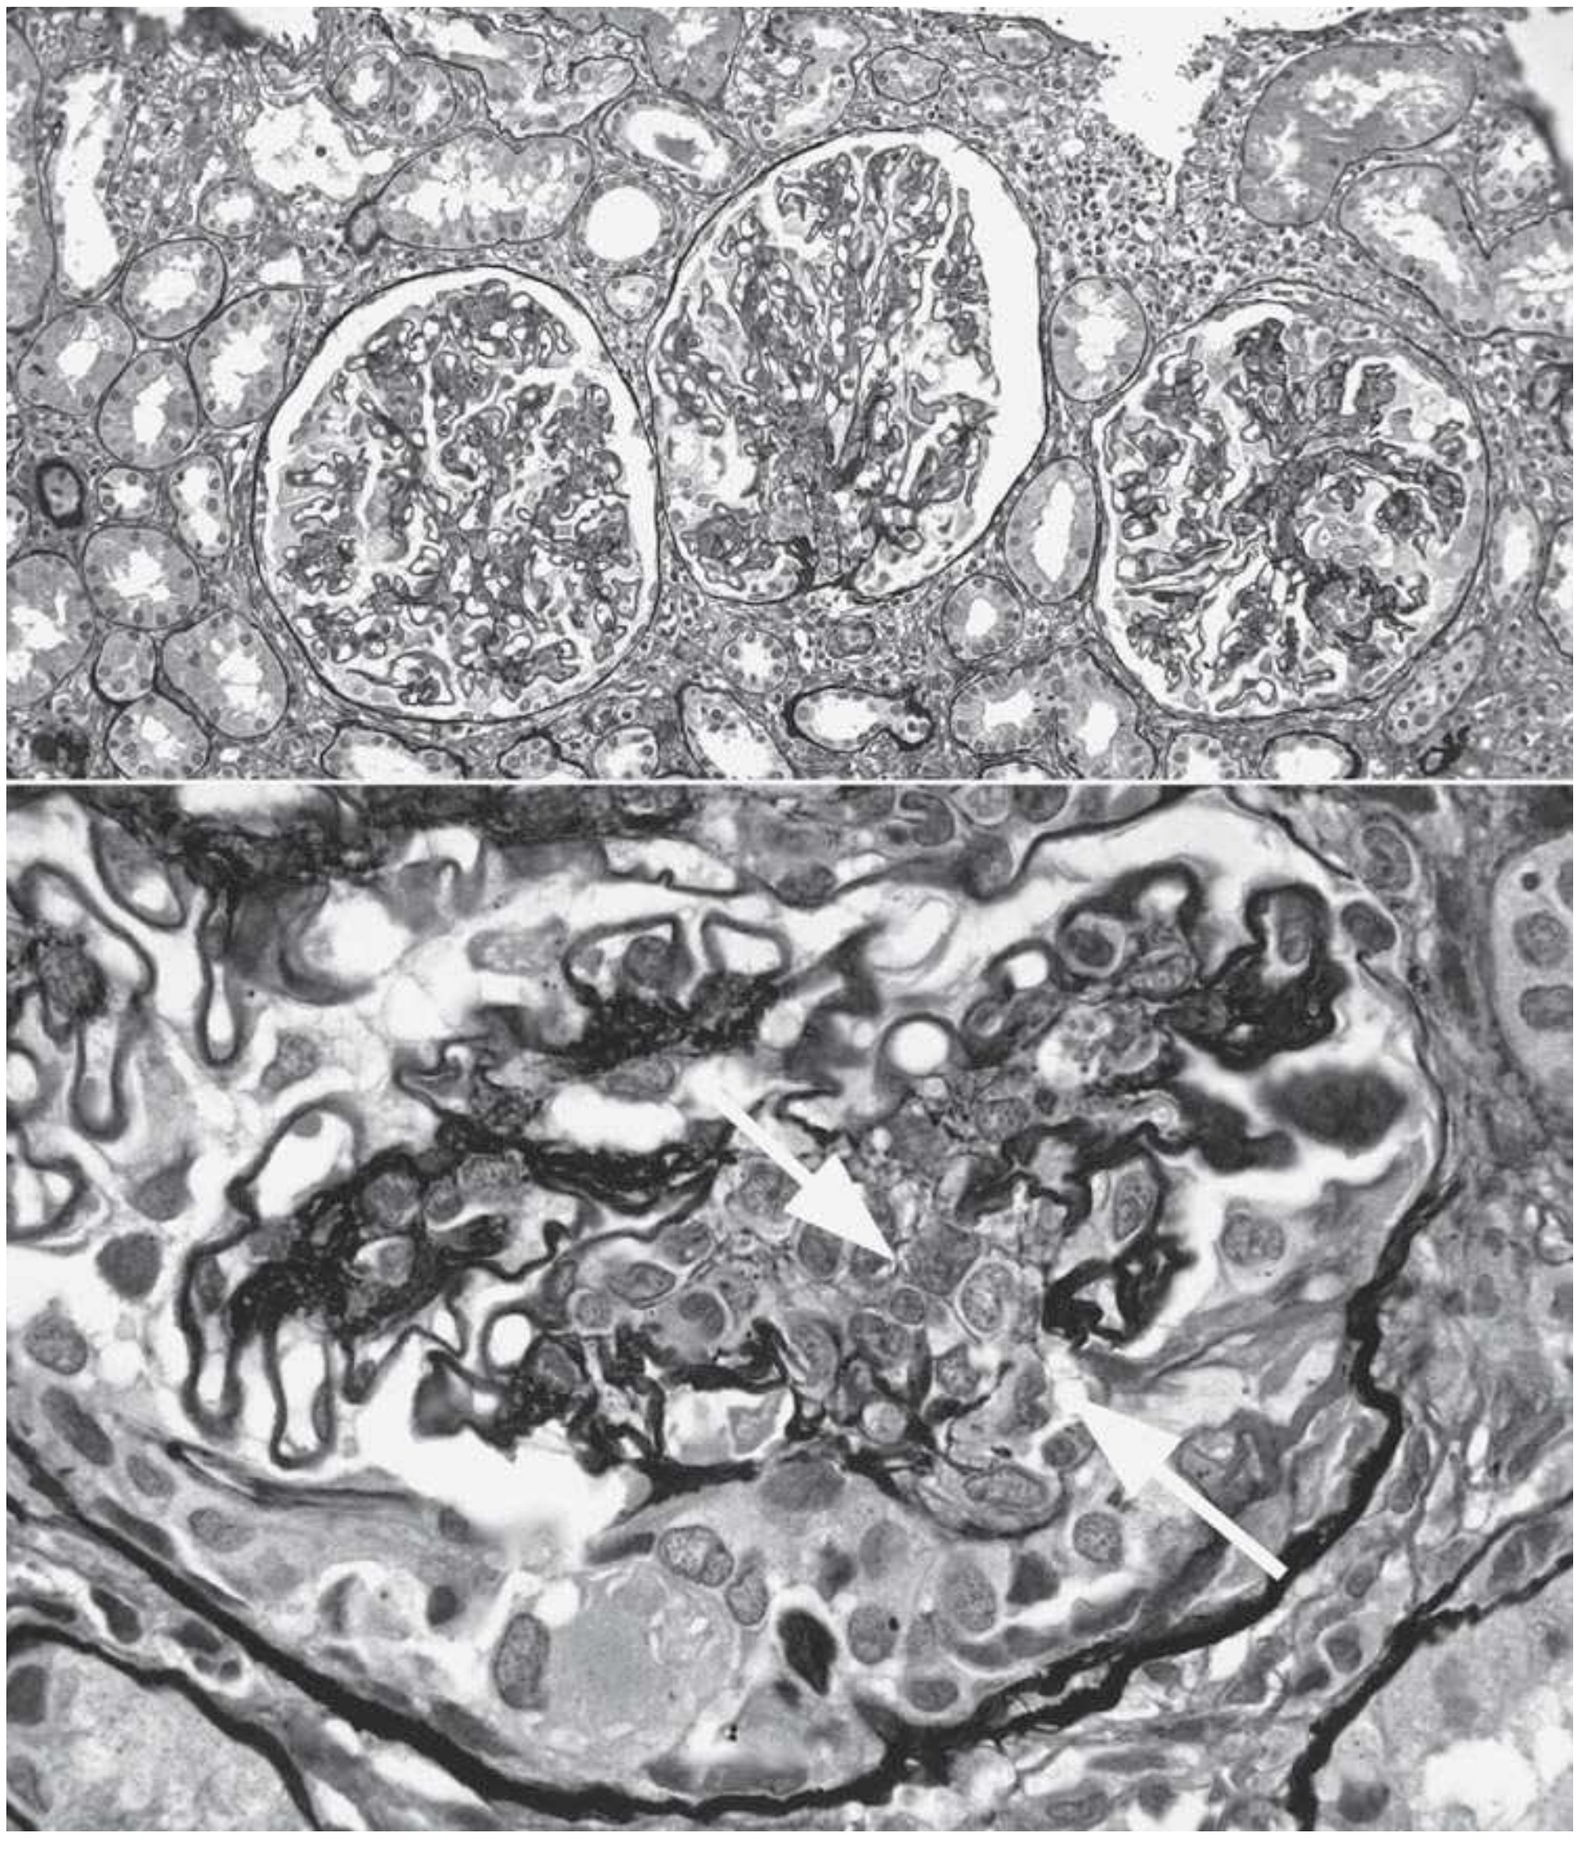

FIGURE 13.26 A segmental class IV lupus nephritis. **A:** This figure shows three glomeruli with segmental involvement (PAMS; magnification ×200). **B:** This is a higher magnification (×500) of a segmental lesion with increased cellularity and fragmentation and disruption of the GBM between the arrows (PAMS).

characterized by the presence of extensive fibrin thrombi and neutrophils in glomerular capillaries. This form of rejection is thought to be secondary to the presence of a preformed circulating antibody in the recipient that was not detected with the usual screening procedures.

Acute vascular rejection can occur from the first week of engraftment. It may be antibody or cell-mediated. It resembles the histologic picture of a low-grade vasculitis, with intimal proliferation or disruption and exudation in the walls of arteries and glomerular capillaries (Color Fig. 13.4E). The vascular lesions usually are patchy and are more frequently missed by light microscopy in biopsies with few arteries. The immunofluorescence findings of IgM, C1q, and C3 in the walls of vessels are more sensitive indicators of vascular rejection (Fig. 13.22F). Immunoperoxidase staining for the complement component, C4d (Fig. 13.27), is a marker for antibody-mediated rejection and is more widely distributed.[223] Electron microscopy reveals a swelling of the glomerular endothelium and the lamina rara interna.

Tubulointerstitial rejection is another type of acute rejection and is a form of acute interstitial nephritis. In most cases, the infiltrate is composed of large active cytotoxic T cells.[224] The cytotoxic T cells identified by immunohistochemical staining (Fig. 13.4F) infiltrate the tubular cytoplasm, a process termed emperipolesis, to produce lymphocytic tubulitis.[225] The differentiation of acute cellular rejection from other forms of interstitial nephritis can be difficult in certain settings, especially when characterized by a delayed-type hypersensitivity (DTH) response with CD4 T cells and macrophages.[198,199,225]

It is also important to note the distribution of the cellular infiltrate. Both native and allograft kidneys may have nodular infiltrates. These are often located in the adventitia of blood vessels and are composed predominantly of T4 cells and B cells. This type of cellular infiltrate is nonspecific.

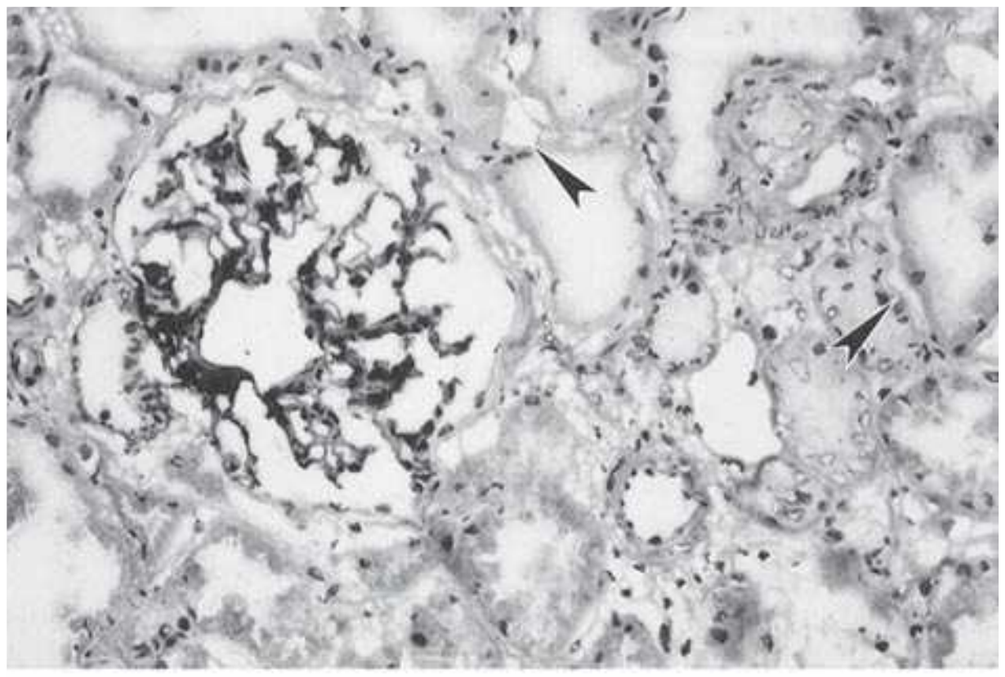
13.2 Immunopathogenic Mechanisms Associated with Renal Allograft Rejection

Type	Onset of Clinical Manifestation	Morphology	Mechanism
Acute Rejection			
Antibody-mediated (Vascular)			
Hyperacute	0–72 hr	Intracapillary PMN inflammation and thrombosis	Preformed antibody with complement and fibrinogen activation
Accelerated acute	3–7 d	Endovascular inflammation similar to above but histologically less intense	Memory antibody response
Acute rejection	7 d or more	Endovasculitis with PMN but without lymphocytes	De novo antibody response
Cell-mediated			
Vascular	7 d to 3 mo	Endovasculitis with varying proportions of CD4 + CD8 lymphocytes and macrophages	May be any of several cell-mediated mechanisms
Tubular		Lymphocytic tubulitis with predominately CD8 cells	Cytotoxic lymphocytes
Interstitial		Mononuclear interstitial inflammation with predominately CD4 lymphocytes and macrophages	Delayed type hypersensitivity
Chronic rejection (3 mo or longer)			
Vascular		Intimal proliferation	Antibody
Cell-mediated		Interstitial nephritis	Continued DTH and cytotoxic responses
Innate response			
Acute		Intrinsic cell activation	Oxidative and other stress injury
Chronic		Chronic interstitial nephritis	Macrophage activation and fibrogenesis

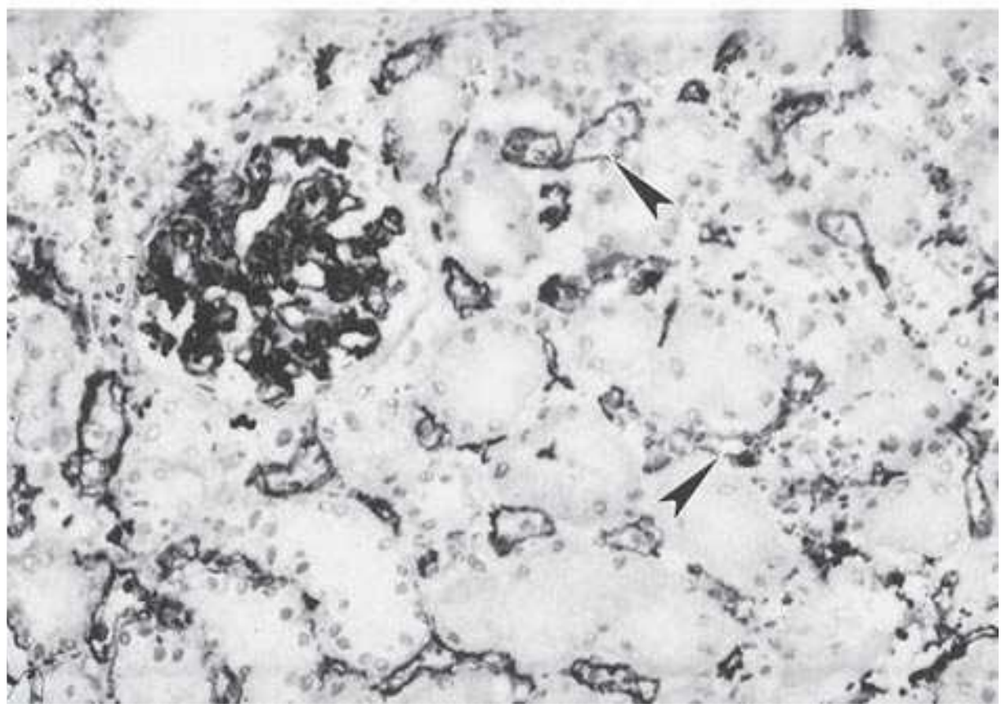
PMN, polymorphonuclear leukocyte; DTH, delayed type hypersensitivity.

In cellular rejection, allografts often exhibit a superimposed diffuse interstitial and tubular cytotoxic T-cell infiltrate.[225] An increase in cytotoxic T cells during cellular rejection has been confirmed in these infiltrates by fine-needle aspiration.[226] B-cell infiltrates suggest PTLD, particularly in the presence of EBV and destructive nodules. The BK virus also produces interstitial nephritis and is indicated by nuclear inclusions and is confirmed by electron microscopy, immunostaining, or molecular studies (Fig. 13.28).[227]

An immunohistochemical examination of the renal biopsy is also beneficial. In particular, the presence of alloantibodies, which classically localize to peritubular and glomerular capillaries, suggests the presence of antibody-mediated rejection.[126] The most commonly employed tests evaluate the presence of C4d deposition in renal transplant biopsies. Feucht et al.[228] initially showed that peritubular capillary C4d deposition predicated a worse prognosis. This was followed by numerous studies demonstrating



A



B

FIGURE 13.27 This figure shows C4d staining. **A:** An allograft with acute tubular necrosis. Peritubular capillaries (*arrowheads*) are unstained (immunoperoxidase, C4d; magnification ×210). **B:** An allograft with antibody-mediated rejection. Peritubular capillaries (*arrowheads*) are staining (immunoperoxidase, C4d; magnification ×210).

an interrelationship between C4d deposition, circulating donor-specific antibodies, and renal histopathologic findings.[126,127] Activation of the classic complement pathway generates C4b, of which C4d is a biologic fragment; C4d does not have a known biologic function, but because it is tightly bound to tissue, it serves as an excellent marker of complement-fixing, circulating antiendothelial antibodies. Peritubular capillary C4d deposition can be seen in hyperacute rejection, acute humoral rejection, and chronic humoral rejection.[126,127] In addition, C4d deposition can be observed in the kidneys of patients who received transplantation across ABO barriers, using special protocols to deplete naturally occurring anti–blood group antibodies, in whom circulating anti–blood group antibodies return but do not cause obvious graft rejection,[126] a state termed accommodation.[229] In addition, C4d deposition can occur in a number of different conditions, including I/R injury, necrosis, and lupus nephritis.[129–133] Correlating findings of C4d deposition with the clinical presentation, the renal histology, and the serologic evidence of anti-donor HLA antibodies is essential to guide appropriate therapy.

Calcineurin inhibitor toxicity is an important cause of decreased renal function in the allograft. The tubular changes were noted in an earlier section (Fig. 13.14). The most widely accepted demonstrations of calcineurin inhibitor-related renal vascular changes have been observed in the setting of transplantation of solid organs other than the kidney (e.g., the heart)[230] or inflammatory diseases of other organs (e.g., type I diabetes).[231]

Although acute changes in renal function are established in many systems,[232] the current data suggest that morphologic changes associated with long-term calcineurin inhibitor use are characteristic, but are not pathognomonic, of this class of drugs.[233] Those features include hyalinosis of arterioles (Fig. 13.29), interstitial fibrosis, and tubular atrophy.[230,231,234] When these lesions are noted in the allograft biopsy, calcineurin inhibitor toxicity should be considered in the differential diagnosis.

Systemic cytomegalovirus infection continues to be a significant cause of morbidity and mortality among recipients of renal transplants.[157] Cytomegalovirus may be detected in the biopsy, whereas viremia is determined best by peripheral blood studies.

Traditionally, rejection has been defined as an immune response directed against the graft antigens or alloimmune response. In more recent years, it has become evident that a

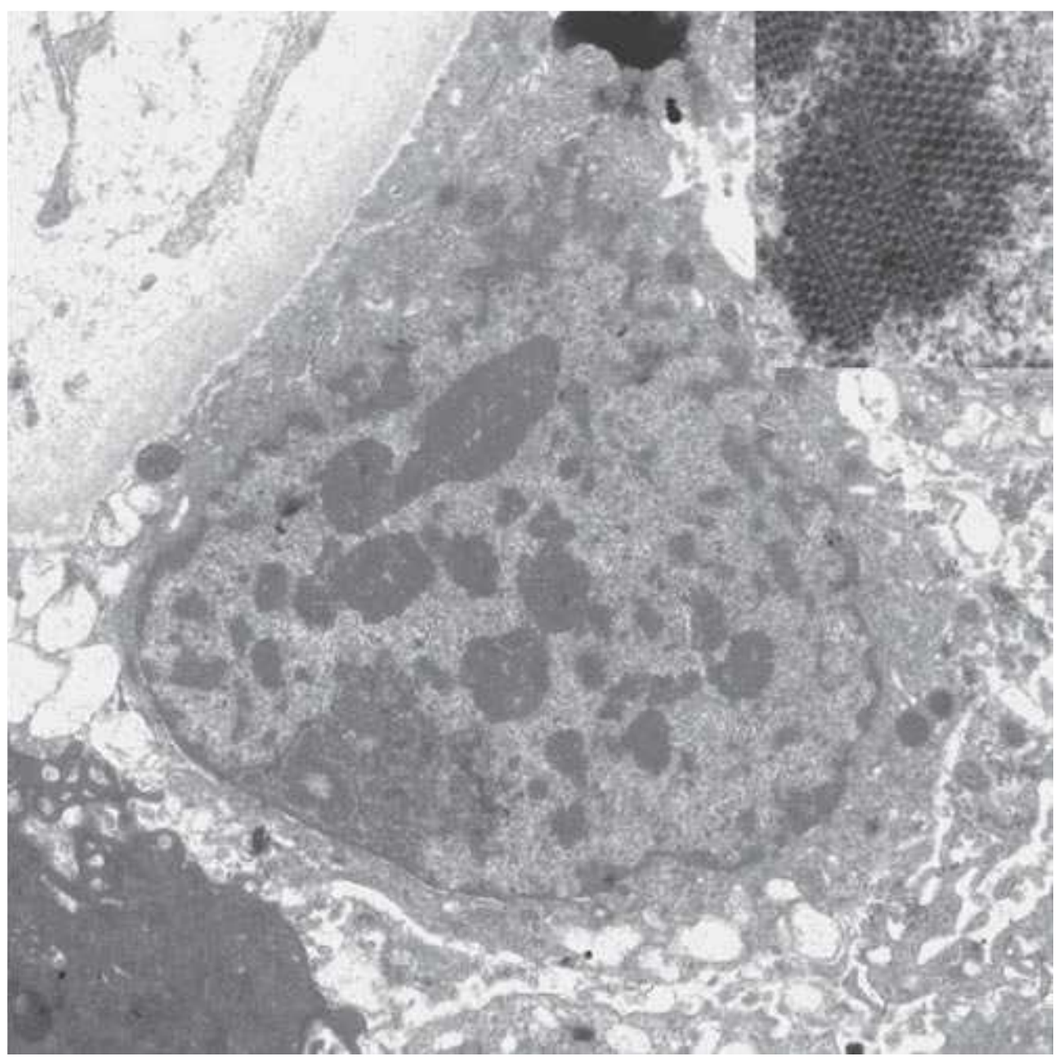


FIGURE 13.28 An electron micrograph of a tubular epithelial cell showing coarse clusters of nuclear material. The identification of the virus is not obvious at this magnification (magnification ×7,500). **Inset:** A higher magnification of nuclear densities (magnification ×33,000) showing the polyoma virus in a crystalloid array.

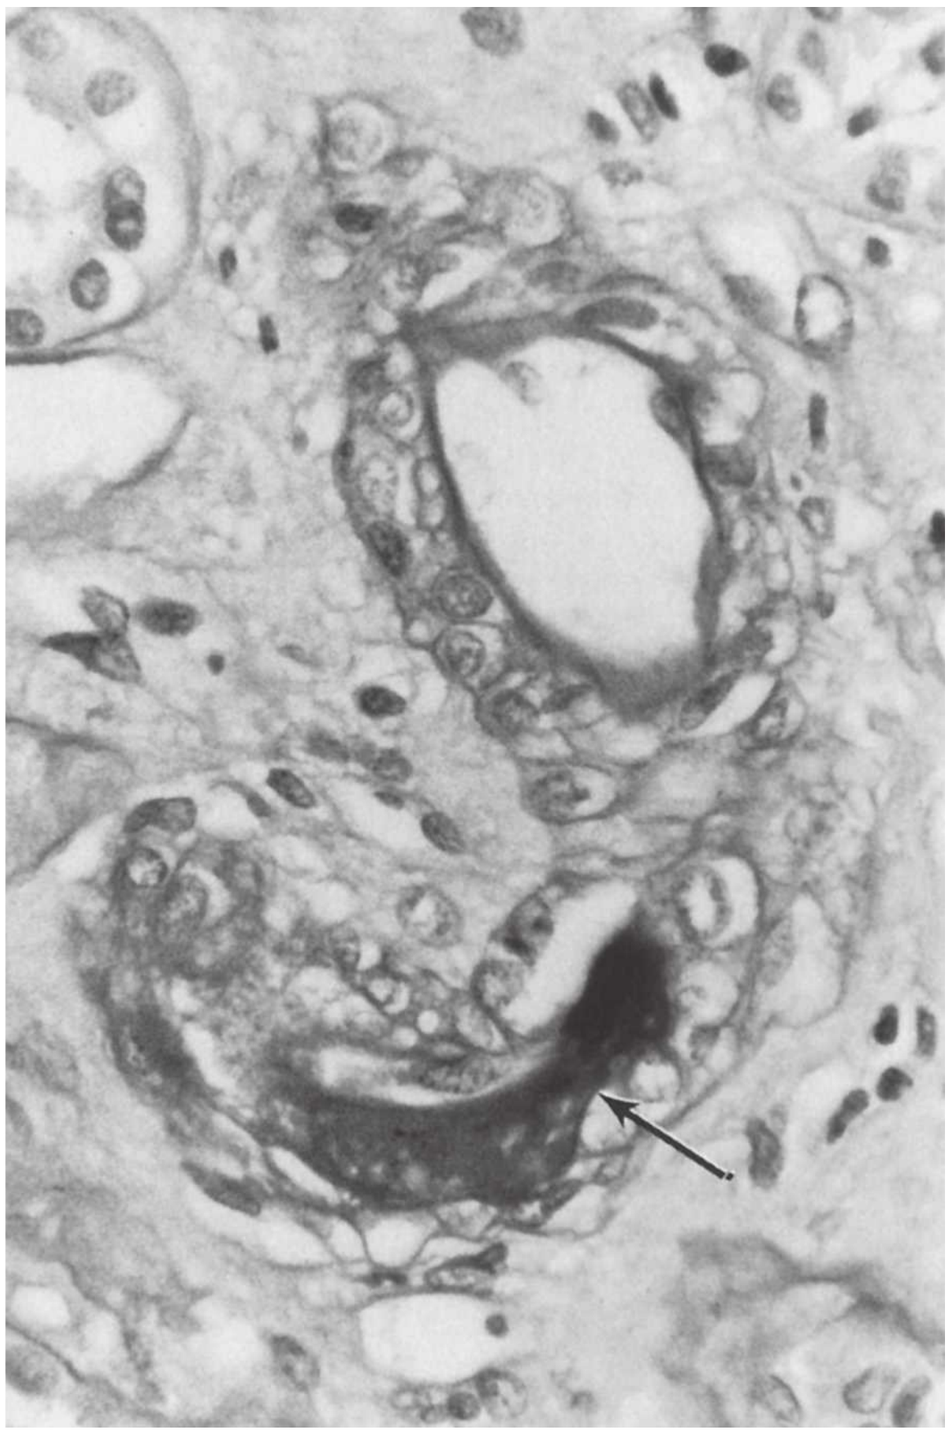

FIGURE 13.29 A photomicrograph illustrating calcineurin inhibitor toxicity in a terminal interlobular artery. Degenerative changes are evident in the muscularis in association with a large dense hyaline deposit (*arrow*) (PAS; magnification ×750).

variety of factors affect graft survival that are unrelated to traditional antigen driven B- and T-cell responses. They include donor factors such as age and gender, and events coincident to organ procurement such as cadaveric donation and ischemia time.[235,236] The kidney response in these settings recapitulates the responses of innate immunity (Table 13.2).

Finally, late irreversible changes in the graft that are associated with chronic azotemia may represent the sequelae of chronic rejection. This is not necessarily a separate entity, but may be the result of repeated episodes of acute rejection and innate immunity. Therefore, the term chronic transplant nephropathy is preferred, rather than chronic rejection, to identify the nonspecific pathologic changes. The morphologic features are those of severe tubular atrophy, glomerulosclerosis, interstitial fibrosis, and arteriosclerosis with varying degrees of chronic inflammation.

In addition to the pathogenetic classification (Table 13.2) noted in the preceding sections, several schemes for the histologic classification of rejection have been developed to facilitate interinstitutional studies and therapeutic trials. The Banff schema[237] was specifically designed toward this end and is based on light microscopic features with readily available histologic stains. With the experience of experimental validation and clinical trials, the original Banff schema was modified in 1995,[238] 1997,[239] and 2003.[128] The National Institute of Health-sponsored Combined Clinical Trials in Transplantation (CCTT) classification[240] is simpler but similar in structure for acute rejection. Clinical correlation in the CCTT study indicated that mononuclear cell margination of the vascular endothelium was an indicator for clinical severity. Although more complex, the strength of the Banff schema is that it captures fundamental histologic data. Although acute rejection continues to be a significant problem, a greater problem (as noted in the preceding section) is chronic rejection and chronic allograft nephropathy. Structural relationships remain the cornerstone for understanding these processes and developing the molecular genomic, the functional proteomic, and the genetic basis for graft failure versus survival continues. Using a classification that incorporates these elements is essential for understanding and categorizing the many features of renal allograft pathology. Any classification must also be flexible to accommodate morphologic changes that may be associated with new therapeutic measures in this rapidly changing field.

CONCLUSION

We have presented a time-tested, step-by-step approach to the use and evaluation of the kidney biopsy. An in-depth discussion of specific diseases that affect the kidney can be found in other chapters of this text. We have selected some common diseases that are amenable to a diagnosis on a kidney biopsy in an effort to demonstrate the necessity and advantage of using a combination of light, electron, and immunohistologic microscopy to obtain the maximum amount of information from a biopsy specimen to aid in the clinical management of the patient. We expect that molecular genetic, functional genomic, and proteomic studies will eventually augment the classic structural and functional approach outlined in this chapter.

CHAPTER 14

Introduction to Genetic Renal Disease

Erum Hartung • Terry Watnick • Gregory G. Germino

GENETIC RENAL DISEASE

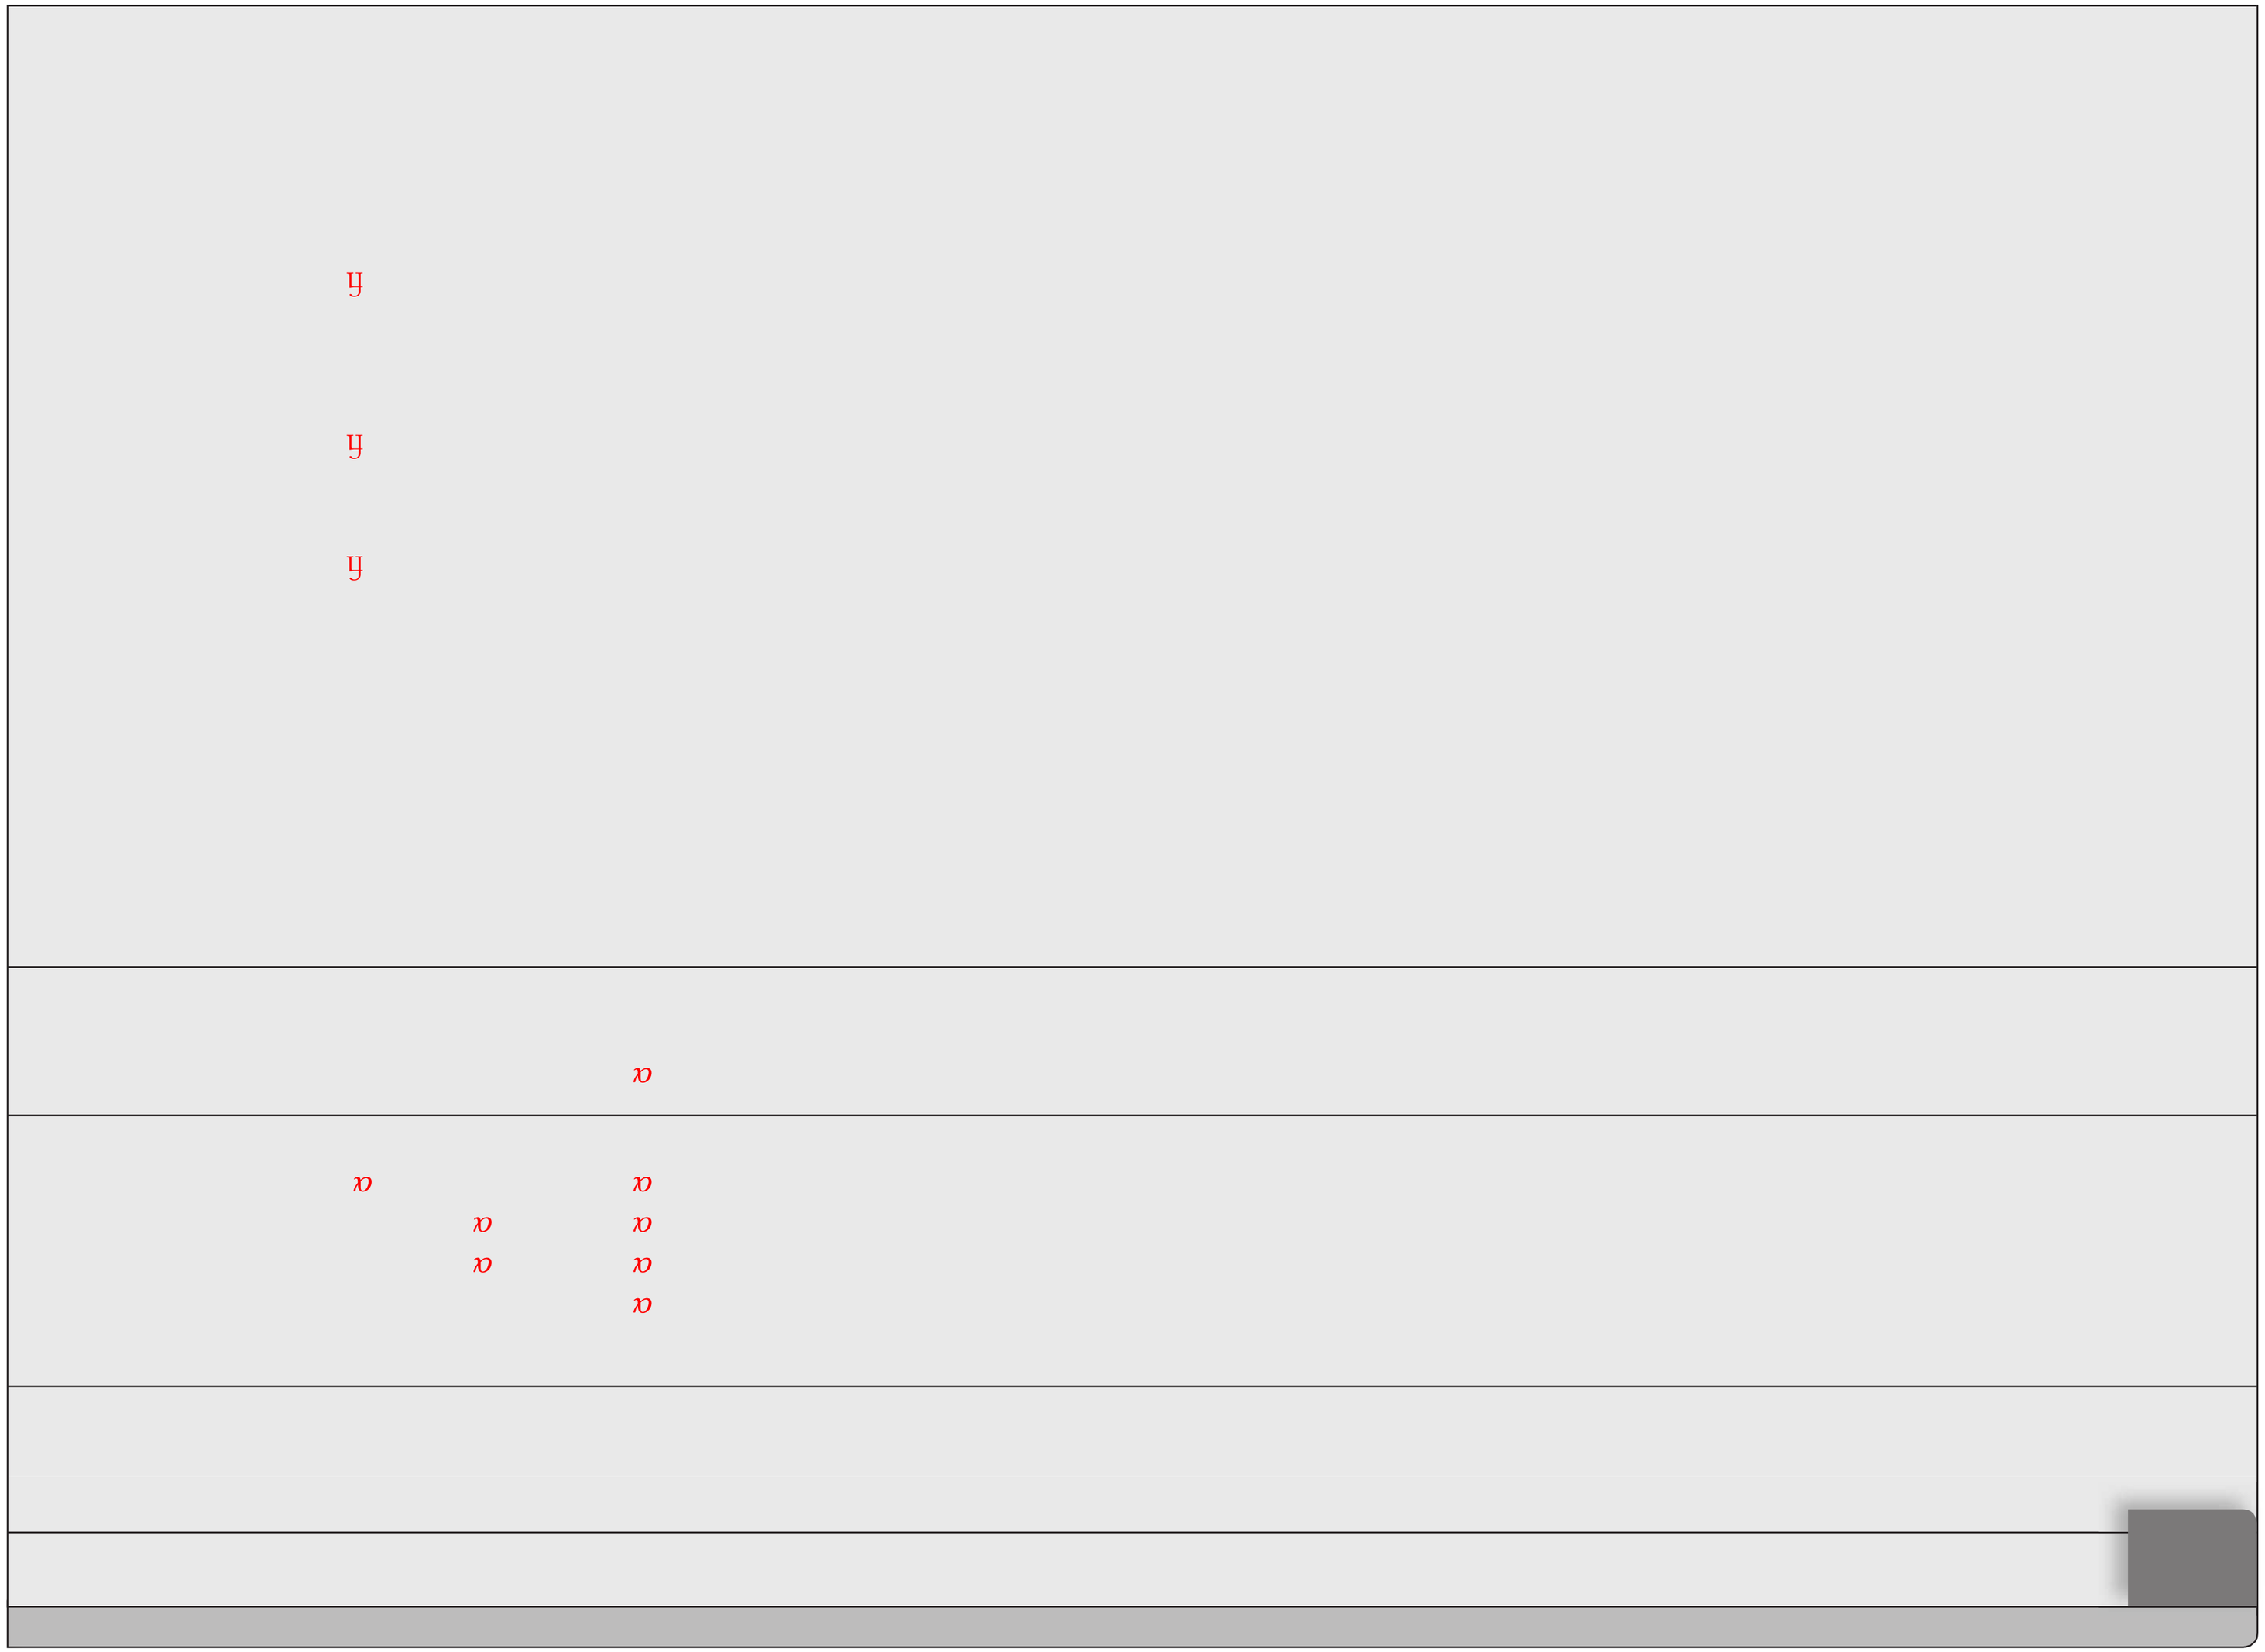
The success of the human genome project has resulted in dramatic advances in our understanding of inherited renal diseases. There has been an explosion in the number of disease-causing genes that have been identified and in our understanding of the pathogenic mechanisms that underlie these disorders (Tables 14.1 to 14.8). The spectrum of physiologic and developmental pathways that are disrupted is broad and includes defects in isolated transport mechanisms (e.g., cystinuria, primary hypomagnesemia, pseudohypoaldosteronism), defects in complex developmental pathways (e.g., autosomal dominant polycystic kidney disease [ADPKD] and renal coloboma syndrome), and defects in structural proteins (e.g., Alport syndrome and congenital nephrotic syndrome of the Finnish type). The tremendous progress in the field over the past 5 years has made an exhaustive discussion of the topic of genetic renal disease far beyond the scope of this chapter. The interested reader is referred to the Online Mendelian Inheritance of Man (OMIM) for a more complete description. This Web-based database provides a complete catalogue of diseases, their clinical features, and their molecular genetics (http://www.ncbi.nlm.nih.gov/Omim/). Instead, we will describe the process of gene discovery and how that process has evolved over the past several years. We will then review some of the scientific tools that have been applied in the postcloning stages of gene discovery in order to understand important aspects of renal biology. Finally, we will consider the clinical implications of these insights and how they may ultimately be applied in patient care.

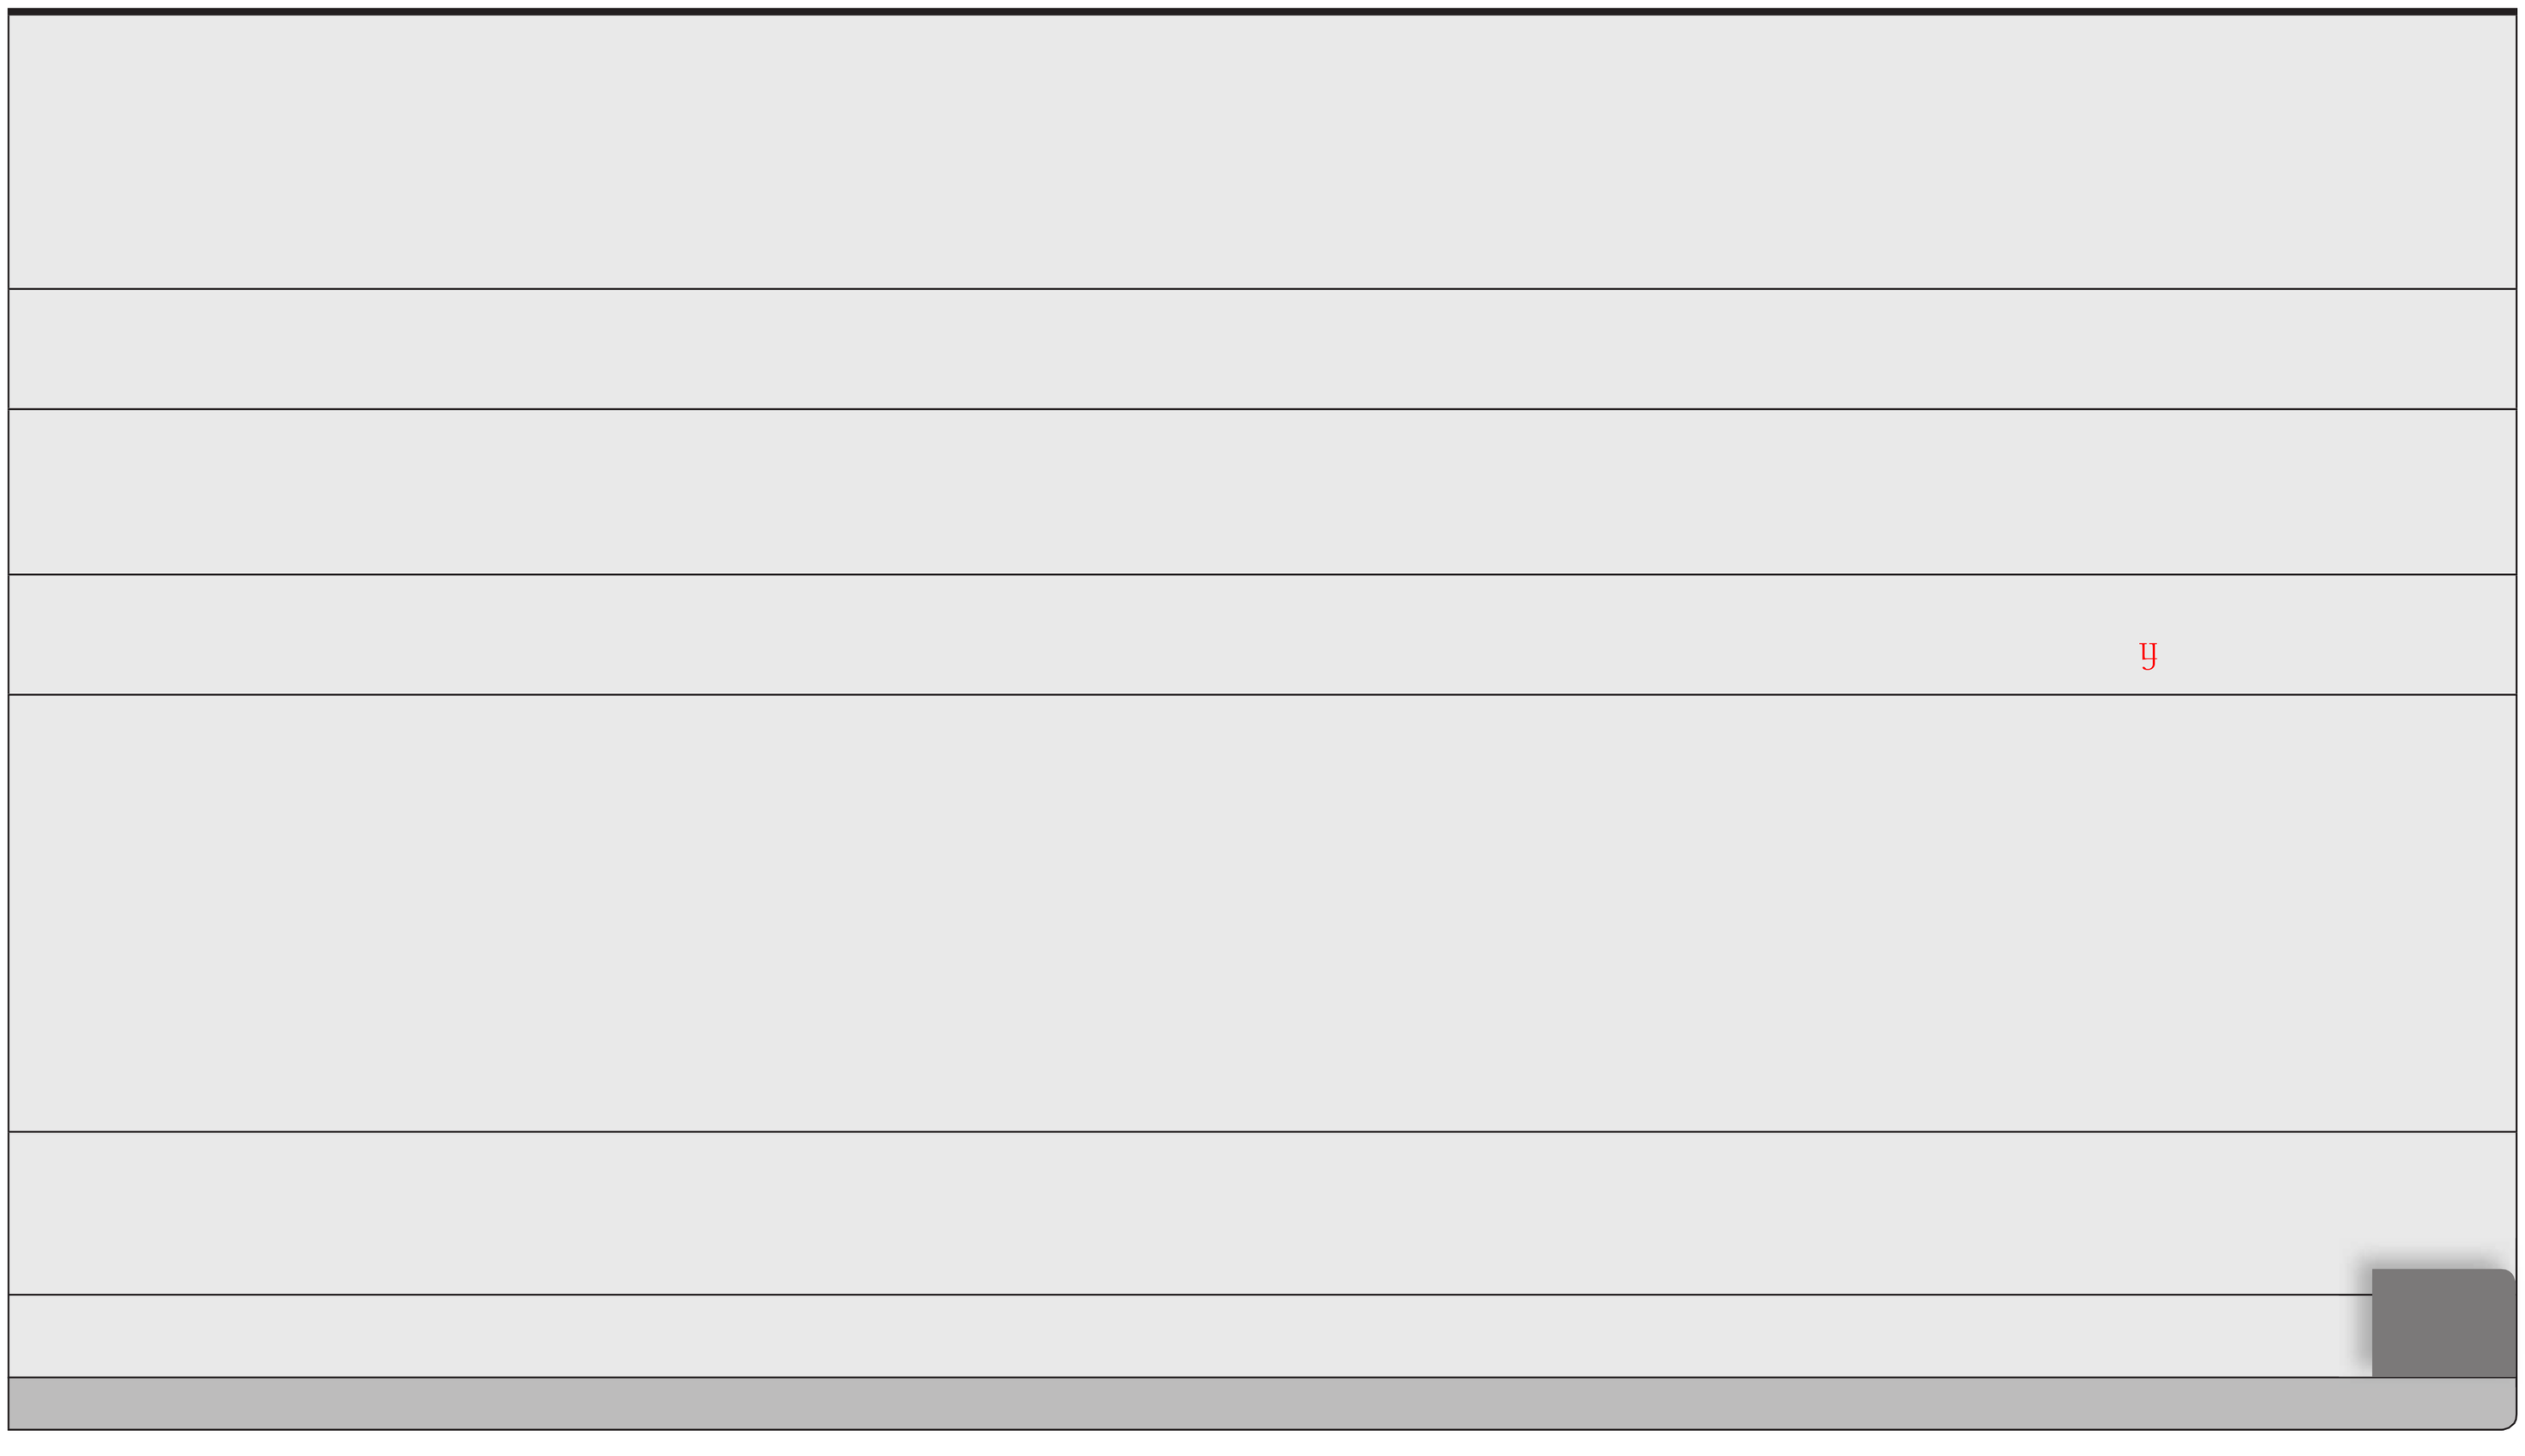
GENE IDENTIFICATION

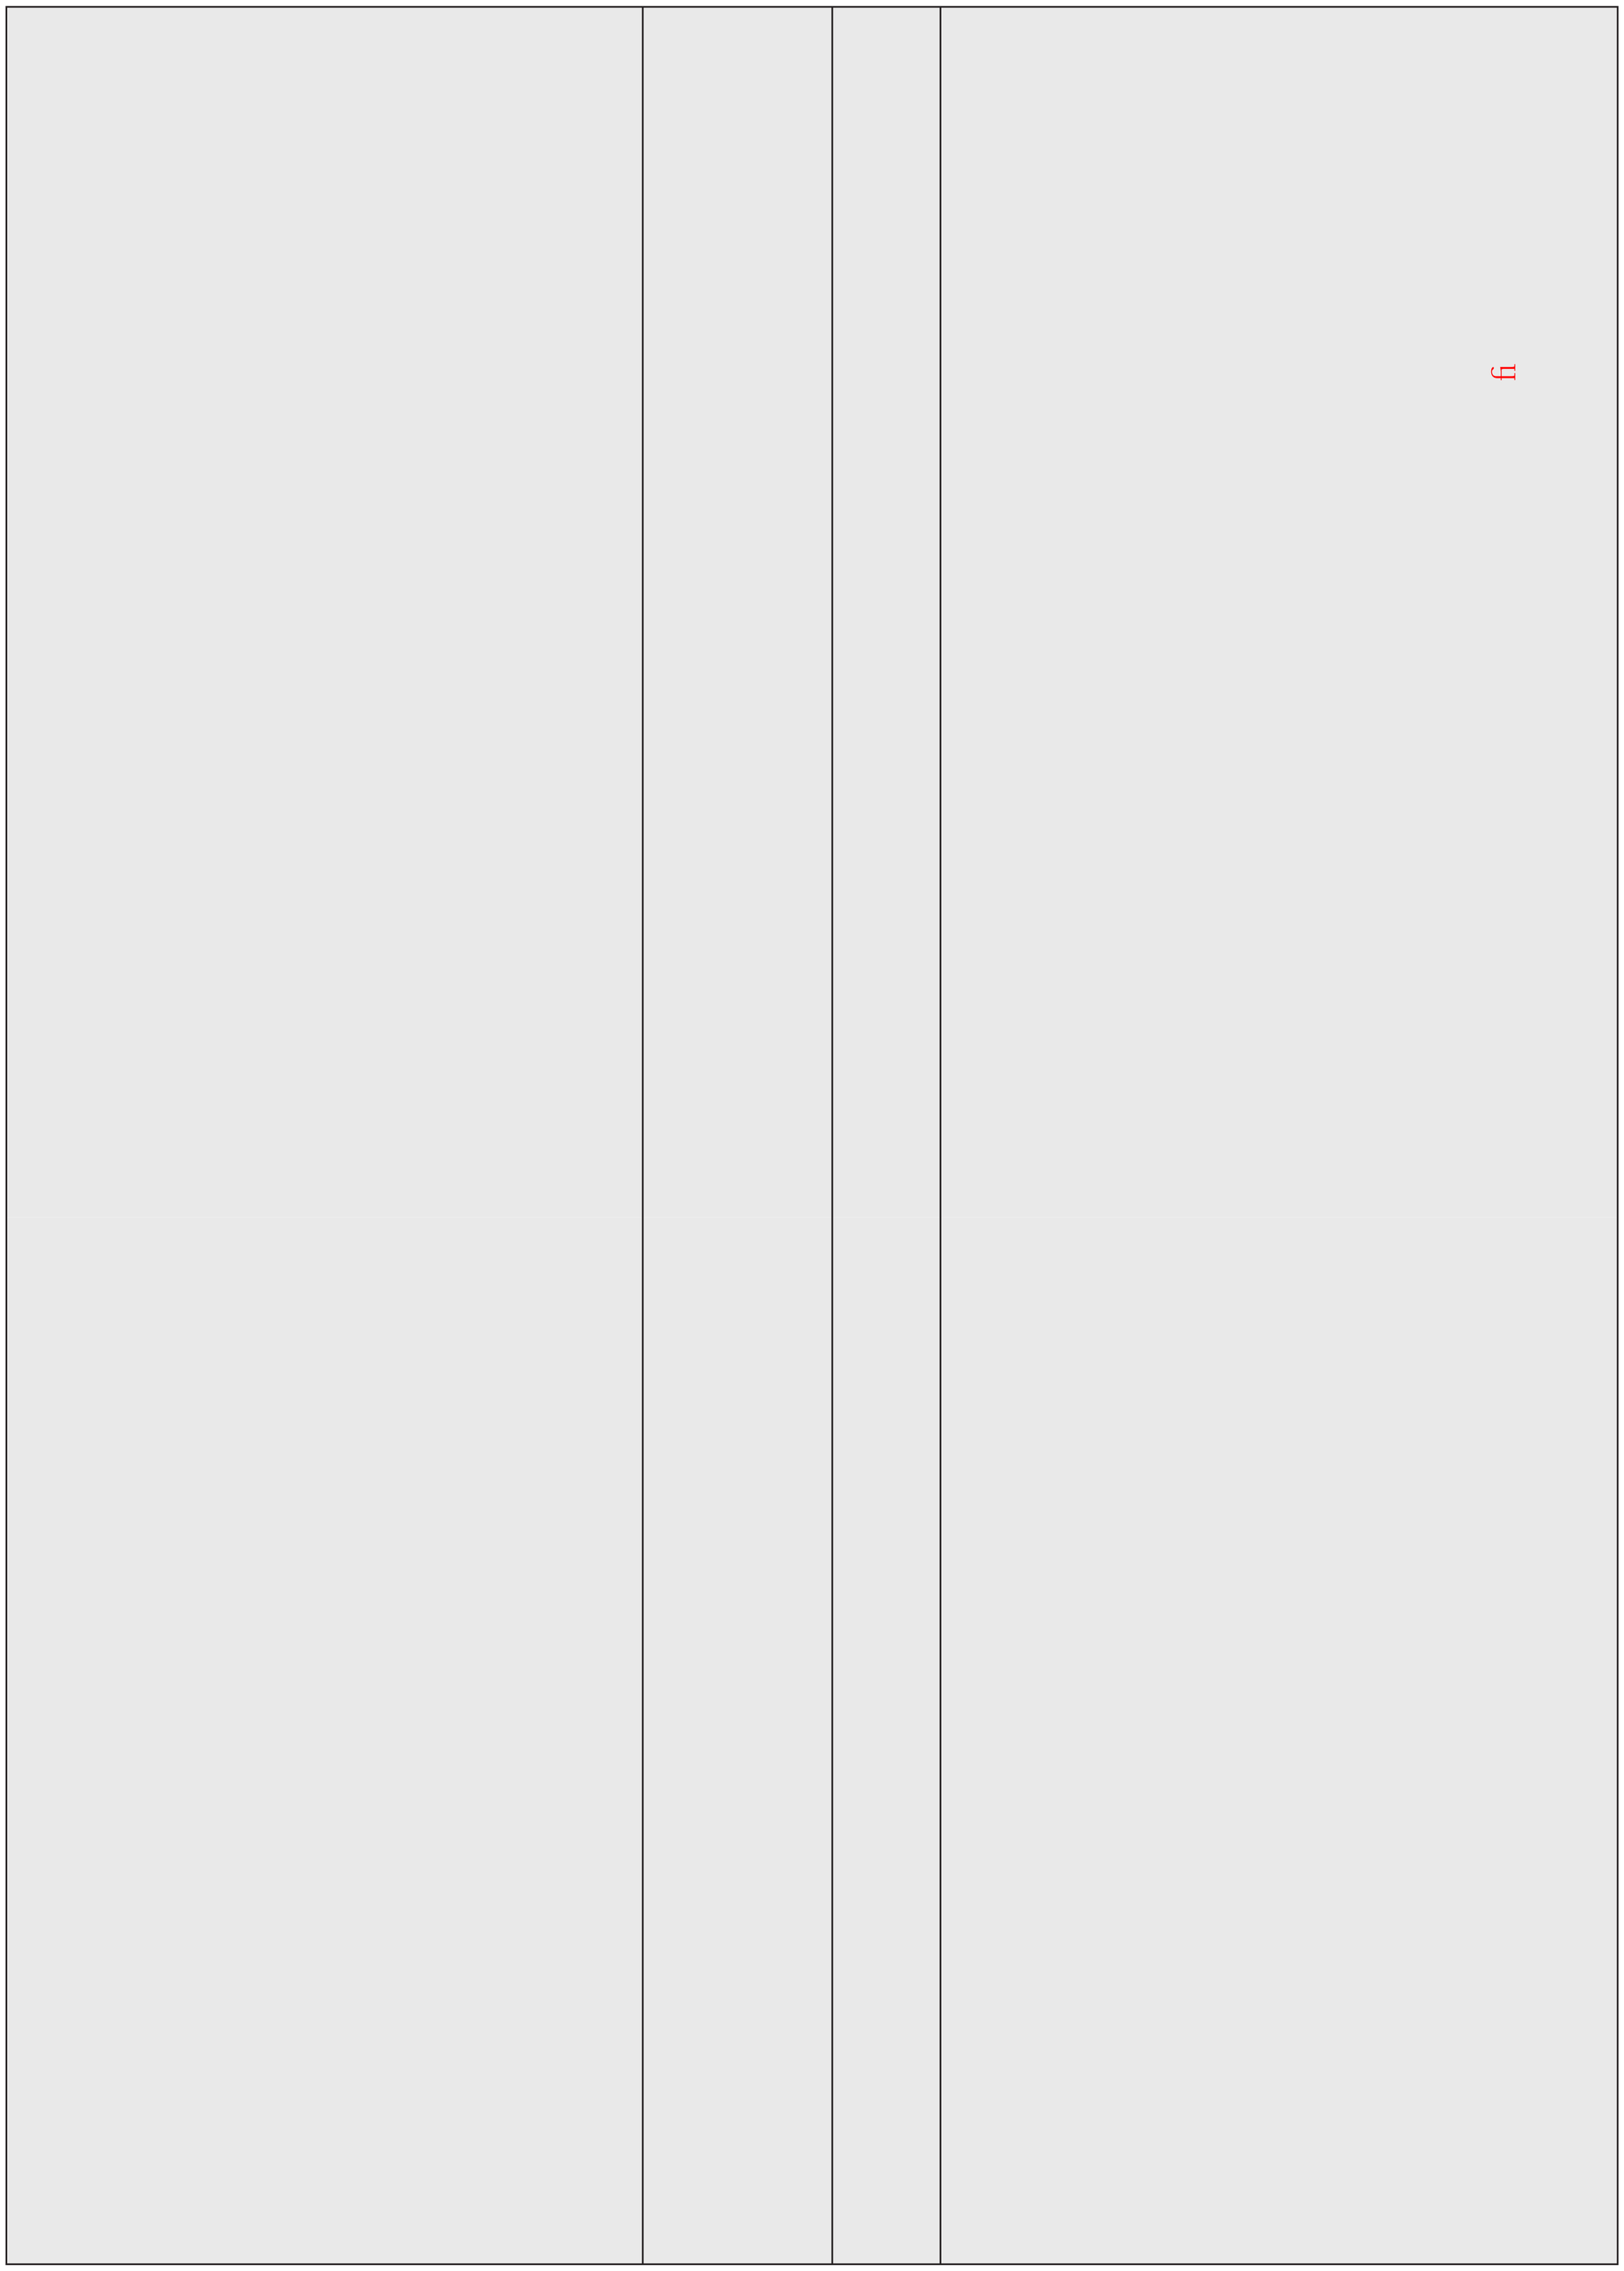
The basis of any inherited disease is an underlying alteration in genomic DNA that is transmitted from parent to offspring. Theoretically, one could compare the entire genomic sequence of an individual affected with a particular disease to that of unaffected individuals in order to identify the pathogenic difference. As simple as this approach sounds, it has, until recently, been a daunting challenge due to the size of the diploid human genome (6×10^9 base pairs [bp]), the limited throughput of traditional DNA sequencing methods (10^6 to 10^7 bp per day), and the high degree of normal variation in human populations. Important technical and bioinformatic developments have greatly changed the genetic disease discovery landscape, however. Whole genome sequencing is now a reality, and the <$1,000 genome will soon be here. Enigmatic clinical disorders that were once deemed too difficult to study using conventional positional cloning approaches because of their rarity are now giving up their secrets. In this section, we will briefly review the history of renal disease gene discovery, highlighting some of the most illustrative examples, and then discuss the impact of next generation sequencing on this field.

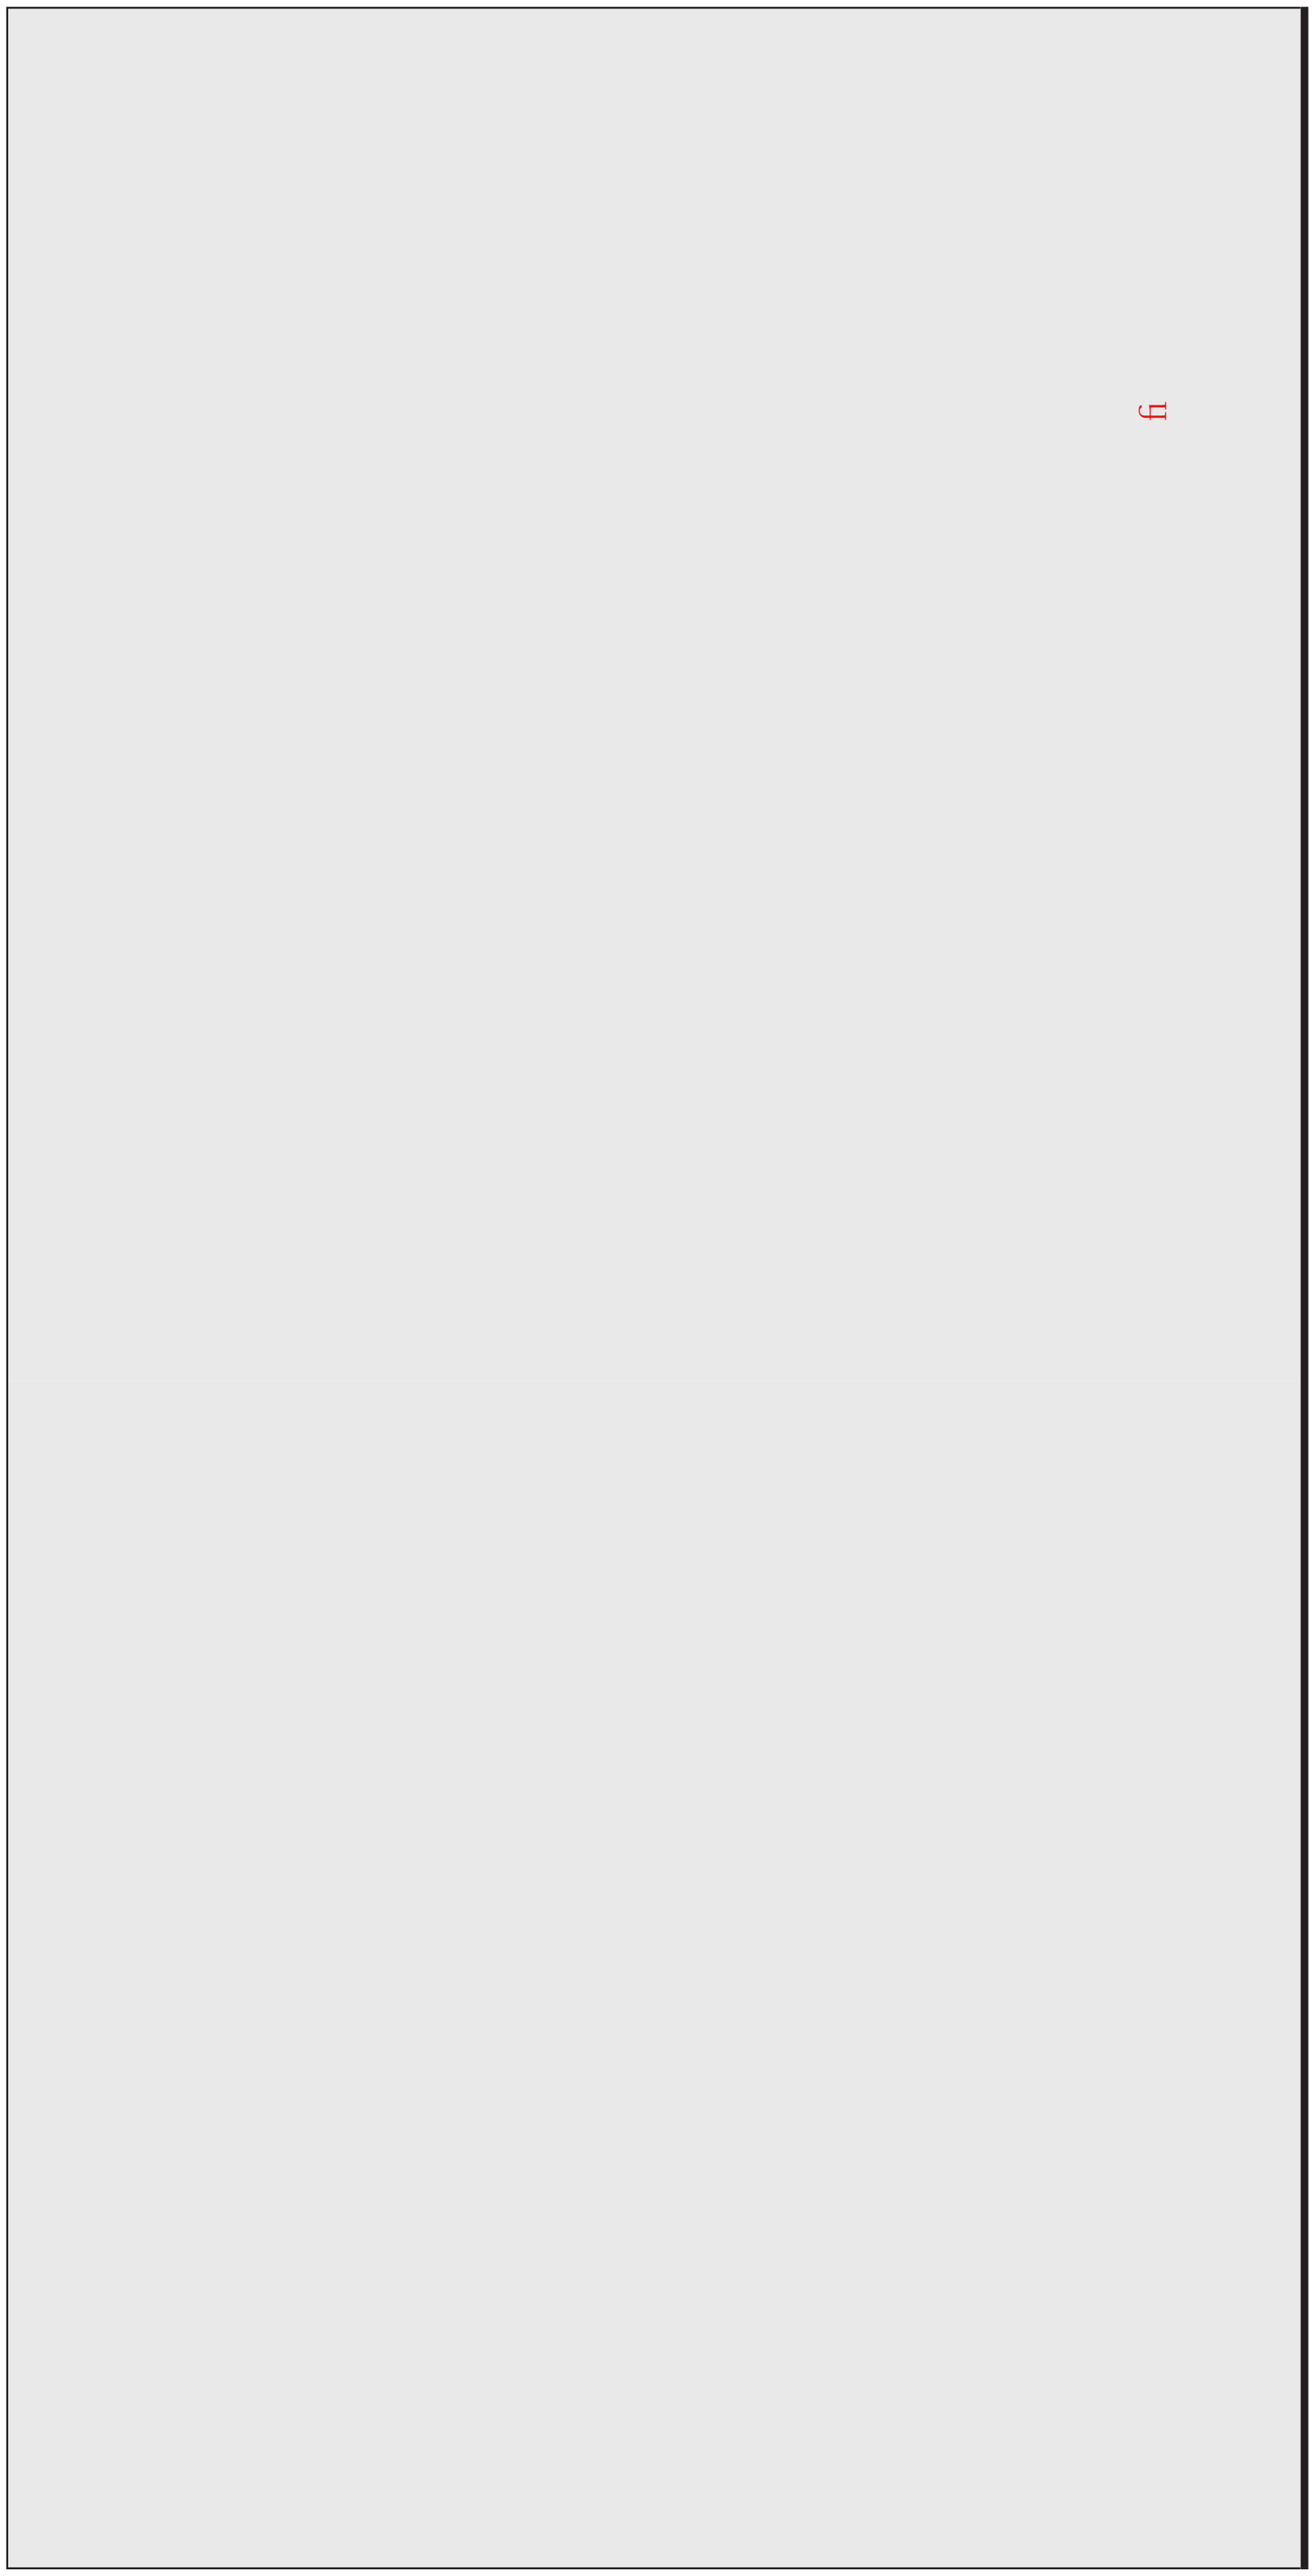
Prior to the easy availability of inexpensive DNA sequencing, multiple approaches had been developed to facilitate disease gene discovery. With some disease entities, a broader understanding of underlying pathogenic mechanisms had enabled the identification of potential "candidate genes." Alport syndrome is an example of the successful application of this approach.[1] Biochemical analysis of the Alport glomerular basement membrane (GBM) identified a set of α chains of type IV collagen that were missing.[2–5] Molecular techniques were then used to clone the type IV collagen genes, and mutation analyses revealed that sequence variants in a subset of these genes segregated with the disease. In a similar manner, the recognition that individuals suffering from the infantile form of Bartter syndrome have a clinical presentation similar to that of patients on loop diuretics prompted investigators to evaluate the drug's target, the Na-K-2Cl cotransporter (SLC12A1), as a probable candidate gene. As predicted for this recessive disease, inactivating mutations were found in both alleles in a subset of families.[6]

For other disorders, the underlying gene defect was identified by expression cloning of candidate genes. In this approach, one identifies genes responsible for a particular function by the transfer of genetic material into cells that lack that function and then screening for activity. Typically, multiple pools of genes are used for the initial screening and then the search is focused on only those pools that demonstrate the









β

β

β

fi
fi

β

γ

desired activity. By using a reiterative process of serial dilutions and functional testing, one can ultimately identify the gene or genes responsible for the observed activity. Finally, the cloned candidate genes are scanned for sequence differences (mutations) that segregate with disease. This approach has been termed expression cloning and has been used most successfully to identify various transporters. The genes implicated in cystinuria, SLC3A1 and SLC7A9, were identified by this approach.[7–11] Likewise, the three subunits that comprise the epithelial sodium channel, ENaC, were isolated in this manner.[12] Inactivating mutations of each of the subunits have been associated with recessive forms of pseudohypoaldosteronism type I,[13,14] whereas activating mutations of either the β or γ subunit have been found in Liddle syndrome, an autosomal dominant form of hypertension.[15,16]

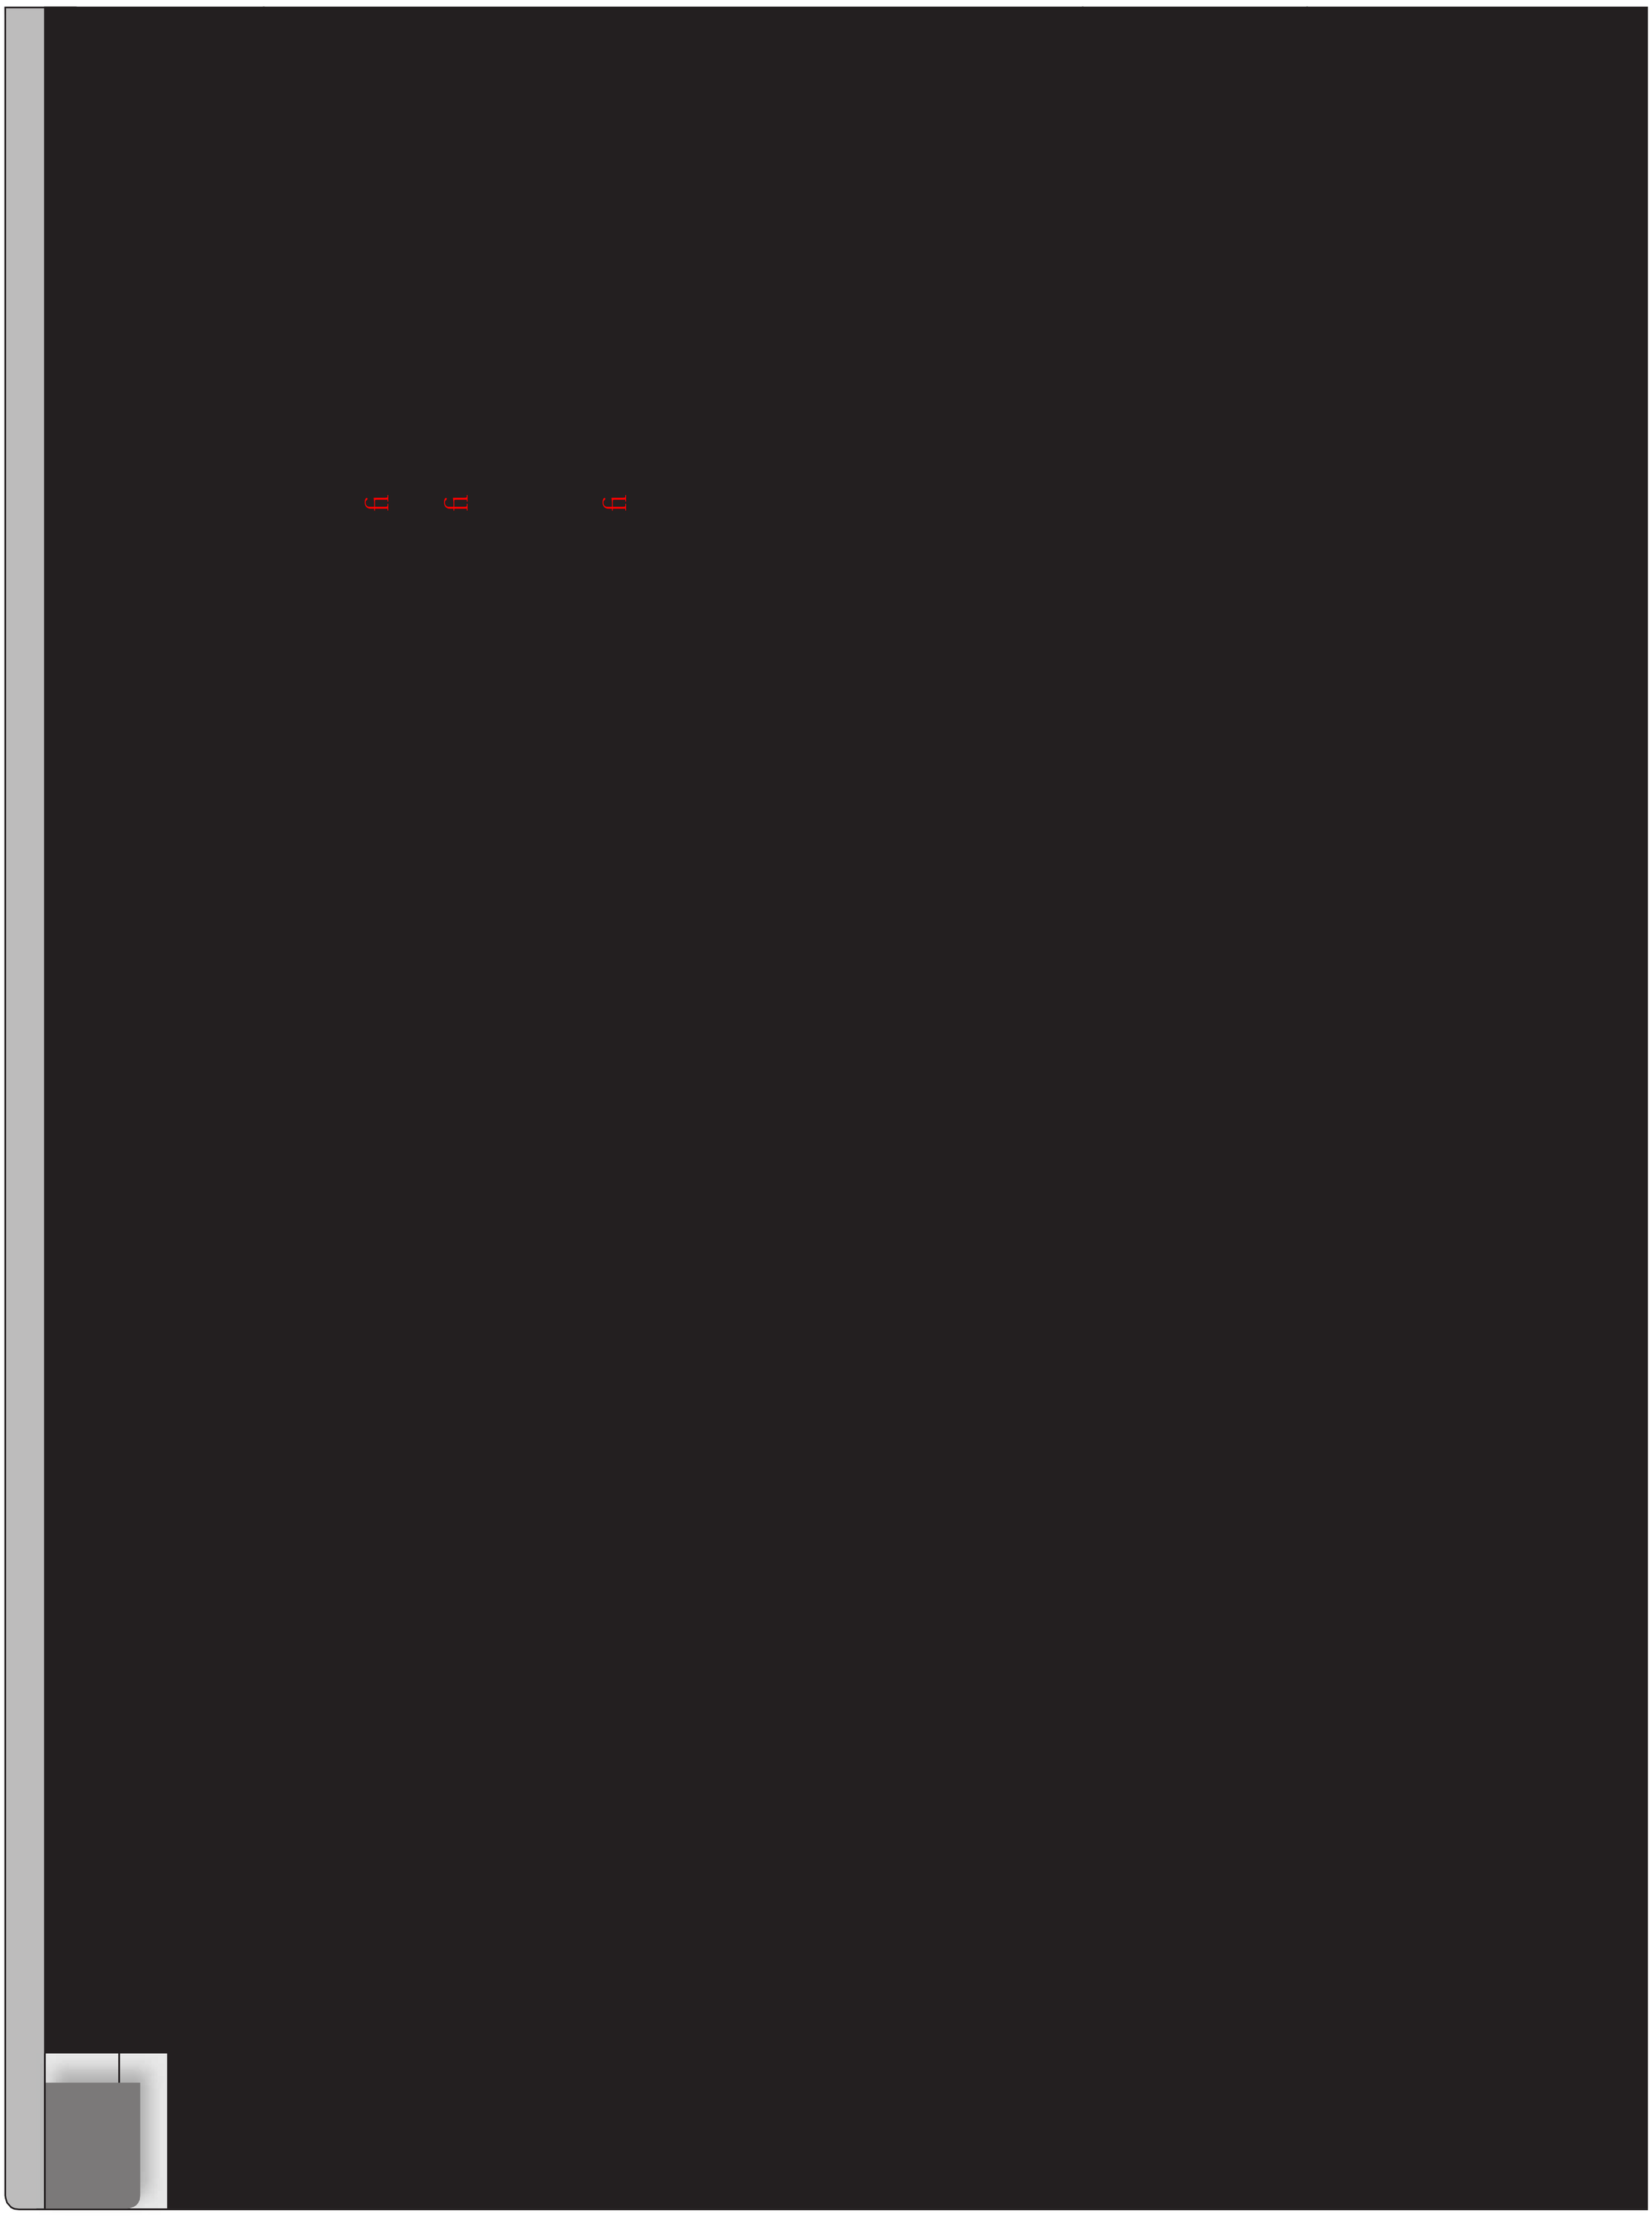
Each of the prior approaches requires an in-depth understanding of the underlying pathobiology of the disease for its success. Unfortunately, we lack this information for most diseases. This necessitated the use of a strictly molecular genetic approach, termed positional cloning, which seeks to identify a disease gene solely on the basis of its chromosomal location.[17]

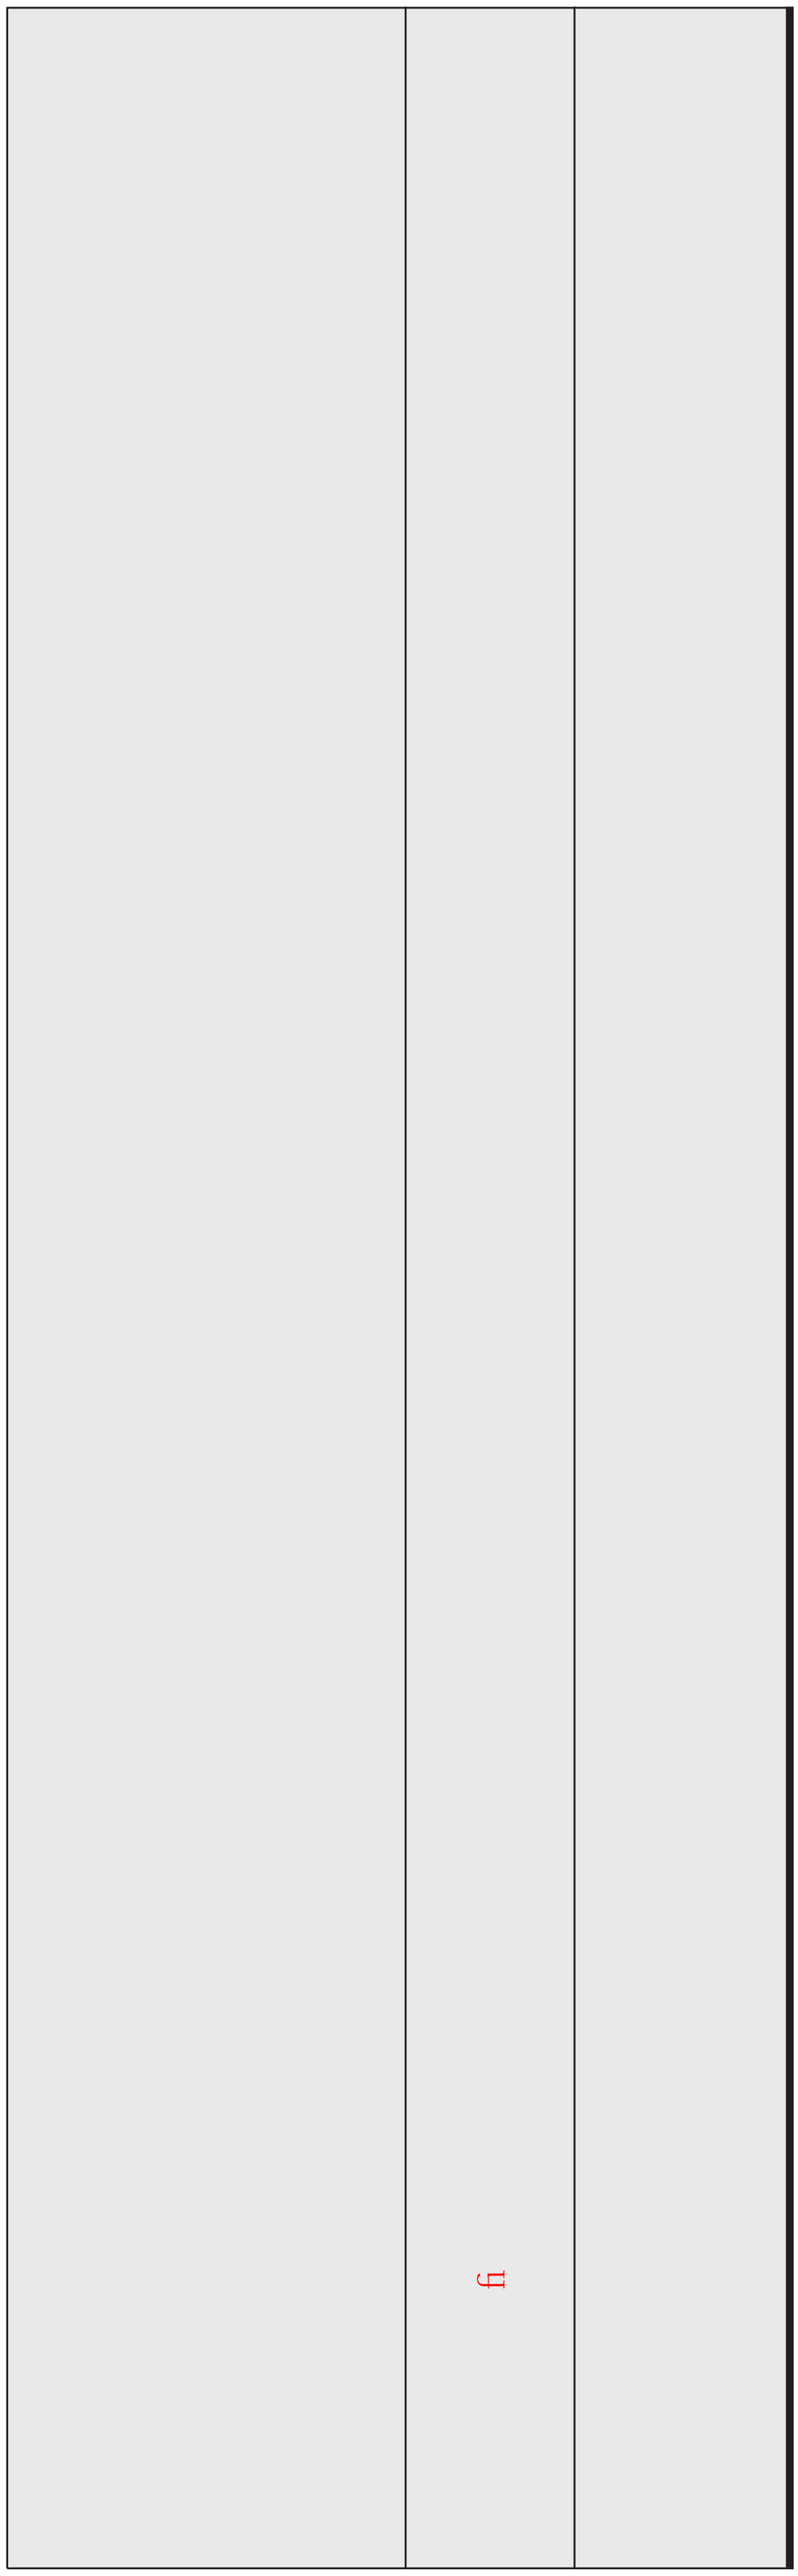
In some cases, important positional clues were provided by a cytogenetic analysis of affected individuals. Several of the loci involved in the origin of renal tumors were identified by this approach (Table 14.4). The gene responsible for the major form of Wilms tumor, WT1, was initially discovered because of its involvement in WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation).[18–20] Individuals affected by this disorder were found to have constitutional deletions of 11p13 involving a zinc finger transcription factor, WT1, a paired box transcription factor (Pax6), and adjacent DNA sequences. Fine mapping proved that WT1 was responsible for the genetic susceptibility to Wilms tumor, whereas Pax6 was responsible for the aniridia phenotype.[21] One of the familial forms of nonpapillary renal cell carcinoma (RCC) also was identified on the basis of its underlying chromosomal rearrangement. A translocation between chromosomes 3p and 8q (t[3;8][p14.2;q24.1]) was found to segregate with renal cell carcinoma.[22] Nearly 2 decades later, investigators identified the genes disrupted by the translocation. They determined that the chromosomal rearrangement resulted in a novel gene that consisted of 5′ elements of a gene called FHIT (fragile histidine triad gene) fused to the coding sequence of TRC8.[23] The protein product of TRC8 has high homology to the basal cell carcinoma/segment polarity gene product, Patched, a signaling receptor, suggesting that it may have a similar function. Since that time, 11 further chromosome 3 translocations have been associated with a susceptibility to RCC, including several that disrupt candidate tumor suppressor genes such as LSAMP and NORE1.[24]

Perhaps one of the most striking examples of the power of cytogenetic abnormalities to expedite gene discovery is that provided by the search for PKD1, the gene responsible for the most common form of ADPKD. A combination of molecular and genetic techniques had rapidly localized the gene to a 500 kilobase (kb) gene-rich segment, but the lack of known chromosome rearrangements or deletions coupled with the large number of potential candidate genes greatly complicated the search.[25,26] Several years of mutation screening had failed to determine which one of the many candidates was in fact PKD1 when an astute clinician identified an unusual family that had individuals with classic ADPKD as well as a child with both tuberous sclerosis and renal cysts. Because it was known that a major form of tuberous sclerosis (TSC2) was located near the PKD1 gene,[27] cytogenetic studies of the family were undertaken. This revealed two individuals in the family with balanced translocations between chromosomes 16 and 22 (t[16;22][p13.3;q11.21]).[28] The child with TSC2 had an unbalanced karyotype and was missing a portion of chromosome 22 as well as the telomeric portion of chromosome 16 (45XY/-16-22+der[16][16qter-16p13.3::22q11.21-22qter]). It was correctly speculated that the TSC2 gene was located in the portion of chromosome 16 that was lost while PKD1 was likely to be the gene bisected by the translocation breakpoint. This was confirmed by additional studies and resulted in the identification of both TSC2 and PKD1.[28,29]

Although chromosomal rearrangements are incredibly helpful when associated with disease, they are uncommon. Therefore, most gene searches began using linkage-based methods. Linkage analysis requires both well-characterized pedigrees and an array of genetic markers. Genetic markers are DNA variants that differ within the normal population in their length or sequence and can be used to trace inheritance of parental chromosomes within families. The principle underlying this approach is as follows: a genetic disease is assumed to be the clinical manifestation of a DNA mutation. Therefore, one can identify the location of the mutant gene by comparing the segregation of the disease phenotype with a battery of genetic markers. Alleles of loci (a specific chromosomal address of a DNA segment) on different chromosomes will appear to segregate randomly, whereas alleles of loci physically close on the same chromosome are inherited together and are linked. Meiotic recombination produces novel haplotypes by exchanging alleles between homologous chromosomes and the frequency with which this occurs depends in part on the distance separating them. In other words, if the alleles of two genes are adjacent to each other on the same chromosome segment, there will be no recombination between them. Statistical programs are used to score the probability that an observed association has not happened by chance. The most common approach determines the ratio of the probability of the observed associations assuming linkage to that of no linkage. The LOD score is the decimal logarithm of this ratio and is considered significant when greater than 3.

Until recently, it was necessary to clone the chromosomal interval in question, identify its genes, and then screen them for mutations. These steps often took many years to complete. The human genome project revolutionized this





fg
fg

process by virtually providing the complete, annotated sequence of the human genome in public databases and producing dense genetic maps that included over a million single nucleotide polymorphisms (SNPs). SNP-chips (which query hundreds of thousands of SNPs in a single hybridization) have facilitated rapid genetic localization of disease loci, and the genomic maps have provided a comprehensive set of all potential candidate genes. Despite these advances, the task of identifying a disease-associated gene still remained a time-consuming endeavor prior to the widespread availability of high-throughput sequencing. The reason for this is that the resolution of genetic mapping is typically on the order of 500,000 to 1,000,000 bp. With an average gene density of one gene per 30,000 bp in gene-dense regions, a segment of this length could harbor between 30 to 40 genes! For diseases that are uncommon, the small number of family members available for testing often limited the resolution of genetic mapping to an area millions of base pairs in length.

Several shortcuts were used to minimize the level of effort. The first strategy was to use publicly available databases to determine the identity and likely function of genes within one's target region. One could use a modest understanding of the pathobiology of a disease to narrow the field of candidates to a set whose functions were consistent with the underlying defect. For example, linkage studies revealed that one of the loci responsible for hereditary papillary renal carcinoma (HPRC) mapped to an interval on 7q31 that included the MET proto-oncogene. The well-established relationship between MET and other carcinomas prompted the investigators to focus their search on this gene, leading to the rapid discovery of pathogenic mutations.[30] In another example, Dent disease was known to be an X-linked disorder often associated with microdeletions of Xp11.[22.31] Fisher et al.[32] initiated their search for the gene responsible for Dent disease by screening for expressed sequences that were encoded by the deleted segment. They identified a novel chloride channel family member that was deleted in many patients with Dent disease, that had a restricted pattern of expression, and whose function was consistent with the pathophysiology of the disease. They subsequently showed that mutations of CLCN5 were responsible for this disease.[33] In the case of ADPKD, investigators seeking the identity of PKD2 determined that one of the candidate genes in their genetic interval had homology to the gene product of PKD1, polycystin-1. This gene was an obvious candidate for PKD2, and mutation analysis quickly confirmed this suspicion.[34]

One of the most interesting examples of this approach was its use to identify a novel locus for Bardet-Biedl syndrome (BBS). Investigators had determined that this rare, autosomal recessive disorder, which is characterized by obesity, mental retardation, anosmia, fibrocystic renal disease, congenital hepatic fibrosis, and left/right axis defects, was genetically heterogeneous. A number of loci were known, and investigators had found that their respective gene products were localized to either the basal body and/or the primary cilium. The overlap in clinical features between BBS and other diseases that result from dysfunction of ciliary proteins gave rise to the idea that candidate genes for BBS and other similar diseases could be identified based on this property. Scientists compared the complete genomic sequence of multiple species that have cilia to those that do not, and identified a set of genes exclusively present in organisms with cilia and basal bodies. Two of the genes mapped to a previously defined interval for BBS5 that contained 230 predicted genes. Molecular testing identified mutations in one of the two genes in BBS5 families.[35] The locus encodes a novel protein of unknown function that would have otherwise been a low priority candidate for further study.

A second approach that had been used to speed the pace of gene discovery was to search for disease-associated microscopic chromosomal abnormalities that were below the level of resolution of standard cytogenetic analyses. The genes responsible for the most common form of nephronophthisis (NPHP1) and for cystinosis (CTNS) were identified in this manner. In the case of NPHP1, large-scale rearrangements were detected in 80% of the patients belonging to inbred or multiplex NPHP1 families and in 65% of the sporadic cases.[36] Most of the time, large homozygous deletions of approximately 250 kb involving a 100-kb inverted duplication were discovered to disrupt the gene. In a small number of individuals, oligo-base pair mutations were identified, proving that NPHP1 was the specific gene responsible for the disorder.[37,38] CTNS was identified in a similar manner. Investigators found that one of the genetic markers used in their study was homozygously deleted in 23 out of 70 patients.[39] They quickly focused their search on the minimal deleted region and identified a ubiquitously expressed transcript that was disrupted in all patients with deletions involving this segment. They subsequently found single or oligo-base pair mutations in many of the remaining patients, thus proving that this gene and not one of its neighbors was in fact responsible for the disease.

A third strategy had been to determine the expression pattern of the various candidates and see if any were consistent with the clinical features of the disorder. Fuchshuber and colleagues[40] had localized a form of steroid-resistant idiopathic nephrotic syndrome (NPHS2) to a 2.5 million-base pair interval on chromosome 1. They had identified multiple putative candidates but focused their search on one whose expression by Northern blot was detectable only in fetal and adult renal tissues. They subsequently discovered recessive, inactivating mutations in NPHS2, and further showed that its expression was restricted to glomerular podocytes.[41] In a similar manner, the kidney-restricted pattern of expression of PCLN1 helped to identify it as a probable candidate gene for primary hypomagnesemia.[42]

In a number of diseases, gene discovery resulted more from good luck than from the pursuit of a particular strategy. The ability to manipulate the murine genome through gene targeting (described in more detail later) has allowed investigators to generate a lengthy list of murine models of human diseases. In most cases, scientists first identified the

disease gene and then created a mutant phenotype in the mouse with the intention of modeling the human disease state (see the subsequent text). In some cases, however, the genes targeted for study had not been previously implicated in a genetic disorder; rather, they had been selected for study because the investigators had a fundamental interest in their biologic properties. Careful analysis of the murine phenotypes revealed surprising similarity to human diseases, leading investigators to test for mutations in their human homologues.

It was in this way that LMX1B, which encodes LIM homeobox transcription factor 1β, was found mutated in Nail-Patella syndrome (NPS). Investigators with an interest in basic developmental processes had targeted this gene for inactivation and discovered limb and kidney defects in Lmx1b mutant mice that were remarkably similar to those observed in human NPS.[43] They quickly identified three independent NPS patients with de novo heterozygous mutations of LMX1B.[44] The identification of CD2AP (CD2-associated protein) as a cause of steroid-resistant nephrotic syndrome is another example.[45,46] CD2AP was thought to be an adapter protein critical for stabilizing contacts between T cells and antigen presenting cells. Mice that were null for Cd2ap had compromised immune function but died unexpectedly at 6 to 7 weeks from renal failure. The investigators showed that homozygotes developed proteinuria associated with defects in epithelial cell foot processes and eventual glomerulosclerosis. CD2AP was found expressed in podocytes where it associates with nephrin, the primary component of the slit diaphragm. Subsequent studies in humans discovered CD2AP mutations in patients with focal segmental glomerulosclerosis.[47–49]

It is likely that additional fortuitous relationships will be established, as the list of murine genes that are inactivated by gene targeting becomes more complete. The National Institutes of Health (NIH)-sponsored Knockout Mouse Project (http://www.komp.org/), in collaboration with the International Knockout Mouse Consortium (http://www.knockoutmouse.org/), is aiming to mutate all protein-coding genes in the mouse and then perform broad, standardized phenotyping on a large subset (https://commonfund.nih.gov/KOMP2/overview.aspx). These studies will likely identify additional, unsuspected candidate genes for human disorders.

Unfortunately, these approaches could not be successfully used for most genetic diseases. In these cases, one had to resort to the use of sequence-based strategies to identify the disease gene. As the reader can understand from the previous discussion, this was often a tedious, time-consuming, and expensive process. For rare diseases where the genetic interval defined by genetic linkage was on the order of millions of base pairs, gene discovery was stalled.

Breakthroughs in DNA sequencing technology have revolutionized this process. As indicated in the introduction, there has been an explosion of new high-throughput methods for determining DNA sequence. A comprehensive review of the subject is beyond the scope of this chapter and surely would be outdated by the time this volume is published. Common to all of the methods is the use of massively parallel systems that determine 10^6 to 10^8 sequence reads of ~30 to 400 bp per read in a single experiment. This is in sharp contrast to standard Sanger sequencing machines that maximally determine up to 384 sequence reads of 600 to 1,000 bp per read. Although the new methods, commonly called next generation sequencing, dramatically increase throughput, they also generally have higher error rates and require much greater levels of redundancy to maximize accuracy. Depths of coverage are routinely greater than 20×, and even with this degree of redundancy, gaps and sequence errors can occur. Most laboratories confirm variants of interest with direct Sanger sequencing because of its greater reliability.

There presently are three different approaches for using next generation sequencing for disease gene discovery. In situations where linkage studies have already localized a gene to a chromosome region, investigators use a variety of methods to "capture" the genomic interval and then subject it to next generation sequencing. When linkage is either not possible or when the investigator prefers to use a generally applicable method, he or she pursues either whole genome or whole exome sequencing. As the respective names imply, whole genome sequencing (WGS) determines the sequence of the entire genome, whereas whole exome sequencing (WES, also known as targeted exome capture) restricts its analysis to the DNA sequence of exonic sequences and flanking intron/exon boundaries for all genes. Although WGS is the most comprehensive approach because it includes all regulatory and intronic sequences, its cost is still limiting and the sheer quantity of data it produces presents significant bioinformatic challenges. WES is currently the preferred option because the exome is less than 5% of the size of the entire genome but is estimated to harbor over 85% of all disease-causing mutations.

WES has been successfully used to identify a rapidly growing list of disease genes. In the renal community, this approach was recently used to identify MYO1E (myosin 1E, a podocyte cytoskeletal protein) and NEIL1 (endonuclease VIII-like 1, a base-excision DNA repair enzyme) as new candidate genes for human autosomal recessive steroid-resistant nephrotic syndrome.[50] In another example, this approach helped to identify NPHP1 mutations as the cause of disease in two families where consanguinity mapping localized the gene to an interval of almost 30×10^6 bp, far too large to tackle with conventional Sanger methods.[51] Using a variation of this approach, Otto et al.[52] identified mutations in SDCCAG8 (serologically defined colon cancer antigen 8) as the cause of a nephronophthisis-related ciliopathy (Fig. 14.1). As the cost drops even further and the technique becomes universally accessible, there is little question that WES is destined to accelerate gene discovery for hundreds of Mendelian disorders.[53]

In summary, the combination of multiple avenues of biologic data with genetic map position has proved to be a

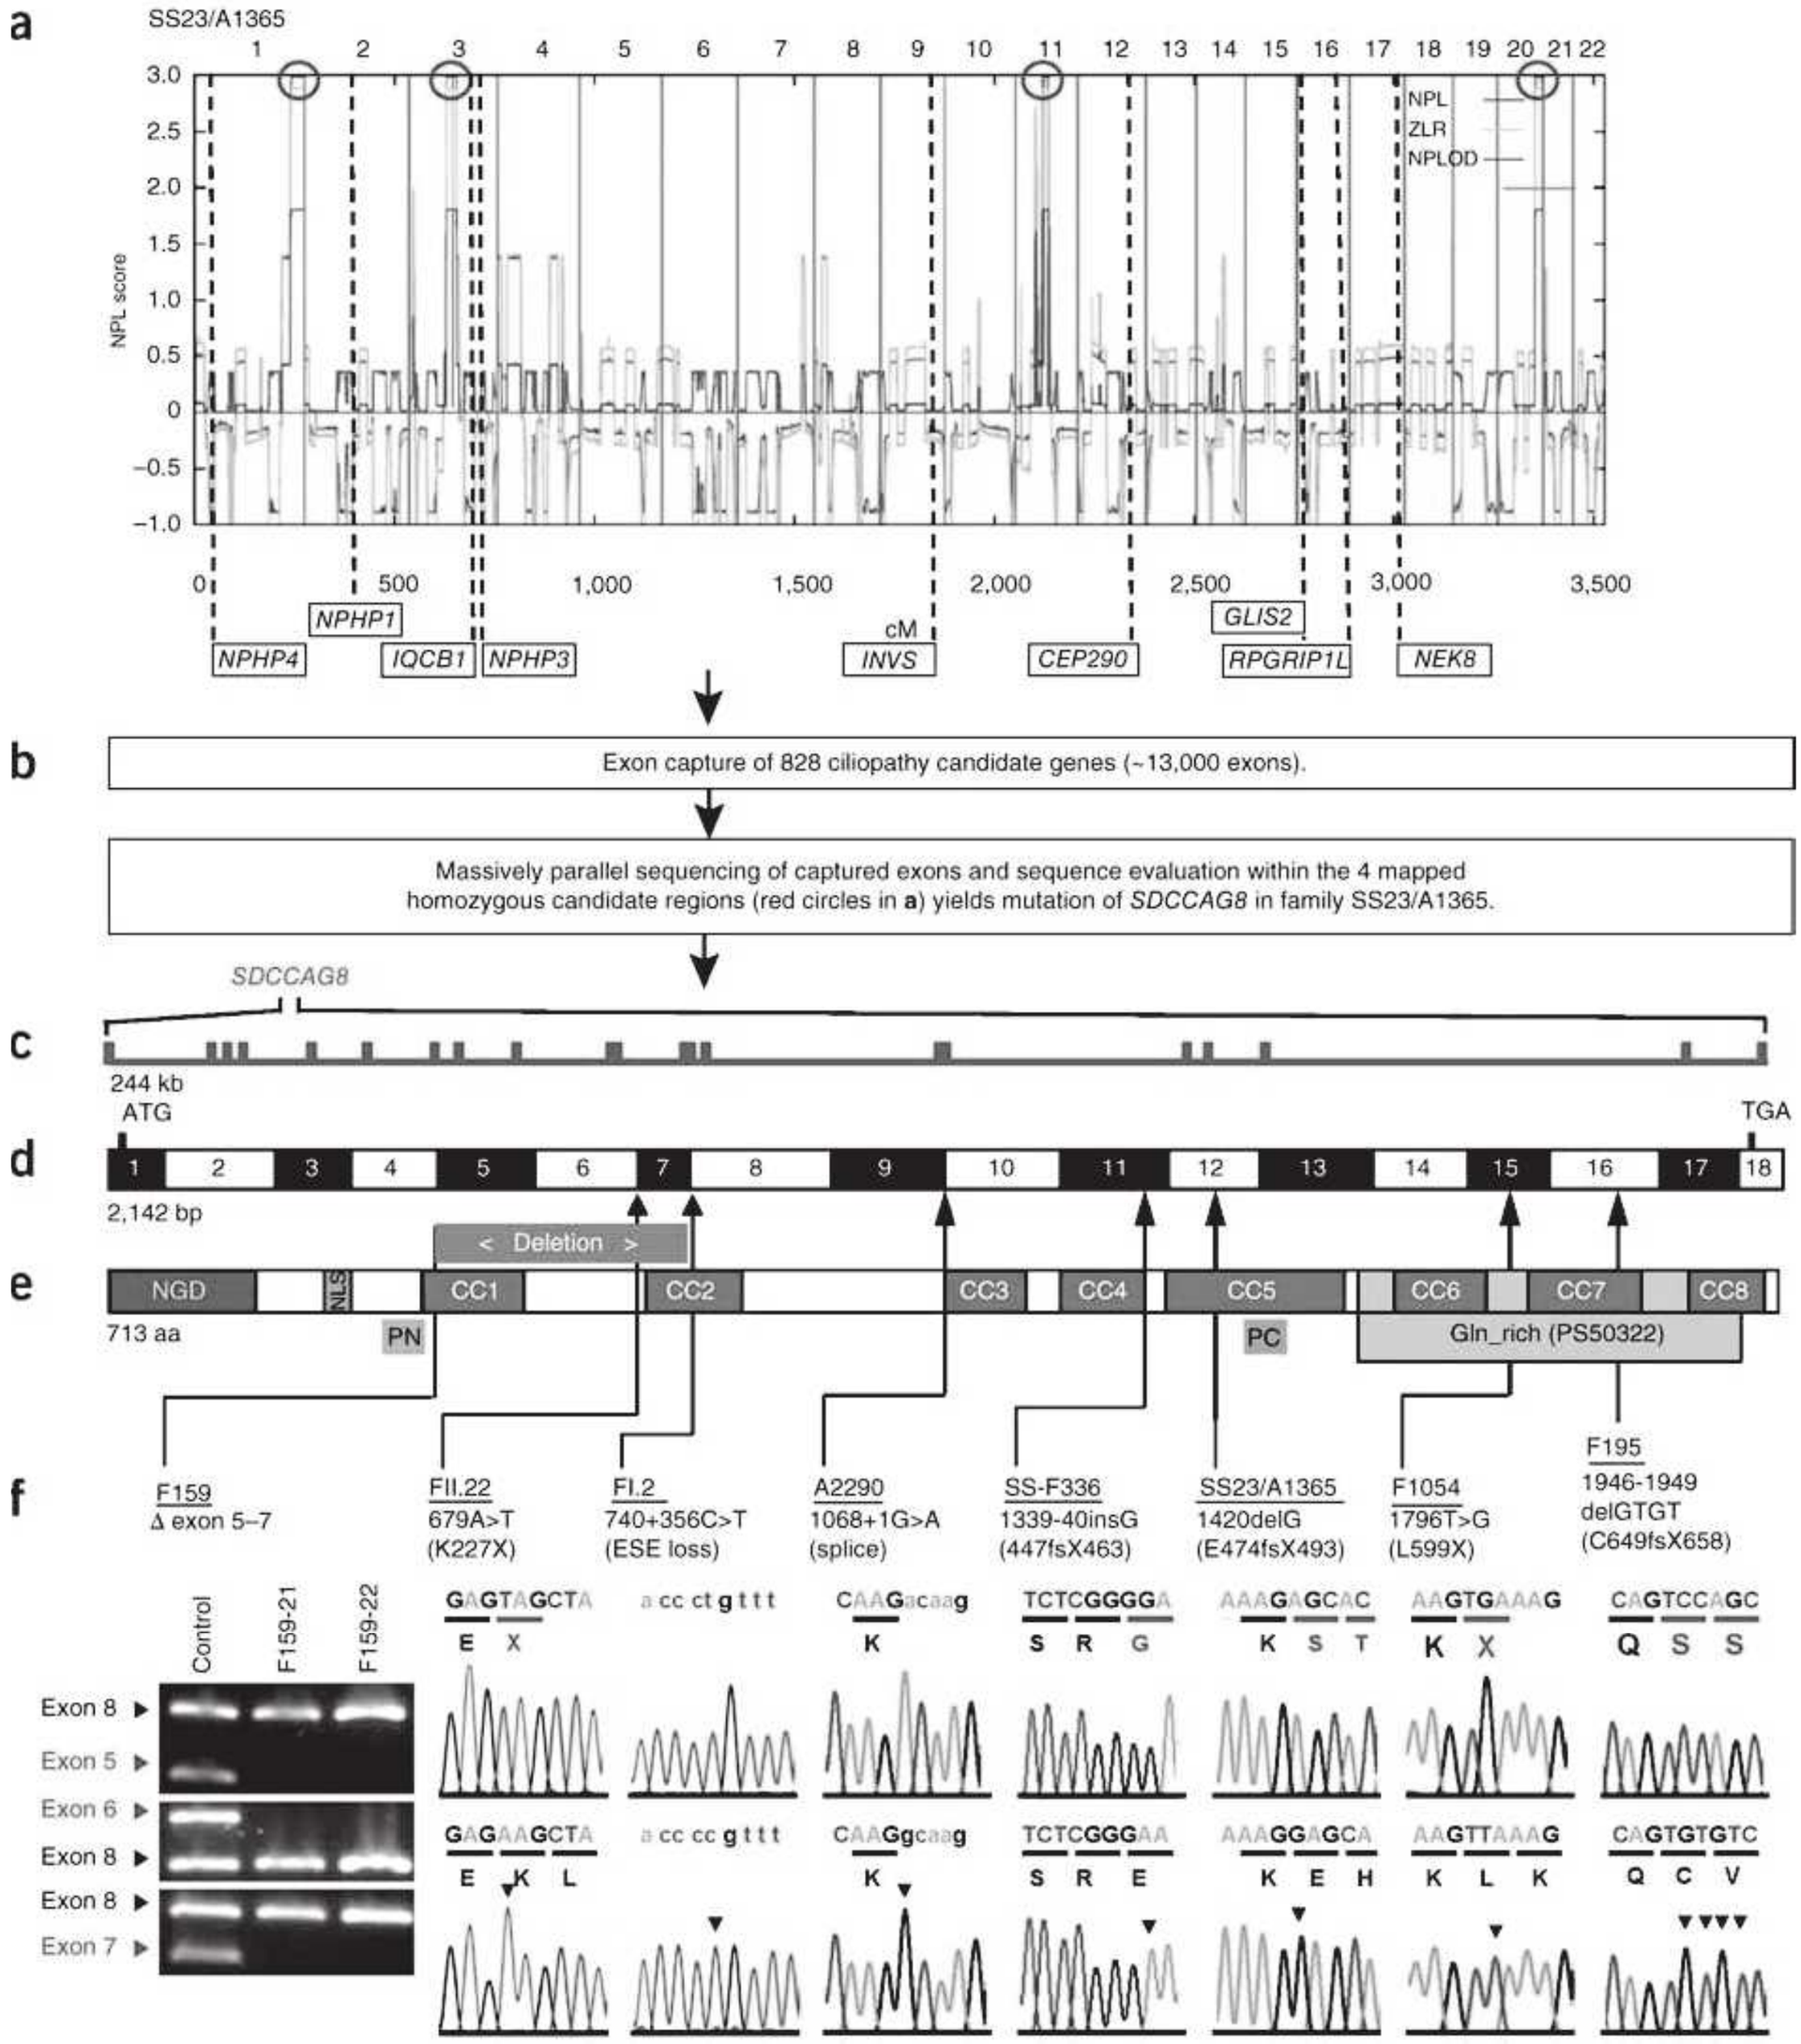


FIGURE 14.1 Homozygosity mapping, exon capture, and massively parallel sequencing identifies *SDCCAG8* mutations as causing nephronophthisis with retinal degeneration. **A:** Nonparametric log of odds (NPL) scores across the human genome in two siblings with nephronophthisis and retinal degeneration of consanguineous family SS23/A1365. Genetic distance is given in centimorgans. Four maximum NPL peaks (*red circles*) indicate candidate regions of homozygosity by descent. **B:** Exon capture of 828 ciliopathy candidate genes with consecutive massively parallel sequencing and sequence evaluation within the four mapped homozygous candidate regions (*red circles* in image **A**) identifies mutation of *SDCCAG8* in SS23/A1365. **C:** The *SDCCAG8* gene extends over 244 kb and contains 18 exons (vertical hatches). **D:** Exon structure of human *SDCCAG8* cDNA. Positions of start codon (ATG) and of stop codon (TGA) are indicated. For mutations detected, *arrows* indicate positions relative to exons and protein domains. **E:** Domain structure of the SDCCAG8 protein. NGD, N-terminal globular domain, NLS, nuclear localization domain, CC, coiled-coil domains, and Gln_rich, glutamine-rich region. PN and PC denote peptides used for antibody generation. **F:** Eight homozygous *SDCCAG8* mutations detected in eight families with nephronophthisis and retinal degeneration. Family number, mutation, and predicted translational changes are indicated. A homozygous deletion covering exons 5 through 7 is demonstrated by agarose gel electrophoresis (see *gray bar* in image **E**). Sequence traces are shown for mutations that are above normal controls. Mutated nucleotides are indicated by *arrowheads* in traces of normal controls. (From Otto EA, Hurd TW, Airik R, et al. Candidate exome capture identifies mutation of SDCCAG8 as the cause of a retinal-renal ciliopathy. *Nat Genet*. 2010 Oct;42(10):840–850. Reprinted by permission from Macmillan Publishers Ltd.) (See Color Plate.)

powerful strategy for finding disease genes. Hence, we have witnessed a remarkable increase in the number of inherited diseases the genetic bases of which have been elucidated.

POSTCLONING PHASE OF GENE DISCOVERY

Using Databases

Identification of a gene is often when the work of defining the biology of a disease begins. This is especially true in diseases such as ADPKD or tuberous sclerosis where a complex phenotype exists and a unifying biochemical defect is not apparent. The first step is usually to perform a series of database analyses, looking for sequence similarities, functional motifs, and structural features that might be used to generate a variety of testable hypotheses regarding a gene's function. In some cases, one finds that a segment of one's query has a high degree of similarity to a family of proteins of known function. In primary hypomagnesemia, the protein encoded by PCLN1 was found to have a sequence and structural similarity to members of the claudin family.[42] All other members of this family localize to tight junctions and appear to bridge the intercellular space by homo- or heterotypic interactions, suggesting a similar function for PCLN1. This result was particularly intriguing in that renal magnesium ion (Mg^{2+}) resorption occurs predominantly through a paracellular conductance in the thick ascending limb of Henle (TAL).

In other situations, one may identify homologous genes in other organisms, vertebrate or invertebrate, that have already been studied and for which a function may be known. The potential power of this strategy to help expedite the study of disease genes is highlighted by the fact that over 60% of human disease genes have a homologue in the common fruit fly, Drosophila melanogaster, and a surprisingly high fraction is even conserved in yeasts.[54–58] The TSC1 and TSC2 genes, mutated in tuberous sclerosis, are representative examples. The sequence of each gene provided little in the way of functional insight. Tuberin, the gene product of TSC2, was found to have a region of homology to the GTPase-activating protein GAP3,[28] whereas hamartin, the TSC1 protein, was homologous to a yeast protein of unknown function.[59] Given that other GTPase activating proteins had previously been identified as tumor suppressors, it was presumed that tuberin would have a similar function but the mechanism by which it would do so was obscure. Slow progress was made in defining the respective function of each TSC protein until the discovery and functional characterization of their homologues in Drosophila (discussed later). As saturation mutagenesis strategies of simpler organisms help to reveal the function of currently unknown genes, these insights will increasingly help us to better understand the human homologues.

Conservation between species is also helpful because it can be used to identify essential functional components that are hidden in otherwise featureless sequences. In the case of PKD1, for example, a comparison of the sequence of human polycystin-1 to that of the puffer fish, Fugu rubripes, two species separated by nearly 400 million years of vertebrate evolution, identified several highly conserved regions with no known sequence homologies.[60] One of these was subsequently identified as a putative 20-amino-acid heterotrimeric G-protein activation sequence.[61] Sequence conservation can also be used to help resolve disputes regarding the putative structure of a protein. In the case of polycystin-1, comparison of the human and Fugu sequences led to the identification of a set of 11 conserved probable transmembrane spanning elements,[60] subsequently confirmed by biochemical methods.[62]

Several databases use specific amino acid patterns culled from an analysis of many proteins to find certain motifs. This can be an especially powerful tool because it can identify patterns otherwise missed by direct sequence comparisons. One example of the successful use of this approach is provided by the identification of a GPS domain (G-protein coupled receptor proteolytic site) in polycystin-1.[63] This domain was first identified as the internal cleavage site for the neuronal G-protein coupled receptor, latrophilin, the putative receptor for α-latrotoxin and a member of the LNB-TM7 family of proteins.[64–66] The GPS site is a feature common to all members of the family, positioned in the extracellular N-terminus approximately 30 amino acids before the first transmembrane (TM) spanning element of each protein. In the case of latrophilin, cleavage at the site yields two fragments: a C-terminal portion that includes a short extracellular stalk followed by the 7 TM-spanning elements and an N-terminal portion that is tethered to the extracellular stalk. It is presumed that cleavage and tethering is essential for creating the active ligand binding site for α-latrotoxin or its endogenous ligands. Subsequent studies by Qian et al.[67] confirmed that the GPS site in polycystin-1 similarly undergoes proteolytic cleavage, and that mice with targeted mutation of the cleavage site (Pkd1 [V/V]) develop rapid cystic dilatation of distal nephron segments, biliary duct dilatation, and uremia.[68] Interestingly, in contrast to Pkd1 knockouts (Pkd1 -/-), Pkd1 (V/V) mice do not demonstrate embryonic lethality, proximal tubular cysts, or severe cystic expansion of the kidneys and pancreas. This finding reveals important differences in the developmental and functional roles between the uncleaved full-length and the GPS-cleaved forms of polycystin-1.[68]

Finally, a variety of algorithms can be used to identify functional protein domains. For example, there are a number of programs that can be used to predict hydrophobic areas in a protein that may signify transmembrane regions. This type of information can be extremely important in deciphering the function of a protein. In the case of PKD2, this type of analysis suggested that polycystin-2 had six transmembrane domains and resembled a known class of cation channels.[69] This hypothesis was testable, and it was

ultimately confirmed that polycystin-2 could function as a nonselective cation channel in appropriate conditions.[69]

MUTATION ANALYSIS AND THE MOLECULAR MECHANISM OF DISEASE

An important step in determining the molecular basis of disease is defining how disease mutations alter the function of the gene product. In recessive disorders, the fact that a mutation of both copies of a gene is required to cause the disease suggests that the mutations must impair or result in a complete loss of the protein's normal function. In dominant disorders, the mechanism by which mutations cause disease is less straightforward because they can act in one of three ways: (1) by reducing the amount of functional protein (via a hypomorphic allele, haploinsufficiency, or by a combination of germ line and somatic mutations); (2) by producing a protein with increased activity or a new function (dominant gain-of-function); (3) or by producing proteins that inhibit the function of the normal allele (dominant negative).

In the case of ADPKD, it was certain clinical features of the disease that provided the clue to unraveling the molecular mechanism of the disease. One of the hallmarks of ADPKD is its focal presentation.[70] Pathologic examination of cystic kidneys has shown that cysts arise as focal outgrowths of normal tubules. The logical question was that if all cells are genetically identical and carry the same germ line mutation, then why don't all cells form cysts? Considered among the many different potential explanations was the possibility that each cyst might be genetically distinct, forming as the consequence of a second, possibly rate-limiting step. By examining epithelial cells lining single cysts, it was demonstrated that renal cysts originate from one cell and thus can be termed monoclonal.[71] Furthermore, somatic mutations affecting the normal allele can be detected in a significant fraction of cysts.[72–79] This model is depicted in Figure 14.2 and suggests that the first step in cyst formation is the functional inactivation of the normal PKD allele. This model implies that PKD is recessive on a molecular level because both copies of PKD are mutated in each cyst. A small minority of cysts from kidneys with a germ line mutation in PKD2 may instead have as their somatic hit an inactivating PKD1 mutation and vice versa.[76,80] This finding has several clinical implications. First, any curative therapy must be directed at replacing the function of the gene product in cells where a "second hit" has actually occurred. Second, these findings explain at least some of the observed clinical variability because the rate at which second hits occur may determine disease severity. Clearly, an understanding of the factors that determine the rate of second hits might be used to slow disease progression. These might include processes that cause DNA instability or increase cellular proliferation.

Mutation analysis of a large number of pedigrees may also be used to establish genotype–phenotype correlations. One may discover that certain patterns of mutation are associated with specific clinical characteristics. For example, some mutations may lead to an unstable message that is never made into protein. This may have more severe functional consequences than a protein that is made but has only partially reduced activity.

Von Hippel-Lindau syndrome (VHL) provides an excellent example of the use of this approach. VHL is a dominantly inherited familial cancer syndrome caused by mutations in the VHL gene on chromosome 3.[81,82] It is characterized by a predisposition to develop renal cell carcinomas (RCC) and hemangioblastomas of the retina and central nervous system. The VHL gene is predicted to function as a tumor suppressor, and somatic mutation of the wild-type VHL allele has been detected in renal tumors from families with germ line VHL mutations.[83] In addition, up to 91% of sporadic clear cell carcinomas demonstrate somatic mutation or inactivating epigenetic changes of the VHL gene.[84] One of the most important functions of the VHL protein is in the regulation of proteasomal degradation of the hypoxia-inducible factors (HIFs),[85] which act as transcriptional regulators for a wide variety of genes important in tumorigenesis.[86,87] The VHL protein targets HIFs for degradation by binding with elongins B and C as part of a multimeric complex.[88–92]

Clinically, VHL falls broadly into two categories differentiated by their risk of pheochromocytoma, which is low in VHL type 1 (VHL1) and high in VHL type 2 (VHL2).[93–95] It turns out that these clinical phenotypes are closely correlated with the class of mutation that is detected. VHL1 is produced by mutations that completely disrupt VHL protein structure (e.g., frameshift mutations, stop codons, and gene deletions). On the other hand, VHL2 appears to be caused by missense mutations in residues that would be predicted to be in contact with elongin B.[94,96,97] Further studies in genotype–phenotype correlations have also been able to stratify risks for other manifestations of the syndrome such as RCC and hemangioblastomas based on variations in the type of amino acid change,[98] the size of the gene deletion,[99] or the presence of contiguous gene deletion.[100,101] Therefore, mutation analysis in this disease can be used both to establish a presymptomatic diagnosis and to provide specific information with respect to the disease phenotype.

Genotype–phenotype studies have recently revealed surprising relationships between three disorders previously thought to be distinct. Nephronophthisis (NPHP) is an autosomal recessive form of fibrocystic kidney disease that is one of the most common inherited causes of pediatric end stage kidney disease. Tubular atrophy and tubulointerstitial fibrosis are dominant features and cysts, if present, are mostly localized to the corticomedullary junction. Retinitis pigmentosa is present in some families. Meckel-Gruber syndrome (MGS) is a much rarer autosomal recessive, neonatal lethal disorder that classically presents with cystic kidneys, occipital encephalocele, and congenital hepatic fibrosis. Joubert syndrome (JBTS) in its typical form has little in common with either NPHP or MGS except being another rare autosomal recessive condition. Affected individuals

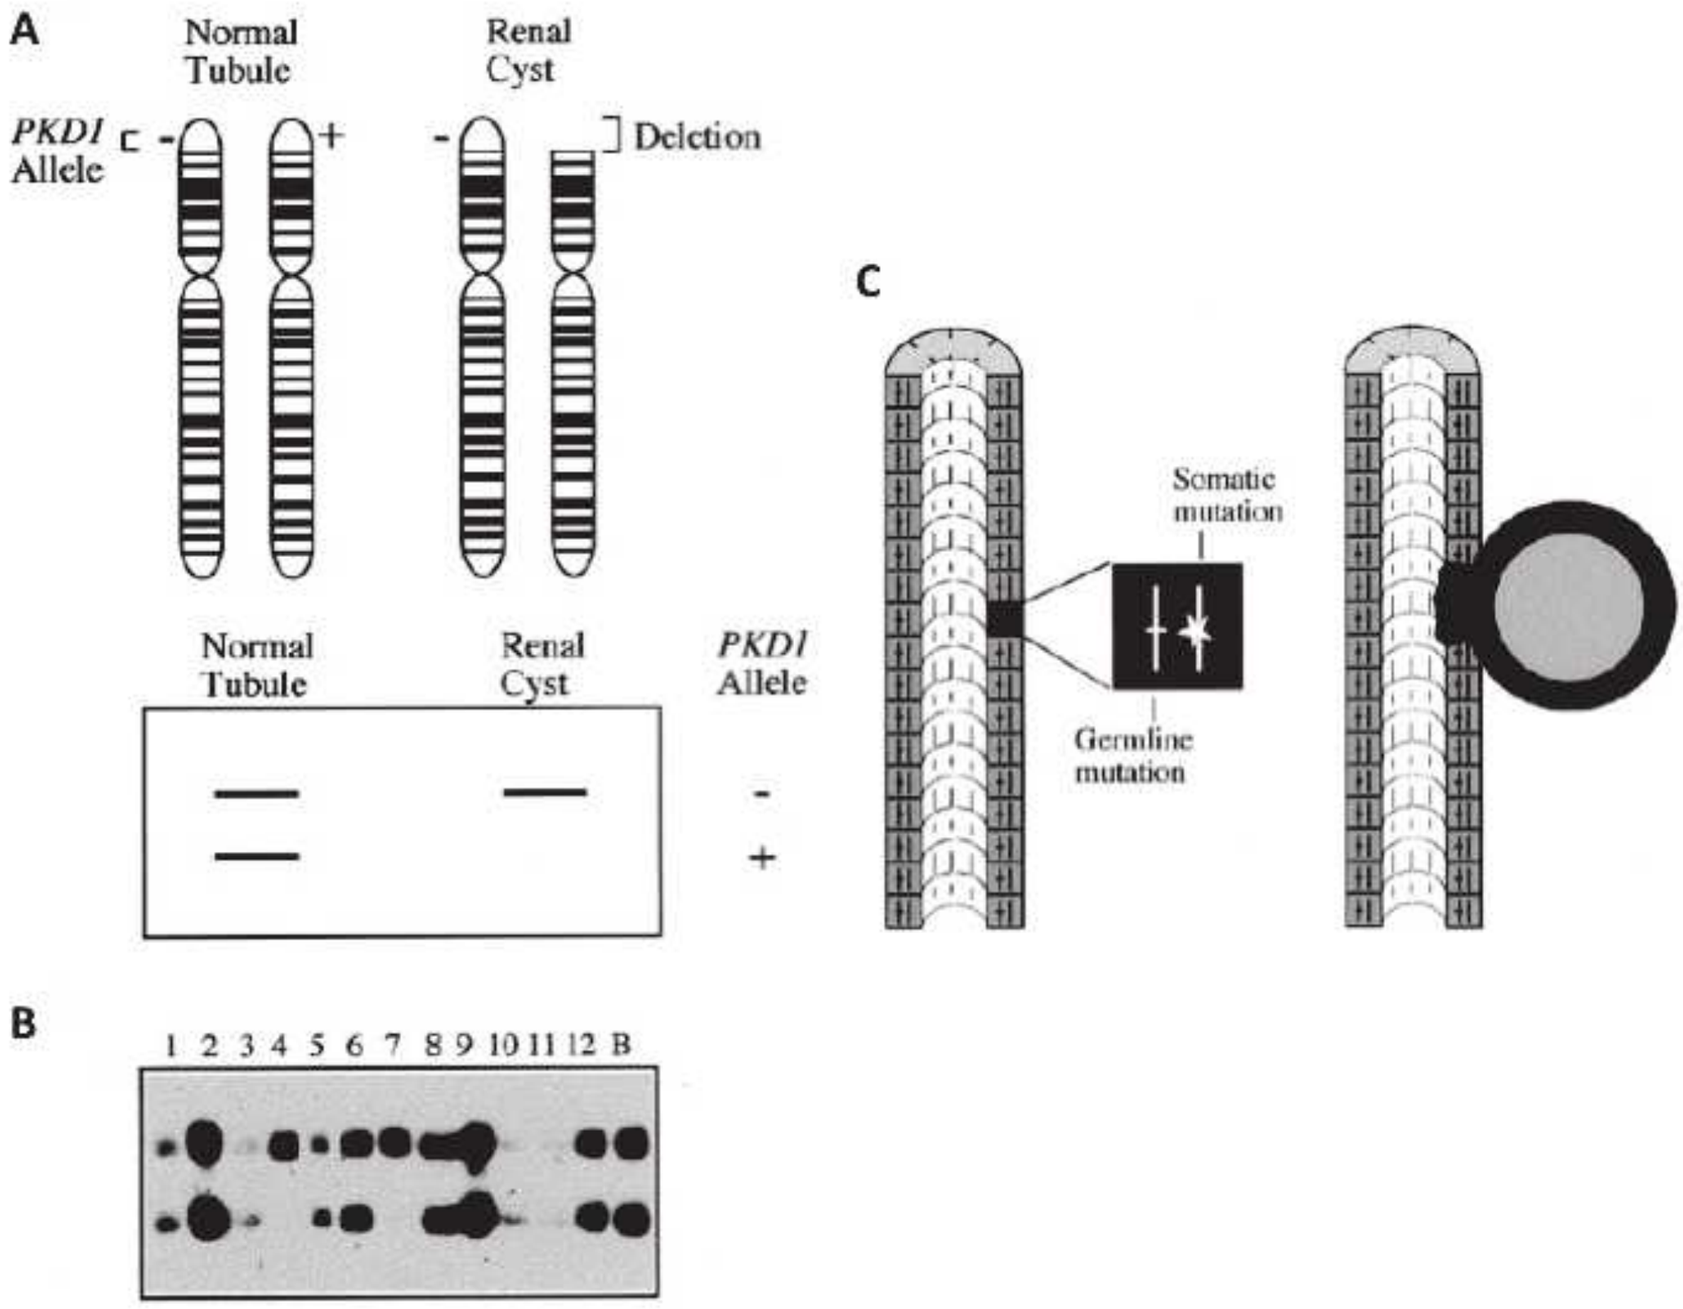

FIGURE 14.2 Loss of heterozygosity (LOH) for the normal *PKD1* allele in renal cystic tissue. **A:** Each renal tubular cell in an individual with ADPKD contains two *PKD1* alleles, one mutant copy (indicated by -) and one normal copy (indicated by +). The two alleles can be distinguished using polymerase chain reaction-based (PCR) assays if the allele-specific PCR products differ in size. Deletions of chromosome 16 that remove the normal *PKD1* locus will lead to LOH, as evidenced by the disappearance of the PCR product derived from this allele. As a result, only one band remains. **B:** Testing for LOH of the *PKD1* locus in 12 renal cysts of an individual with ADPKD using the marker KG8, an intragenic PKD1 marker. Most of the cysts have two *PKD1* alleles, but cysts #4 and #7 have only one band because each has lost the normal *PKD1* allele (*bottom band*). **C:** "Two-hit" model of cyst formation in ADPKD. Each epithelial cell in a renal tubule has the same germ line mutation of one *PKD1* allele. The normal allele presumably produces sufficient quantities of polycystin to permit a normal differentiation and the maintenance of tubular integrity. When a cell acquires a somatic mutation in the normal allele (indicated by a *star*), the level of polycystin falls below a critical threshold. The cell harboring the somatic mutation undergoes clonal expansion and forms a cyst via pathways that not yet have been identified. (From Qian F, Watnick TJ. Somatic mutation as mechanism for cyst formation in autosomal dominant polycystic kidney disease. *Mol Genet Metab.* 1999 Oct;68(2):237–242. Used with permission.)

typically present with midbrain and hindbrain anomalies and a distinctive "molar-tooth sign" on radiologic imaging of the brain.

Each of these conditions is genetically heterogeneous and, in its classic form, results from mutations at distinct loci. There is a subset of patients, however, that presents with an overlapping constellation of features of JBTS, NPHP, and MKS that includes NPHP, retinitis pigmentosa, cystic dysplasia, congenital hepatic fibrosis, or a small encephalocele. Mutations have been found in loci responsible for causing JBTS, NPHP, and MKS.[102] The diseases are now thought to represent a spectrum of disorders, which also includes BBS and orofacial digital syndrome, with phenotypic expression in part determined by the nature of the mutation.[52,103–106] The overlap of identified genetic loci and phenotypic features of these disorders is illustrated in Figure 14.3.

Mutation studies of affected individuals may also provide a database of allelic variants that can be used to guide the study of important functional domains. Missense mutations that have phenotypic consequences are particularly instructive because they identify essential amino acid residues and critical functional elements. Perhaps the best example of this is a mutation in the mineralocorticoid receptor (MR), S810L, which causes early onset hypertension in heterozygous carriers.[107] This mutation affects an amino acid that lies in the MR hormone-binding domain (HBD), which is conserved in MRs across a wide evolutionary span. In order to test the functional significance of this change, investigators expressed wild-type and mutant MRs in Cos-7 cells and were able to show that in the absence of added steroid, the mutant MR retained a significant level (27% of maximal) of activity. This suggested that the mutant receptor was constitutively

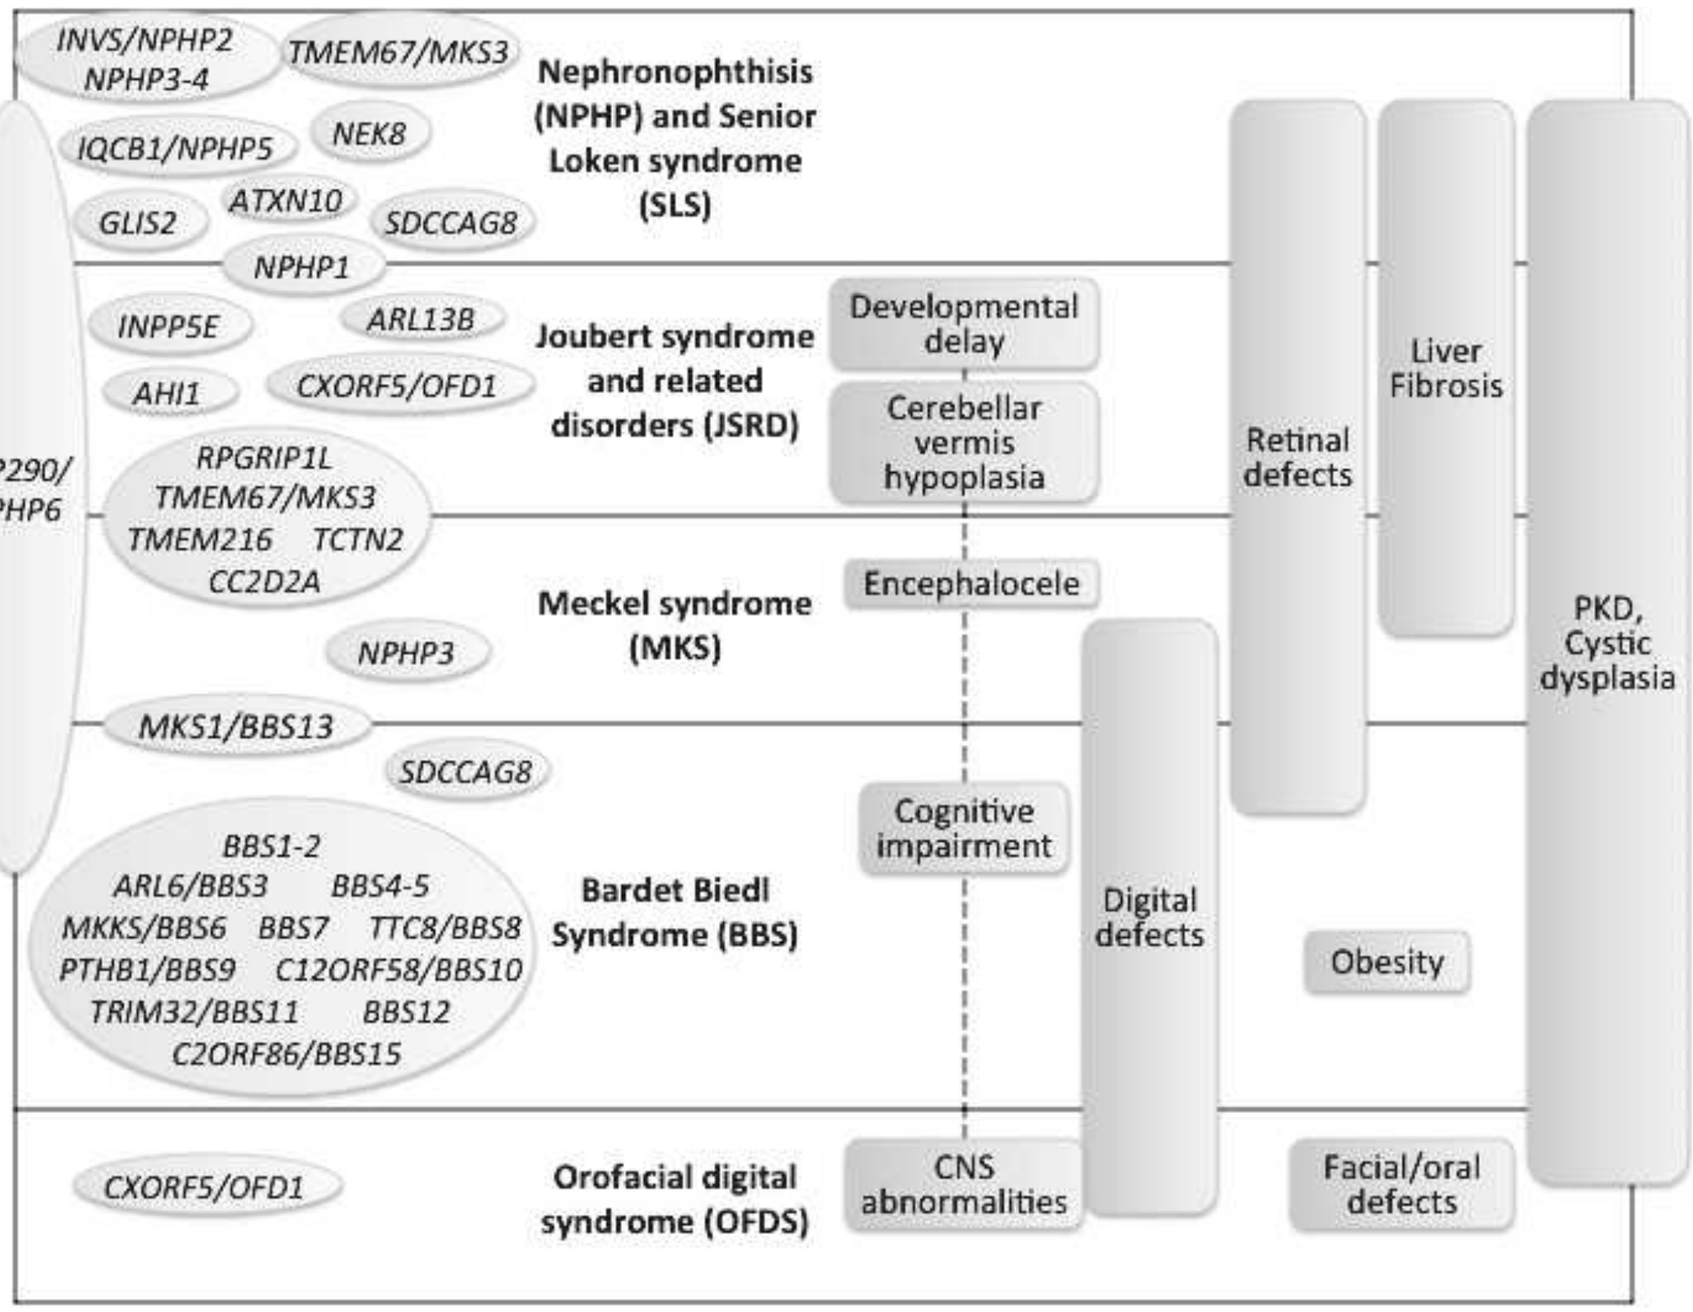

FIGURE 14.3 The genes and phenotypic abnormalities associated with syndromic forms of cystic kidney disease. Diseases are listed in the center; genes associated with them are shown on the left (*gray ovals*). On the right are phenotypes found in these different disorders (*blue boxes*). Note the high degree of overlap in genes and phenotypes between the different disorders. (Adapted from Harris PC, Torres VE. Polycystic kidney disease. *Annu Rev Med.* 2009;60:321–337. active. In an elegant series of experiments, they then showed that steroids that normally bind but do not activate wild-type MRs were able to activate the mutant receptor. Steroids with 21-hydroxyl groups such as aldosterone were able to bind and activate both proteins, whereas steroids with 17-keto groups (i.e., estradiol and testosterone) activated neither. Steroids such as progesterone, which lacked both modifications, were found to be potent activators of the mutant MR, leading to the conclusion that activation no longer required a steroid 21-hydroxyl group. Using computer manipulation of an established structural model of the steroid HBD, the authors were able to understand that the mutation resulted in increased van der Waals interactions between helix 5 and helix 3 of the HBD (Fig. 14.4). This essentially substituted for the interaction of the steroid 21-hydroxyl group with helix 3 in the wild-type receptor.

These analyses result in several important insights. First, these findings explained why several affected women in families with the S810L mutation developed severe hypertension during pregnancy, a state that is associated with a drastic increase in progesterone levels. Second, it provided a critical understanding of the general basis for steroid hormone activation because the helix 5–helix 3 interaction is highly conserved among diverse nuclear hormone receptors. Last, this type of in-depth structural understanding is often a prerequisite for rational drug therapy.

DEFINING THE EXPRESSION PATTERN OF A GENE AND ITS PROTEIN PRODUCT

The expression pattern of a gene may provide valuable information about its function. Northern blots of tissue are commonly used as a screening tool but are very insensitive and provide little information regarding the specific cell types that express the gene of interest. For example, NPHS1 and PCLN1 have a similar pattern on Northern blot—each detects a kidney-specific signal—though they have very different functions.[42,108] More precise localization can be achieved using in situ hybridization techniques (Fig. 14.5A,B). Using this method, one can readily distinguish the podocyte-specific expression of NPHS1 from the TAL-specific expression of PCLN1. The temporal and spatial distribution of gene expression is invaluable in defining developmental pathways and identifying cofactors of a gene of interest. RNA-based studies are particularly useful in tracking the expression of genes that encode secreted products (i.e., growth factors

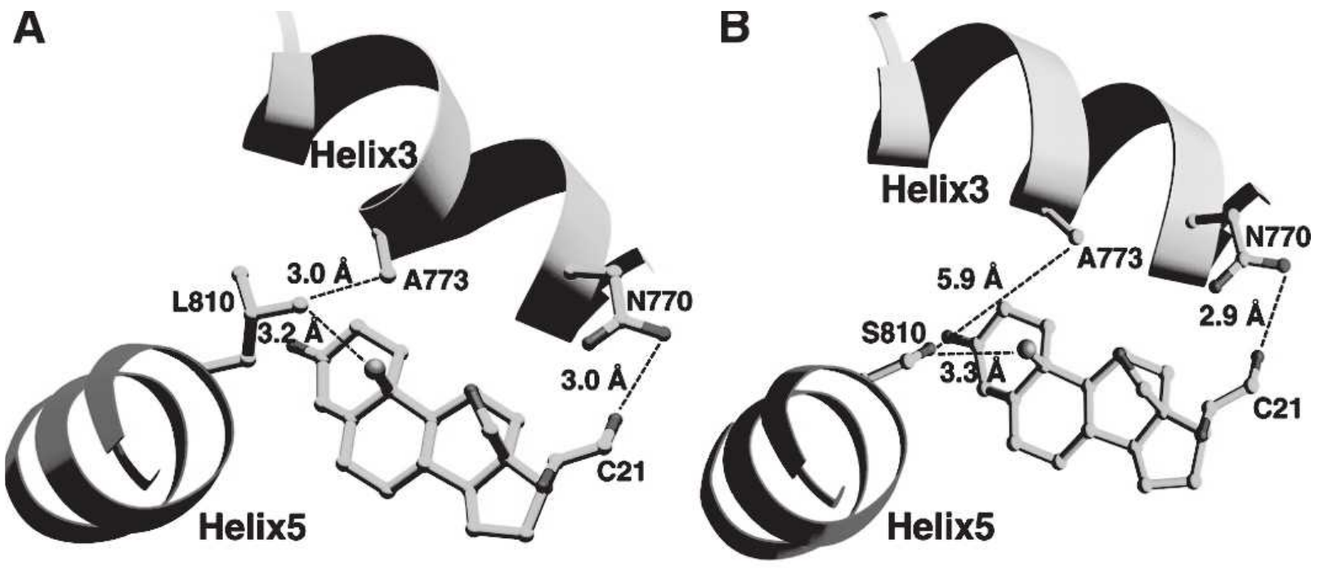

FIGURE 14.4 Helix 3–Helix 5 interaction in a progesterone-mediated activation of mutant mineralocorticoid receptor, MR_{L810}. **A:** The structural model of a portion of the hormone-binding domain of MR_{L810} bound to aldosterone, based on the crystal structure of progesterone receptor. This model predicts that the side chain of L810 lies sufficiently close to A773 and the C19 methyl group of the steroid to form van der Waals interactions. **B:** A model of $MR_{wild\ type}$. The side chain of S810 does not interact with A773 because the distance between them is too great. **C:** The activity of mineralocorticoid receptors (MRs) with various amino acid substitutions at residues 810 and 773. Mutant receptors containing the indicated substitutions at the two positions were assayed using a luciferase reporter assay in the presence of 1 nM aldosterone or 19-NP (19-norprogesterone, a progesterone derivative). MRs with amino acid substitutions that contained larger side chains were activated by 19-NP, as predicted by the model in **A** and **B**. A, alanine; G, glycine; L, leucine; M, methionine; S, serine; V, valine. (From Geller DS, Farhi A, Pinkerton N, et al. Activating mineralocorticoid receptor mutation in hypertension exacerbated by pregnancy. *Science*. 2000 Jul 7;289(5476):119–123. Used with permission.)

and cytokines) that are difficult to identify using immunohistochemical methods. In situ techniques also have the advantage that they can be used in cases where the specificity of an antibody for one's target has not been adequately demonstrated.

One important limitation of RNA-based studies is that they reveal nothing about the fate of the protein that they encode. Therefore, immunolocalization studies aimed at providing detailed characterization of a protein's cellular and subcellular distribution are key steps in its initial evaluation. In many cases, the protein structure provides clues as to where it is likely to be positioned within the cell. Nuclear localization signals, transmembrane-spanning elements, and homologies to other known proteins offer hints, but each of these predictions must be confirmed in cells and tissues. For membrane proteins, one must determine the specific membrane compartment in which they reside because this could have profound implications for understanding their function. Costaining studies using antisera that recognize known proteins are often helpful.

For novel proteins, one must first develop a set of antibodies that have a specific recognition for their target. The strategy used to generate antibodies is straightforward: immunize rabbits, chickens, or other species with either synthetic peptides or recombinant polypeptides derived from the gene of interest; screen for immunoreactivity; and then affinity-purify the reactive antibodies using the antigen against which it was raised. Antibodies are generally thought to be specific if they recognize the epitope against which they were raised and if the immunoreactivity was the direct result of the immunization process (i.e., preimmune sera lacked the activity).

In many cases, the results are unambiguous and provide important functional insights. As noted previously, nephrin, the gene product of NPHS1, the gene mutated in congenital nephrotic syndrome of the Finnish type, was found to be exclusively expressed in the glomerular podocyte.[108] An immunohistochemical analysis of renal tissue showed that the protein was confined to the slit diaphragm in the pore region of the glomerular basement membrane (Fig. 14.5C).[109–113] This invaluable information is unlikely to have been obtained by any other method, and has important implications for understanding the protein's function. This result also helped to explain why a loss of this protein could result in the massive nephrotic syndrome observed in those affected with this disease. In a similar manner, immunolocalization

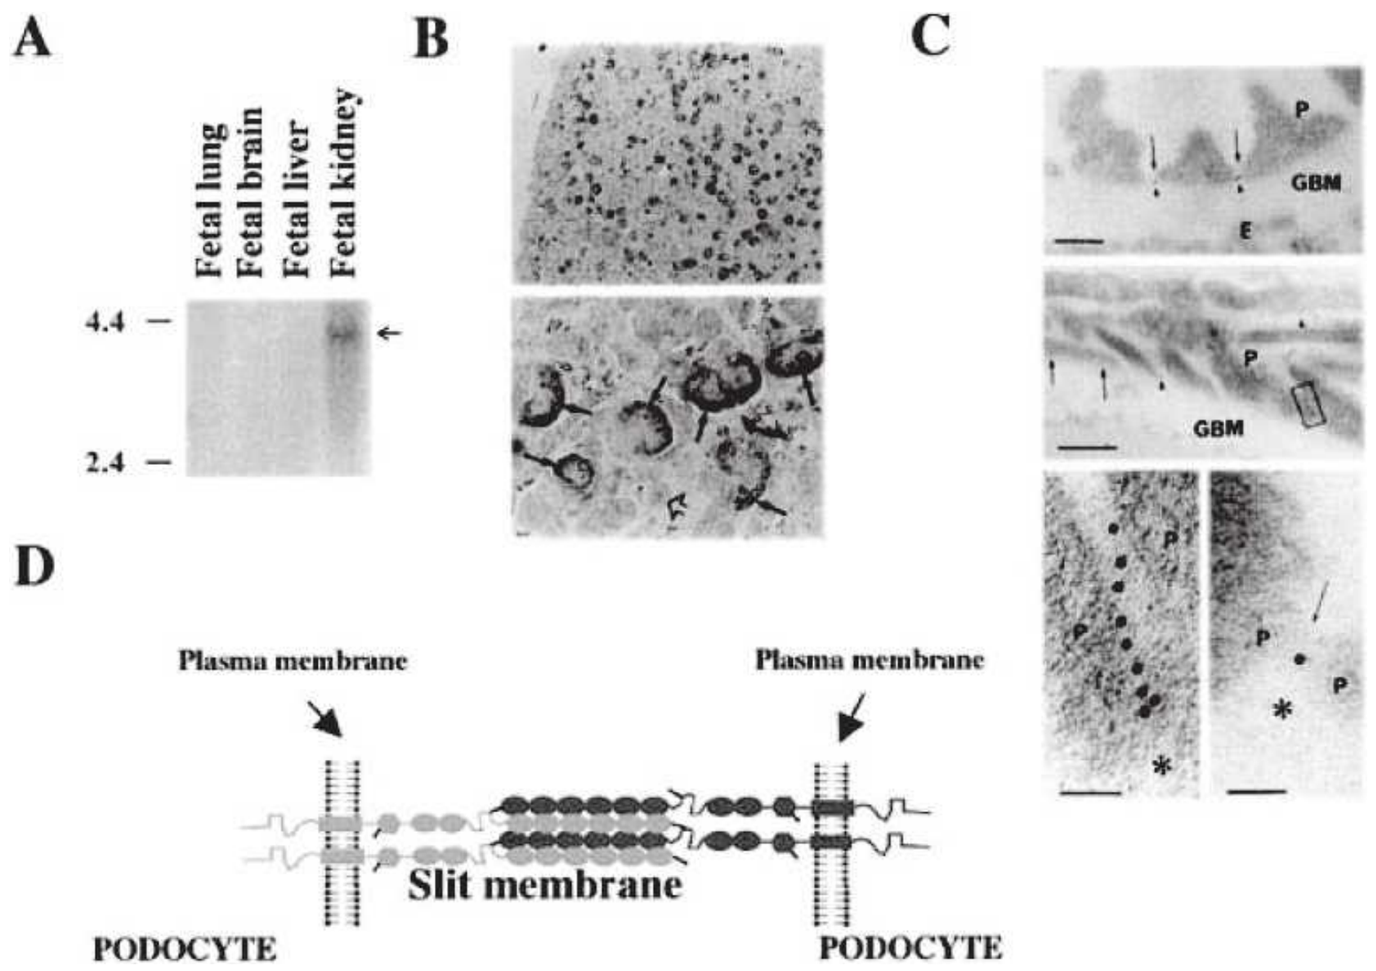

FIGURE 14.5 The expression of *NPHS1* and its protein product, nephrin. **A:** A Northern blot of poly(A) RNA from four fetal human tissues, hybridized with a fragment of *NPHS1* cDNA probe. A specific signal can be seen only with the fetal kidney RNA (*arrow*). **B:** The expression of *NPHS1* in the human fetal kidney by in situ hybridization. The *top panel* shows intense expression in the glomeruli throughout the renal cortex with little expression in other structures. A higher magnification is shown in the *lower panel*, revealing intense expression in the periphery of the glomeruli and little or no expression in the Bowman capsule (*bent arrow*), the proximal tubules (*open arrow*), or the endothelial cells of vessel walls. **C:** Nephrin is localized to slit membranes. Immunoelectron microscopic localization of nephrin in human renal glomeruli. In the *top panel*, gold label (*arrowheads*) can be seen between foot processes of podocytes (*P*). The label is located in the central area of the slit, between the glomerular basement membrane (*GBM*) and the barely visible slit diaphragm (*arrows*). The endothelium is unlabeled. Bar = 200 nm. In the *middle panel*, several gold particles can be seen lying in a row (*box*) between tangentially sectioned podocytes (*P*) foot processes. The *lower left panel* presents a close-up of the boxed section, whereas the *lower right* shows a gold particle between the slit diaphragm (*arrow)* joining two podocytes (*P*) and the GBM (*asterisk*) in cross-section. Bar = 50 nm. **D:** A hypothetical model of how nephrin molecules assemble to form the slit diaphragm. In this example, four nephrin molecules are shown to associate in the slit between two foot processes. The interdigitation is mediated by immunoglobulin (Ig) repeats 1 through 6 (*ovals*) and disulfide bridges that cross-link the molecules. (**Panels A and B** from Kestila M, Lenkkeri U, Mannikko M, et al. Positionally cloned gene for a novel glomerular protein—nephrin—is mutated in congenital nephrotic syndrome. *Mol Cell.* 1998 Mar;1(4):575–582. **Panels C and D** from Ruotsalainen V, Patrakka J, Tissari P, et al. Role of nephrin in cell junction formation in human nephrogenesis. *Am J Pathol.* 2000 Dec;157(6):1905–1916. Used with permission.)

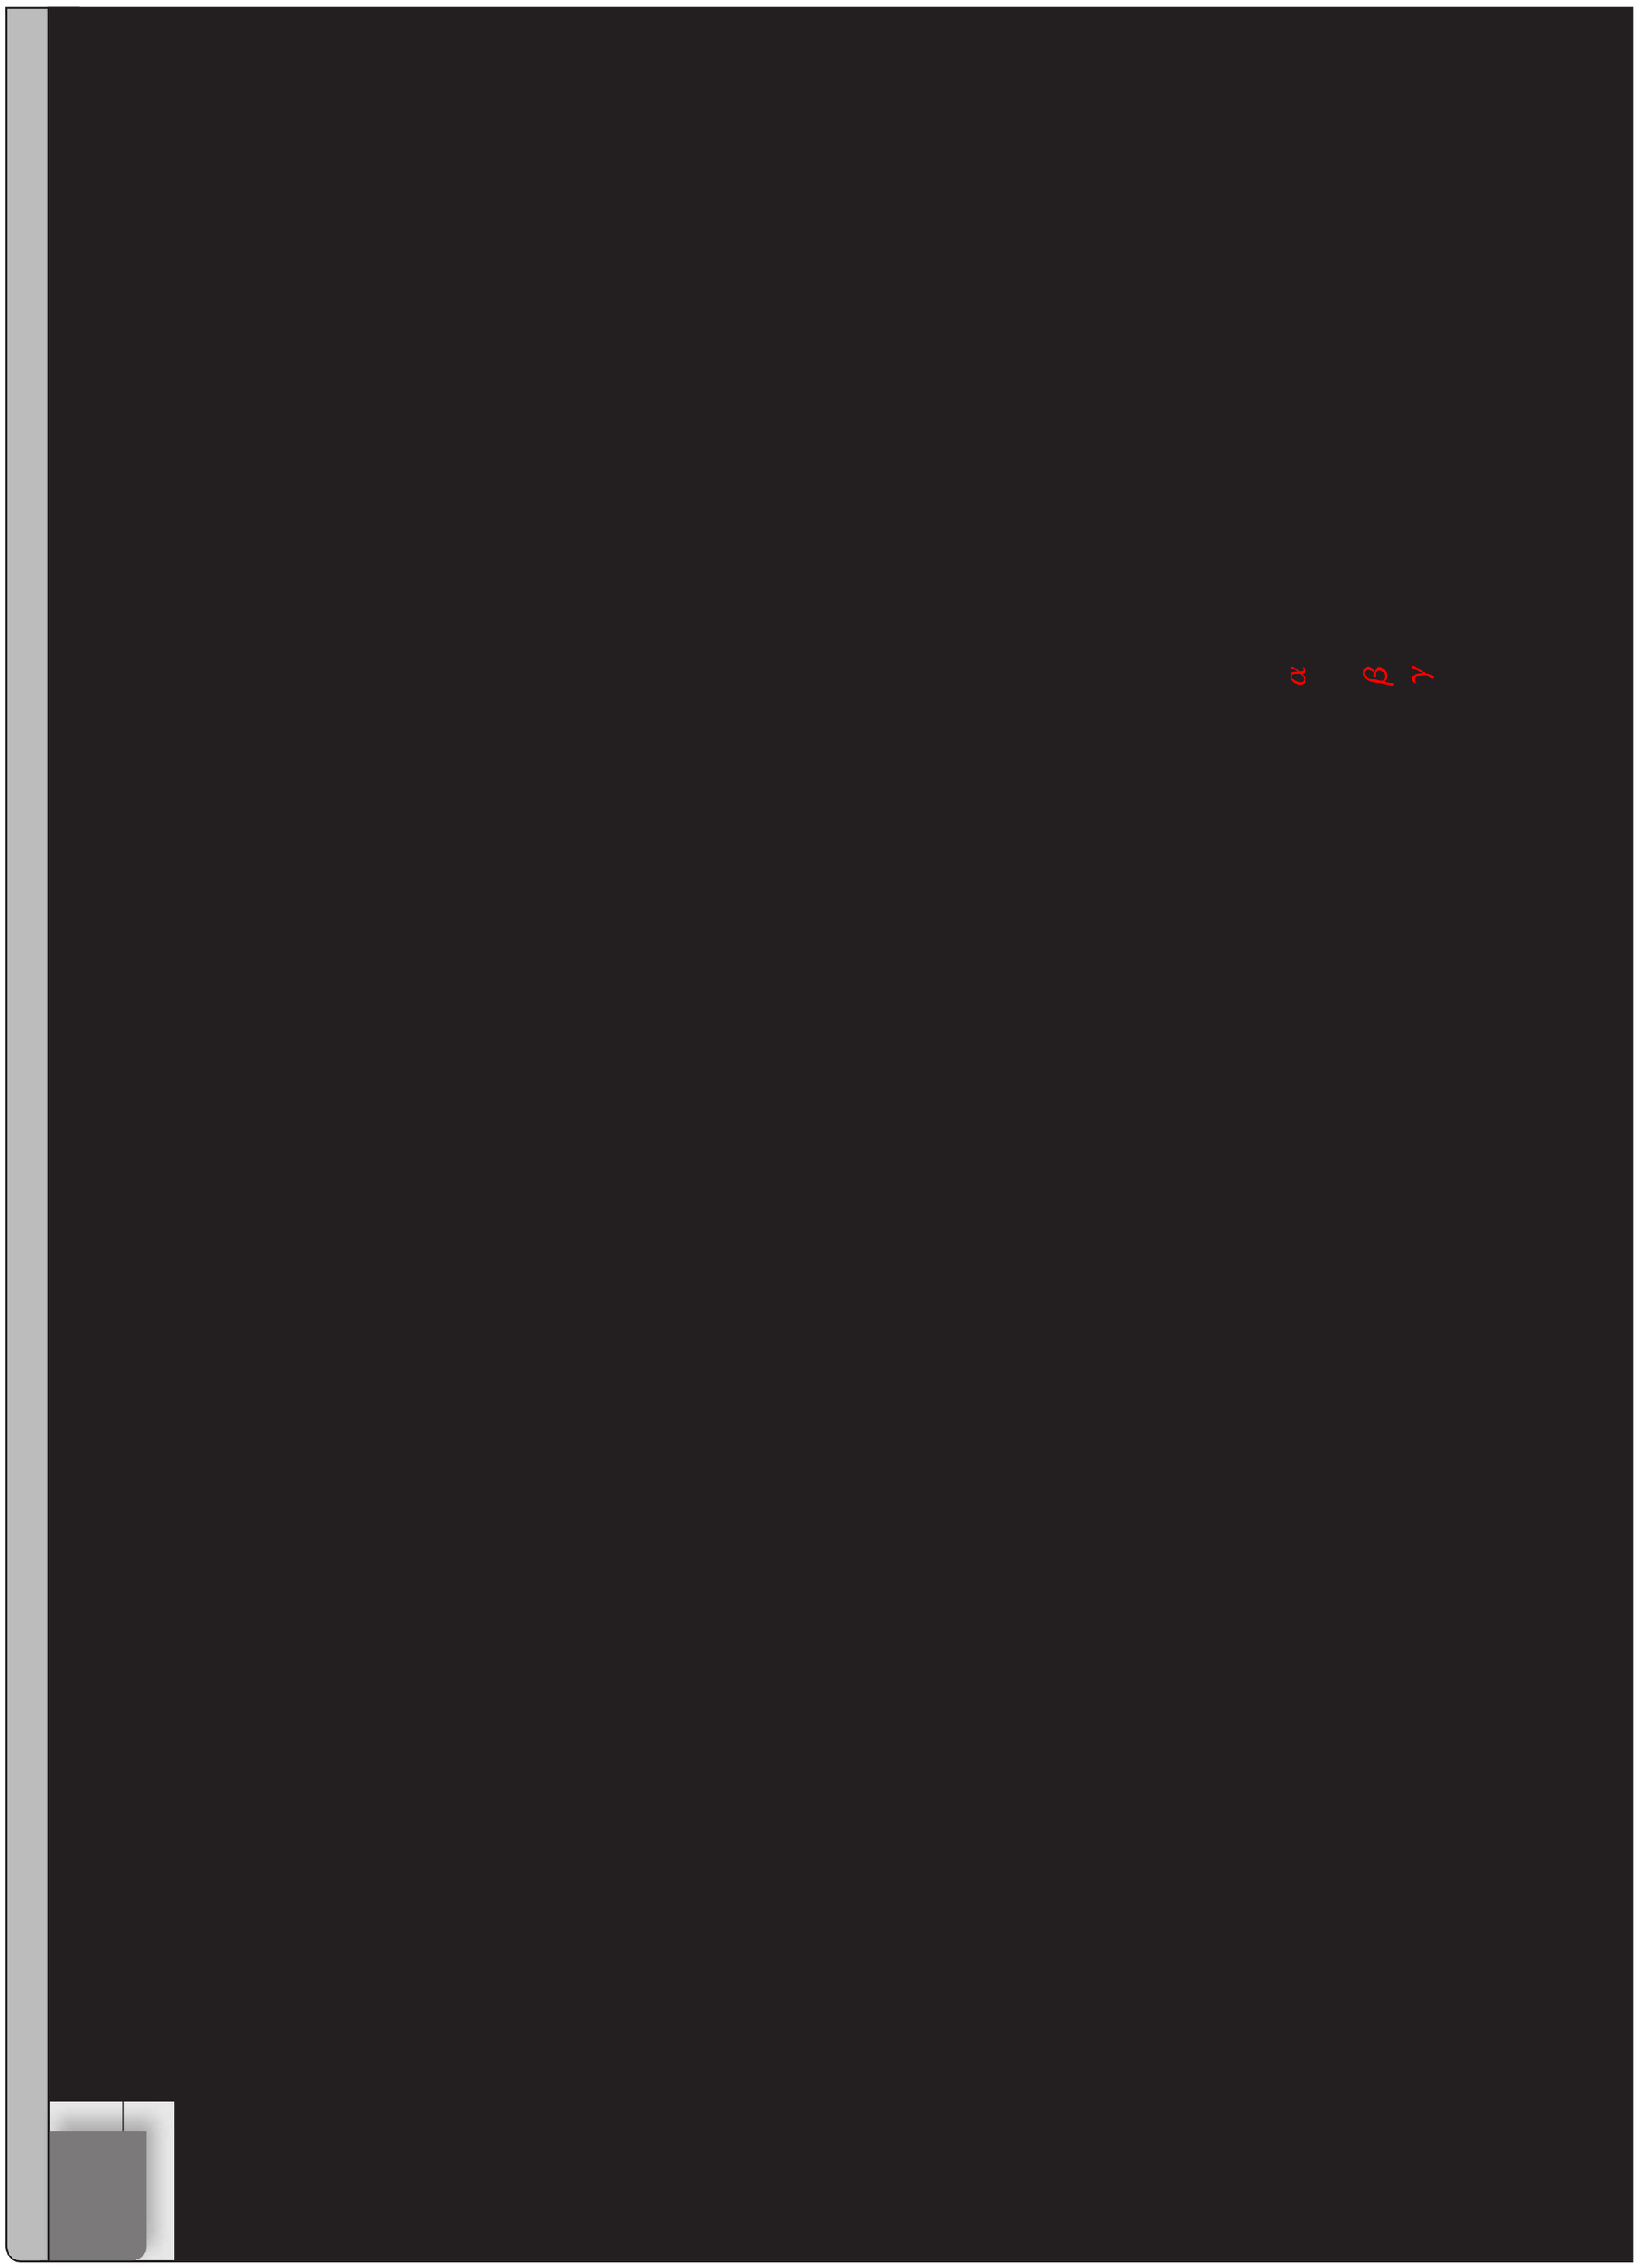
studies of PCLN1, the protein that is defective in primary hypomagnesemia, revealed that it is located in tight junctions of the thick ascending limb of Henle.[42]

Unfortunately, the process of antisera characterization is far less straightforward than it appears, and the commonly accepted standards are insufficiently stringent to ensure that one's antiserum is truly specific exclusively for one's target. A further complication is that many proteins are present in very low abundance, so even highly specific antisera have difficulty detecting them. These problems often result in conflicting data and uncertainty about the true nature of the disease gene product, and they likely account for the confusion regarding the detailed characterization of polycystin-1 (PC1).[69,114–136]

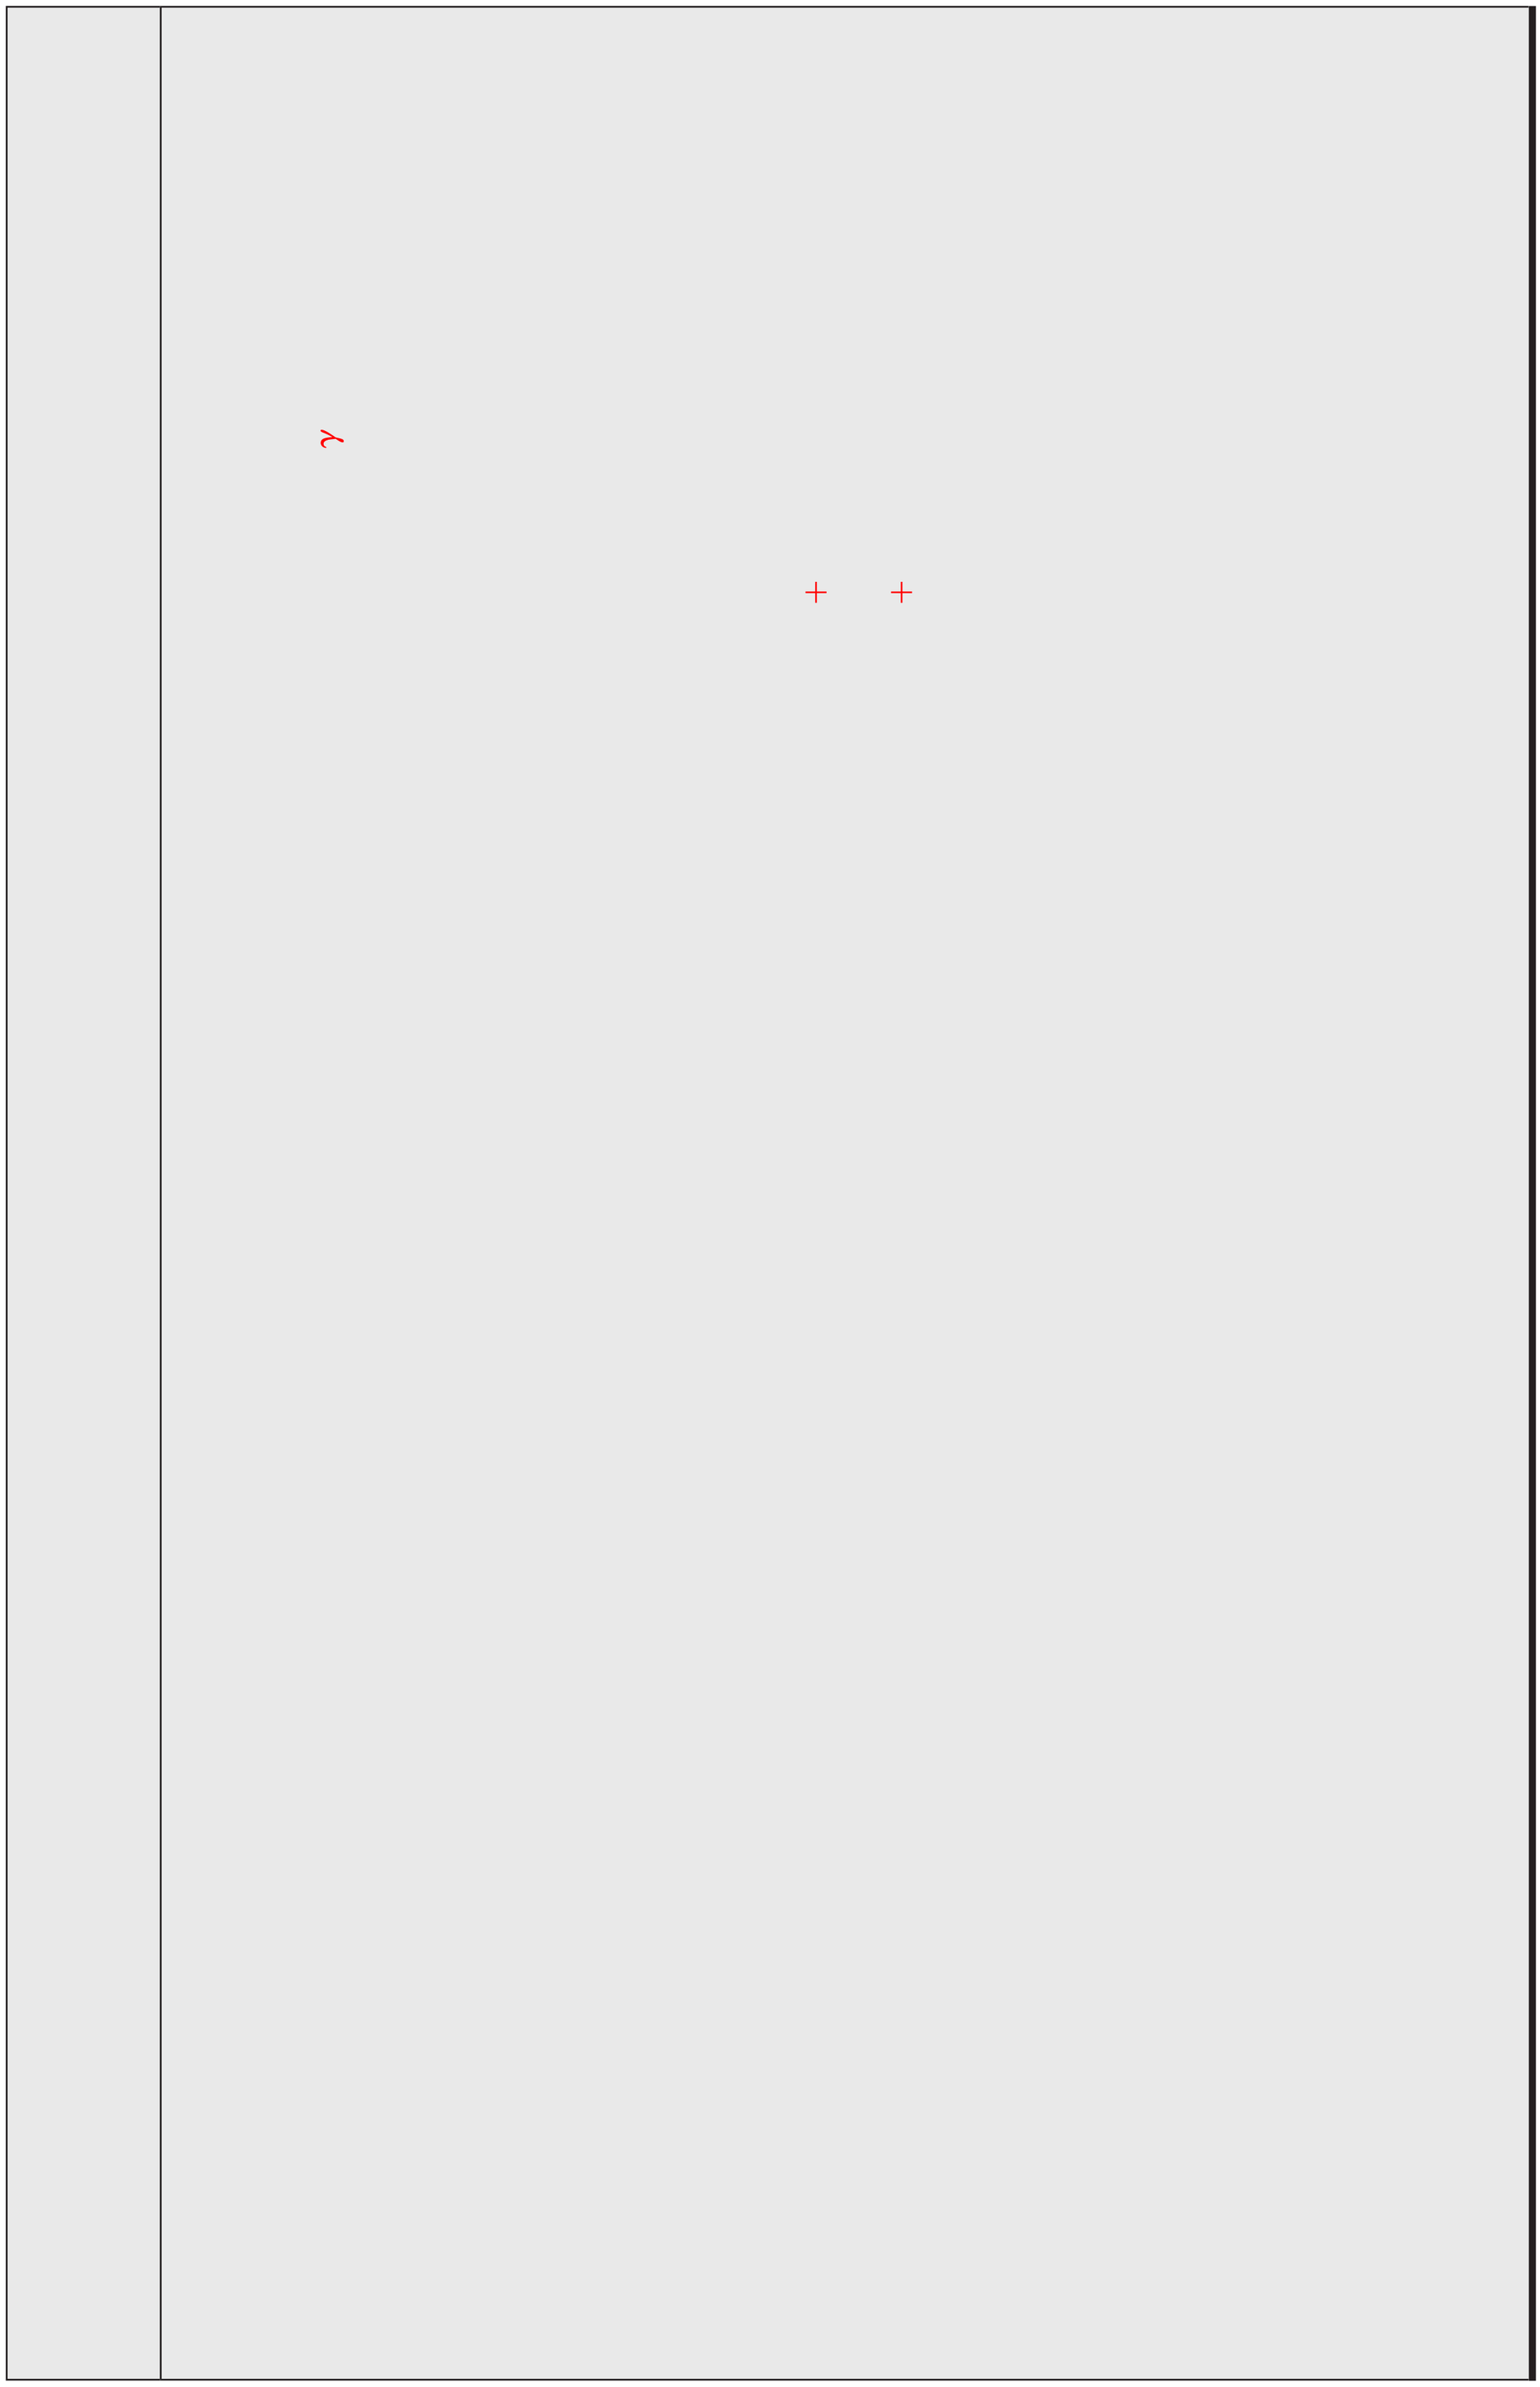
Antibodies specific for one's protein of interest are extremely useful for other essential steps in its characterization. For example, many proteins are subject to a number of functionally important posttranslational modifications such as proteolytic cleavage, glycosylation, and phosphorylation. These properties are often best assessed by immunoblot and immunoprecipitation studies, and they often are disrupted by missense mutations. As will be discussed in more detail in the next section, most proteins also act in concert with others via pathways, and antibodies are useful tools for identifying these protein networks.

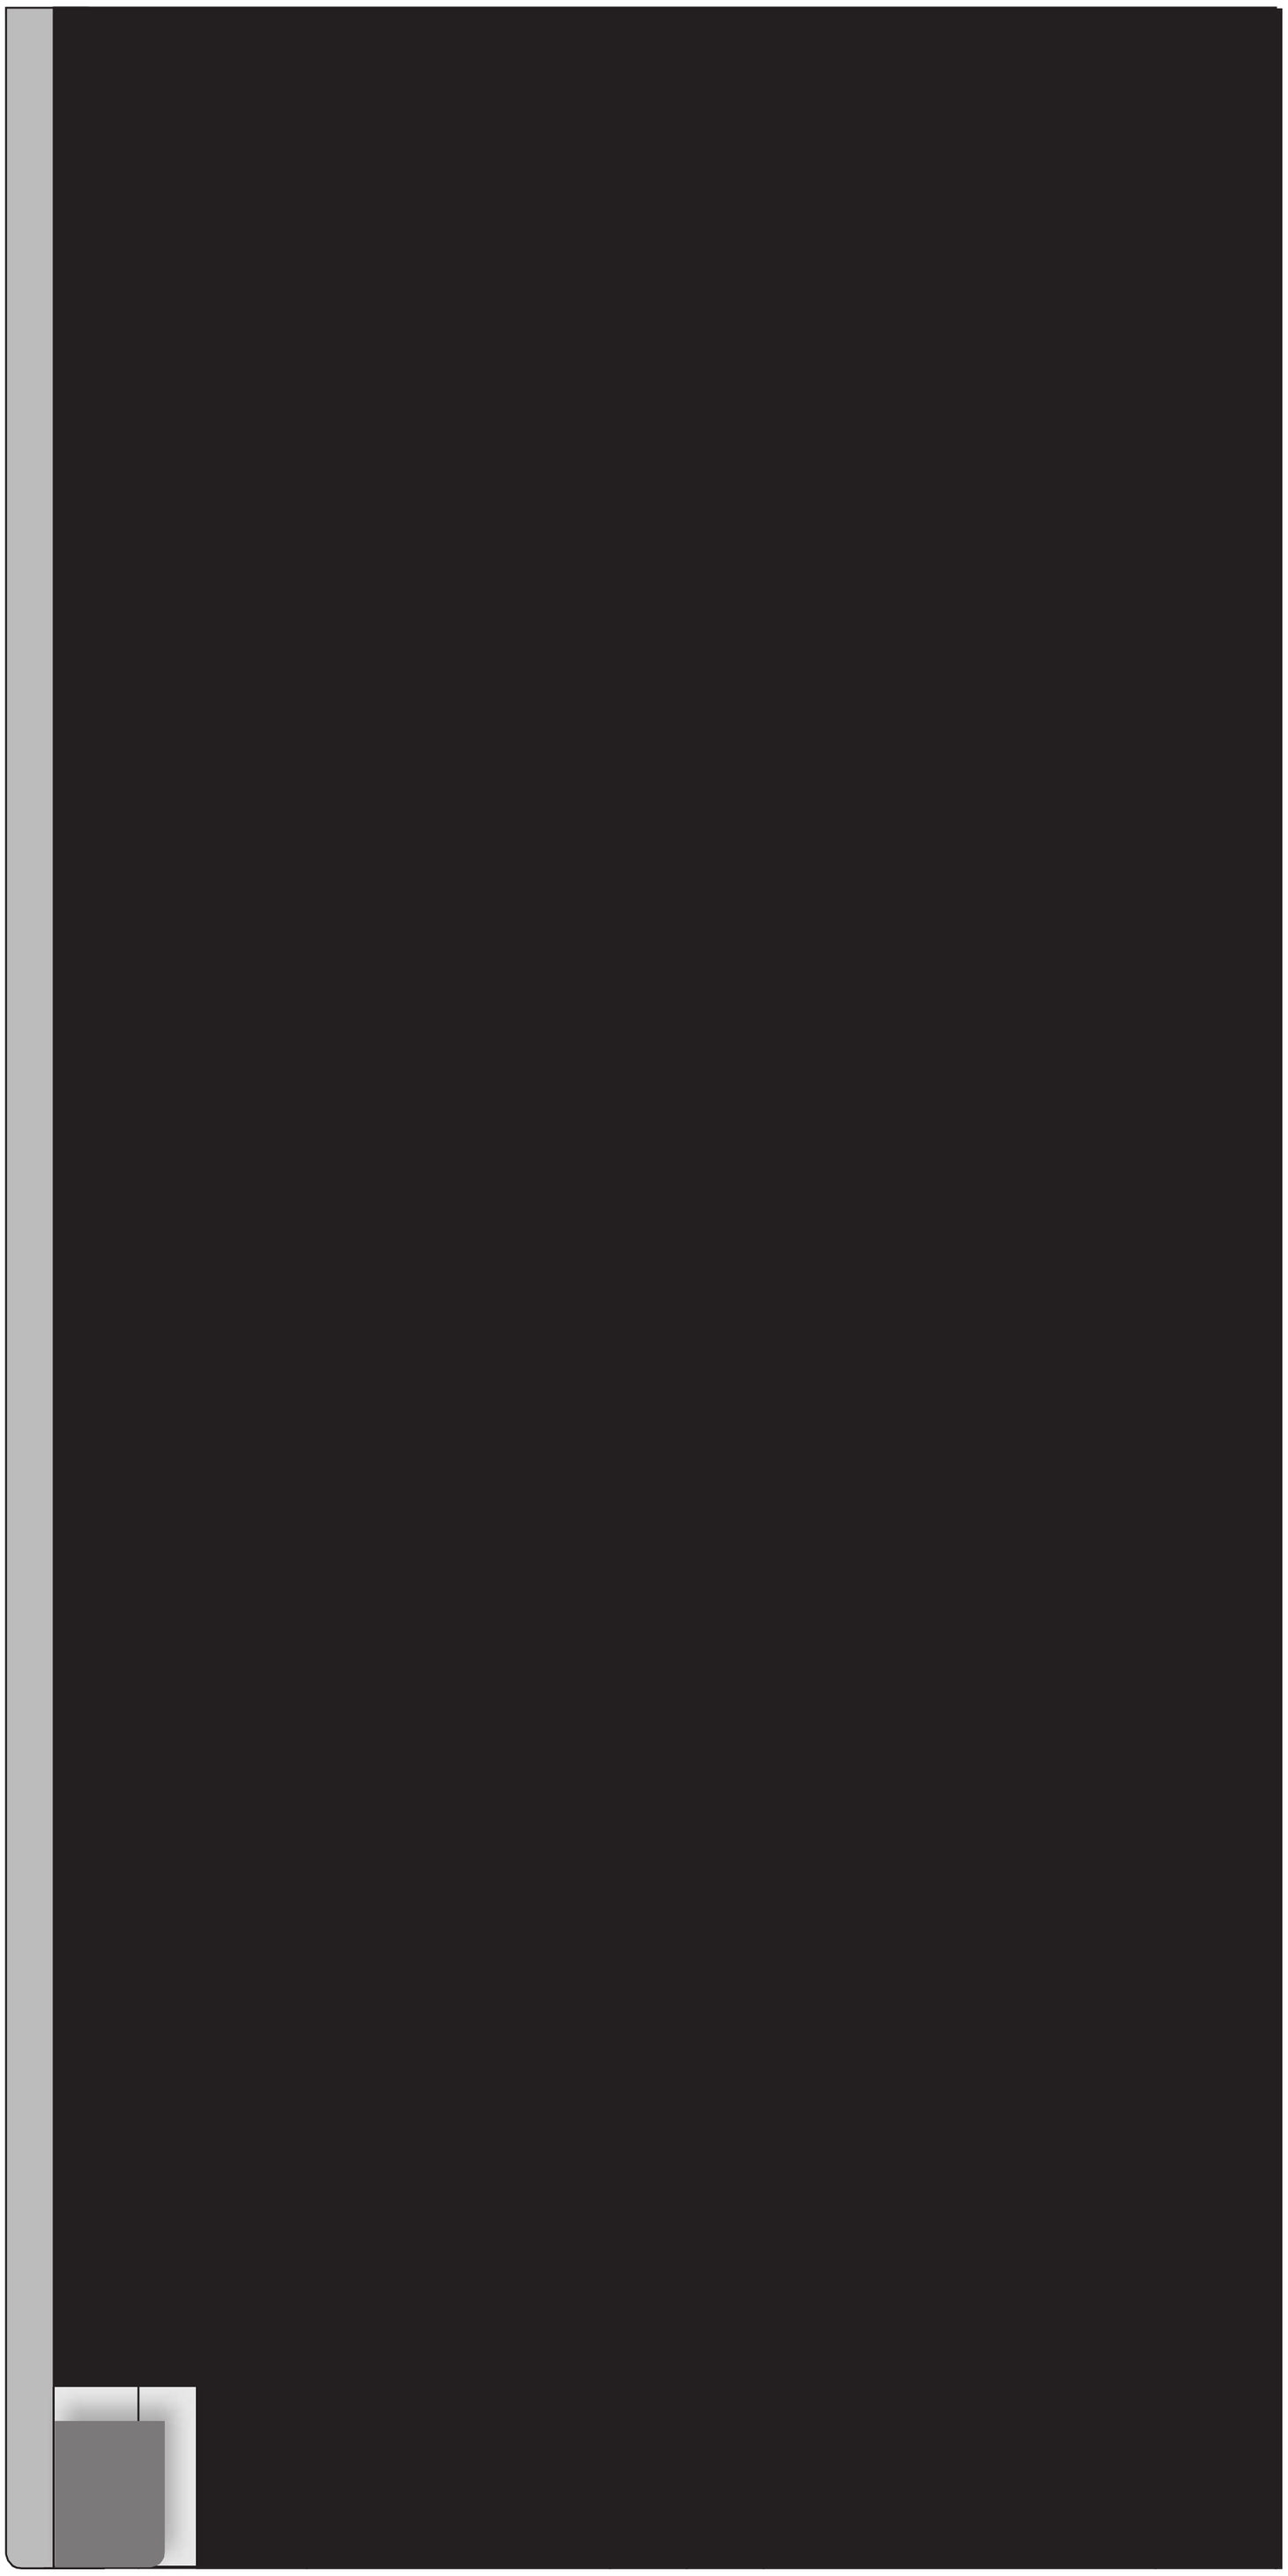
FUNCTIONAL ANALYSES

Once the initial description of a new gene is completed, the next goal is to begin its functional characterization. For many of the genes listed in Tables 14.1 to 14.8, their roles have been obvious because they were identified based on their functional properties. For example, each of the transporters listed in Tables 14.5 and 14.6 had been cloned and



α
β
γ





fig

characterized prior to the discovery of its mutation in the disorder with which it is associated. In these conditions, the focus is on determining how mutations alter the protein's function and how these abnormalities result in the observed pathology. A subset of the genes listed in the tables was discovered to be homologues of known genes that had not been previously associated with the human disease phenotype. For example, mutation of INVS (NPHP2), one of the genes associated with nephronophthisis, had been previously found to result in situs inversus and severe polycystic disease in mice.[137,138] Its subsequent association with human NPHP provided a critical insight into the functional properties of NPHP-related proteins.[139,140] Members of this group are now thought to comprise essential components of the primary cilia and the basal body. A similar approach is applied to the study of novel genes, like PKD2, that have a predicted but unproven function based upon their sequence. A final subset of genes, like VHL and NPHP1, encode novel proteins of unknown function, the sequence of which provides few clues.

It is obvious that the particular set of experiments that one uses to characterize a gene depends on the nature of the protein that it encodes. The strategy for studying a putative transporter is very different than the one used to examine a transcription factor. Likewise, one will approach the study of a known gene product like the Na-K-2Cl cotransporter differently than one would a more enigmatic one like nephrocystin-1, the NPHP1 gene product. In this section, we will provide both a brief review of some of the general methodologies used to determine a protein's functional properties and several illustrative examples.

The Identification of Interacting Partners

The specific nature of interactions between proteins is often an important determinant of their functional characteristics. One paradigm of functional protein–protein interactions is that of receptor-based signaling. According to this schema, the receptor, often situated in a membrane, binds to one or more ligands. This binding usually leads to a cascade of signaling events that may begin, for example, with phosphorylation of the receptor by itself or some other protein. This event may recruit other proteins such as adapter molecules with src homology 2 or src homology 3 domains to the receptor-ligand complex. These proteins may also be phosphorylated, and when activated in this way, they move to the nucleus, ultimately leading to the transcription of new genes. Frequently, one receptor may participate in a number of signaling pathways that "talk to one another." In many cases, these factors serve to amplify the signal, whereas parallel or negative feedback systems act to dampen or balance it. In either case, each step in this pathway critically depends on the interaction of proteins capable of transmitting the signal.

Proteins involved in receptor-based signaling are by no means the only types of proteins whose activity depends on protein–protein interactions for their normal function. Many channels or transporters are formed by multimeric complexes of a single subunit (in the case of potassium channels) or multiple independent subunits (e.g., H^+ ATPase). Moreover, the activity of most channels is regulated by the direct binding of other non-channel proteins. Likewise, transcription factors depend on interactions with specific cofactors, transactivators, or inhibitors for their activation or repression. It is fair to say that most proteins critically depend on protein–protein interactions for their functional activity, and identifying the partners of one's protein of interest can provide important clues into its function. This is especially true if the partners are discovered to be factors that participate in well-defined pathways or regulatory systems. Given the tremendous impact such studies can have on one's understanding of the pathobiology of a new protein, much effort is often directed at identifying the protein partners of a gene product of interest.

Several strategies can be used. The first is guided by an understanding of the disease process. A growing body of literature suggests that inherited disorders that are characterized by genetic heterogeneity often result from mutations of genes the products of which either form a multimeric complex (such as a transporter) or function in a common pathway. This property is exploited in Drosophila research as a tool to define the functional pathways of novel genes. In the case of human renal diseases, there are numerous examples that fall into this group: ADPKD, NPHP, tuberous sclerosis (TSC), distal RTA (OMIM# 267300 and 602722), Liddle syndrome, PHA type I (recessive forms), and cystinuria. In some of these examples, like Liddle syndrome, the genes associated with the disease had been known to encode interacting subunits prior to their discovery as disease-causing loci.[12] In others, like ADPKD, NPHP, and TSC, the functional interactions of their respective gene products were discovered solely because of a focused search.[69,139,141–146]

Sometimes it is possible to make an "informed guess" about potential partners based on the known properties of the protein of interest. For example, a protein that had been shown in immunolocalization studies to be located in focal adhesion plaques might be expected to associate with other components of that complex. One would then pursue a directed search to look for functional associations between the protein and a battery of pertinent interacting factors. Other clues might be provided by homology to known proteins. The identification of a putative G-protein binding site in polycystin-1 resulted from such an analysis.[61] In other cases, a protein may have domains that are known to be generalized sites of protein–protein interaction. Ankyrin repeats and coiled-coil motifs are examples of such structures and are good places to begin to look for interacting partners.

Finally, in many cases, a protein is truly novel and there is no way to predict to what it might bind. This is common when a gene has been identified using a strictly positional approach or when there is no sequence homology to serve as a guide. The VHL gene product is an example of this situation. Truly novel proteins require the use of methods that make few prior assumptions about the nature of interacting partners. In such situations, an investigator can purify the protein (either the endogenous protein or a recombinant,

epitope-tagged version purified from tissue or cells) and determine the peptide sequence of any factors that copurify. As one might predict, the rate of progress in understanding the function of proteins that fall into this class is usually far slower than it is for others.

The strategies used to determine the functions of the genes linked to BBS and NPHP nicely illustrate some of these principles. Multiple loci have been linked to each disease, and it was suspected that many if not all of their respective gene products likely formed multimeric protein complexes. In the case of BBS, investigators identified a complex they called the "BBSome" that is composed of seven highly conserved BBS proteins and at least one novel subunit that, when depleted in zebra fish, results in a BBS phenotype.[147,148] They subsequently showed that the BBSome is recruited onto membranes by another BBS protein (Arl6, encoded by BBS3) that is not part of the BBSome to form a coat complex that sorts membrane proteins to primary cilia.[149] These findings help to explain the ciliopathy phenotype common to the genetically distinct forms of the disease.

A similar strategy was used to investigate the relationships between NPHP, JBTS, and MKS proteins. Investigators purified nine disease gene products from a kidney cell line and identified the set of proteins interacting with each by mass spectrometry. They identified 850 interacters, performed proteomic network analysis, and discovered three connected modules: one functioned at the apical surface, a second at centrosomes, and a third that was linked to Hedgehog signaling. Reasoning that some of the interacting proteins may represent unrecognized disease loci, they screened 38 of the genes for mutations and identified two novel loci as causes of NPHP-JBTS (ATXN10, TCTN2).[150] In sum, this approach not only elucidated some of the functional properties of the NPHP-JBST-MKS protein family, but it also helped to identify new causes of the disease.

Taken together, these examples highlight the tremendous insights that a search for protein interactions can provide.

MODEL SYSTEMS

Cell Culture Systems

The biochemical approaches described in the preceding section are limited by the nature of in vitro studies. They do not generally provide information about the physiologic consequences of activation or disruption of a particular pathway. It has become increasingly obvious that cell culture systems can be especially valuable in this regard. Cell culture systems have the advantage that they often can be easily scaled up to perform "bucket biochemistry," they can be used under carefully controlled and well-defined conditions, and they can be scaled down to the single-cell level to study molecular processes. They are invaluable tools for studying a molecule's transport properties, its growth-regulatory characteristics, or the signaling pathways in which it participates. If one transfects a cell with a cDNA for a putative ion channel, one can demonstrate and characterize its channel activity using patch clamp methods or calcium photometry for calcium fluxes. Likewise, one can test for the transport of other molecules by simply modifying the approach to look for the movement of the molecules in question. Cell transfection experiments also can be used to quantitate the growth effects of a protein of interest. Once an effect is defined, one can perform cell-cycle analysis to determine whether it acts through a cell-cycle dependent process, by altering the rate of programmed cell death, or through some other mechanism. Regardless of which mechanism is implicated, there is a series of well-defined steps that can be followed to define in a precise manner how the protein affects its activities. In the case of transcription factors, cell culture systems may be used to identify potential targets.

A complete review of the many insights that have resulted from the use of cell-culture systems is far beyond the scope of this chapter. Several select examples will serve to illustrate the use of this approach.

Pseudohypoaldosteronism type II (PHA2, Gordon syndrome/familial hypertensive hyperkalemia) is a rare autosomal dominant disease that is distinct from most other Mendelian genetic forms of hypertension in that affected individuals have both hypertension and hyperkalemia.[151] Mutations in WNK1 and WNK4, two related members of the serine threonine kinase superfamily, were found to cause the disease. A series of studies performed using recombinant proteins and cell culture systems demonstrated that the proteins act as a molecular switch that allows the kidney to alternate between NaCl-reabsorbing and K^+-secreting states through their inhibitory effects on the thiazide-sensitive NaCl cotransporter and the renal outer medullary K^+ (ROMK) channel. The observation that the proteins had been localized to the tight junctions in renal epithelia prompted Kahle et al.[151] to investigate whether WNKs also function to regulate paracellular ion flux using canine renal epithelial cells (MDCKII cell line). They generated stable cell lines that had inducible expression of either wild-type or mutant WNK4 and showed that the recombinant proteins localized to tight junctions by immunofluorescence. They then showed that WNK4 decreased transepithelial resistance in MDCK cells grown in monolayers by selectively increasing the paracellular conductance of chloride. They ruled out gross structural changes of the tight-junction complex as a trivial explanation for their findings by transmission and freeze-fracture electron microscopy. The authors concluded that the WNKs likely help coordinate transcellular and paracellular flux to achieve NaCl and K^+ homeostasis.

A different kind of cell culture system has been developed to study the function of polycystin-1. This protein has been difficult to analyze because of its large size and low abundance in tissues and cells. Boletta et al.[152] used novel methods to establish cell lines with stable overexpression of PKD1. They had selected the MDCK cell line for this study because it is a renal epithelial cell line commonly used to study the process of tubulogenesis. Under normal conditions, MDCK cells form cysts when cultured in collagen, but produce branching

tubules if treated with hepatocyte growth factor (HGF).[153] Boletta et al.[152] found that the expression of recombinant PKD1 in MDCK cells resulted in spontaneous tubulogenesis, a reduced rate of growth, and induced resistance to apoptotic stimuli. The effects of PKD1 expression in this model are remarkably similar to what had been predicted based on the study of human and murine cystic tissues, and suggest that it may serve as a useful tool for understanding pathways regulated by polycystin-1. This unique system offers three phenotypic assays that can be used to test for the functional consequences of altering any of polycystin-1's domains. Given that each of the distinct phenotypes could be affected in a different way, this strategy might allow one to dissect out the various signaling pathways regulated by this multifunctional protein. One might also use such a system to test for functional consequences of missense changes identified solely in affected individuals but of uncertain consequence.

Mouse Models

Although cell culture systems are relatively easy to manipulate, they may not always mimic faithfully what occurs in vivo. Overexpression of proteins could conceivably activate pathways that are not important in the whole organism and, therefore, the significance of any phenotypic readout may be difficult to interpret. Animal models that faithfully reproduce human disease are therefore invaluable tools. They can be used to help define the pathophysiology of a disorder, identify factors that modulate the severity of disease, and to test therapeutic interventions.

For diseases that result from gain-of-function or dominant negative mutations, transgenic mice with overexpression of the mutant gene can be useful.[154] In this method, the cDNA of interest is injected into the pronuclei of fertilized eggs and then reimplanted in the uterus of females for carriage to term. Advantages of this approach include its wide availability, relatively low cost, and rapid readout. Transgenic animals can be produced within less than a month of producing the recombinant construct. Its major limitation is that the spatial and temporal pattern of gene expression of the transgene often fails to recapitulate that of the endogenous gene in a faithful manner. A second problem is that this strategy generally cannot be used for diseases that are recessive in nature. Overexpression of a null or functionally null allele is unlikely to reproduce the human disease, because the endogenous murine forms of the genes will be normally expressed. Finally, in most cases, the construct used to generate the mice exclusively contains the exonic sequences of one's gene and lacks all but perhaps a single intron (the latter has been shown to improve transgene expression). One consequence is that the transgene does not undergo any of the splicing normally observed for the endogenous gene.

In light of these limitations, a second approach that avoids many of these pitfalls has now become the standard of the community. Its goal is to generate mice with targeted mutations of the endogenous murine gene.[155] By altering the gene in situ, one preserves most of its intrinsic structural features such as regulatory elements and introns. In most examples to date, the technique has been used to produce a "knockout" through the introduction of deletions that abrogate a gene's function. More recent refinements allow one to introduce more subtle changes such as nucleotide substitutions that encode missense changes ("knockin"). Such strategies allow one to generate models that carry the exact genetic defects observed in humans in a much more faithful manner.

The ability to do gene targeting depends on two principles. First, one must be able to perform an in vivo "swap" of the engineered gene segment for the endogenous sequence through the process of homologous recombination. Next, one must have a way of creating an animal from cells with the targeted mutation. Sperm and egg cells would seem like natural choices but unfortunately cannot be used for this purpose. Embryonic stem (ES) cells, removed from the earliest stages of development, do work well because they are easily cultured and totipotent—they can give rise to any organ system or cell type. This allows one to "pass" the mutation through the mouse germ line.

The first step in gene targeting is to design a targeting construct that contains a genomic segment of the target gene into which has been inserted a neomycin resistance gene. The latter step allows for the selection of ES cells that have "taken up" one's construct. For "knockout" constructs, the neomycin gene has replaced a portion of the coding sequence of the target gene so that its integration would interrupt the target's coding region. For "knockin" constructs, the neomycin gene is typically placed within an intron where it is less likely to disrupt the gene's function. To create the mutation, the targeting construct includes a segment of the normal gene that has been altered to include the desired variant. Properly targeted clones are identified by Southern blot analysis. The appropriate ES cells are then injected into a mouse blastocyst in a process that produces an adult chimeric mouse. Chimeric mice can be readily identified by their mixed black and agouti coat color, because the ES cells typically come from mice with agouti coat colors and the blastocysts are derived from animals whose coat color is black. The chimeric mice are bred and if their germ line is also chimeric, then the F1 generation should have some progeny that are heterozygous for the targeted disruption. In order to produce homozygous mice, the F1 generation can be interbred to one another.

"Knockout" models are useful in a number of ways. For example, they may confirm the genetic basis of a disease. As noted in a previous section, genetic studies of cystic tissue have indicated that ADPKD is likely to be recessive on a molecular level. This would suggest that mice heterozygous for Pkd mutations should survive to adulthood with few, if any, symptoms. In contrast to their human counterparts, they would be predicted to have relatively few cysts because of their far shorter lifespan and much smaller organ size. A smaller kidney or liver would have far fewer cells at risk of acquiring mutations over a period of 1 to 2 years of observation. These predictions were confirmed in studies

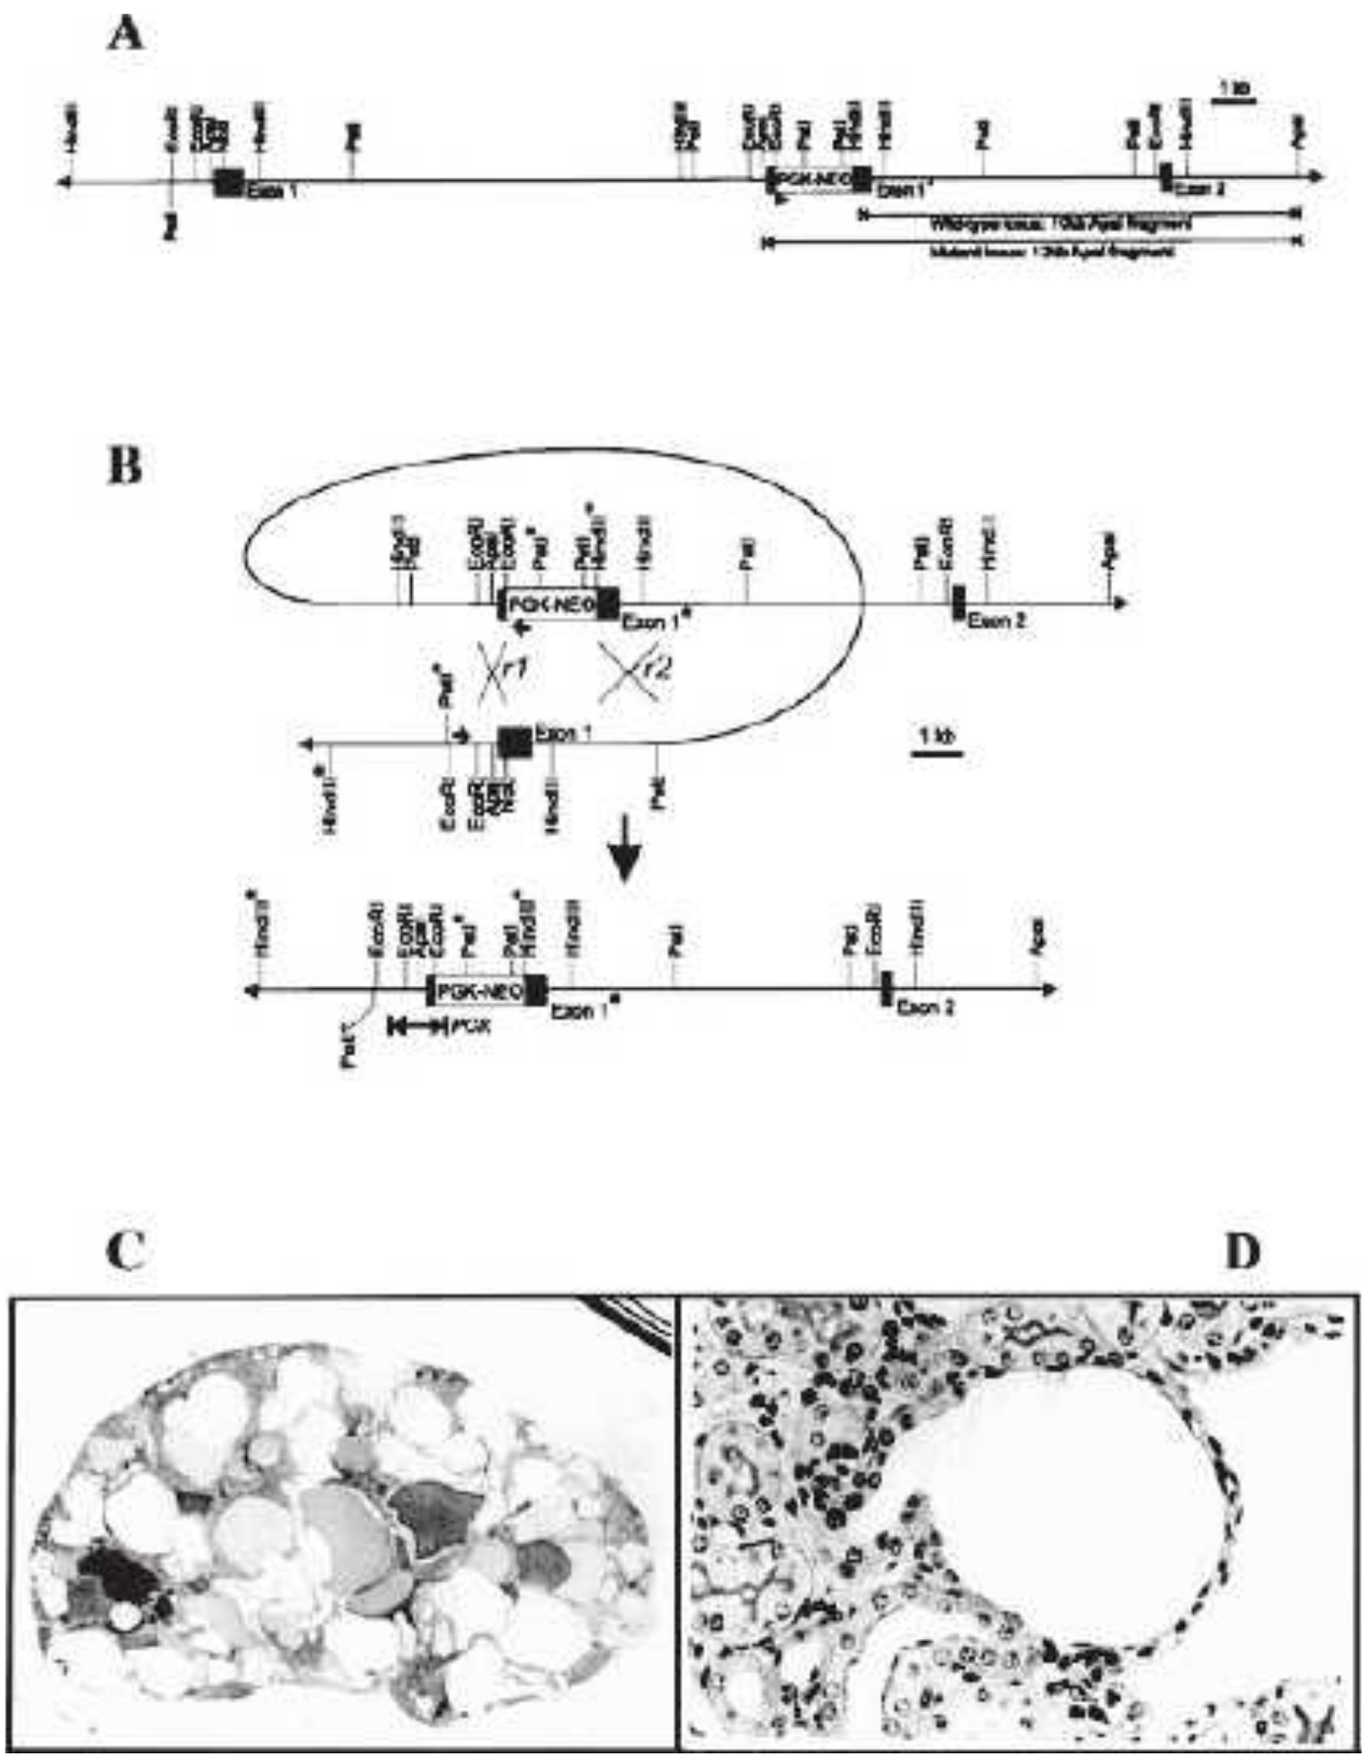


FIGURE 14.6 **A:** Restriction map of the *Pkd2*^{WS25} allele created by gene targeting. Instead of replacing the normal 5′ end of the *Pkd2* with the mutant sequence, the targeting construct integrated within the 5′ end to create a local duplication. Locally duplicated sequences are known to be prone to genomic rearrangement by unequal sister chromatid exchange. **B:** A schematic representation of intragenic homologous recombination that is observed for the unstable *Pkd2* allele, *Pkd2*^{WS25}. Two different recombination processes can occur. Recombination r1 produces a null allele, whereas recombination r2 results in a wild-type allele. Both the wild-type and the unrecombined *Pkd2*^{WS25} allele have normal functional activity. **C:** A cross-section of a murine kidney taken from a homozygous mouse carrying two unstable *Pkd2* alleles (Pkd2$^{WS25/WS25}$). Severe cystic disease is observed, mimicking the pattern of human ADPKD (2.5×). **D:** Cysts have a focal origin. A magnified view of a murine kidney with the Pkd2$^{WS25/WS25}$ genotype. An incipient cyst is shown forming as an outpouching from a normal tubule. Presumably, the cyst developed as the result of homozygous inactivation of the *Pkd2* gene in one tubular cell (320×). (From Wu G, D'Agati V, Cai Y, et al. Somatic inactivation of Pkd2 results in polycystic kidney disease. *Cell.* 1998 Apr 17;93(2):177–188. Used with permission.)

of mice that were heterozygous for inactivating mutations of either Pkd1 or Pkd2.[156–159] Wu and associates[156] had developed a particularly elegant model. They had generated an unstable Pkd2 allele by inserting a second copy of the first exon of Pkd2 in tandem to the endogenous exon (Fig. 14.6). This allele was prone to acquiring somatic mutations via intragenic homologous recombination. Mice heterozygous for the null allele and the unstable allele consistently developed an ADPKD phenotype similar to that observed in humans. These mice did not die in utero but developed significant renal and hepatic cystic disease by 11 weeks of age. This model has proven to be an invaluable tool for studying the pathophysiology of the disease[160] and testing putative therapies.[161,162] One can easily imagine how it also might be used to identify factors that predispose to the acquisition of somatic mutations or influence the progression of disease.

A common problem limiting the use of standard gene knockout technology is that complete homozygous inactivation of a gene often results in a nonviable fetus that fails to complete gestation. This situation is usually recognized by a distortion in the Mendelian ratio of observed versus expected genotypes of living offspring. In the case of Pkd1, this property severely limited the use of the many models that had been generated by gene targeting. However, newer technologies have allowed investigators to circumvent this problem and have expanded the capability to manipulate the murine genome at will. Gene-targeting techniques can be used to create mice that have latent mutations, which can be activated upon demand (conditional mutations, otherwise known as "floxed alleles").[163–169] In this approach, the targeting construct is designed to include very short DNA sequences that serve as specific recognition sites for nonnative DNA recombinase enzymes in introns flanking key functional aspects of a gene of interest. If carefully positioned, the short DNA sequences (either loxP or frt sites) have no effect on the function of the gene until after recombination has been induced. Since the recombinase enzymes (Cre and Flp) are not normally present in mice, one can determine when and where one wishes to inactivate the gene of interest by controlling the spatial and temporal expression of the recombinase. This usually is

achieved by breeding mice with either the loxP- or frt-allele to animals transgenic for the corresponding recombinase (Cre and Flp, respectively). By altering the regulatory elements that control Cre or Flp expression, one can define the conditions under which one wishes to inactivate the gene.

This strategy has been successfully used to generate viable adult mice that otherwise would have died in utero of their homozygous mutations. For example, this approach has been used to create mouse models that allow for the conditional inactivation of Pkd1.[170–172] These models have proven to be invaluable in the study of ADPKD, particularly with respect to defining how developmental context influences renal cyst development. For example, Piontek et al.[173] showed that Pkd1 inactivation in mice before postnatal day 13 results in the rapid development of severe polycystic kidney disease, whereas inactivation on or after postnatal day 14 results in much slower cyst development. These experiments defined a key developmental switch influencing cyst development and provided important mechanistic insights into the acquisition of cysts in human ADPKD. In addition, mouse models with slower, adult onset cystic disease will be an extremely valuable resource for testing therapeutic interventions and may prove more predictive of human responses to therapy.

Finally, a conditional model of gene inactivation also allows for the study of organ-specific properties of a gene's function. In the case of ADPKD, germ line homozygous mutations of Pkd1 and Pkd2 in mice result in embryonic or perinatal lethality.[156,157,159,170,174] Mutants uniformly demonstrate cystic kidneys, polyhydramnios, edema, and hemorrhage, but the primary cause of fetal death remained unclear. Using a series of mouse models with conditional Pkd1 and Pkd2 mutations, Garcia-Gonzalez et al.[175] were able to show that placental abnormalities appear to be the primary cause of fetal demise, but that deletion of Pkd1 or Pkd2 in endothelial cells alone is not sufficient to cause the dramatic vascular phenotypes observed in null animals. These findings revealed a surprising complexity in the functional roles of the polycystins, and further studies with organ-specific Cre recombinases will allow for the further delineation of tissue-specific functions of the proteins.

The Use of Nonvertebrate Organisms as Models

The numerous genetic tools available for manipulation of the mouse genome along with the wide availability of genetically defined strains has fostered great interest in using mouse models to identify genetic loci that encode modifiers of disease severity or potential interacting partners. Unfortunately, there are currently no efficient techniques for using large-scale genetic screens to identify enhancing or suppressing genes. In some cases, crossing inbred mutant strains to mice of a different background has revealed the influence of genetic modifiers that have been mapped to large chromosomal regions by quantitative trait analysis. Despite great success in localizing many of these factors,[176–181] progress in identifying the precise loci has been very slow. For this reason, many groups have turned to the use of invertebrate organisms such as Caenorhabditis elegans (roundworm) and Drosophila melanogaster (fruit fly) to complement the human and mouse studies. As noted in an earlier section, greater than 60% of human disease genes are estimated to have orthologs in Drosophila. In addition, the signaling systems involved in a number of basic processes such as cell–cell signaling (i.e., JAK/STAT/cytokine, Wingless/WNT) appear to have conserved components in vertebrates and flies. We have already alluded to one of the most striking examples of how this approach has enhanced our understanding of a vertebrate gene linked to renal disease. Ito and Rubin[182] identified Drosophila homologues of Tsc2 and showed that its loss resulted in a dramatic change in cell size. Several groups linked Drosophila Tsc1 to the same pathway soon thereafter and, capitalizing on the model system's many advantages, linked both proteins to the insulin-signaling pathway.[183–185] Subsequent studies soon showed that the Tsc1/Tsc2 complex regulates the TOR kinase in both Drosophila and vertebrate systems and identified Rheb as the small GTPase that is the likely target of Tsc2 GAP (GTPase-activating protein) activity.[186–196] The most exciting consequence of these studies is that they led to a possible therapy (discussed in the following text). The subsequent development of methodologies that can create Drosophila mutants by homologous recombination have now allowed investigators to manipulate its genome at will to make simple models of human disease "on the fly."[197–202]

Insights are also likely to come from unanticipated sources. In the case of PKD, a strategy of randomly inactivating genes by insertional mutagenesis revealed that the mutation of the Tg737 gene resulted in a phenotype similar to that of human autosomal recessive polycystic kidney disease.[203] The gene sequence initially provided few clues as to the protein's function. In an unrelated project focused on identifying genes in algae (Chlamydomonas) that regulate formation and function of flagella, investigators determined that one of the genes that caused flagellar defects was a homologue of Tg737.[204] The gene encodes a protein, IFT88, that helps to carry "cargo" to the flagella in a process called intraflagellar transport. Subsequent studies showed that IFT88 homologues in other organisms have an essential function in the formation and function of a related structure, the cilium.[205] In vertebrates, cilia have been found on almost all cells and are either motile or nonmotile. The latter are thought to possibly function as sensory organelles for a variety of stimuli.[206] In the kidney, they may act as mechanosensors for flow.[207,208] There now is a very large body of data that links defects in cilia and related structures such as the basal body/centrosomal complex to renal cystic disease (Fig. 14.7),[206,209–212] and a comparative genomic approach capitalized on this observation to identify a locus for BBS.[35] In sum, appreciation of the central role that the primary cilium appears to play in normal development and in renal cystic disease was sparked by studies of simple algae.

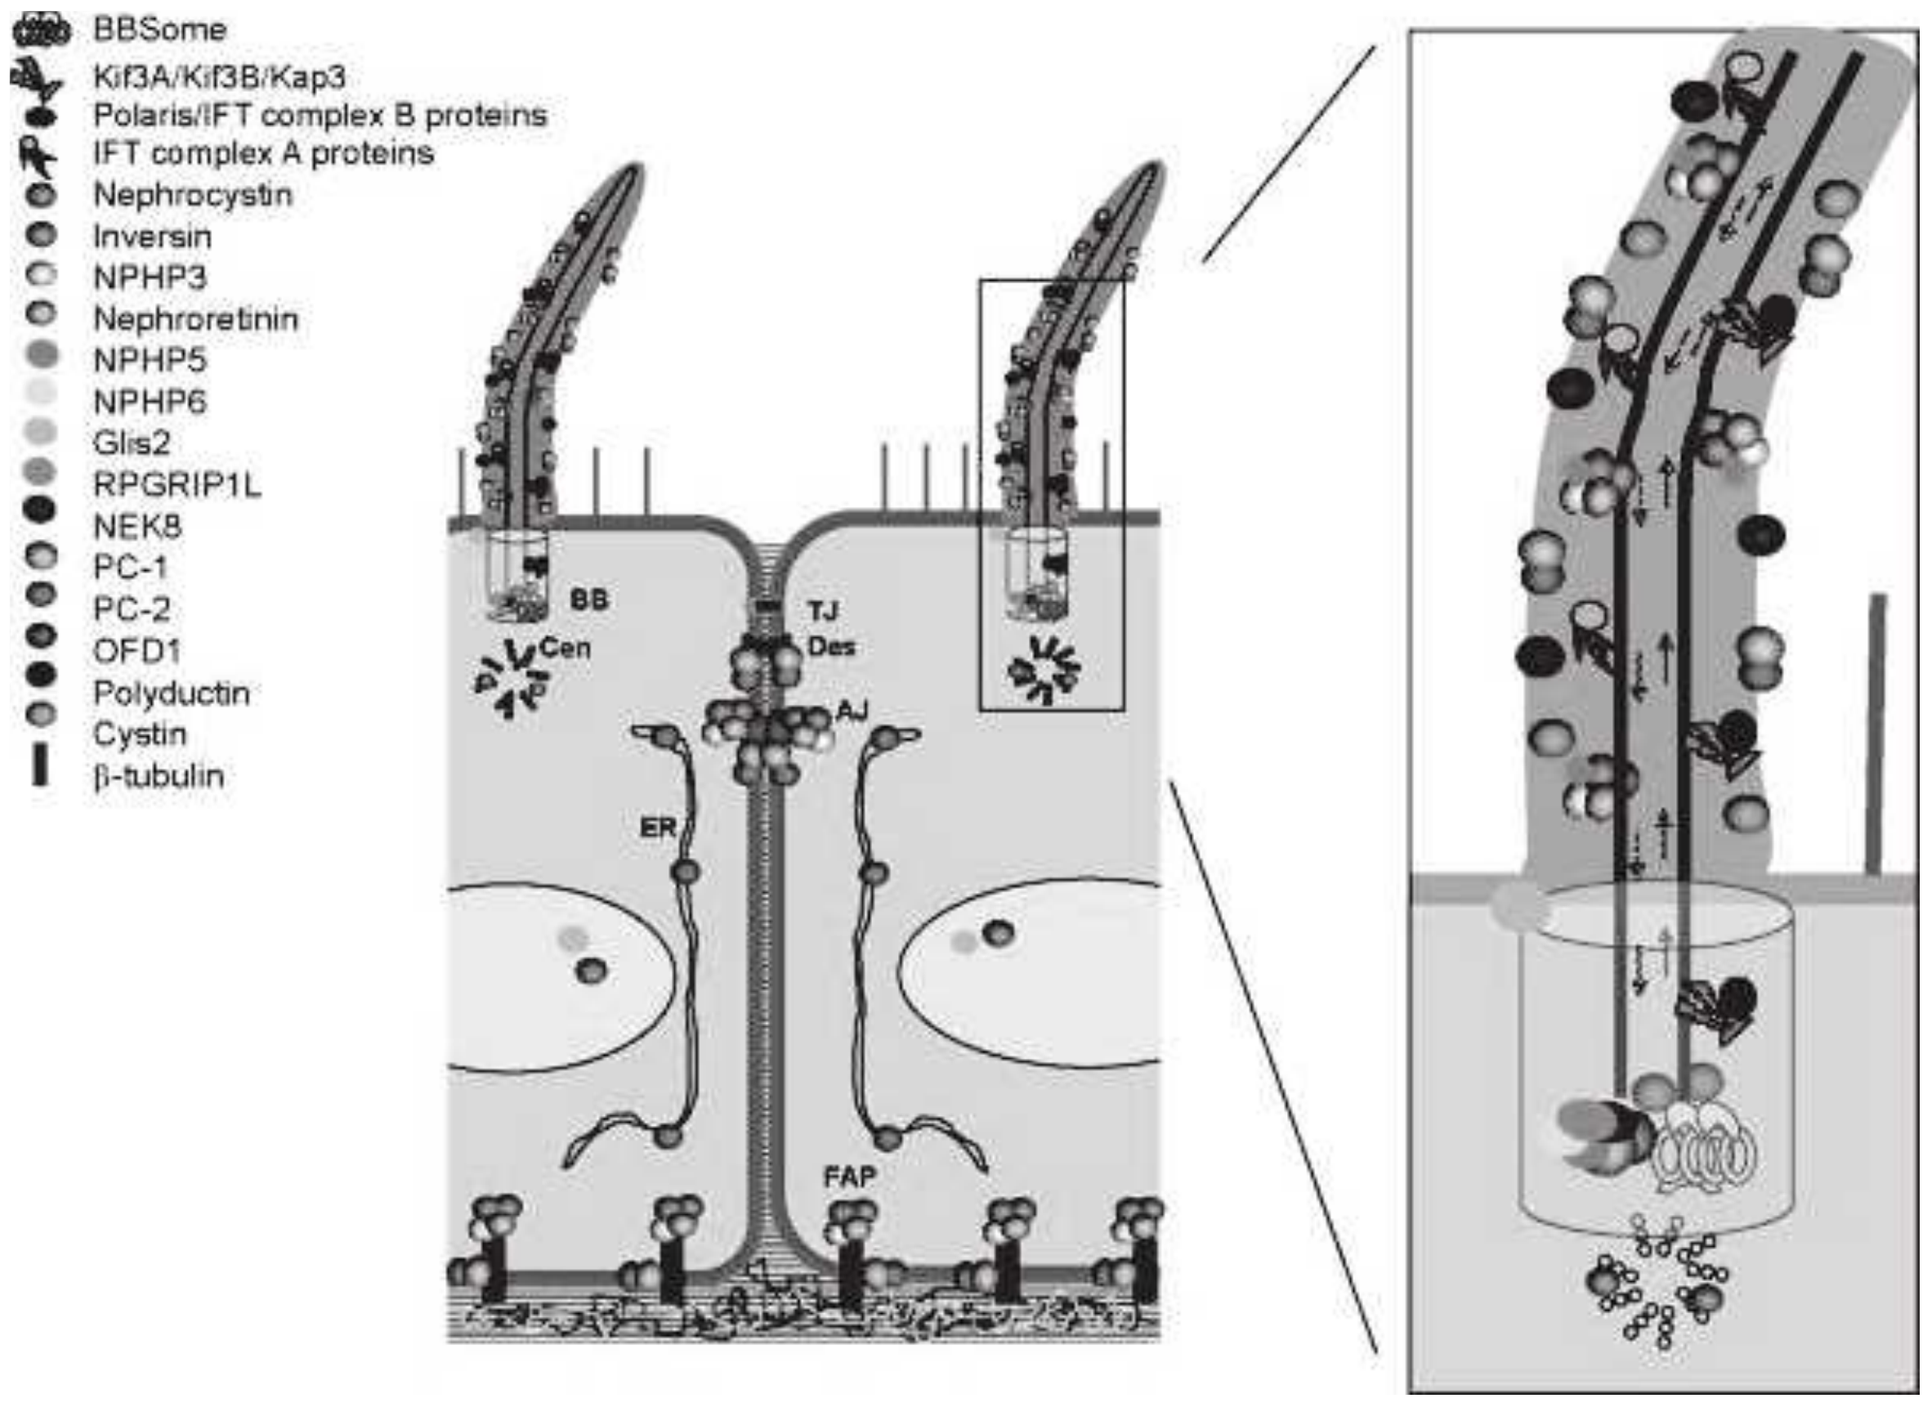

FIGURE 14.7 The subcellular localization of cystoproteins. Numerous cystoproteins have been localized to more than one intracellular domain. In this illustration, all known members of an interacting complex are shown colocalized to the same locations, even though this has not necessarily been shown for each unit. There are two exceptions: (1) polycystin-2 has been reported to have endoplasmic reticulum-specific functions as a calcium release channel that are independent of polycystin-1, and (2) at least one form of inversin has been localized to the centriole and to the nucleus. The *speckled arrow* in the primary cilium indicates the direction of anterograde transport along the microtubule system mediated by kinesin-II, a heterotrimeric protein composed of two motor units (Kif3a, Kif3b) and one nonmotor unit (KAP3). AJ, adherens junction; BB, basal body; Cen, centriole; ER, endoplasmic reticulum; FAP, focal adhesion plaque; TJ, tight junction; PC-1, polycystin-1; PC-2, polycystin-2. (Adapted from Watnick T, Germino G. From cilia to cyst. *Nat Genet*. 2003 Aug;34(4):35–56 and Menezes LF, Germino GG. Polycystic kidney disease, cilia, and planar polarity. *Methods Cell Biol*. 2009;94:273–297. Used with permission.) (See Color Plate.)

CLINICAL IMPLICATIONS AND FUTURE DIRECTIONS

The advances described thus far may seem basic in their scope, but they also have far-reaching implications with respect to diagnosis and, ultimately, the treatment of inherited renal diseases. The most immediate clinical impact of gene identification is the development of molecular diagnostic tests. There are a number of circumstances in which DNA-based diagnoses may be helpful to clinicians managing the care of affected individuals and their families. In the case of X-linked nephrogenic diabetes insipidus, DNA testing can be used to identify at-risk male fetuses or newborns before they suffer repeated episodes of dehydration.[213] DNA testing is particularly useful in the management of families with VHL syndrome.[214–216] This information can provide reassurance to noncarriers and can focus close attention on those individuals most likely to develop complications that will need repeated computed tomography (CT) scans or magnetic resonance imaging (MRI). An additional benefit of DNA testing in this disorder is that it can identify the subgroup most likely to develop pheochromocytomas.

DNA tests are also used to evaluate presymptomatic individuals who seek genetic counseling regarding their prognosis or for the purpose of family planning. In general, presymptomatic DNA testing will probably be more widely used in the future if protective therapies for diseases such as ADPKD are developed that must be administered early in life before a clinical diagnosis can be made. A final use of DNA testing is in the evaluation of "at-risk," presymptomatic individuals as potential living-related transplant donors. This application is particularly important for diseases like ADPKD that have a late onset.

Historically, the primary methodology for DNA testing was by linkage analysis. This has been largely supplanted by newer methodologies (discussed in the following text). However, linkage analysis remains an important tool for diagnosis in families in whom the affected gene is unknown, or when a mutation cannot be detected in the gene of interest. Linkage analysis can also be helpful when results of direct DNA sequencing are indeterminate. For example, Zhao et al.[217] described a family in which a 28-year-old woman with a strong family history of ADPKD was being considered as a living kidney donor for her affected father. Because ultrasound screening in younger individuals cannot definitively rule out ADPKD, a genetic confirmation was pursued before clearing her as a kidney donor. Direct sequencing of the PKD1 and PKD2 genes in her father revealed two PKD1 variants of unknown clinical significance, so linkage analysis using markers at both PKD1 and PKD2 loci was performed on several affected and unaffected family members. This revealed that only a certain PKD1 haplotype cosegregated with all of the affected individuals, and the 28-year-old woman did not share this haplotype (Fig. 14.8). She was therefore cleared as a kidney donor.

Direct DNA sequencing is currently the most commonly used method of testing because it can often unequivocally determine whether the proband has inherited a disease-causing mutation without the participation of family members. There are certain limitations of direct mutation analysis, however, that need to be considered in interpreting a negative test. For example, one must consider whether genetic heterogeneity exists for the disease in question, and if so, whether all genes had been systematically evaluated. A second problem arises when a disease is not associated with a set of common mutations. In these cases, a laboratory will have to evaluate the gene's entire length for mutations. Depending on the size and complexity of the gene, the laboratory may elect to use screening techniques such as denaturing high performance liquid chromatography (dHPLC) rather than direct sequencing to search for suspected mutations, with DNA sequence analysis reserved only for suspicious changes.[218–221] None of the screening methods in common use have 100% sensitivity. A related problem is that the laboratory usually screens for mutations in a set of overlapping PCR products that includes only the coding region and the immediately adjacent splice sites. This strategy will miss pathogenic changes occurring in intronic sequences. Inevitably, a proportion of mutations will be missed, which may limit the conclusions that can be drawn from the data. Lastly, the implications of all changes may not be absolutely clear. Although some mutations (such as deletions or insertions) are clearly pathogenic, the status of amino acid substitutions may not be obvious. For example, it may be difficult to distinguish between a simple polymorphism and an amino acid change that disrupts a particular protein function.

The list of diseases for which DNA testing is available has grown considerably since the previous edition of this text and includes some forms of nephronophthisis, ADPKD, autosomal recessive polycystic kidney disease (ARPKD), medullary cystic disease, and hereditary nephrotic syndrome. In some cases, both linkage testing and direct mutation analysis is available. GENETests, an invaluable Web-based resource hosted at the University of Washington and funded by the NIH (http://www.genetests.org/) provides a comprehensive list of academic and commercial facilities that offer testing on either a clinical or research basis. The website also provides a library of contemporaneous reviews on numerous disorders as well as a variety of very informative educational resources.

The $1,000 genome, soon to become a reality, will significantly change the approach to DNA testing. The reduced cost and the increased throughput of "massively parallel" sequencing technologies will likely dramatically increase the number of diseases that can be evaluated. With these technologies, neither the number of genes that need to be considered nor the length of their respective sequences pose challenges. DNA testing services in the future may simply evaluate all nephrotic syndrome, NPHP, or PKD genes in a single test. Some investigators have suggested a future in which every individual has his or her DNA sequence determined as part of routine clinical practice and then given a risk assessment for both Mendelian and more common diseases. In addition to the obvious clinical challenge of how to interpret the numerous presymptomatic "risk variants" that will be identified by this approach, there are important technical, ethical, privacy, and intellectual property issues that must first be resolved. Without question, though, these technologies are rushing forward and will certainly impact clinical practice.

The impact of molecular studies on the treatment of disease has been, to date, somewhat limited. For diseases that result from inadequate amounts of functional protein (recessive diseases, haploinsufficiency states, tumor suppressor-type genes like PKD1 or VHL), strategies aimed at replacing the lost activity may treat the disorder. The most direct manner is by using gene therapy to express normal amounts of the correct protein in the target tissues. There remain huge obstacles to the widespread implementation of this approach for any disorder. Nonetheless, this strategy remains the "holy grail" of the field and may, in time, yield rich rewards.

Parallel efforts are underway to develop a detailed understanding of disease-associated proteins and the pathways in which they participate. The hope is that this knowledge will be used to target intermediate steps in disease pathogenesis for therapeutic intervention. This strategy may yield effective treatments before the barriers to gene therapy can be overcome. The cell culture and animal model systems described in earlier sections of this chapter are invaluable reagents for this type of research, and recent studies highlight the important contributions these resources offer. In the case of TSC, the studies first in Drosophila and then in vertebrate cells linked the TSC proteins to the regulation of mTOR kinase. Rapamycin, an agent widely used to prevent rejection in transplant patients because of its immunosuppressive properties, is known to inhibit this kinase.

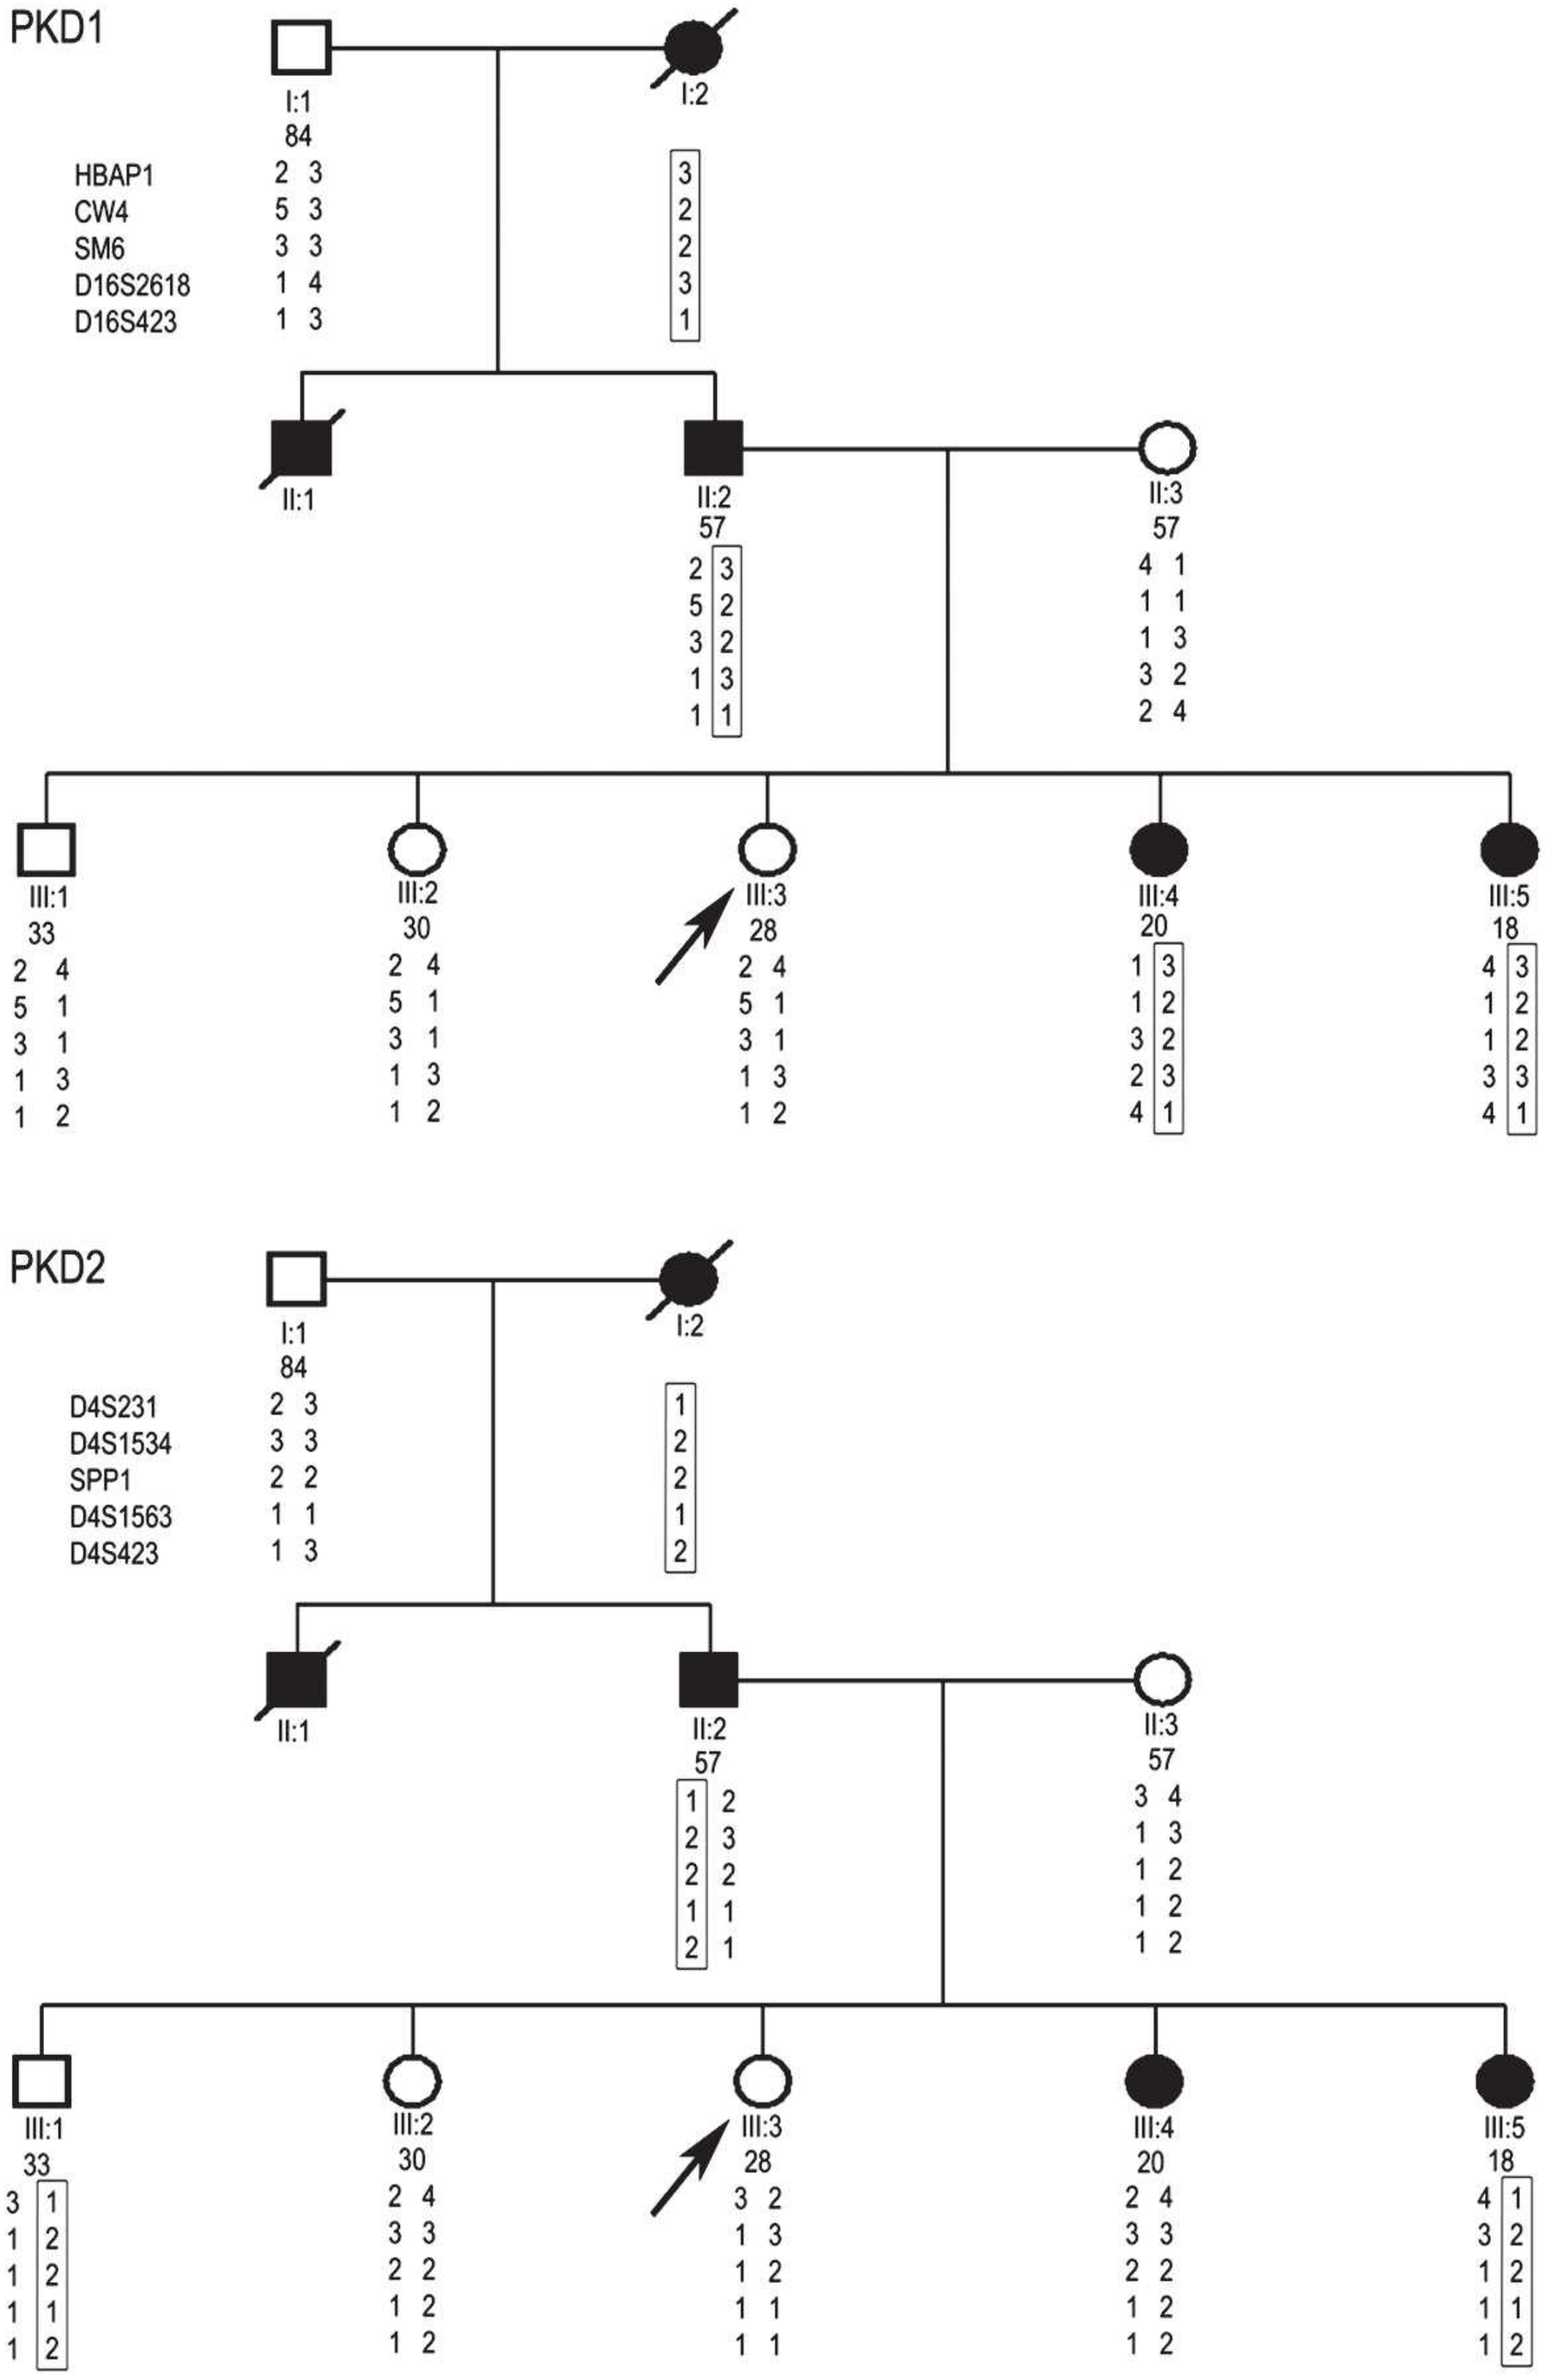

FIGURE 14.8 A haplotype analysis of an autosomal dominant polycystic kidney disease (ADPKD) family. The proband, a 28-year-old woman, is denoted by the *slanted arrows*. *Filled symbols* represent clinically affected individuals, and *unfilled symbols* represent unaffected individuals. Individual identification and age are indicated below each symbol. In this family, only the *PKD1* haplotype 3-2-2-3-1 (*top*) but not the single *PKD2* haplotype (*bottom*) cosegregated with the affected members. These data are consistent with this family's disease being *PKD1*-linked. The finding that the proband (III:3) did not carry the putative *PKD1* disease haplotype provided further reassurance that she was unaffected. (From Zhao X, Paterson AD, Zahirieh A, et al. Molecular diagnostics in autosomal dominant polycystic kidney disease: utility and limitations. *Clin J Am Soc Nephrol.* 2008 Jan;3(1):146–152. Used with permission of the Clinical Journal of the American Society of Nephrology.)

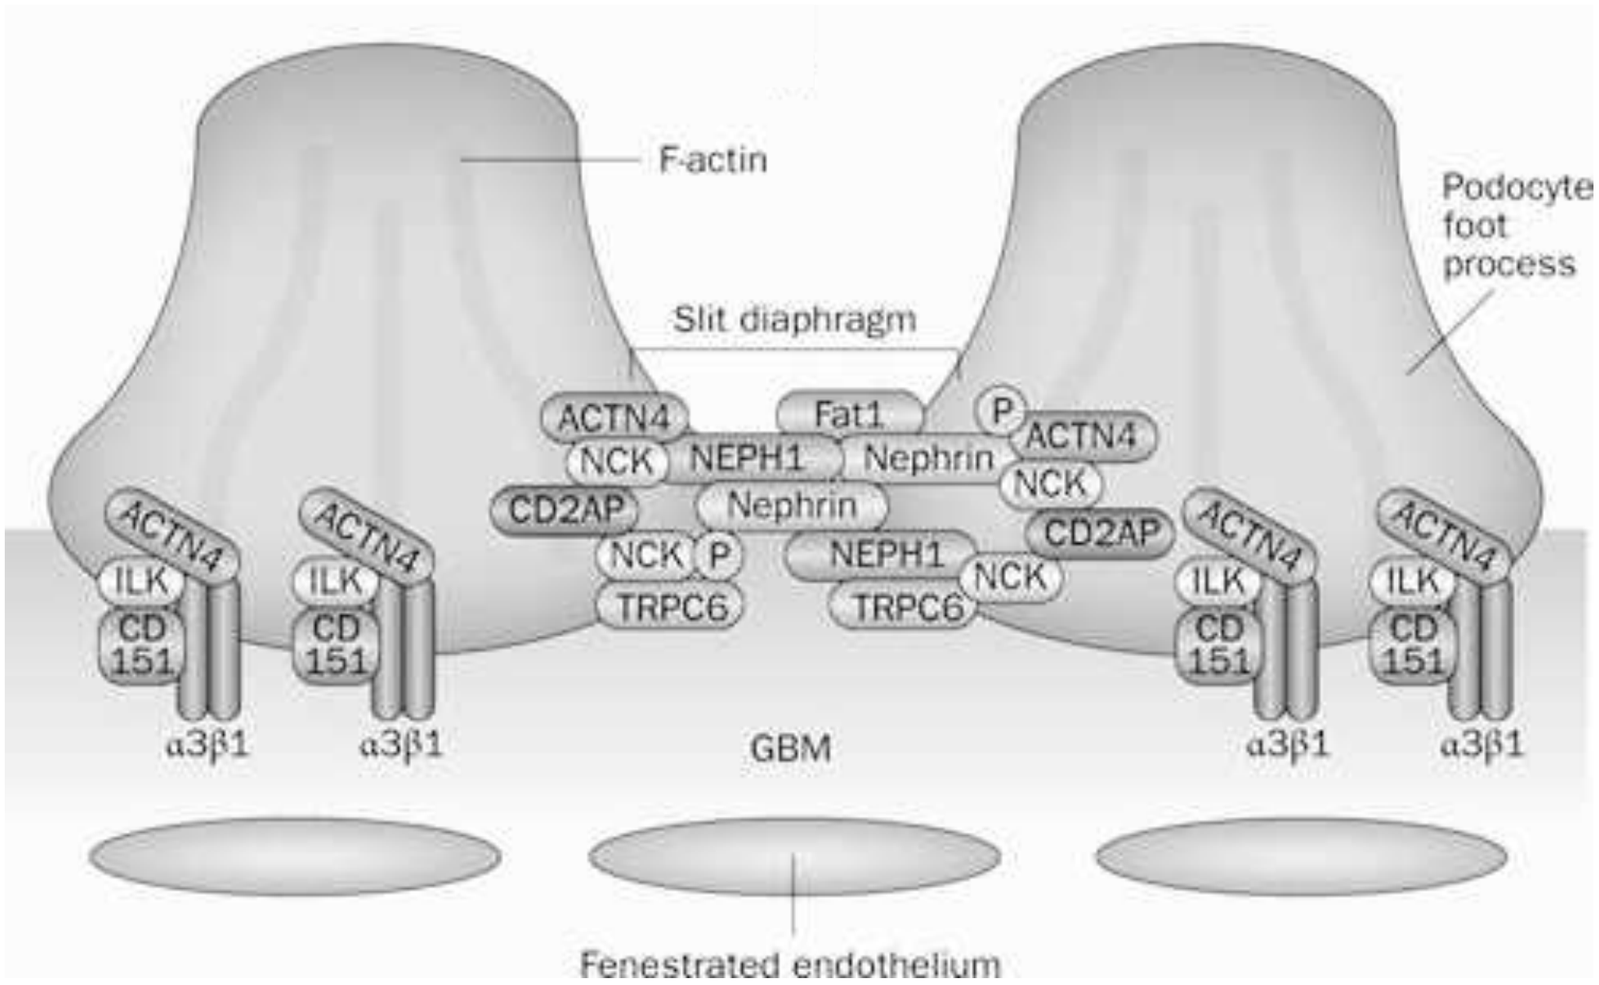

FIGURE 14.9 Podocyte foot processes, interconnected by slit diaphragms, form the final barrier for filtration. Normal function of the filtration barrier depends on proteins that anchor the foot processes to the GBM, including $\alpha 3\beta 1$ integrin, ACTN4, ILK, and the tetraspanin CD151, as well as those that are associated with the slit diaphragm, such as nephrin, NEPH1, podocin, Fat1, ACTN4, the adaptor protein NCK, CD2AP, and TRPC6. As outlined in Table 14.1, defects in many of these proteins have been found in various hereditary forms of nephrotic syndrome. ACTN4, α-actinin-4; CD2AP, CD2-associated protein; GBM, glomerular basement membrane; ILK, integrin-linked kinase; P, podocin; TRPC6, transient receptor potential cation channel 6. (From Patrakka J, Tryggvason K. New insights into the role of podocytes in proteinuria. *Nat Rev Nephrol.* 2009 Aug;5(8):463–468. Reprinted by permission from Macmillan Publishers Ltd.)

Studies in mice and rats have shown that rapamycin or related compounds are effective at reducing the severity of TSC-related disease,[222–225] and clinical trials in humans are ongoing.[226–230]

In the case of ADPKD, insights gleaned from a variety of approaches culminated in an exciting new therapeutic initiative. In vitro studies of cultured cyst-lining cells from human specimens suggested that cystic epithelia responded to increased cyclic adenosine monophosphate (cAMP) activity with an increase in cell proliferation.[231–233] Reasoning that the vasopressin V2 receptor was the predominant regulator of cAMP activity in the collecting duct, the most prevalent site of cyst formation, Gattone and colleagues[234] tested a V2 receptor antagonist previously developed to treat hyponatremia in rodents with a syntenic form of ARPKD (PKHD1) and nephronophthisis (NPHP3). The investigators found a striking reduction of cyst volume and decreased interstitial fibrosis. In a follow-up report, they tested the same agent in a Pkd2 mouse model and found the same beneficial effects.[161] A clinical trial examining the efficacy of this class of drugs on the progression of human ADPKD is underway and should be completed in 2012.

Last, much of the focus of this chapter has been on advances in relatively rare monogenic disorders. Knowledge that has been gleaned from these studies, however, may also be applied to understanding the pathophysiology of more common disorders. For example, as a result of the identification of the genes involved in hereditary nephrotic syndromes, we have been able to synthesize a more coherent model of normal and abnormal podocyte structure and function (Fig. 14.9).[235] Similarly, mutations of the VHL gene have been implicated in the majority of clear cell renal carcinoma.[236,237] The result of studies of BBS have blurred the boundary between "traditional" Mendelian disorders and complex traits, and highlighted the likely continuum that exists between the two sets of conditions.[238] Significant advances in the ability to perform large-scale, population-based genome-wide association studies (GWAS), using databases such as the International HapMap Project (http://www.hapmap.org) and the 1000 Genomes Project (http://www.1000genomes.org) have allowed investigators to uncover associations between genetic variants and diseases with complex non-Mendelian inheritance such as hypertension, chronic kidney disease (CKD), and focal segmental glomerulosclerosis (FSGS). Notable discoveries using this approach include the association of variants in UMOD (uromodulin) with increased risk for CKD,[239–241] and of variants in APOL1 (apolipoprotein L1) with increased risk of FSGS in African Americans.[242,243] Continuing advances in population genetics research will likely provide further insights to decipher the genetic basis of these and other common polygenic disorders.

CHAPTER

15 Nephronophthisis—Medullary Cystic Kidney Disease

Friedhelm Hildebrandt • Rannar Airik • John A. Sayer

A group of hereditary renal diseases is summarized under the term NPHP-MCKD complex,[1,2] because the different disease entities share several features regarding (1) macroscopic pathology, (2) microscopic pathology, and (3) clinical symptoms (Table 15.1A). In this way the complex describes a distinct clinicopathologic entity.[3] The term nephronophthisis (NPHP) is used for the autosomal recessive variants, which lead to end-stage renal disease (ESRD) in the first 3 decades of life, whereas the term medullary cystic kidney disease (MCKD) refers to the autosomal dominant forms, in which ESRD develops in the third to seventh decade of life. Extrarenal manifestations such as ocular motor apraxia, retinitis pigmentosa, hepatic fibrosis, skeletal defects, and cerebellar vermis aplasia have exclusively been described in association with juvenile nephronophthisis. The only extrarenal associations in MCKD are hyperuricemia and gout. The identification of causative recessive genes in nephronophthisis has implicated the function of primary cilia and centrosomes in its pathogenesis.

FEATURES SHARED AMONG DISEASES OF THE NEPHRONOPHTHISIS-MEDULLARY CYSTIC KIDNEY DISEASE COMPLEX

Macroscopic Pathology

A major feature shared among the disease entities of the NPHP-MCKD complex (Table 15.1A[i]) is the appearance on macroscopic pathology as described in 27 patients with juvenile NPHP by Waldherr et al.[1] Kidney size is normal or moderately reduced. Cysts primarily appear at the corticomedullary border of the kidneys (Fig. 15.1). This is quite distinct from autosomal dominant and recessive polycystic kidney disease, where kidneys become grossly enlarged as a result of cystic dilatation throughout the organ. From the external surface, the kidney is indistinguishable from the kidney affected by glomerulonephritis or pyelonephritis. The surface usually has a finely granular appearance, most likely due to the protrusion of dilated cortical collecting ducts. Calices and pelvis appear completely normal. There are from 5 to over 50 cysts of 1 to 15 mm in diameter located preferentially at the corticomedullary border (Fig. 15.1). The cysts primarily arise from the distal convoluted and medullary collecting tubules as shown by microdissection,[4] but may also appear in the papilla. Cysts are not always present, but do occur in about 70% of autopsy cases. They apparently arise late in the course of the disease[5] and do not seem to be important for disease progression to renal failure.[6] Therefore, the presence of cysts is not a prerequisite for diagnosis.

Microscopic Pathology

The second shared feature among diseases of the NPHP-MCKD complex pertains to renal histology (Table 15.1A[ii]). The histologic changes are characteristic, but not pathognomonic, for the disease group. The characteristic histologic triad of NPHP-MCKD consists of (1) tubular basement membrane disintegration with irregular thickening as well as attenuation of the tubular basement membrane, (2) interstitial round cell infiltration with marked fibrosis and, (3) later in disease development, tubular atrophy with cyst development, which occurs predominantly at the corticomedullary junction (Fig. 15.2). Cysts seem to be the result rather than the cause of the atrophic process, although this time course could not be corroborated by statistical analysis.[1,7] Sometimes, a communication between a cyst and a tubule can be seen. The tubular basement membrane (TBM) is extremely thickened and multilayered. Fibroblasts are noted between the membrane layers. TBM changes and diverticulum formation are most prominent in the distal tubules, where cysts are lined with a single layer of cuboidal or flattened epithelium. In the advanced stage, the picture merges into a diffuse sclerosing tubulointerstitial nephropathy, the characteristic picture of end-stage NPHP-MCKD. The only significant glomerular change in early stages involves periglomerular fibrosis with a splitting and thickening of the Bowman capsule and glomerular obsolescence only in nephrons that

15.1 Shared and Distinguishing Features Among Diseases of the NPHP-MCKD Complex

A. Shared Features		
(i) Macroscopic pathology:	Corticomedullary cysts	
(ii) Microscopic pathology:	Tubuli: basement membrane disruption (thickening and attenuation), distal tubular atrophy and cysts Interstitium: round cell infiltration, fibrosis Glomeruli: periglomerular fibrosis only

have been destroyed by the tubular alterations. An escape of Tamm-Horsfall (uromodulin) protein from damaged collecting tubules into the interstitium has been demonstrated in about 50% of patients with NPHP-MCKD as a periodic acid-Schiff (PAS)-positive material and by specific immunofluorescence staining with an anti-THP antibody.[8] Immunofluorescence does not otherwise contribute to the diagnosis of NPHP-MCKD.

Characteristic changes demonstrated by transmission electron microscopy include thickening, splitting, attenuation, and granular disintegration of the TBM (Fig. 15.3). The transition between these alterations is abrupt.[7] Fibroblasts are seen in direct contact with the TBM. At the base of the tubular epithelial cells, a marked increase of microfilaments is seen. The thickening is either homogeneous or has a lamellated, annular, and ringlike appearance. The glomerular basement membrane is normal. Multiple tubular diverticula are seen but the connections between cysts and distal tubular segments are patent.

Clinical Presentation

The third group of features shared among different diseases of the NPHP-MCKD complex involves clinical symptoms (Table 15.1A[iii]). Classical symptoms are polyuria, polydipsia, decreased urinary concentrating ability and, in children, anemia and growth retardation. The insignificance of the symptoms together with the lack of edema, hypertension, and urinary tract infections characteristically leads to a delayed diagnosis and therapy in NPHP-MCKD. In all variants of NPHP-MCKD, terminal renal failure insidiously ensues at characteristic age ranges, necessitating renal replacement therapy (Fig. 15.4). Disease recurrence has never been reported in kidneys transplanted to NPHP patients.[9]

FEATURES DISTINGUISHING DISEASE ENTITIES OF THE NPHP-MCKD COMPLEX

There are three features that clearly distinguish different disease entities of the NPHP-MCKD complex: (1) the mode of inheritance, (2) the age of onset for ESRD, and (3) the type of extrarenal organ involvement (Table 15.1B).

The Mode of Inheritance

In the NPHP-MCKD complex, the mode of inheritance can be either autosomal recessive or autosomal dominant.

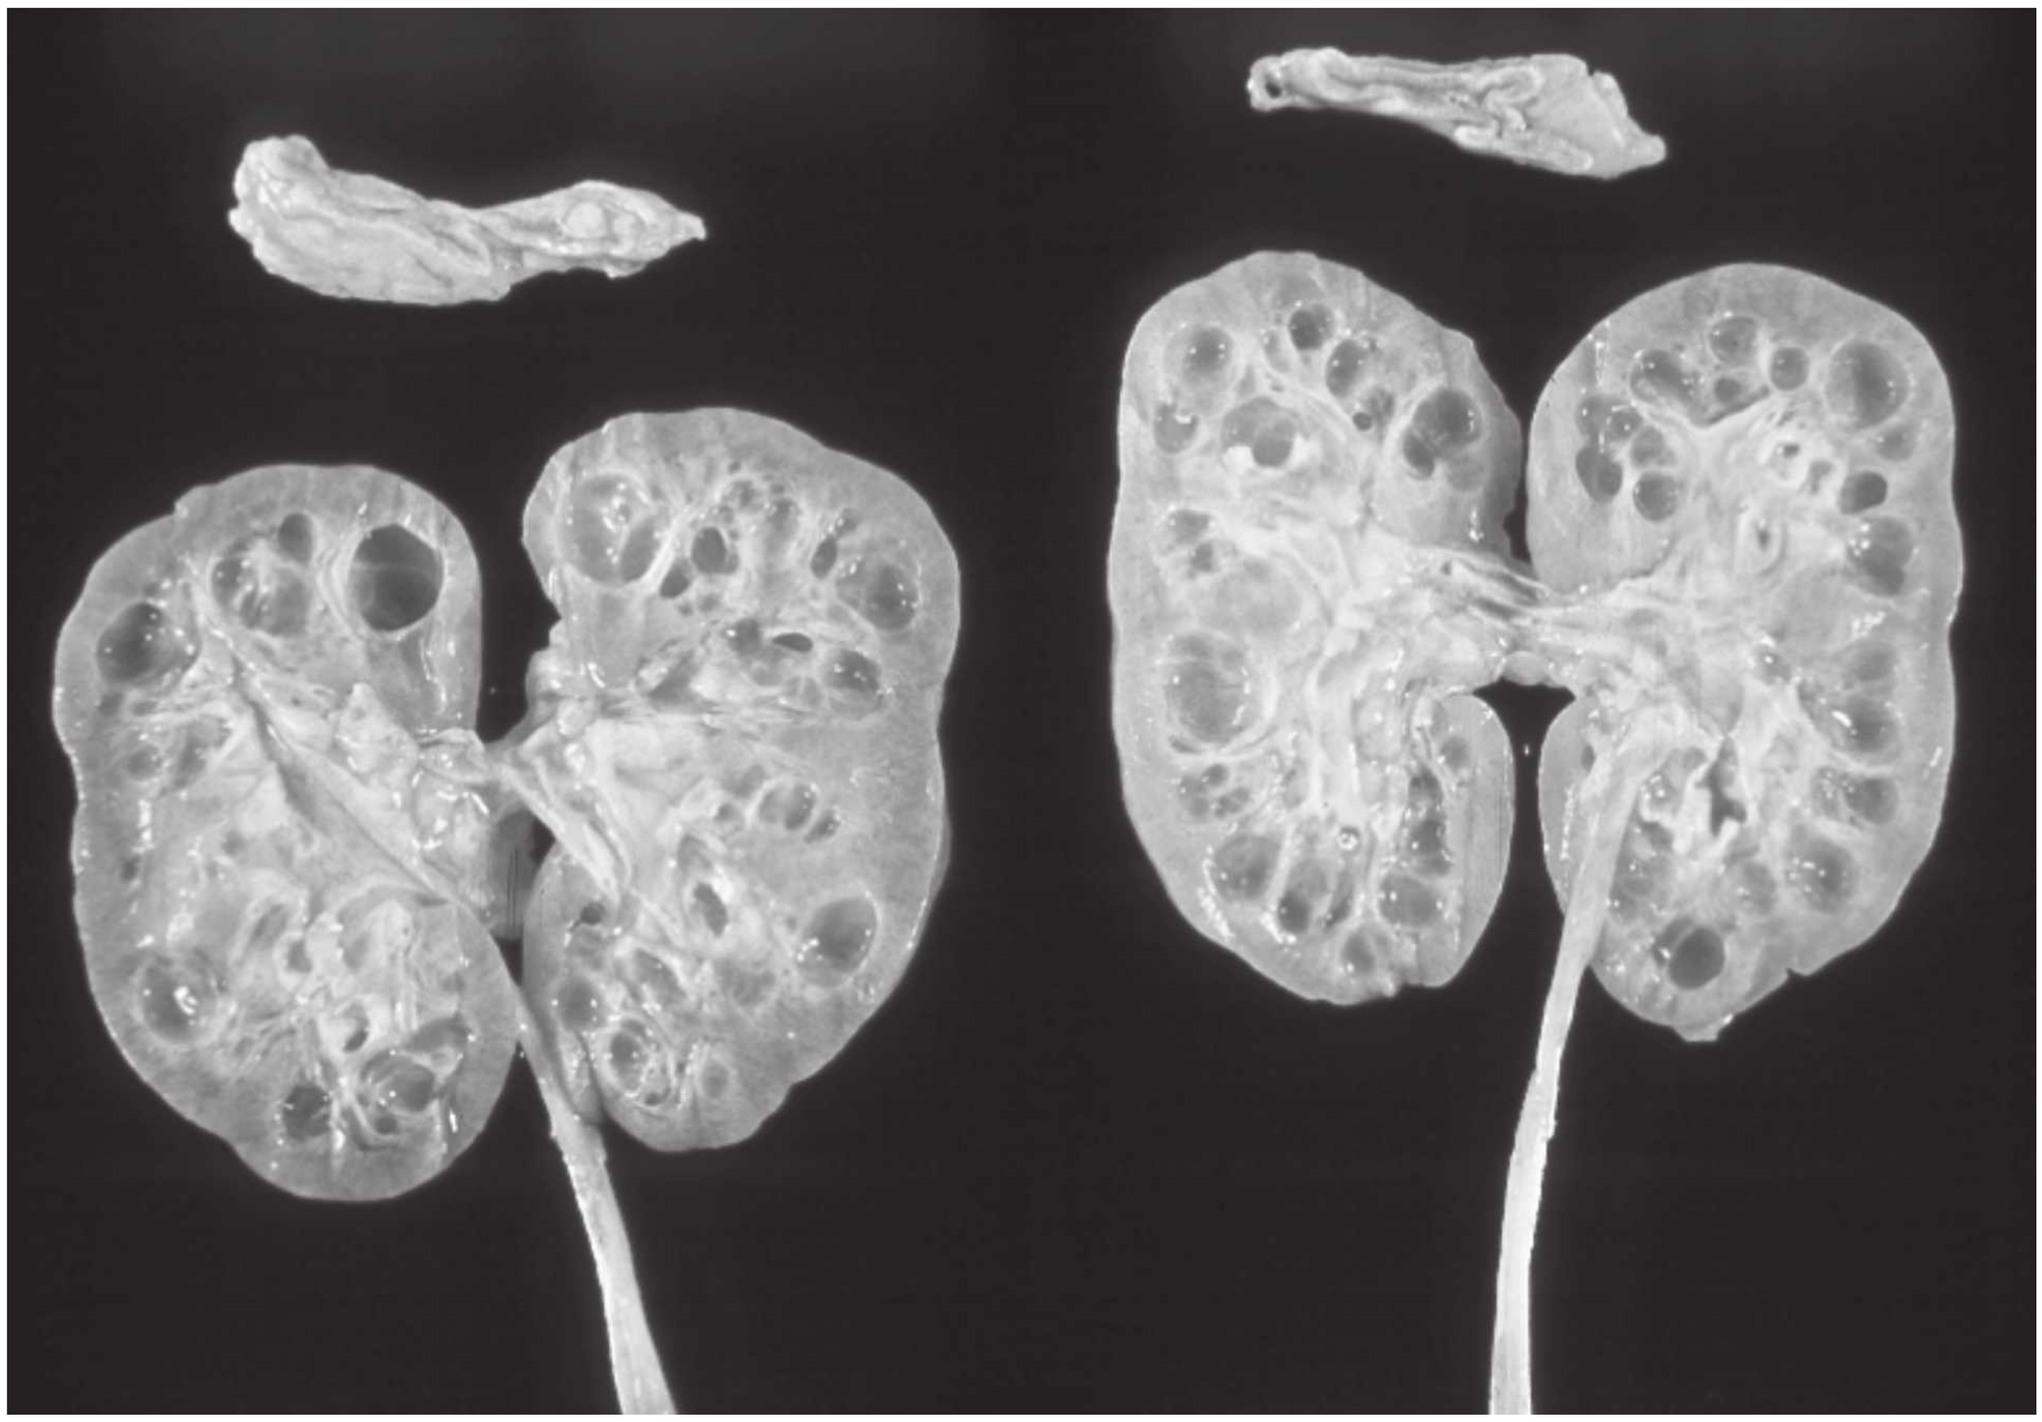

FIGURE 15.1 Juvenile nephronophthisis (autopsy case, 13-year-old girl). Note the numerous cysts of varying size in the medulla and at the corticomedullary junction. (Reproduced with permission from Hildebrandt F, Waldherr R, Kutt R, et al. The nephronophthisis complex: clinical and genetic aspects. *Clin Invest* 1992;70:802.)

For the recessive forms the term nephronophthisis (NPHP) is used, whereas the designation medullary cystic kidney disease (MCKD) denotes the dominant variants of the complex (Table 15.1B[i]).[10,11]

The Onset of End-Stage Renal Disease

The second distinction pertains to the age of onset of ESRD (Table 15.1B[ii]). In all variants of NPHP-MCKD, ESRD ensues at characteristic age ranges, necessitating renal replacement therapy (Fig. 15.4). In NPHP, chronic renal failure develops within the first 3 decades of life.[12–14] In a study conducted in 46 children with juvenile nephronophthisis (NPHP1), a serum creatinine value of 6 mg per deciliter was reached at a median age of 13 years (range: 4 to 20 years).[12,15] In a study by Waldherr et al.[1] ESRD was reached at a median age of 11.5 years. Gretz et al.[16] showed that the rate of deterioration of renal function was homogeneous in a study of 29 patients with NPHP1. The median time elapsing between a serum creatinine of 2 and 4 mg per deciliter was 32 months, between 4 and 6 mg per deciliter was 10 months, and between 6 and 8 mg per deciliter was 5 months.[16] A high concordance of the development of renal failure was noted in monozygotic twins.[17,18] Infantile nephronophthisis (NPHP2) is characterized by an early onset of ESRD between the neonatal period and 3 years of age.[14] In adolescent nephronophthisis (NPHP3), terminal renal failure develops at a median age of 19 years, which is 6 years later than in NPHP1.[13] The median age of ESRD in patients with NPHP4 and NPHP5 mutations is 20 years[19] and 13 years,[20] respectively. If renal failure has not developed by the age of 25 years, the diagnosis of recessive NPHP should be questioned and a pedigree analysis should be intensified to exclude dominant MCKD.

In MCKD, terminal renal failure occurs only in adult life. Two different variants are known, MCKD1 and MCKD2, with a median onset of ESRD of 62 years[21] and 32 years[22] respectively (Fig. 15.4).

Extrarenal Associations

The third distinguishing feature among variants of NPHP-MCKD is represented by the degree to which extrarenal associations occur (Table 15.1B[iii]). Extrarenal disease manifestations have only been described in recessive forms. One exception to this rule is the occurrence

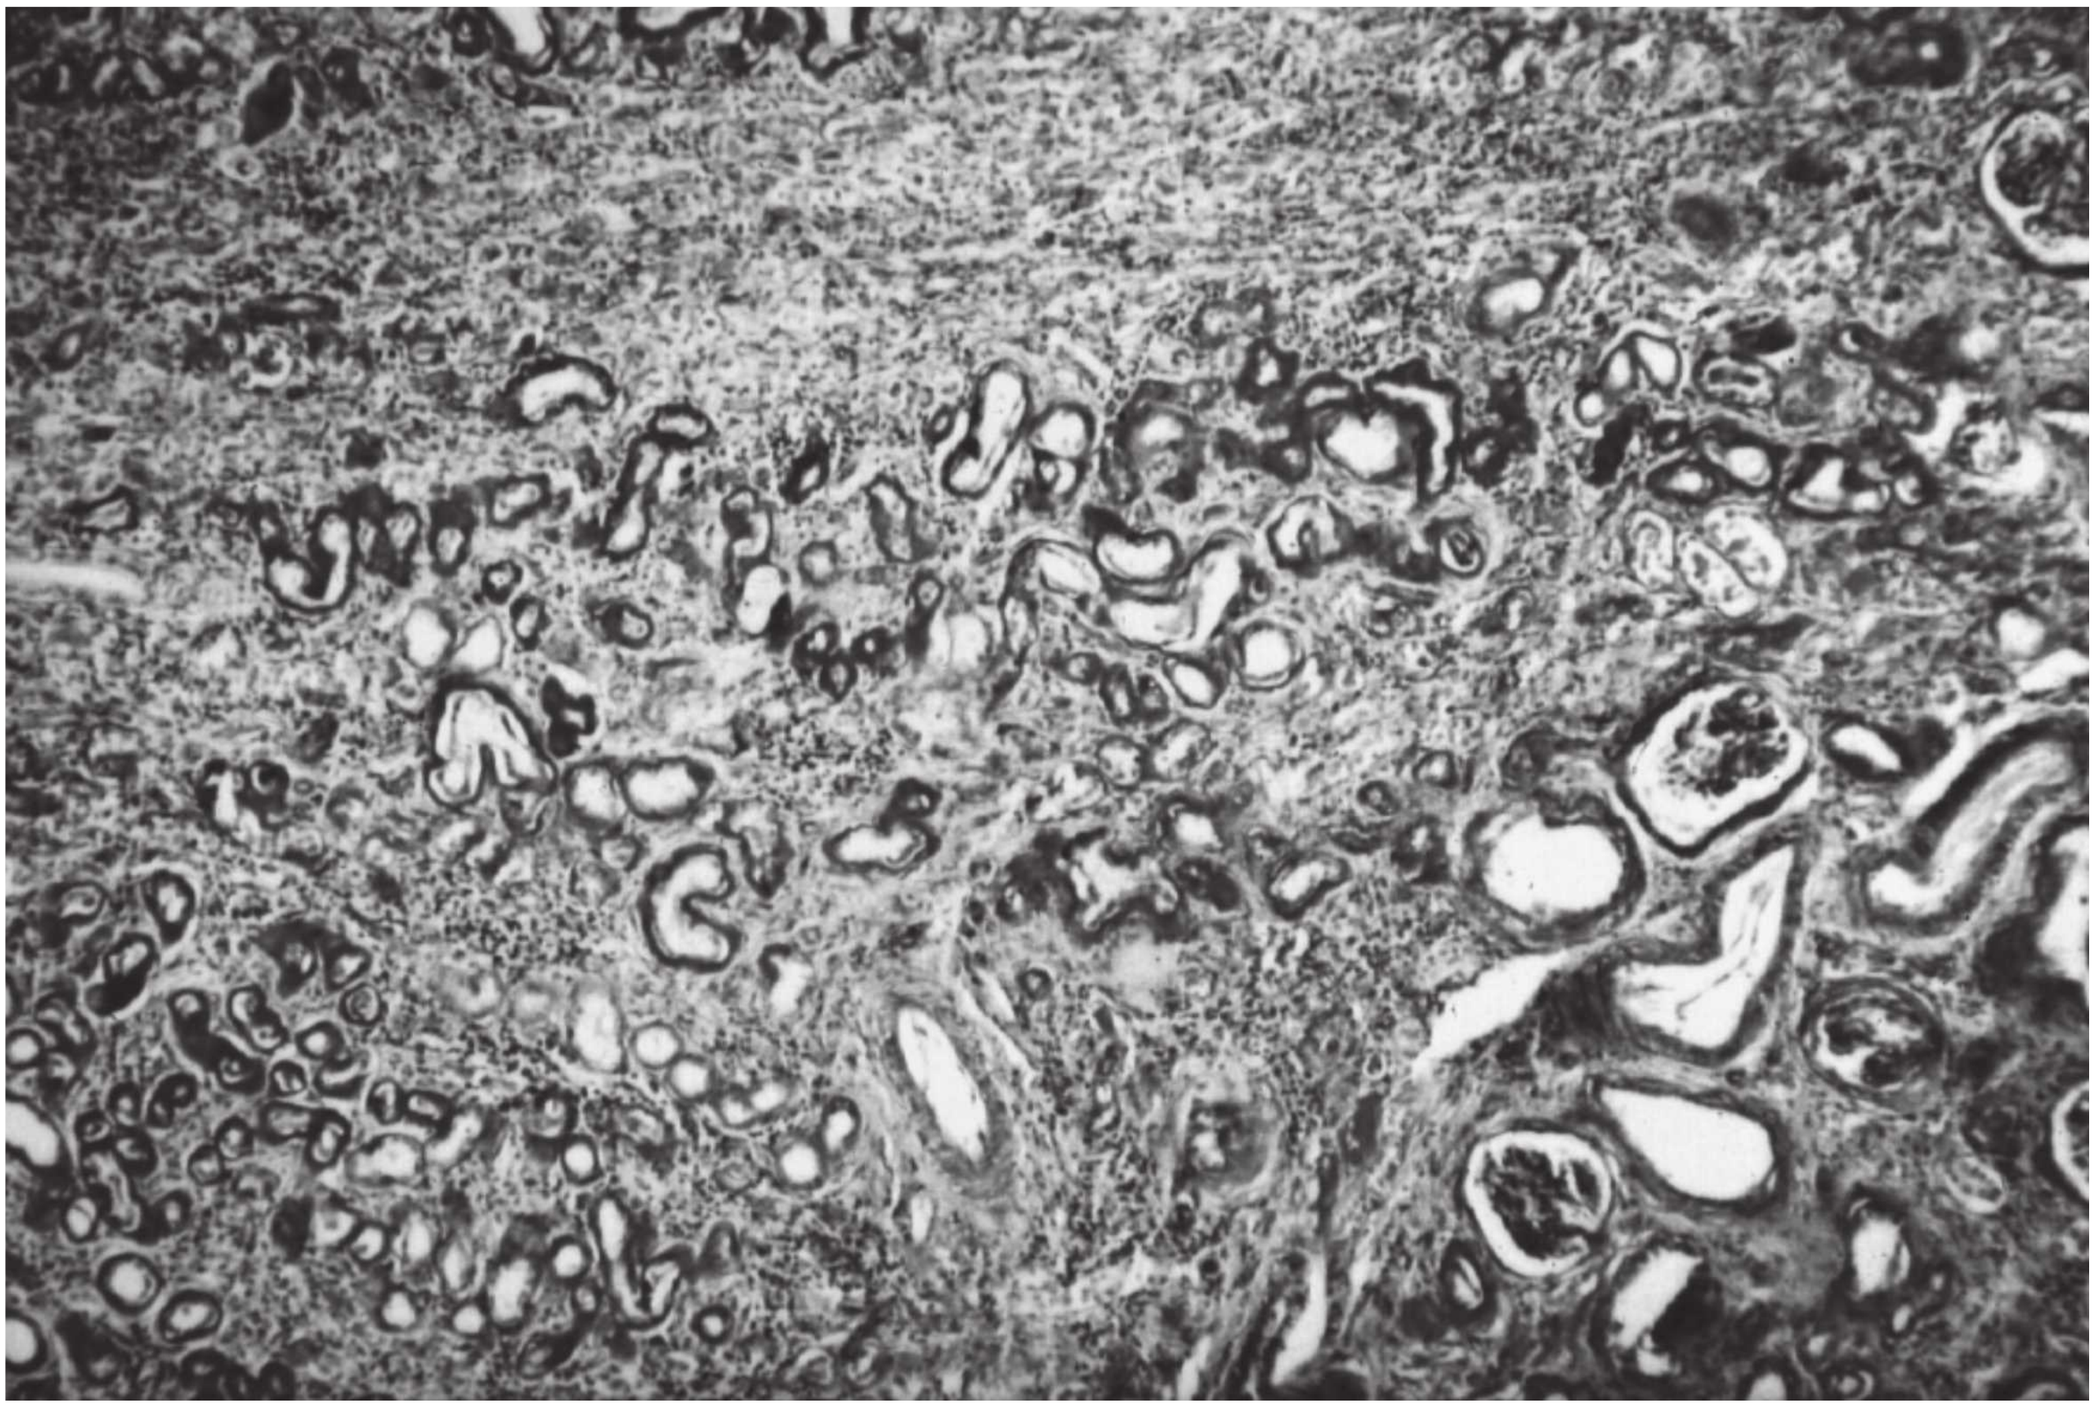

FIGURE 15.2 Renal histology in juvenile nephronophthisis (NPHP1). Note the characteristic triad, which consists of (1) tubular basement membrane disintegration with thickening as well as attenuation of the tubular basement membrane, (2) interstitial round cell infiltration with marked fibrosis, and later on (3) tubular atrophy and cyst development. (Courtesy of Prof. R. Waldherr, Heidelberg, Germany.)

of hyperuricemia and gout in MCKD1[23] and MCKD2.[22] MCKD2 patients with UMOD mutations also may exhibit defects in urine concentrating ability.[24] Recently, an extensive study on genotype–phenotype correlations in mutation of NPHP genes has been published.[25] NPHP1 can occur in combination with ocular motor apraxia Cogan type,[26,27] with retinitis pigmentosa in Senior-Løken syndrome (SLSN),[20] with liver fibrosis[28] with cone-shaped epiphyses in Mainzer-Saldino syndrome,[29] and with coloboma of the optic nerve and cerebellar vermis aplasia in Joubert syndrome type B (JBTSB) (Tables 15.1B[iii] and 15.2).[30] Infantile NPHP (type 2) can be associated with situs inversus[31] and one case report describes a patient with a nonsense inversin mutation with retinitis pigmentosa.[32] NPHP4 patients may have retinitis pigmentosa (SLSN) and Cogan syndrome.[33] NPHP5 patients display early onset retinitis pigmentosa (SLSN) in all known cases.[20] NPHP6 and NPHP8 patients have SLSN, Joubert syndrome, or Meckel-Gruber syndrome (MKS).[25,34,35] NPHP9 is associated with SLSN.[36] NPHP10 patients display SLSN and Bardet-Biedl syndrome (BBS)-like phenotypes,[37] whereas patients with NPHP11 show JBTS, MKS, and liver fibrosis.[38,39] NPHP12 patients exhibit Jeune asphyxiating thoracic dystrophy.[40]

Epidemiology

NPHP and dominant MCKD seem to be distributed evenly among males and females. NPHP has been reported from virtually all regions of the world.[41] Information on the incidence of the disease has been estimated at 9 patients per 8.3 million[42] in the United States or 1 in 50,000 live births in Canada.[1,43] The condition constitutes the most frequent genetic cause for ESRD in the first 3 decades of life and is a major cause of ESRD in children, accounting for 10% to 25% of these patients.[41,44,45] In contrast, in the North American pediatric ESRD population, pooled data indicate a prevalence of less than 5%.[46,47]

MCKD has initially been reported in the United States.[10] Its prevalence in Europe might have been underestimated because recently, kindred have been reported from Cyprus,[23] Italy,[22,48] France,[49] England, Finland,[50,51] Belgium, Czech Republic,[52] and Germany.[53,54] The diagnosis of MCKD may be frequently missed because clinical symptoms and signs are subtle.[55]

MOLECULAR GENETICS OF THE NEPHRONOPHTHISIS-MEDULLARY CYSTIC KIDNEY DISEASE COMPLEX

Classification of disease variants of the NPHP-MCKD complex has recently become more definite through the identification of distinct genes for the different variants. The disease complex is genetically very heterogeneous. Aspects of disease nomenclature, known genes, and extrarenal involvement within the NPHP-MCKD complex are summarized in Table 15.2.

Recessive Disease Variants: Nephronophthisis

Within recessive variants of the NPHP-MCKD complex, the different forms are distinguished on the basis of the mutated gene. To date, thirteen distinct genes (NPHP1–12, NPHPL1) have been identified by positional cloning and massively parallel sequencing.

Nephronophthisis Type 1 (Juvenile Nephronophthisis): Clinical Features

The first case of juvenile nephronophthisis was described by Smith and Graham[56] in 1945. This report of a sporadic case was followed by the publication of two large kindred with familial disease by Fanconi et al.,[57] who introduced the term familial juvenile nephronophthisis. This disease variant is now classified as nephronophthisis type 1 (NPHP1). Since the first description, over 300 cases of NPHP have been published in the literature.[2] NPHP1 is the most common variant within the NPHP-MCKD complex. Penetrance of recessive mutations is 100% by adolescence.

In juvenile NPHP, the symptoms of polyuria, polydipsia, decreased urinary concentrating ability, and secondary enuresis are the earliest presenting symptoms in over 80% of cases[41] and occur at around 4 to 6 years of age. Pallor, weakness, and generalized pruritus are also common. Anemia[51] and, in children, growth retardation occur later and are pronounced. In juvenile NPHP, children usually start to drink regularly at nighttime around age 6 years. This characteristic symptom should actively be sought when taking the patient's history. The mild nature of symptoms, together with a frequent lack of edema, hypertension, and urinary tract infections, characteristically leads to delayed diagnosis and therapy in NPHP-MCKD. Due to the late detection of symptoms, there is a small but definite risk of sudden death from fluid and electrolyte imbalance. For NPHP1, definite molecular genetic diagnosis is possible (see the text that follows). Disease recurrence has never been reported in kidneys transplanted to NPHP patients.[9]

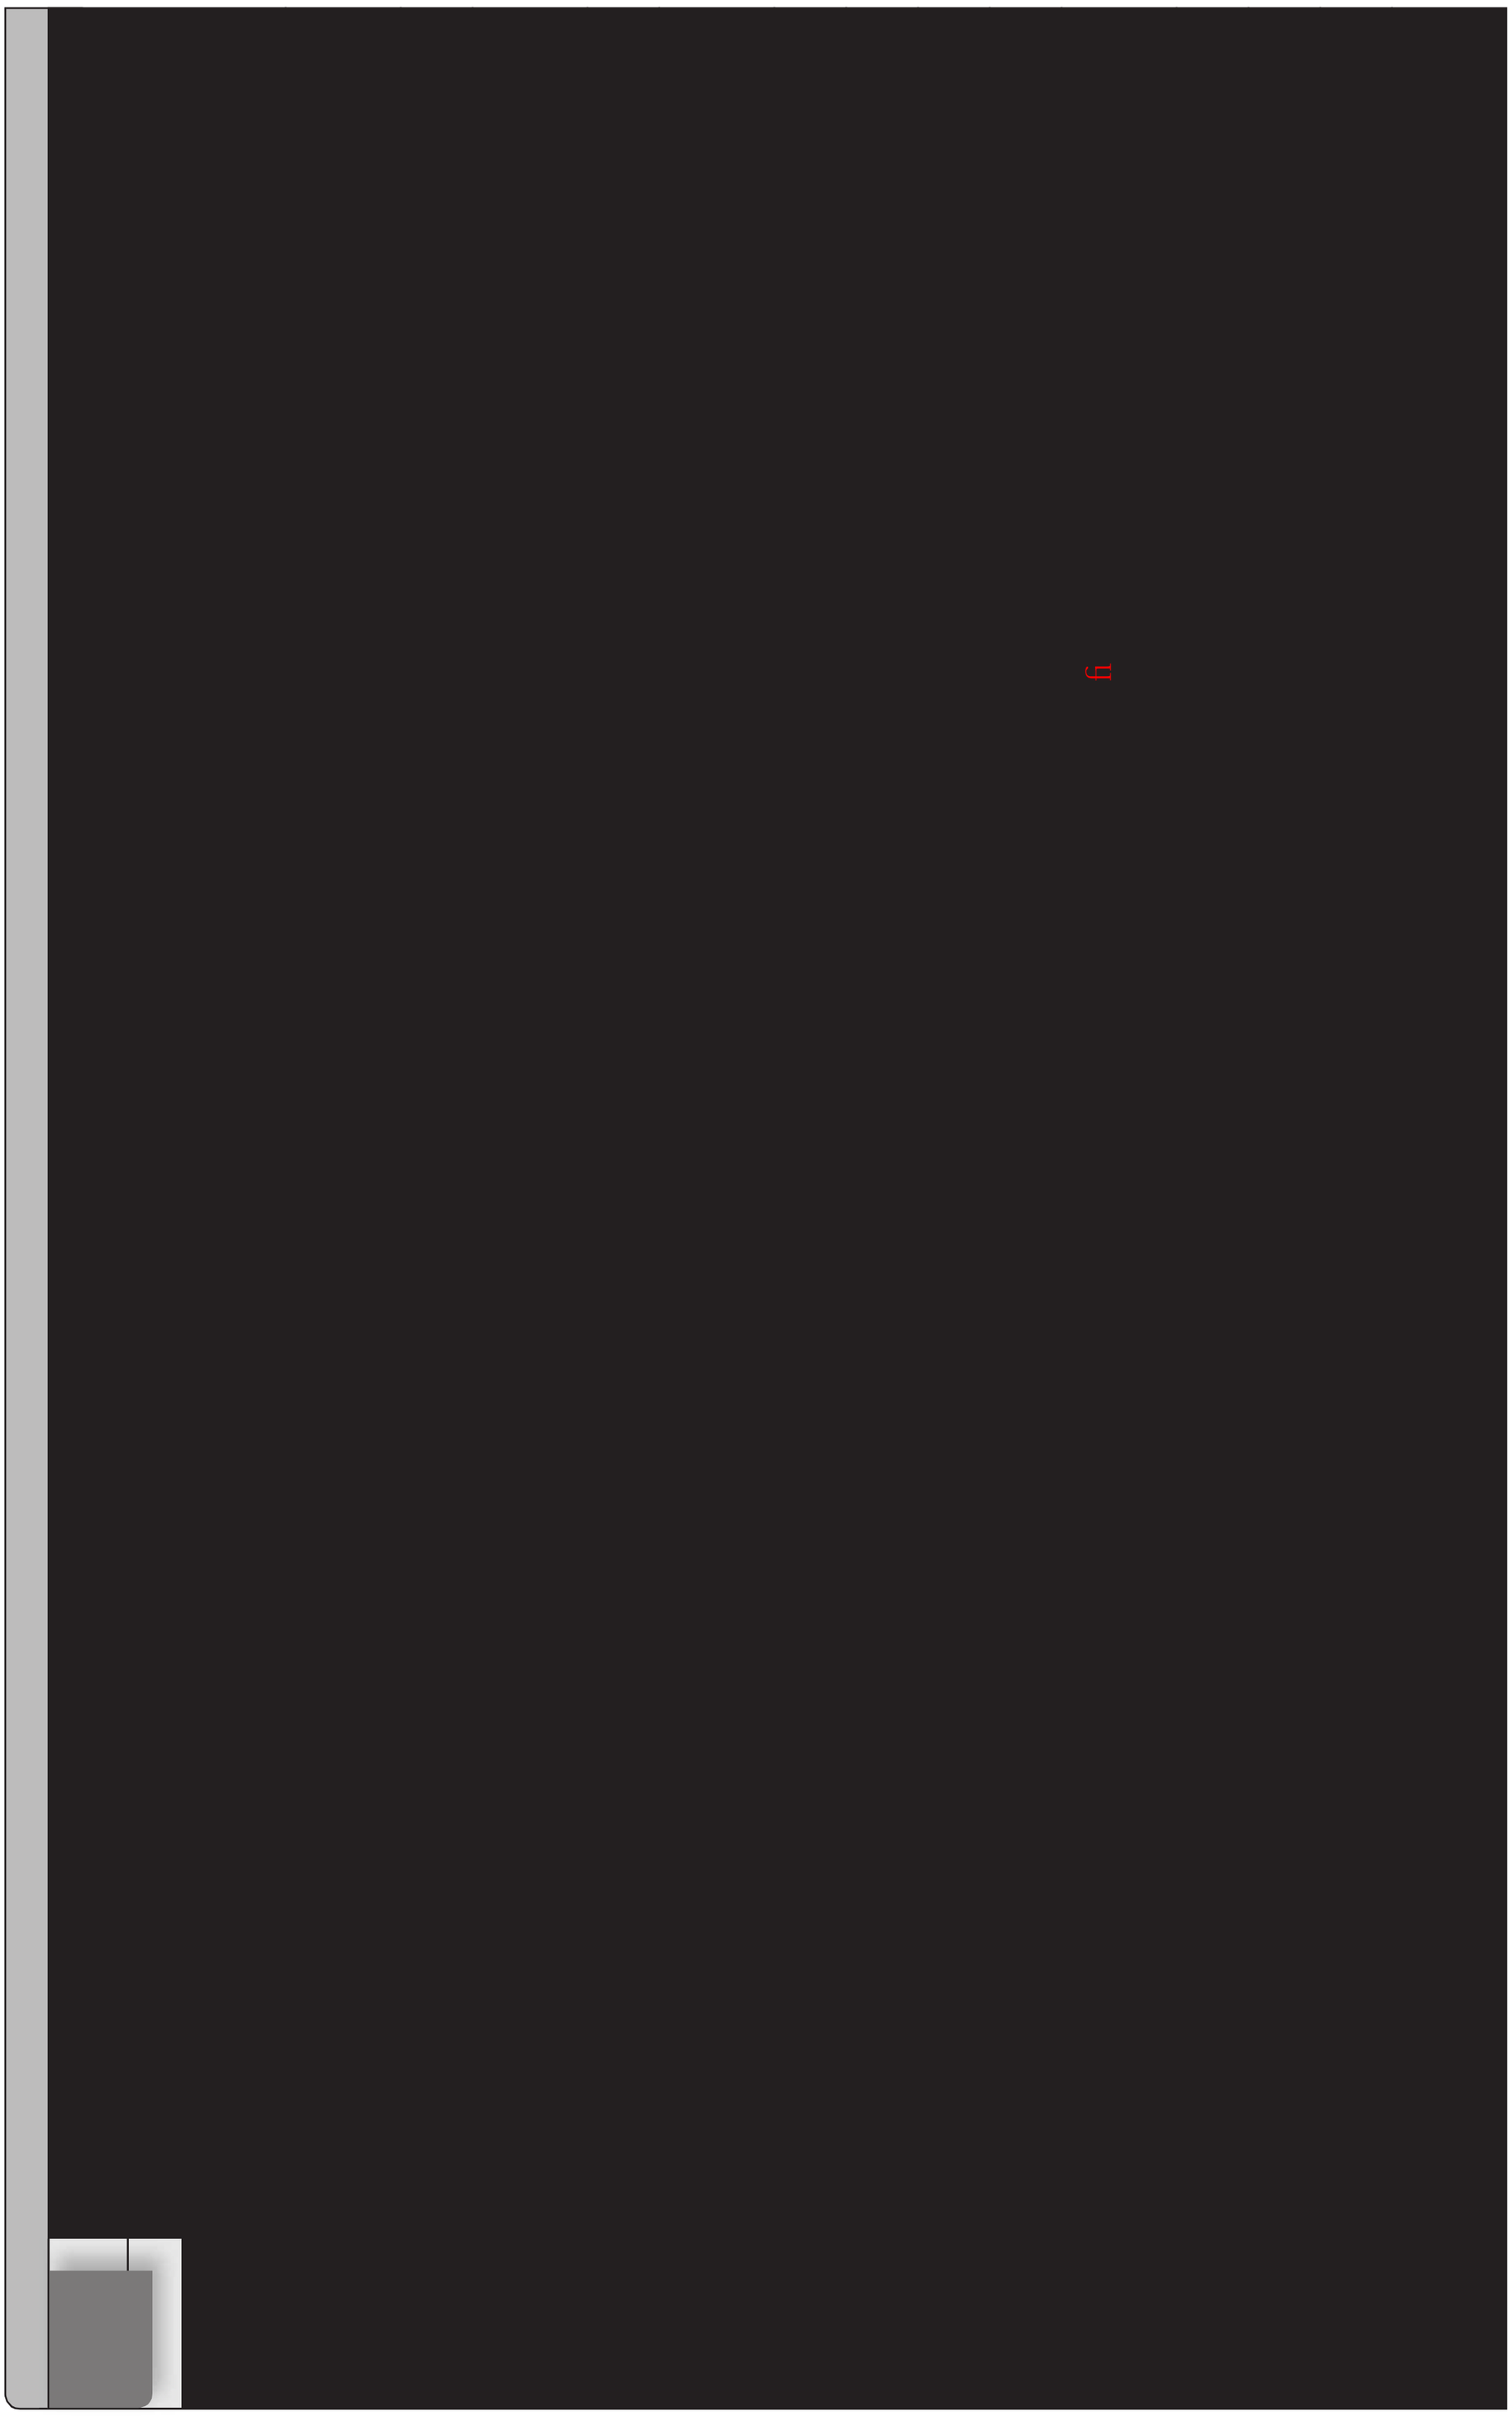
Nephronophthisis Type 1: Molecular Genetics

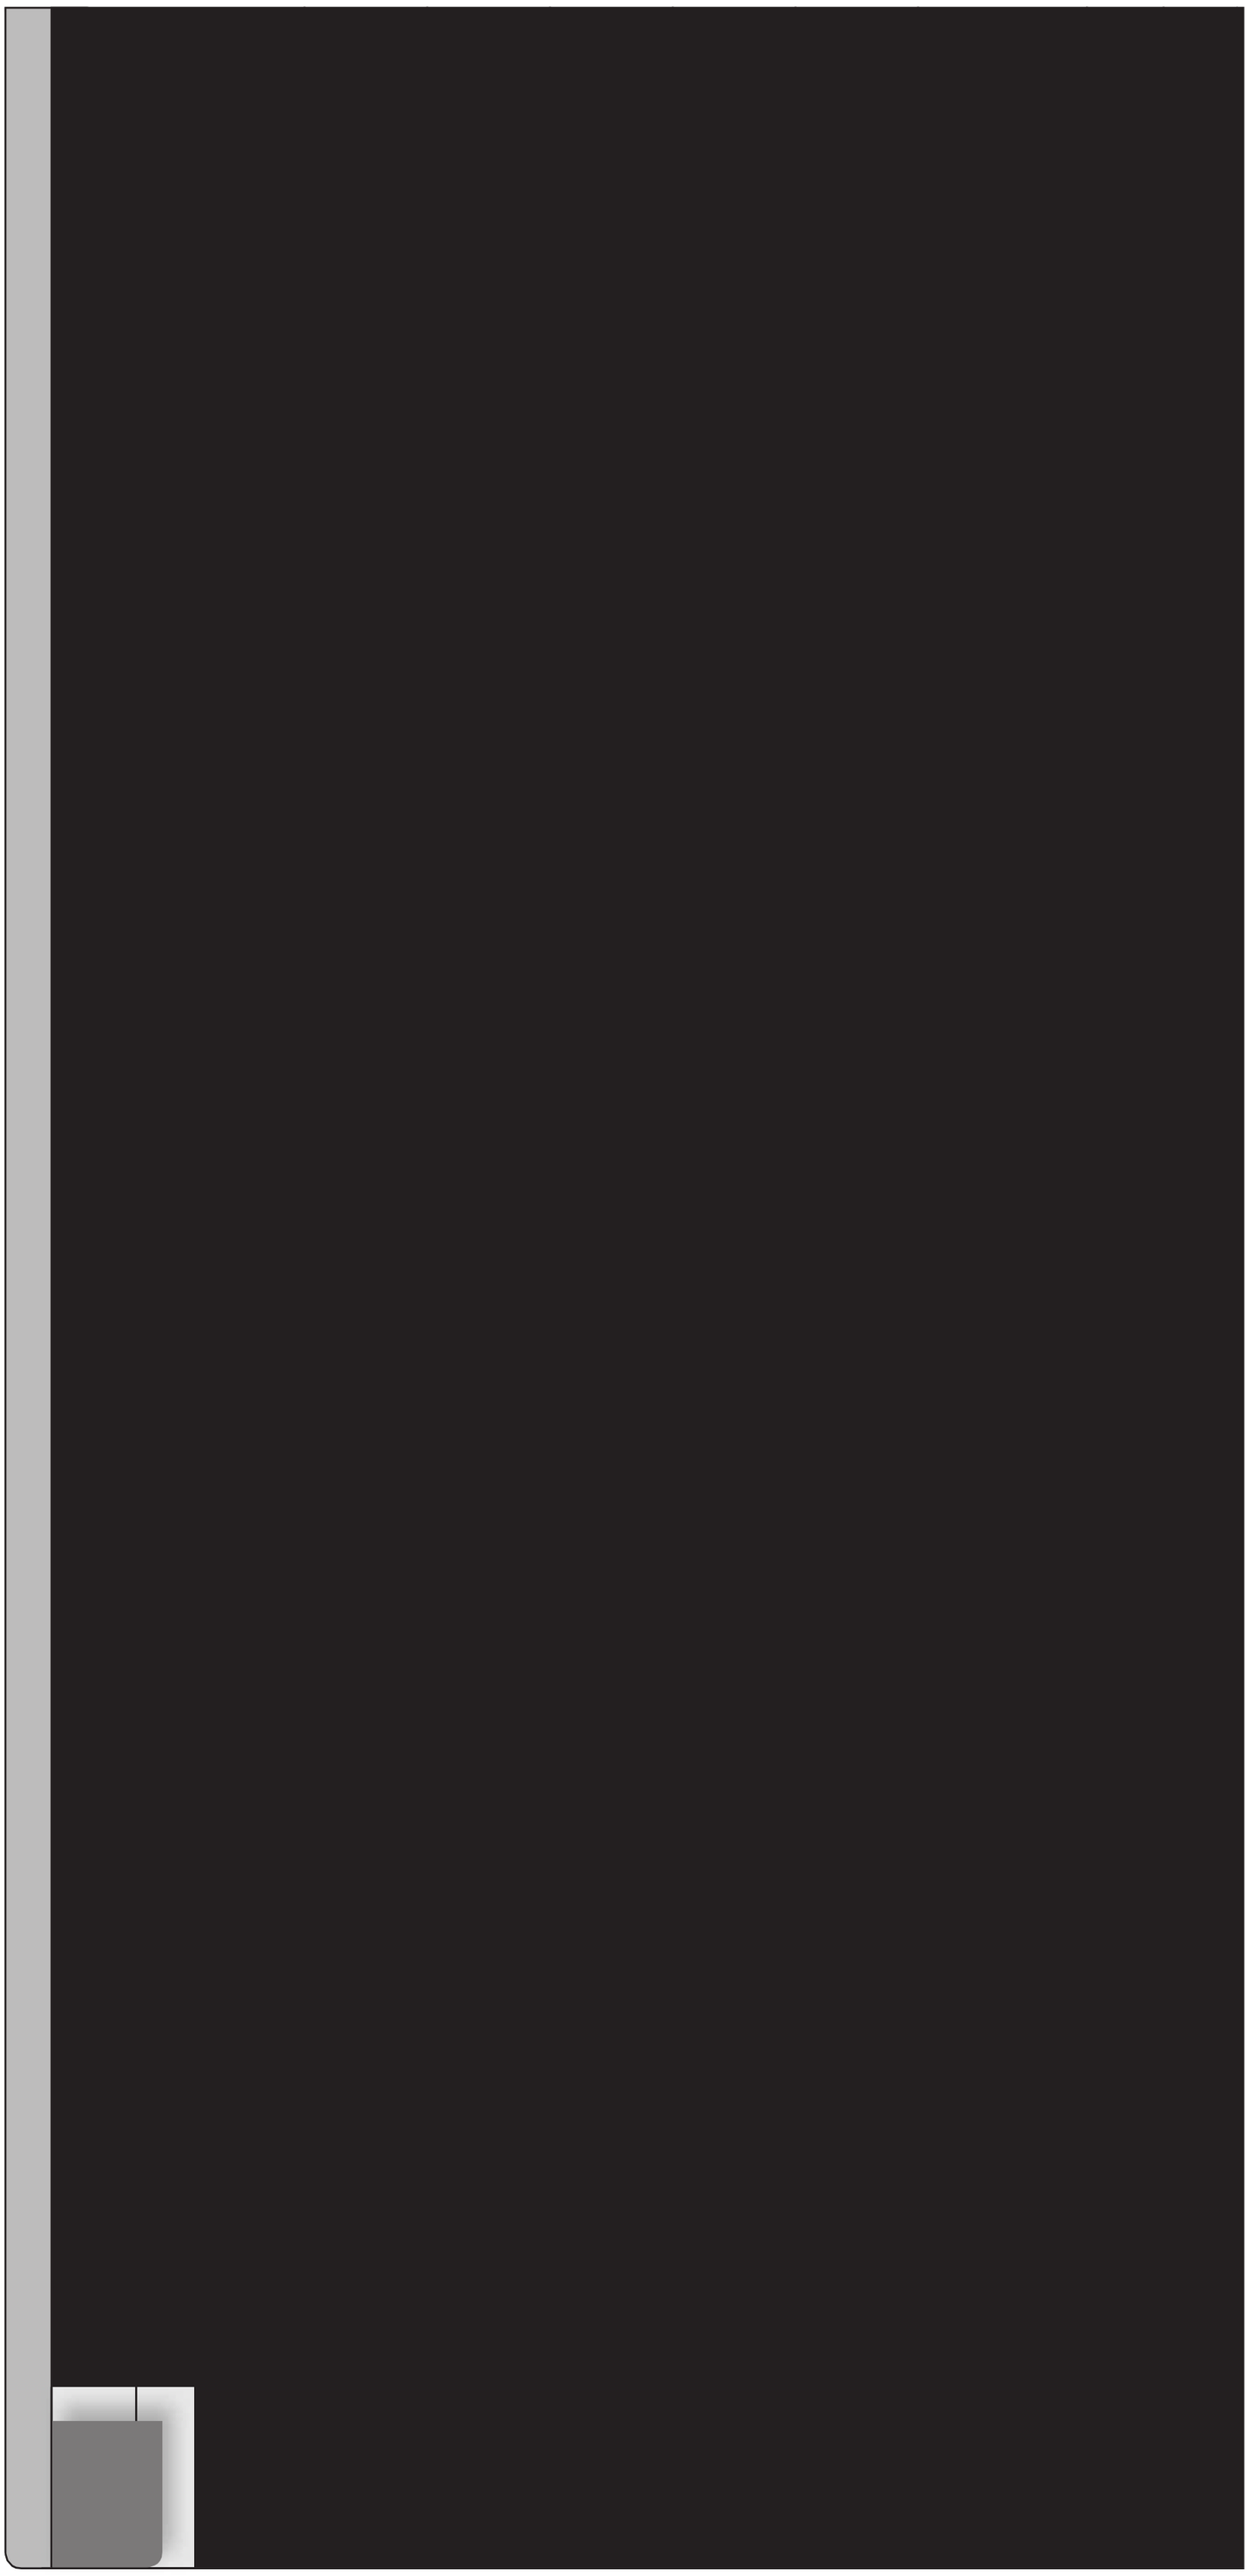
Because little was known about the pathogenesis of NPHP, a positional cloning approach was used for gene identification. By total genome search for linkage, a gene locus for juvenile NPHP1 was mapped to human chromosome 2q12-q13.[58,59] The critical genetic region was subsequently cloned in yeast artificial chromosome (YAC) and P1-derived artificial chromosome (PAC) contigs, which led to the identification of the NPHP1 gene, defects in which are responsible for NPHP1.[60,61] About 66% of children with juvenile NPHP harbor large (250 kb) homozygous deletions of the NPHP1 gene, whereas some carry point mutations in combination with heterozygous deletions.[62–64] Through gene identification, a molecular genetic diagnosis in NPHP1 has become possible (see the text that follows).[64–67]

The NPHP1 gene spans 83 kb, consists of 20 exons, and encodes an mRNA of 4.5 kb. It is flanked by two large (330 kb) inverted duplications. In addition, a second sequence of 45 kb, which is located between the centromeric inverted duplication and the NPHP1 gene, is repeated directly within the telomeric inverted duplication. In several NPHP1 families, the deletion break points have been localized to the 45 kb direct repeats using pulsed field gel electrophoresis.[63] Chromosomal misalignment followed by unequal crossing over or the formation of a loop structure on a single chromosome has been suggested as a potential cause for these deletions. In addition, there is a high degree of further rearrangements known to occur in this region of chromosome 2.[63] Furthermore, an unusual maternal deletion in a child with NPHP1 molecularly characterized, showing that the centromeric break point occurred within a long interspersed nuclear element-1 (LINE1).[68] The NPHP1 gene is a novel gene, which is not related to any known gene families. Expression studies in humans and mice revealed a broad tissue expression pattern. In addition, in situ hybridization studies of whole mount mouse embryos showed ubiquitous but weak Nphp1 expression at all embryonic stages between days 7.5 and 11.5 postconception.[69] In the adult mice, there was also a strong expression in testes.

Nephronophthisis Type 2

A second gene locus (NPHP2) for recessive NPHP has been localized to chromosome 9q31.1 in a large Bedouin pedigree by homozygosity mapping (Table 15.2).[14] This disease variant is termed infantile nephronophthisis (NPHP2) due to its prenatal, perinatal, or infantile onset. The clinical course and histology in this disease are quite different from other forms of NPHP.[70] The inv mouse model, in which a disruption of the protein inversin led to a consistent reversal of the left–right body axis,[71] was noted to have cystic kidney disease.[72,73] These observations led to the identification of inversin (INVS) as the gene mutated in NPHP2 with and without situs inversus.[31] INVS encodes a 1,062 amino acid protein containing 16 ankyrin repeats, a nuclear localization signal, and an IQ calmodulin domain.[74] Yeast two-hybrid and coimmunoprecipitation experiments have confirmed the interaction between inversin and calmodulin. By a knockdown of inversin expression in zebra fish, a polycystic kidney disease (PKD)-like phenotype in addition to a randomization of heart looping was observed.[31]





Inversin localizes to primary cilia, mitotic spindles, and centrosomes[74] and is intimately associated with the microtubule cytoskeleton.[75] INVS/NPHP2 mutations remain a rare cause of NPHP, accounting for <1% of cases.

Nephronophthisis Type 3

A third locus (NPHP3) for NPHP was mapped to chromosome 3q22.1 in a large Venezuelan kindred by a total genome search for linkage by applying the strategy of homozygosity mapping (Table 15.2).[13,76,77] This disease variant was termed adolescent nephronophthisis (NPHP3) because the onset of ESRD occurs 6 years later than in juvenile NPHP1, with a median onset of terminal renal failure occurring at age 19 years (Fig. 15.4).

Identification of the gene NPHP3, which causes adolescent NPHP, was carried out in the same Venezuelan kindred.[78] The novel NPHP3 protein interacts with nephrocystin-1. NPHP3 mutations were found in patients with isolated MPHP and in families with NPHP and hepatic fibrosis or tapetoretinal degeneration. Murine Nphp3 was shown to be expressed in the embryonic node, kidney tubules, retina, respiratory epithelium, liver, biliary tract, and neural tissues. A homozygous missense mutation in Nphp3 was identified as the underlying defect in the polycystic kidney disease (pcy) mouse phenotype.[78]

Nephronophthisis Type 4

By a total genome search for linkage, a fourth gene locus (NPHP4) was localized to chromosome 1p36,[79] including a family with SLSN. The respective gene (NPHP4) was subsequently identified as causing NPHP type 4 and SLSN type 4.[19,33] The gene and its gene product, nephroretinin/nephrocystin-4, are highly conserved in evolution. Nephrocystin-4 protein expression has been demonstrated in primary cilia, centrosomes, and near the cortical actin cytoskeleton, showing partial colocalization with β-catenin in polarized MDCK cells.[33] Co-immunoprecipitation experiments showed that nephrocystin, p130Cas, and Pyk2 are in a complex with nephrocystin-4.[33] More recently, it was demonstrated that NPHP4, in conjunction with NPHP1, interacts with the conserved polarity complex PALS1/PATJ/Crb3.[80] This data may reconcile the involvement of the nephrocystin complex of proteins in both, at the adherens junction and at the cilia/centrosomes (Fig. 15.5).

Nephronophthisis Type 5

NPHP5 (ICQB1) is a novel gene, which was identified by positional cloning as a cause of NPHP type 5.[20] All of the mutations found in NPHP5 and its protein product, nephrocystin-5, are the result of truncating mutations. Interestingly, all mutations were associated with the presence of early onset SLSN/retinitis pigmentosa where blindness occurred before the third year of life.[20] The nephrocystin-5 protein directly interacts with calmodulin and is in a protein complex with the retinitis pigmentosa GTPase regulator (RPGR), thus explaining the renal–retinal phenotype of the disease.

Nephronophthisis Type 6

By positional cloning, mutations in NPHP6 (CEP290) were identified as causing NPHP type 6.[81,82] Patients with truncating NPHP6 mutations displayed JBTS phenotype (JBTS6), whereas missense mutations caused SLSN. NPHP6 was shown to regulate the activity of the cAMP-regulated transcription factor CREB2/ATF4, suggesting that the loss of NPHP6 function leads to aberrant gene expression that may contribute to disease progression in NPHP6.[81] A direct interaction between NPHP5 and NPHP6 was demonstrated in zebra fish, where the depletion of either gene led to almost identical phenotypes.[83]

Nephronophthisis Type 7

Mutations in NPHP7 (GLIS2) have been identified in a single family as causing NPHP type 7.[84] GLIS2 is a transcription factor that negatively regulates the Sonic hedgehog pathway mediator GLI1 transcriptional activity by binding to GLI-binding sites.[85] NPHP7 activity is required in the adult kidney to suppress the Shh pathway activation. Loss of Nphp7 leads to the inactivation of the Snail and Wnt4 genes, which in turn initiates tubular dedifferentiation and epithelial-to-mesenchymal transition in the kidney, resulting in intestinal fibrosis.[86] NPHP7, together with NPHP6, is the second NPHP gene that is implicated in gene expression and regulation.

Nephronophthisis Type 8

Mutations in NPHP8 (RPGRIP-like 1, [RPGRIPL1]) were shown to cause NPHP type 8 in cerebello-oculo-renal syndrome (Joubert syndrome type B) and Meckel-Gruber syndrome.[35,87,88] Mutations in NPHP8 cause a wide range of phenotypes.[25]

Nephronophthisis Type 9

Homozygous mutations in NPHP9 (never in mitosis A-related kinase 8 [NEK8]) were shown to cause NPHP type 9.[36] NEK8 interacts and colocalizes with NPHP2/INV and NPHP3 to the proximal segment of the primary cilia.[89] The interaction of NEK8 with the autosomal dominant polycystic kidney disease (ADPKD) protein PKD2 suggests that NEK8 may regulate both the expression and posttranslational modification (phosphorylation) of both PKD1 and PKD2.[90]

Nephronophthisis Type 10

Mutations in the NPHP10 (SDCCAG8) gene were recently identified by candidate exome capture and massively parallel sequencing as causing NPHP type 10.[37] All patients carried two truncating mutations and developed juvenile NPHP with associated retinitis pigmentosa (SLSN). Interestingly, some patients presented Bardet-Biedl syndrome-like features, including obesity and hypogonadism.[37]

Nephronophthisis Type 11

Homozygous and compound heterozygous missense mutations in the NPHP11 (transmembrane protein 67 [TMEM67/MKS3]) gene were shown to cause NPHP type 11.[39] Similar

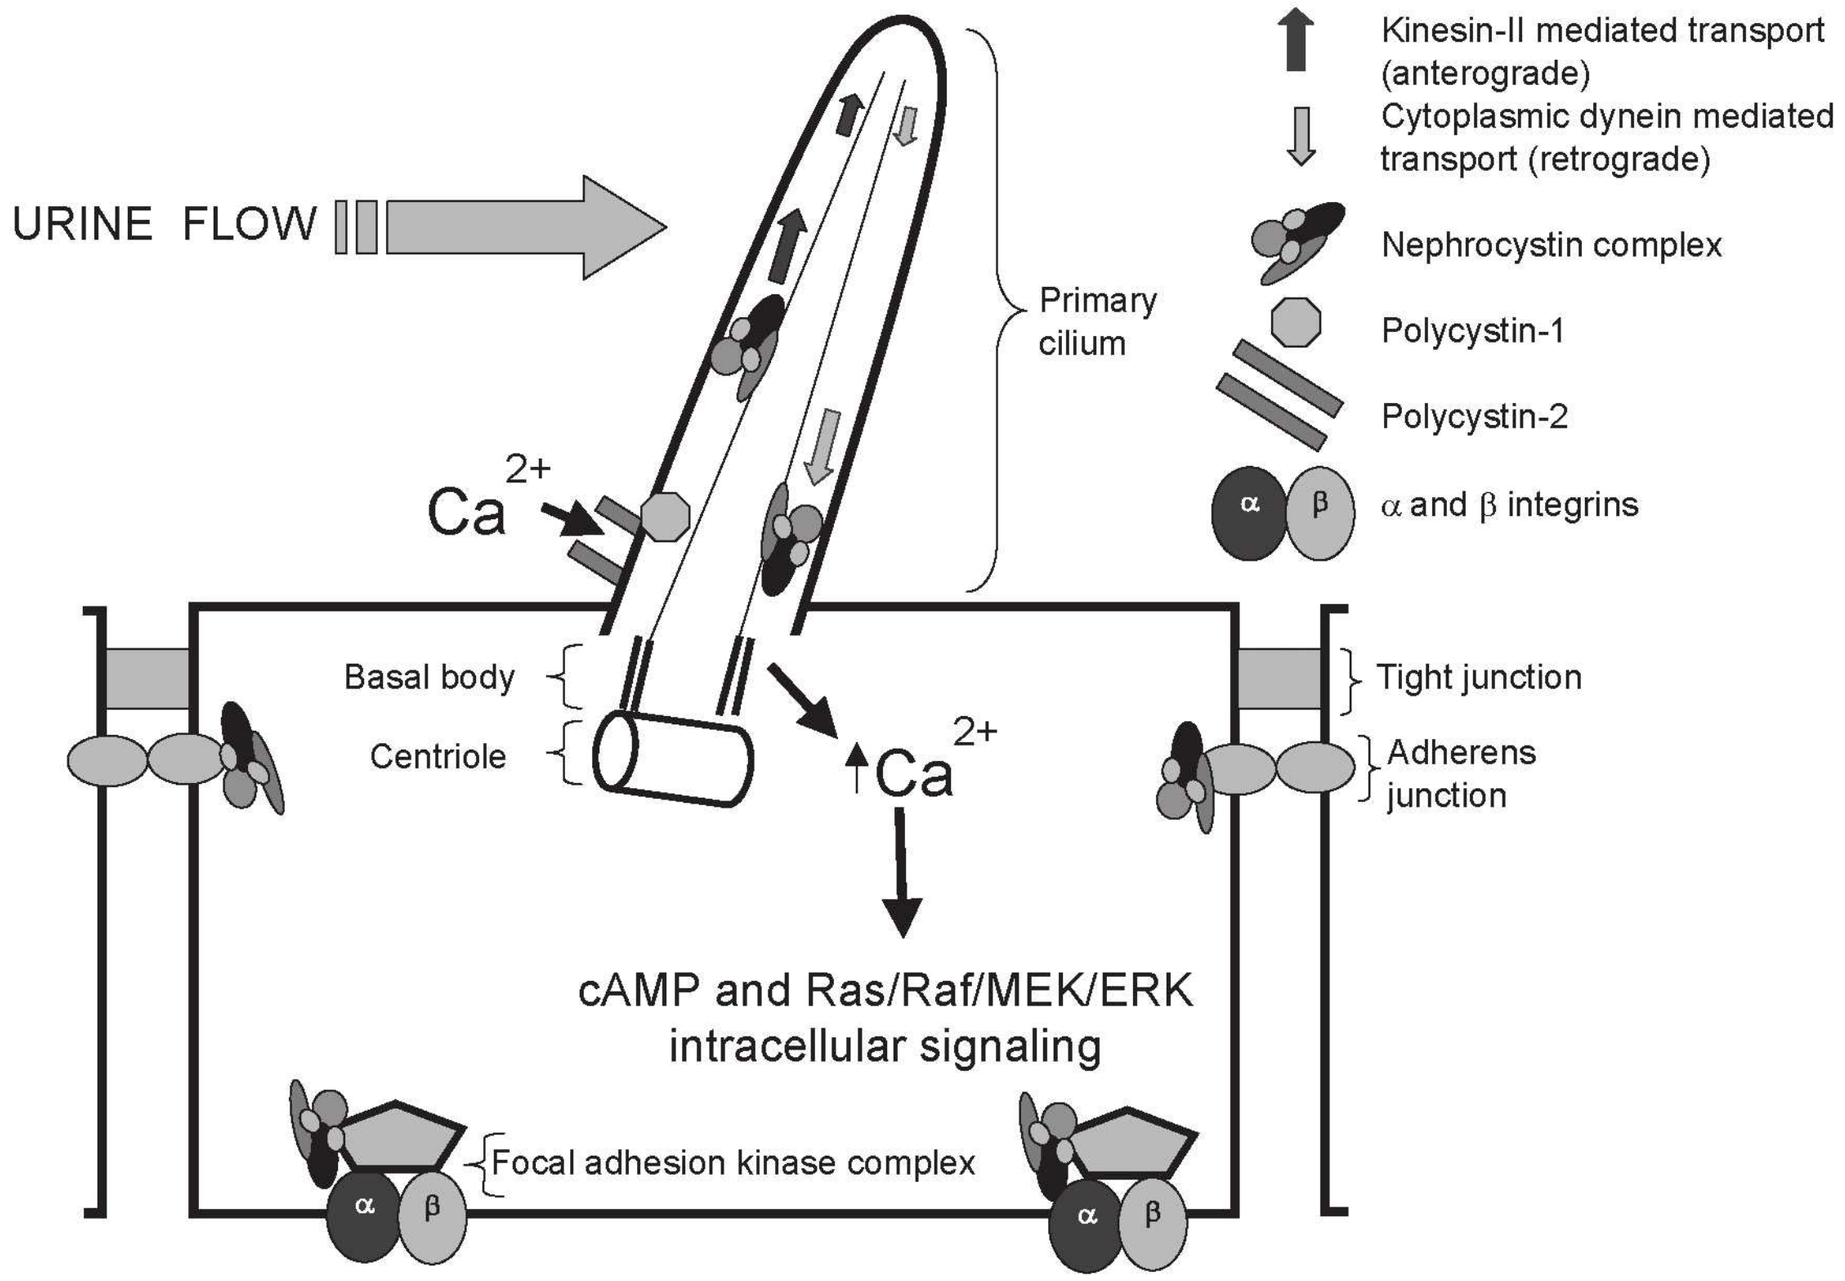


FIGURE 15.5 Localization of the nephrocystin complex to the renal epithelial cell primary cilium, the adherens junction, the focal adhesions, and the microtubule organizing centers (centrosomes). A primary renal cilium is shown bending as a result of urinary flow. Fluid shear forces lead to an increase in intracellular calcium, mediated by calcium permanent channels, such as polycystin-2, localized to the surface of the cilia. This initial calcium influx may lead to multiple downstream effects including calcium-induced calcium release, targeted fusion of cytoplasmic vesicles with the plasma membrane, protein kinase signaling cascades, and gene expression, which may modulate cellular proliferation, differentiation, and apoptosis. (Modified from Nauli SM, et al. Polycystins 1 and 2 mediate mechanosensation in the primary cilium of kidney cells. *Nat Genet* 2003;33:129; and Praetorius HA, Spring KR. Bending the MDCK cell primary cilium increases intracellular calcium. *J Membr Biol* 2001;184:71.) Nephrocystin complexes are shown within the cilium, where they are moved up the cilium by intraflagellar transport protein complexes (kinesin-II) and down via the cytoplasmic dynein. The precise function of the nephrocystin complex within the cilium remains to be established. In addition to the cilium, inversin and nephrocystins have been localized to the adherens junctions, the centrosomes, and the nucleus (not shown). Nephrocystin complexes are also shown localized to the focal adhesion kinase complex, which includes proteins, such as pyk2 and p130Cas, and binding partners of nephrocystin-1 and nephrocystin-4. (Modified from Mollet G, et al. Characterization of the nephrocystin/nephrocystin-4 complex and subcellular localization of nephrocystin-4 to primary cilia and centrosomes. *Hum Mol Genet* 2005;14:645; and Benzing T, et al. Nephrocystin interacts with Pyk2, p130 (Cas), and tensin and triggers phosphorylation of Pyk2. *Proc Natl Acad Sci USA* 2001;98:9784.) Cell adhesion signaling events and polarity may be regulated by the nephrocystin complex at this location.

to NPHP3, NPHP6, and NPHP8, mutations in NPHP11 can cause a syndromic ciliopathy, with phenotypes ranging from SLSN and JBTS to MKS.[91]

Nephronophthisis Type 12

NPHP12 (tetratricopeptide repeat domain 21B [TTC21B]) is a novel gene that has very recently been identified as the cause of NPHP type 12.[40] Because mutations in NPHP12 were identified in 5% of other ciliopathy cases, it was suggested that NPHP12 mutations may have a role as genetic modifier mutations in ciliopathies.[40]

Nephronophthisis-like 1

Mutations in the XPNEPEP3 (X-prolyl aminopeptidase 3) gene were shown to cause an NPHP-like 1 (NPHPL-1) nephropathy.[92] Unlike other NPHP proteins, the NPHPL-1 gene product does not localize to the primary cilia or centrosomes. Instead, the enzyme XPNPEP3 harbors a mitochondrial leader sequence and localizes to mitochondria.[92] Possible involvement of NPHPL-1 in ciliary function is suggested by the presence of putative XPNPEP target sequences on several centrosomal proteins, including NPHP6/CEP290.[92]

Nephronophthisis with Extrarenal Associations

With the exception of the occurrence of hyperuricemia and gout in MCKD, extrarenal disease manifestations have only been described in recessive forms of nephronophthisis (Tables 15.1B and 15.2). Ocular motor apraxia Cogan type is a transient inability of horizontal eye movements occurring in the first few years of life. This has been described in patients with mutations in NPHP1[26,27] or NPHP4.[33]

SLSN, represented by a concomitant occurrence of NPHP with retinitis pigmentosa, was first described by Contreras et al.,[93] Senior et al.,[94] and Løken et al.[95] The designation SLSN seems more appropriate than the term retinal-renal dysplasia, because both renal and retinal changes are degenerative rather than dysplastic.[96] In NPHP types 1 through 4 retinitis pigmentosa occurs in about 10% of all affected families. In NPHP type 5, all patients exhibited early onset retinitis pigmentosa,[20] whereas in NPHP type 10, nearly all patients display late onset retinitis pigmentosa.[37] Retinitis pigmentosa is diagnosed by its specific findings on an ophthalmoscopy including increased pigment, attenuation of retinal vessels, and pallor of the optic disc, and is coupled with the results of an electroretinography and electrooculography. Retinal degeneration is characterized by a constant and complete extinction of the electroretinogram, which precedes the development of visual and funduscopic signs of retinitis pigmentosa.[97,98] The early onset and the late onset type of SLSN have been distinguished. The early onset type seems to represent a form of a Leber congenital amaurosis because children exhibit coarse nystagmus and/or blindness at birth or within the first 2 years of life.[99] Funduscopic alterations are present in all SLSN patients by the age of 10 years. The late onset form is characterized by the development of blindness during the school age years after a preceding night blindness. Other eye symptoms besides tapetoretinal degeneration include nystagmus, myopia, and coloboma of the choroidea.[57] The age of onset, symptoms, and a histology of renal disease is identical to what is known from patients with juvenile nephronophthisis without ocular involvement.

The association of NPHP with the degenerative phenotype of liver fibrosis was first noted by Boichis et al.,[28] and was later also reported by others.[100–102] All patients had hepatomegaly and moderate portal fibrosis with mild bile duct proliferation. This pattern differs from that of classical congenital hepatic fibrosis, where biliary dysgenesis is prominent. Cases with skeletal changes, predominantly in the form of cone-shaped epiphyses (type 28 and 28A) are known as Mainzer-Saldino syndrome, and were first published by Mainzer et al.[29] in combination with cases of retinal degeneration and cerebellar ataxia. Recessive mutations in the NPHP3, NPHP4, NPHP6, NPHP8, and NPHP11 genes have been described in patients with NPHP and liver degenerative phenotypes[25,78] where NPHP11 mutations seem to be the most frequently associated.[39]

In Joubert syndrome type B (JBTS), a developmental disorder with multiple organ involvement, NPHP occurs in association with coloboma of the eye or retinal degeneration, aplasia of the cerebellar vermis with ataxia, the facultative symptoms of psychomotor retardation, and neonatal tachy/dyspnea.[30,103,104] A diagnostic feature of Joubert syndrome on an axial magnetic resonance imaging (MRI) of the brain is prominent superior cerebellar peduncles, termed the molar tooth sign (MTS).[104] Thirteen genes have now been shown to cause Joubert syndrome. NPHP1 gene defects are a rare cause of Joubert syndrome in a subset of patients with NPHP.[105] Additionally, patients with mutations in NPHP3, NPHP6, NPHP8, NPHP11, and NPHP12 genes display JBTS.[25,35,39,40,81] A homozygous deletion of NPHP1 was found in two siblings and in a third patient with mild features of Joubert syndrome type B. The second gene defect was found in the Abelson Helper Integration Site (AHI1) gene, and its protein product has been termed Jouberin. The Jouberin protein has three known isoforms and possesses a coiled coil domain, at least six WD40 domains, and an SH3 domain. It is thus likely to be part of the nephrocystin complex of proteins. In the initial reports of AHI1 mutations, the phenotype included cerebellar abnormalities, but no renal phenotype was reported. Recently, Jouberin mutations were detected in patients with NPHP and JBTS.[106]

Additional phenotypes have been described in association with NPHP. These include Jeune syndrome (asphyxiating thoracic dysplasia)[107–109]; Meckel-Gruber syndrome[25,35,91]; Ellis van Creveld syndrome[110]; ulcerative colitis[111]; retinitis pigmentosa, hypopituitarism, nephronophthisis, and mild skeletal dysplasia (RHYNS) syndrome[112]; Alstrom syndrome[113]; Sensenbrenner syndrome[114–117]; and Arima syndrome.[118,119]

BBS[120,121] has been reported to exhibit renal histology findings reminiscent of NPHP. Recently, it was shown by using candidate exome capture and massively parallel sequencing that mutations in SDCCAG8/NPHP10 cause BBS-like phenotype (without polydactyly) in NPHP type 10 patients.[37] Gene identification of NPHP genes has revealed that the molecular relation between these diseases may lie in the expression of the respective gene products in primary cilia, basal bodies, or centrosomes of renal epithelial cells.[2]

Animal Models of NPHP

Genetic animal models resembling NPHP have been fruitful in the identification of underlying gene defects, and more recently in the experimental treatment of cystic kidney disease.

The Invs gene, when mutated, gives rise to renal cysts as well as left–right asymmetry, cardiovascular defects, hepatobiliary defects, and premature death in inv/inv knockout mice.[72,122] Collecting ducts of newborn inv/inv mice demonstrate diffuse cystic dilatation.[123] Mutations in INVS give rise to human NPHP type 2, with and without situs inversus. The pcy mouse model[123] demonstrates interstitial fibrosis and cystic kidneys. The underlying defect was shown to be a missense mutation in the Nphp3 gene.[78] Recently, mouse

models of Nphp1,[124] Nphp4,[125] Nphp7/Glis2,[86] and Nphp9/jck[126] have been reported. Unexpectedly, the phenotype of Nphp1$^{-/-}$ mice is relatively mild, affecting only spermatogenesis.[124] Another study, with a different Nphp1 knockout design, uncovered an epistatic relationship between Nphp1 and Ahi in regulating the severity of retinal degeneration phenotype first in mice and then in humans,[127] underlining the strength of the animal models in studying the pathomechanisms of NPHP. Similarly to Nphp1 knockout mice, homozygous mutant Nphp4 mice do not display renal phenotype, but present a severe retinal degeneration and male infertility phenotype.[125] The Nphp7 knockout mouse model has been instrumental in deciphering the underlying molecular defects causing NPHP7 by showing that the derepression of Sonic hedgehog (Shh) signaling in the adult kidney leads to epithelial to mesenchymal transition and, ultimately, interstitial fibrosis—the disease phenotype in NPHP7 patients.[84,86] The juvenile cystic kidney (jck) mouse model has been used extensively as a model for PKD, and its renal phenotype is caused by a recessive missense mutation in the Nphp9 gene.[126] This model has been fruitful for testing different modalities to ameliorate renal cystic disease progression. It was shown that cyst formation in jck mice can be suppressed by treatment with the CDK inhibitor roscovitine[128] or the glycosylceramide synthase inhibitor.[129]

The kd (kidney disease) mouse strain has also been reported as a genetic animal model of NPHP.[130,131] It shares several clinical and histologic[131] features with human NPHP. The mice are born healthy, but by 8 weeks of age, they develop severe interstitial nephritis that progresses to ESRD by 4 to 8 months of age. The defect is caused by a mutation of a gene that encodes a mitochondrial protein, namely prenyltransferaselike mitochondrial protein (PLMP).[132] Kd/kd mice were shown to have dysmorphic mitochondria within renal tubular epithelia.[132] Additional transgenic mouse models for NPHP, such as the tensin knockout mouse,[132] the bcl-2 knockout mouse,[133–135] and the Ace knockout mouse[136] will hopefully aid our understanding of the pathophysiology of NPHP.[137] A canine model of NPHP has also been reported.[31,138–140]

The Pathogenic Hypotheses of Nephronophthisis

The identification of mutations in the inversin gene, which cause NPHP type 2, established a link between the pathogenesis of NPHP to disease mechanisms of PKD.[31] The knockdown of invs in the zebra fish embryo causes a renal cystic phenotype. In addition, the positional cloning of the novel gene NPHP3, mutated in adolescent NPHP (type 3) and in the renal cystic mouse model pcy,[123] confirmed this paradigm. Nephrocystin interacts with both inversin and with b-tubulin, with colocalization of all three proteins in the primary renal cilia of epithelial cells.[74] Inversin was also shown to be localized to mitotic spindles and centrioles.[74] The IQ calmodulin-binding motif containing protein-1 (IQCB1), also known as nephrocystin-5, also reveals a ciliary and basal body colocalization.[20] All NPHP proteins identified so far share the localization to cilia, centrosomes, or the basal body, with the exception of mitochondrial NPHPL1. The finding that such nephrocystins colocalize to primary cilia, basal bodies, or centrioles together with other proteins that, if defective, cause renal cystic diseases, suggests a role within a functional module shared with other proteins (Fig. 15.5). Therefore, recently, a unifying hypothesis of renal cystogenesis has been established, thus characterizing renal cystic diseases as ciliopathies.[141] This hypothesis states that proteins, which, if mutated, cause renal cystic disease in humans, mice, or zebra fish, are part of a functional module, as defined by their subcellular localization to primary cilia, basal bodies, or centrioles.[2] This applies to polycystin-1 and -2, fibrocystin/polyductin, nephrocystin-1, -2 (inversin), -3, -4, -5, BBS-associated proteins, cystin, polaris, ALMS1, oral-facial-digital syndrome type 1 (OFD1), and others. The existence of such functional modules in ciliopathies was recently demonstrated by proteomic studies, showing that NPHP-JBTS-MKS proteins function in distinct modules that are mechanistically connected.[142]

A model of evolutionary conserved proteins involved in cilia has also recently added weight to the "cystogenes" hypothesis. Following identification the NPHP1, 2, and 4 genes, orthologs of these genes in the nematode Caenorhabditis elegans have been identified.[19,60,69] This strong evolutionary conservation of genes that, if defective, cause NPHP in humans, suggests that their products may be part of a functional module conserved in C. elegans. This assumption was also supported by the finding of cell-specific GFP expression under the nephrocystin-1 and -4 promoters in the same cell types of head and tail ciliated neurons, in which the C. elegans orthologs of other renal cyst-causing genes are expressed, such as pkd-1 (lov-1), pkd-2, and polaris (osm 5).[143]

In addition to the ciliary hypothesis, an adherens junction/focal adhesion hypothesis has also been suggested on the basis that nephrocystin-1 contains an SH3 domain.[60,144] This theory is based on the fact that most SH3 domains are found in adapter proteins, which have a function in focal adhesion signaling complexes of cell-matrix contacts.[145,146] Several findings support this hypothesis, such as:

1. Nephrocystin was shown to bind to the protein p130Cas ("crk-associated substrate"),[147–149] which is a major mediator of focal adhesion assembly[145] and to compete for binding with Src and Fyn.[147]
2. In children with NPHP, Rahilly and Fleming[150] described strong $\alpha 5\beta 1$ integrin expression in proximal tubules, from which $\alpha 5$ integrin is normally absent, which most likely results from defective $\alpha 6$ integrin expression. The $\alpha 5\beta 6$ complex is an important receptor for focal adhesion signaling in renal tubular cells.
3. The knockout mouse models for tensin[132] and for the Rho GDIa gene[151] both exhibit an NPHP-like phenotype, thereby implicating proteins of the focal adhesion signal transduction cascade in the pathogenesis of NPHP-like diseases.

Together, these findings may point to a pathogenesis of NPHP, which involves focal adhesion and/or adherens junction signaling processes. Data from Mollet et al.[152] demonstrated, in addition to ciliary and centrosomal localization, that NPHP4 was part of a subplasmalemmal protein complex which included NPHP1, p130Cas, and Pyk2. These data confirm the role of the nephrocystin proteins within both a cilial/centrosomal hypothesis and an adherens junction/focal adhesion hypothesis.

Medullary Cystic Kidney Disease

The first large kindreds of autosomal dominant medullary cystic kidney disease (MCKD) were reported by Goldman and by Gardner.[10,153,154] Dominant MCKD by a renal macroscopic pathology and histology is indistinguishable from recessive NPHP. In MCKD, terminal renal failure develops later than in NPHP, within the seventh decade of life (Fig. 15.4). The only extrarenal associations known to occur with MCKD are hyperuricemia and gouty arthritis, which have been described in the majority of the kindred reported.

Medullary Cystic Kidney Disease Type 1 (MCKD1)

A gene locus for MCKD1 was mapped to chromosome 1q21 in large pedigrees from Cyprus.[21] Further refinement of this locus has been possible using an observed recombinant from within a Belgian kindred,[155] reducing the critical genetic region to 2.1 Mb (Table 15.2). This disease form was associated with hyperuricemia and gout.[23] ESRD occurred at a median age of 62 years (Fig. 15.4).

Medullary Cystic Kidney Disease Type 2 (MCKD2)

A second locus (MCKD2) for medullary cystic kidney disease was localized to chromosome 16p12 (Table15.2).[22,156,157] In this variant, ESRD develops much earlier, at a median age of 32 years (Fig. 15.4). MCKD2 and an autosomal dominant disease formerly known as familial juvenile hyperuricemic nephropathy (FJHN)[158] have been shown to map to the same chromosomal region and suggest that they represent the same disease entity.[159,160] This was confirmed with the identification of mutations within the uromodulin (UMOD) gene in affected patients with phenotypes of FJHN and MCKD2.[161] UMOD encodes the Tamm-Horsfall protein, which is a GPI-anchored glycoprotein and is present abundantly in normal urine. It has been suggested that mutations within UMOD may disrupt the tertiary structure of UMOD.[161] A clustering of UMOD mutations was noted within the highly conserved exon 4 of the encoded sequence of UMOD.[162] An investigation of UMOD mutations in the urine of affected individuals and renal biopsies revealed an abnormal accumulation of uromodulin within tubular cells and reduced urinary excretion of wild-type uromodulin.[163] Glomerulocystic kidney disease (GCKD), characterized by dilatation of the Bowman space and the collapse of the glomerular tuft, is a renal disorder distinct from MCKD/FJHN, although some clinical features are shared. A clinical variant of GCKD demonstrates a reduced fractional excretion of uric acid, resulting in hyperuricemia. A mutation in UMOD was recently described in one family (three patients) with this condition, thus broadening the phenotype associated with UMOM mutations further.[164] Finally, there is evidence for at least one additional locus for MCKD.[53,54]

MOLECULAR GENETIC DIAGNOSIS, IMAGING, AND LABORATORY STUDIES

Molecular Genetic Diagnosis in Nephronophthisis

Nephronophthisis types 1 through 12 can now be unequivocally diagnosed, because direct molecular genetic diagnosis has become available through the identification of the responsible genes (www.renalgenes.org). Molecular genetic analysis is the only diagnostic procedure by which the diagnosis of NPHP can be made with certainty. It should be initiated to noninvasively prove or exclude NPHP before the invasive procedure of renal biopsy is performed. However, due to the presence of additional genes for NPHP, the lack of detection of mutations in NPHP1–12 and NPHPL-1 genes does not exclude the diagnosis of NPHP. In a similar manner, UMOD mutational analysis will allow a precise genetic diagnosis of MCKD2, but a lack of any mutations will not exclude MCKD. Molecular genetic testing should be performed only in the context of genetic counseling and within the guidelines of the National and International Societies for Human Genetics (www.ethics.ubc.ca). Prior to genetic counseling, a thorough pedigree analysis to distinguish recessive (early onset) from dominant (late onset) disease is mandatory, and extrarenal organ involvement should be sought.

Imaging Techniques

Renal ultrasound is a very useful imaging technique in the NPHP-MCKD complex. Kidneys are normal or moderately reduced in size and exhibit, typically, a loss of corticomedullary differentiation and an increased echogenicity. Later in the course of the disease, mostly when patients have reached ESRD, cysts can be detected at the corticomedullary junction (Fig. 15.6).[165–167] Garel and associates[168] have seen medullary cysts in 13 out of 15 children studied at the time of renal failure (mean age: 9.7 years).

Magnetic resonance tomography and computed tomography demonstrate the presence of cysts in MCKD.[169–173] The invasive procedure of renal arteriography is not indicated to demonstrate the presence of medullary cysts,[174] and caution must be exercised when performing contrast studies in patients with renal failure.

Laboratory Studies and Urinary Concentrating Ability

Besides a molecular genetic diagnosis of NPHP1-12, NPHPL-1, and UMOD, there are no chemical laboratory tests in

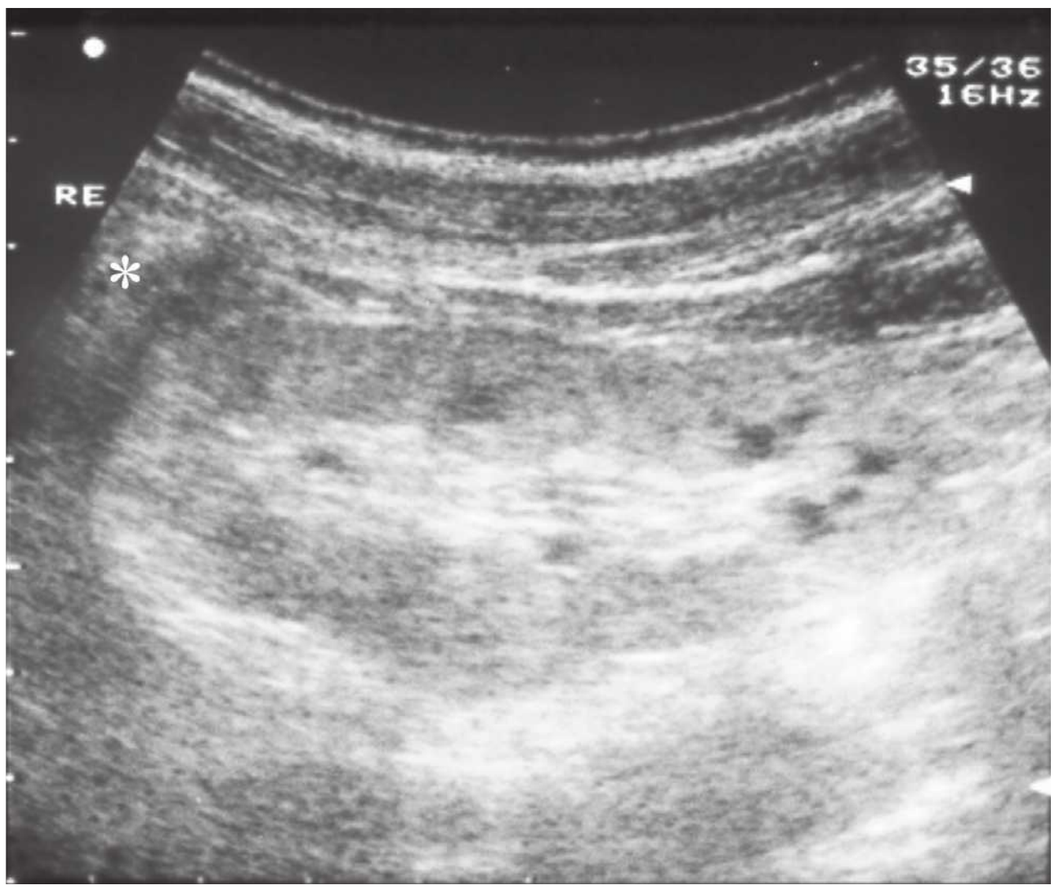

FIGURE 15.6 Characteristic renal ultrasound findings in juvenile nephronophthisis (NPHP1). Note the normal kidney size, the loss of corticomedullary differentiation, and the increased echogenicity, which renders the pattern of the kidney similar to that of the liver (*), together with the presence of cysts at the corticomedullary border of the kidney. (Courtesy of Prof. J. Dippel, Frankfurt, Germany.)

the NPHP-MCKD complex that specifically establish the diagnosis. Hematuria, proteinuria, and bacteriuria are typically absent in NPHP. In rare cases where proteinuria is present, it is usually mild and of the tubular type. Laboratory studies are needed to assess the severity of renal failure and generally demonstrate elevated serum creatinine, blood urea nitrogen (BUN), phosphorus, a metabolic acidosis, and anemia at the characteristic ages of the onset of ESRD for the different disease entities. Ophthalmoscopy should be performed in any patient to exclude SLSN. Liver function and hepatic ultrasonography should also be performed to facilitate the detection of patients with hepatic fibrosis.

A characteristic early finding in NPHP is the decreased ability to concentrate the urine following a water deprivation test.[41] An impairment of tubular function, with the constant finding of a renal concentration defect, usually precedes any documentable reduction in the glomerular filtration rate[10] and may be present with minimal histologic abnormalities.[175]

An intermediate defect of urinary concentration ability has been inconsistently demonstrated in the parents and some siblings of children with NPHP, and has been suggested to reflect the heterozygous state of the disease.[176] An 8-hour water deprivation test or vasopressin administration can be used to demonstrate a tubular concentration defect. Such tests should be performed with caution because dehydration may precipitate acute renal failure in patients with the disease or in unrecognized affected family members. In affected individuals, urine osmolality after 8 hours of water deprivation or vasopressin administration is $<$800 mOsm per kilogram of water. The diseases of the complex have also become known as salt losing nephritis. Poor renal uptake of 99^{m}-technetium-DMSA has been proposed as diagnostic of NPHP.[177]

Differential Diagnosis of Nephronophthisis-Medullary Cystic Kidney Disease

On histopathology, the NPHP-MCKD complex has to be differentiated from other forms of interstitial nephropathies like chronic pyelonephritis or drug injury. In oligomeganephronic dysplasia[178] kidney size is reduced and histology is distinct from NPHP. The paucity of urinary abnormalities, the frequent lack of hypertension, and the localization of renal cysts (if present) readily differentiate variants of the NPHP-MCKD complex from recessive or dominant polycystic kidney disease. Finally, a medullary sponge kidney[179] (see the subsequent text) does usually not lead to chronic renal failure and shows calcifications and calculi on renal ultrasound, and is, therefore, readily distinguishable from the complex.

PROGNOSIS, THERAPY, AND COUNSELING

Therapy of NPHP and MCKD is symptomatic and will pertain to the treatment of hypertension, if present, as well as the correction of disturbances of electrolyte, acid–base, and water balance. Hypokalemia may contribute to the polyuria, so that oral potassium supplementation may alleviate this symptom. Metabolic acidosis should be corrected, and osteodystrophy and secondary hyperparathyroidism should be treated with adequate calcium supplementation, phosphorus restriction or binders, and vitamin D therapy. Anemia can be treated with erythropoietin and growth retardation may require the administration of growth hormone if the diagnosis is made early enough for an intervention. Adequate nutrition (caloric and amino-acid supplementation) should be maintained with the help of a dietician. Salt wasting seems to be more frequent in the phase just preceding the development of end-stage renal disease. Patients are at risk for sudden water and electrolyte disturbances due to the high urinary output and salt loss. In some cases, an event of severe dehydration with acute renal failure can abruptly precipitate chronic renal failure. Sufficient salt and water supplementation is important at this stage, but may have to be restricted because hypertension develops late in the course of renal failure. Psychological counseling of the patients is an integral part of therapy because of the poor self-image associated with growth retardation and to alleviate pressures resulting from the need to comply with complicated medications and dietary prescriptions. All patients will require renal replacement therapy during childhood, adolescence, or in dominant disease, in adulthood.

At present, renal transplantation is the treatment of choice for ESRF associated with both NPHP and MCDK. Stavrou et al.[179] recently reported the outcomes of renal transplantation for 19 patients with MCKD type 1. Five-year graft survival was 90% with no evidence of recurrence of disease or specific complications.

Prior to genetic counseling, a thorough pedigree analysis to distinguish recessive (early onset) from dominant (late onset) disease is mandatory, and diseases other than renal organ involvement should be excluded. Siblings below 13 years of age should be reevaluated yearly by maximal urinary concentrating ability to allow for early detection and early prevention of complications. If a transplant recipient's renal histology suggests NPHP or MCKD and a living related donor is considered, an extensive search should be made to exclude or detect renal disease within the family.

Future therapeutic strategies targeted at renal cyst expansion may lead to the successful delay of ESRD. Vasopressin, a major adenyl cyclase agonist, acts via V2 receptors in the collecting duct. Recently, an antagonist of the V2 receptor (OPC31260) has been shown to inhibit renal cystogenesis in the pcy mouse, which is the murine equivalent of human NPHP3.[180] Clinical trials in patients with NPHP are eagerly awaited. Similarly, the antiproliferative agent rapamycin has been used in the Han:SPRD rat model of polycystic kidney disease, where a reduction in cyst volume density and a preservation of renal function was observed.[181] Thus, additional studies into therapeutic interventions in animal models are necessary to enable the development of therapeutic approaches to NPHP-MCKD.

CHAPTER

16 Autosomal Dominant Polycystic Kidney Disease

Stefan Somlo • Arlene B. Chapman

INTRODUCTION

Autosomal dominant polycystic kidney disease (ADPKD; MIM 173990) is the most common hereditary renal disease occurring in 1:400 to 1:1000 individuals. It accounts for over 90% of all hereditary renal cystic diseases (Table 16.1). ADPKD is characterized by the presence of bilateral renal cysts that gradually grow and expand over time, resulting in significantly increased total kidney volume, progressive renal injury, and ultimately, end-stage renal disease (ESRD), usually in the sixth decade of life.

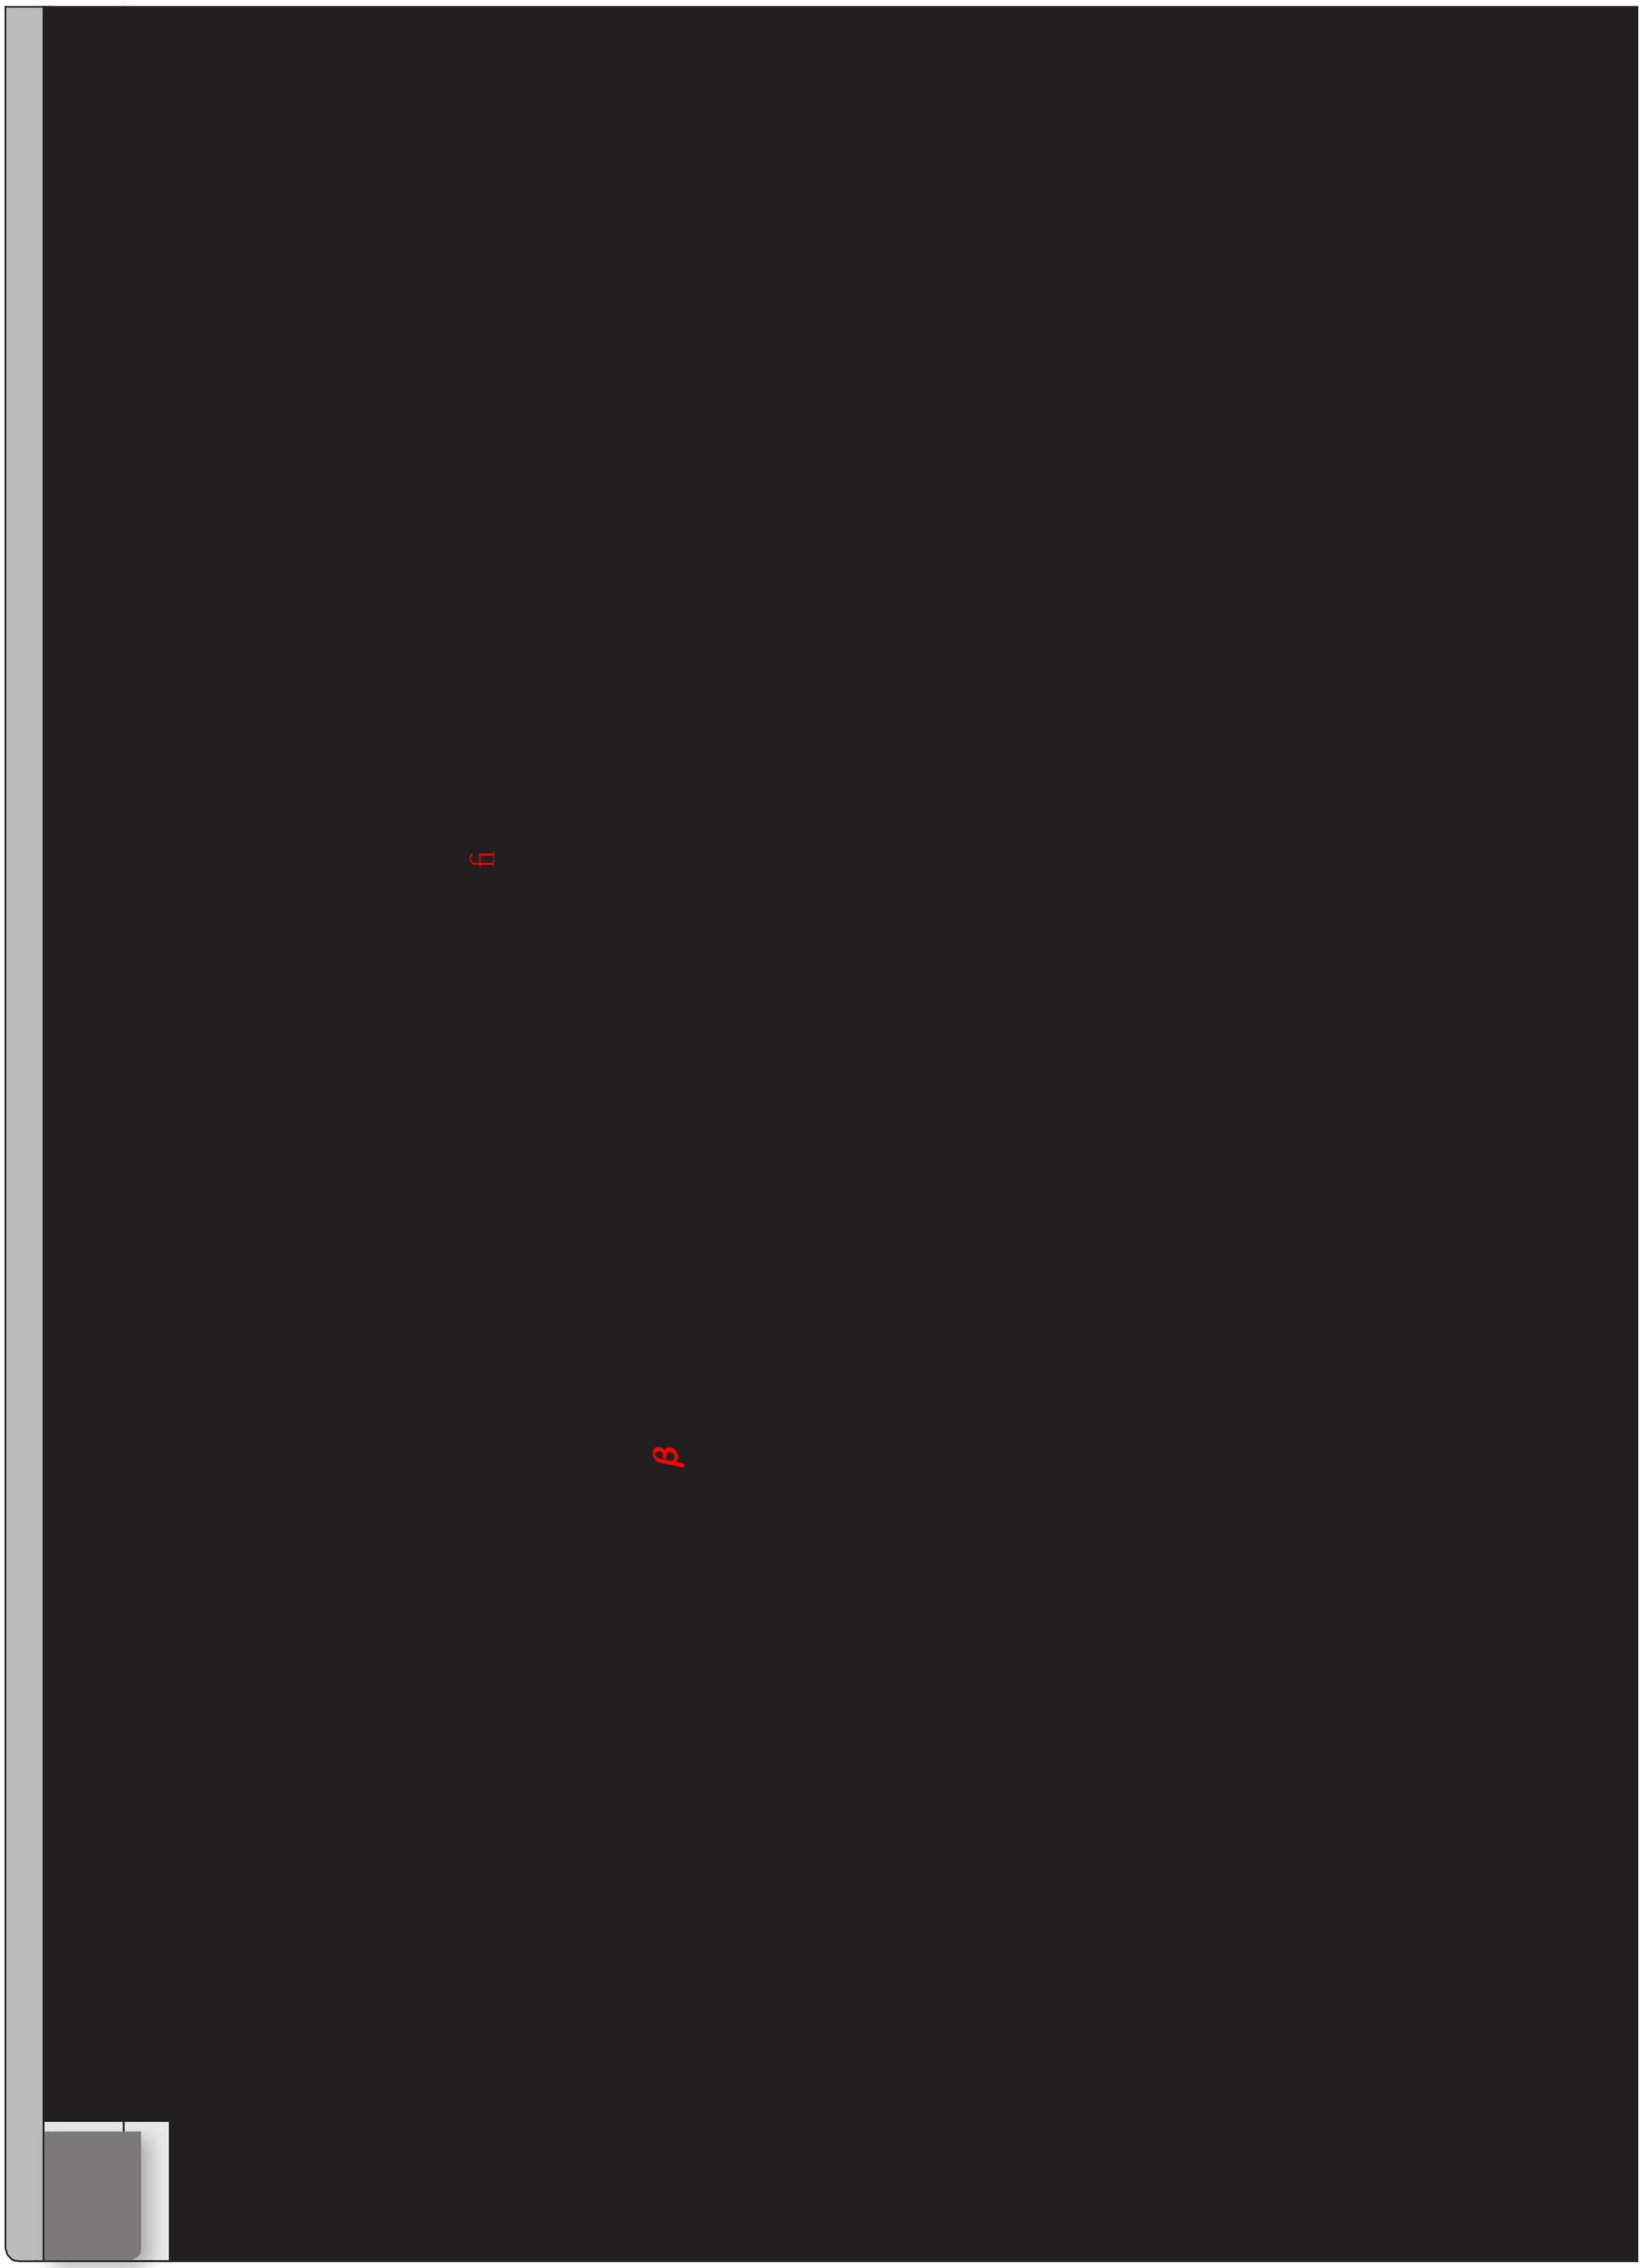
Other Mendelian diseases with varying degrees of fibrocystic involvement of the kidney are relatively rare. Autosomal recessive polycystic kidney disease (ARPKD; MIM 606702) occurs in 1:25,000; autosomal dominant tuberous sclerosis complex (TSC; MIM 191100 and 613254) occurs in 1:10,000; autosomal dominant medullary cystic disease or UMOD (MIM 174000) occurs in 1:35,000; and autosomal recessive familial juvenile nephronophthisis (NPHP; MIM 256100 and 602088) occurs in 1:40,000. In addition to the Mendelian diseases described previously, a variety of hereditary syndromes, such as Bardet-Biedl syndrome (BBS; MIM 209900) and Meckel Gruber syndrome (MKS; MIM 249000), result in a constellation of clinical manifestations that include renal cysts and are collectively termed ciliopathies (Table 16.1). In terms of clinical disease burden, however, all of the hereditary ciliopathies combined account for less than 1% of all renal cystic diseases.

This chapter will focus primarily on the single most common renal cystic disease, ADPKD. Current understanding of the epidemiology, clinical characteristics, and the pathology of ADPKD will be elucidated, and the appropriate approaches to the diagnosis and management of ADPKD will be provided. An overview of the genetics and the molecular pathways involving the polycystins is provided. Finally, a review of molecularly targeted therapeutic interventional trials will be presented to establish the potential future management for ADPKD individuals.

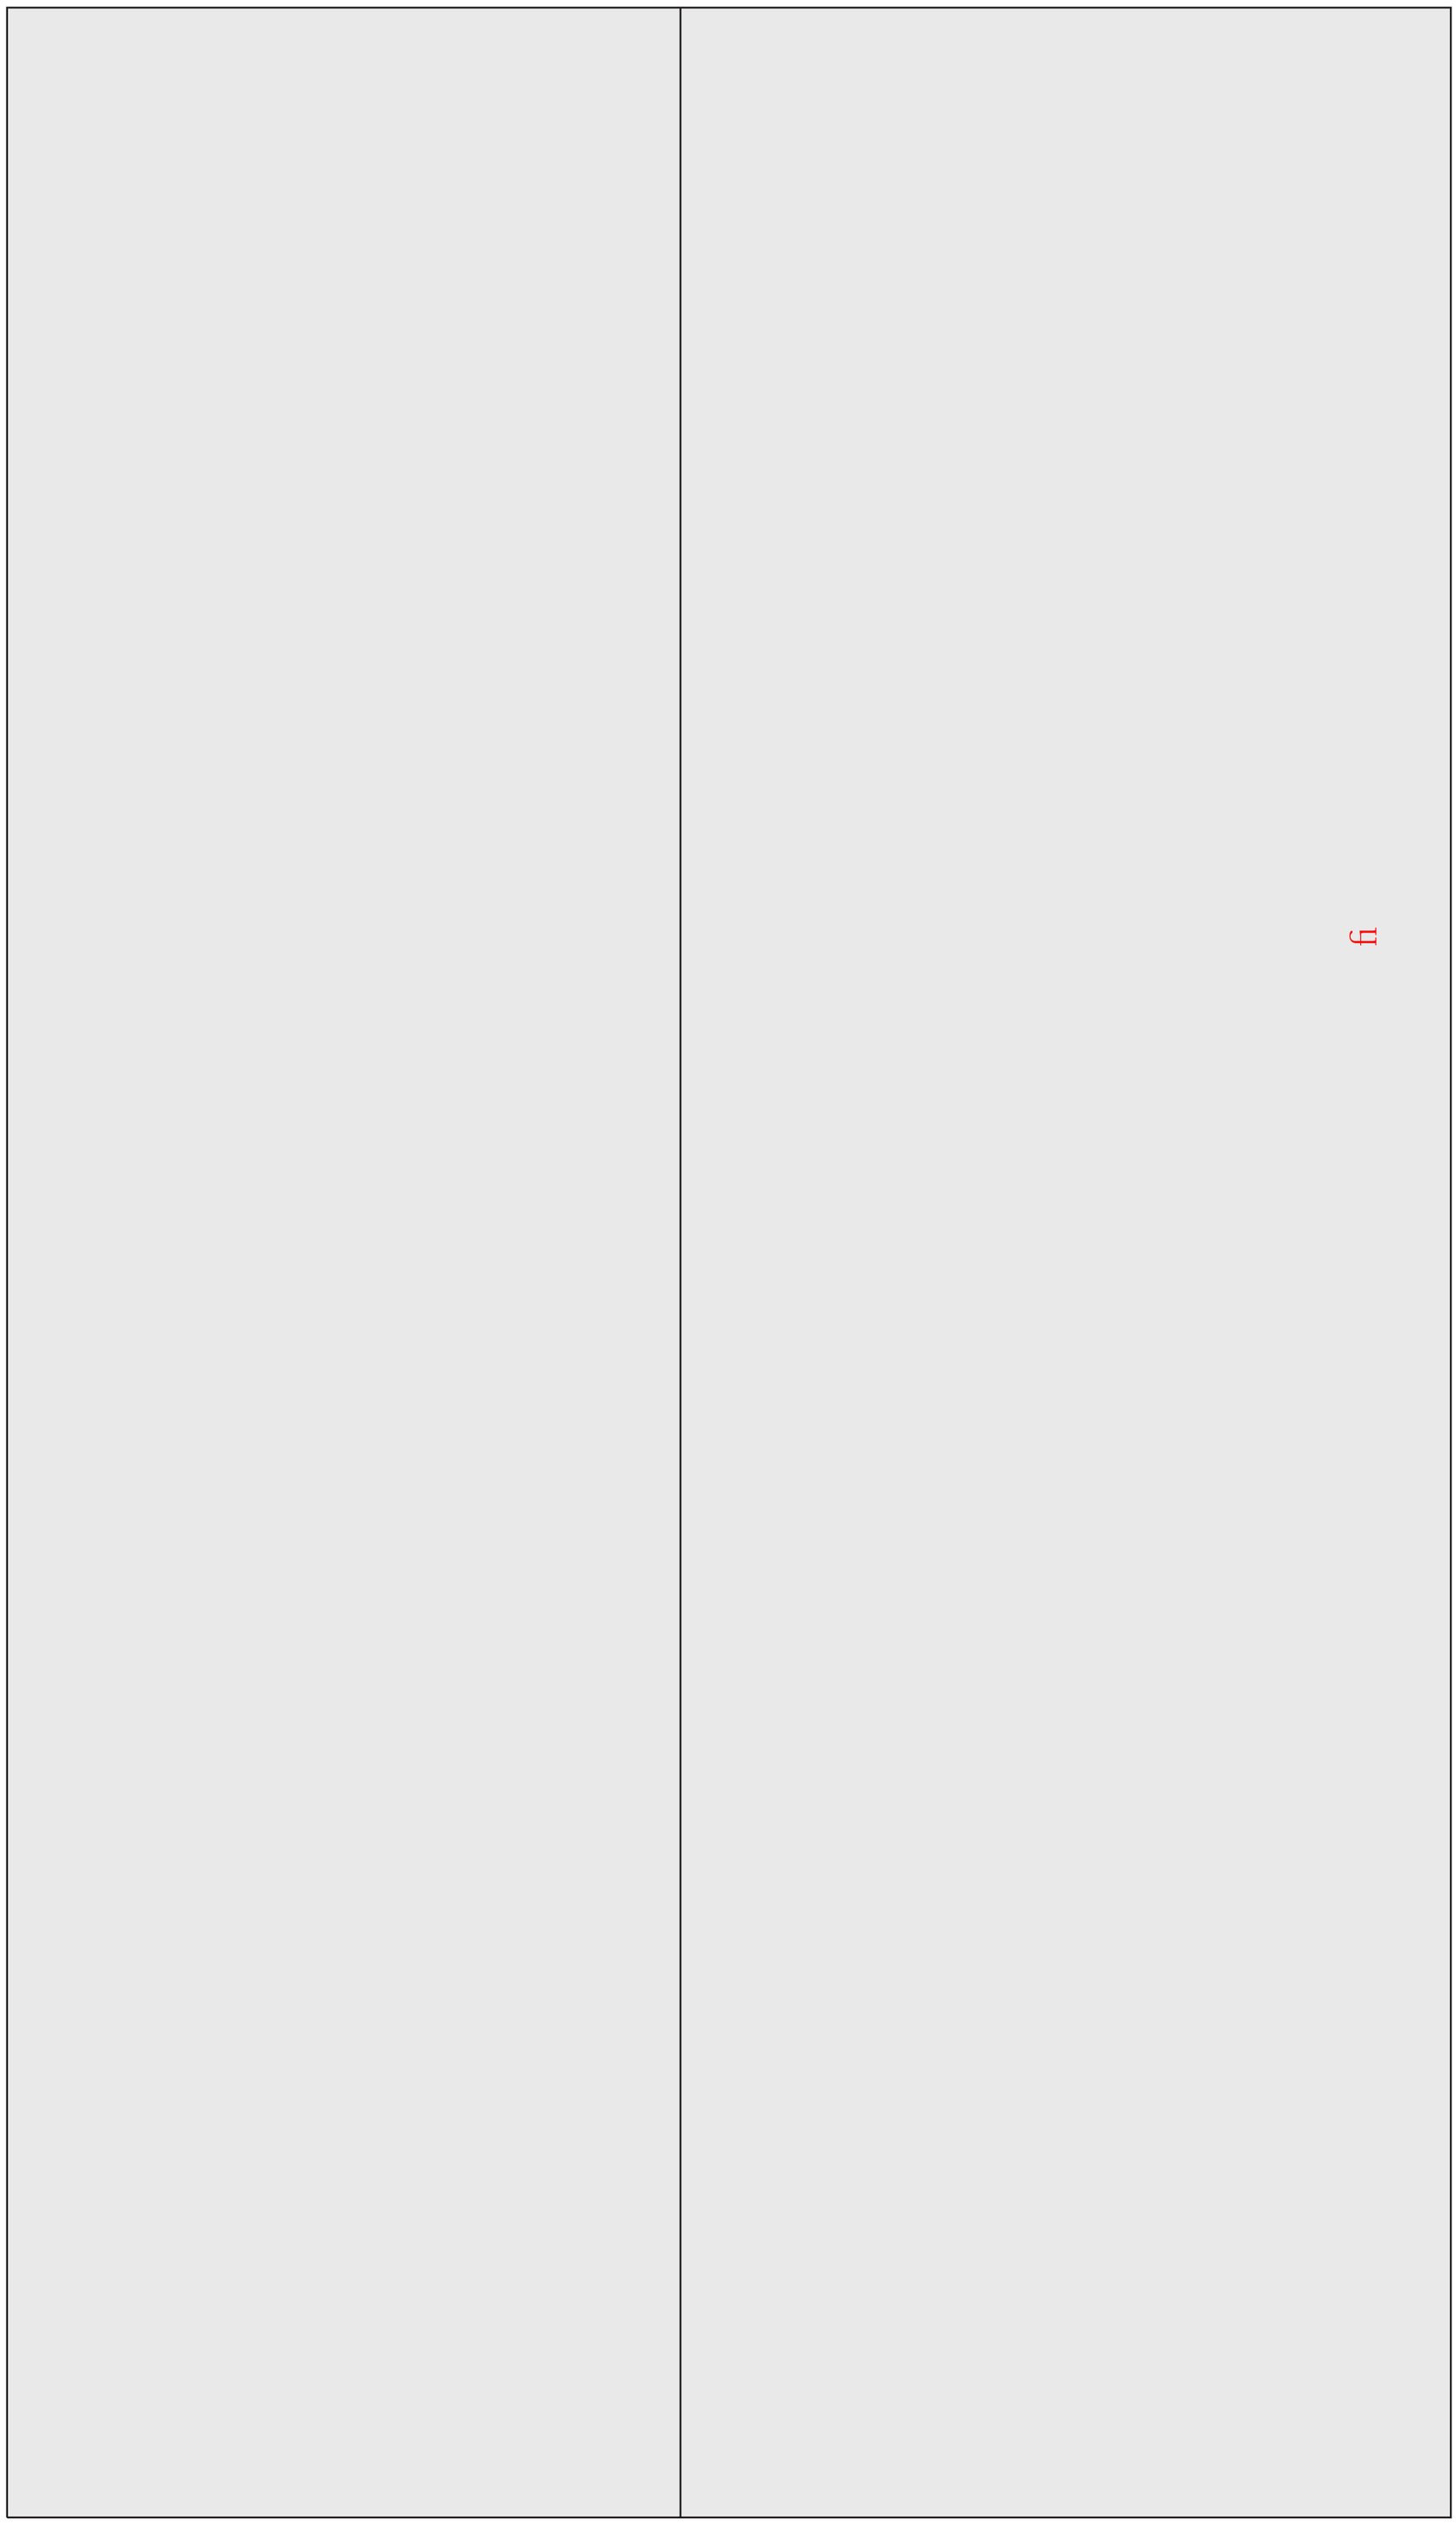
EPIDEMIOLOGY

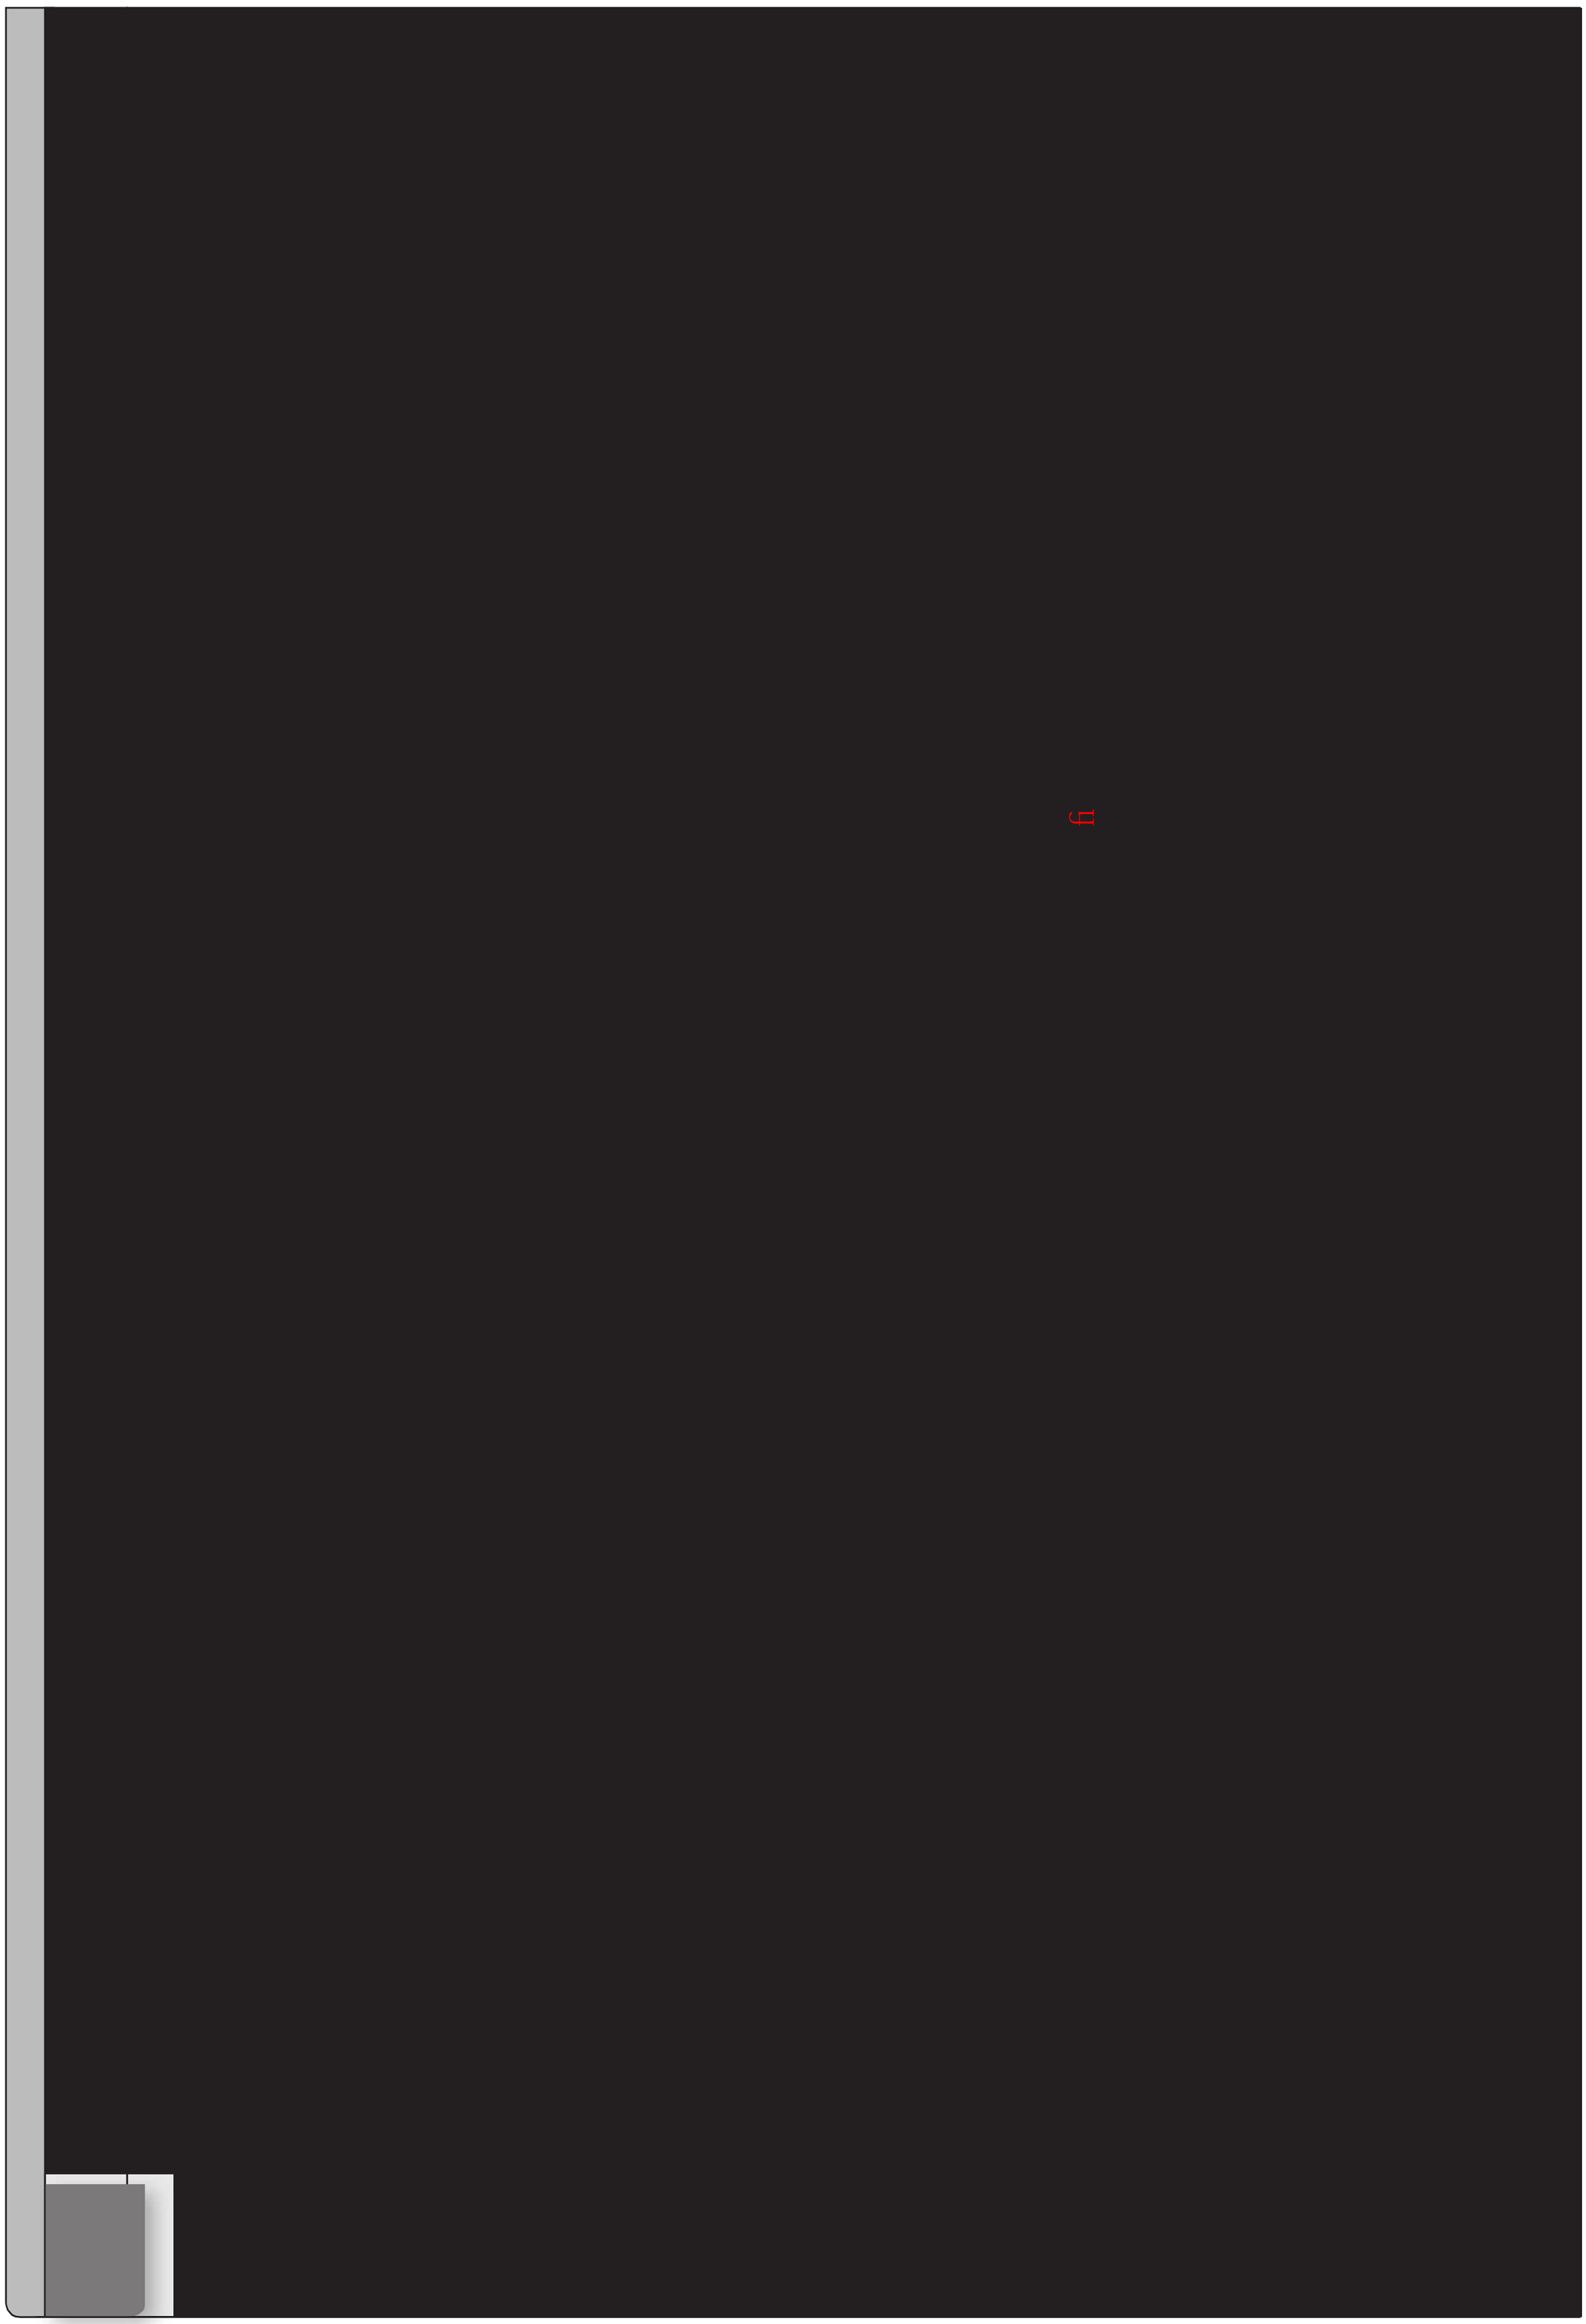
Worldwide, ADPKD occurs between 1:400 and 1:1000 live births in all ethnicities when including ascertainment by autopsy.[1–3] Epidemiologic studies suggest that fewer than half of those with the disease are diagnosed during their life, with a majority of diagnoses occurring on autopsy after death from other causes.[1] Although not specifically evaluated in those studies, it is plausible that these individuals had a milder manifestation of disease. ADPKD has been estimated to be present in up to 600,000 individuals in the United States of America, and 12.5 million people worldwide (www.pkdcure.org). The disease accounts for about 6% of all patients on hemodialysis.[4] The incidence of ADPKD varies by genotype. PKD1 occurs in approximately 1:700 live births and PKD2 occurs in 1:15,000 live births. Reports from Japan, Denmark, the United States, Europe, India, Saudi Arabia, and Turkey show similar incidence rates, with no racial or ethnic predilection.[5–9] Patient and renal outcomes differ by PKD genotype. ADPKD resulting from mutations in PKD1 result in earlier mean age of onset of hypertension (29 versus 41 years of age), ESRD (55 versus 74 years of age), and death (68 versus 79 years of age) when compared to ADPKD due to PKD2 mutations.[10–12]

Current worldwide yearly incidence rates for ESRD due to ADPKD are 7.5 and 6.1 per million population for men and women, respectively. Gender differences with regard to disease progression and severity have been reported, with women having a more favorable renal outcome than men.[10,13] However, when gender differences and genotype are considered together, little or no differences in the age of onset of renal failure are found in PKD1 individuals. Importantly, significant differences in survival are found between men and women with PKD2 mutations (67.3 versus 71.0 years). In addition, previous age-adjusted sex ratios of the incidence of ESRD, which were greater in men than in women (1.4 to 1.6), are now beginning to reach parity in various countries, including Denmark and the United States.



γ
β





African American ADPKD patients have been reported to have a more aggressive renal course than their non-African American counterparts.[14–16] However, these reports are limited due to the small number of patients and the presence of other diseases affecting renal function, including the sickle cell disease or trait. Importantly, the relative incidence of ESRD due to ADPKD per million population in African Americans is lower than their non-African American counterparts.[4,17,18] Whether this relates to earlier mortality in African Americans or improved renal survival has not yet been determined.

During the past 3 decades, the average age of onset of ESRD, the incidence and prevalence rates of ADPKD in ESRD, and the survival rates of ADPKD in ESRD have increased. Incidence rates of ADPKD patients entering ESRD have increased significantly from 1990 to 2010 in the United States (35%), Japan (30%), and Denmark (33%).[5,17,19] The average age of onset of ESRD has increased in the United States (4.5 years), Denmark (5.1 years), and Japan (4.6 years). Importantly, the use and the number of antihypertensive agents, specifically inhibitors of the renin-angiotensin-aldosterone system (RAAS) are associated with decreased patient mortality and an increased age of onset of ESRD.[20,21] Taken together, these data suggest that patients are now more often surviving to start renal replacement therapy, and improved patient care has extended both renal and patient survival with a positive impact on patient mortality for those receiving renal replacement therapy.

DIAGNOSIS OF AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Although symptoms in ADPKD individuals can present at a young age, a diagnosis of ADPKD is confirmed either with radiographic imaging or genetic testing. Before undertaking a diagnostic evaluation, counseling should be done to educate the family about the risk for inheritance. The mode of presentation for diagnostic screening has not changed over the last half century, with approximately 40% of individuals with a positive family history presenting asymptomatically.[13,22] The remaining patients present with clinical complications such as new onset hypertension, gross hematuria, acute flank pain, or fevers. The average age of presentation for diagnosis has also remained unchanged for the last 4 decades. With a number of potential beneficial therapies becoming available and evidence for improved mortality due to standard medical care, an earlier presentation for screening of at risk individuals will most likely occur.

The risk for discrimination in terms of insurability and employment has been reduced, but not eliminated, by the passage into law of the Genetic Information Nondiscrimination Act (GINA).[23,24] GINA prohibits insurers from canceling, denying, refusing to renew, or changing the terms or premiums of coverage based on genetic information. It also prohibits employers from making hiring, firing, promotion, and other employment-related decisions based on genetic factors. Genetic information is defined as information about an individual's genetic tests, the genetic tests of family members, or occurrence of a disease in family members of the individual. GINA, however, applies only to individuals who are asymptomatic, does not prohibit underwriting based on information about current health status, and does not apply to life insurance, disability insurance, or long-term care insurance.

Ultrasound imaging is the initial imaging modality of choice for a diagnosis of ADPKD (Fig. 16.1). Ultrasound is cost-efficient as compared to magnetic resonance imaging (MRI) or computed tomography (CT) and is not associated with the radiation exposure that occurs with CT imaging. The vast majority of affected ADPKD patients can be diagnosed by ultrasound imaging alone. Since the initial ultrasound criteria for a diagnosis of ADPKD were developed in 1994,[25] the imaging resolution for detection of small cysts with ultrasound, CT, and MRI have vastly improved.[26,27] The limit of detection of cysts using CT and MRI is now as low as 1 mm in diameter as compared to 0.5 to 1 cm with ultrasound.[28] Importantly, and relevant to the value of diagnostic imaging in ADPKD, simple renal cysts >1 cm in diameter remain relatively rare in childhood, occurring in <0.1% in the general population.

MR- and CT-based imaging studies of healthy young adults without a family history of ADPKD show that simple renal cysts of diameters as small as 1 mm are relatively common, even in young adults, occurring in 11 out of 35 or 28% in 18- to 29-year-olds and 97 out of 190 or 51% in 30- to 44-year-olds.[26] Therefore, if Ravine criteria using cyst number alone is used with CT or MRI in individuals between the ages of 18 and 45 years of age, more than one third would erroneously qualify for a diagnosis of ADPKD. However, if only those with cysts >1 cm in diameter are considered, the size of the cyst commonly seen in ADPKD individuals and detectable by ultrasonography, the number of incorrectly diagnosed individuals would remain <1%. Therefore, in at-risk individuals, sensitivity and specificity for a correct diagnosis of ADPKD using ultrasound remains intact and a single renal cyst in an at-risk child from a family with ADPKD is sufficient to make a diagnosis (Table 16.2).[29]

An age-based renal cyst number is required for a diagnosis of ADPKD, given that simple renal cysts are present with increasing frequency as age increases in the general population. Ultrasound still carries high sensitivity and specificity for the majority of PKD1 individuals over the age of 30 years.[30,31] At age 30, a negative ultrasound indicates a less than 5% likelihood of having ADPKD in individuals from PKD1 families. Negative ultrasound imaging is also informative at earlier ages in at-risk individuals from PKD1 families, with a negative ultrasound in an at-risk 20-year-old conferring a less than 10% chance of carrying the disease. Additional experience with screening PKD2 individuals provides a more accurate estimate of the relatively high false–negative rates when screening at-risk individuals under the age of 40.[32] Although the specificity and positive predictive value of sonographic criteria is very high in PKD1 individuals, their sensitivity and negative predictive value are low when applied to PKD2 in the 15 to 29 age group (69.5 and

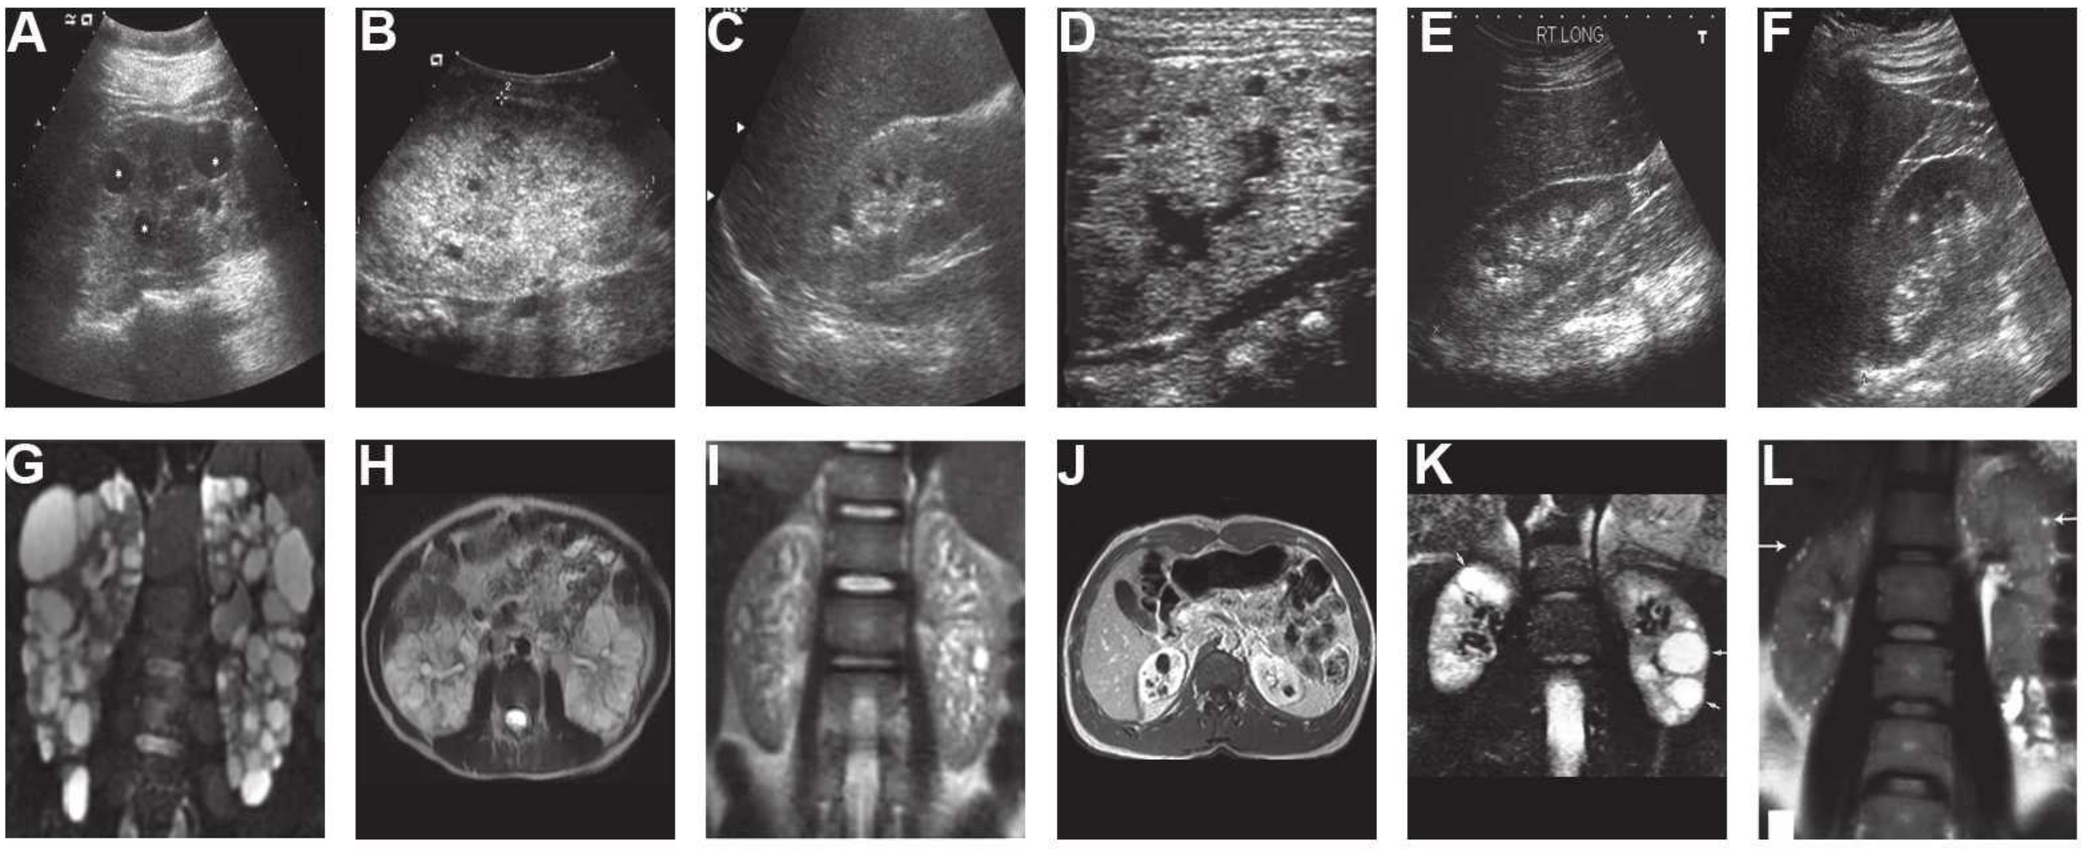


FIGURE 16.1 A radiographic appearance of hereditary renal cystic disorders. The top panels show ultrasonographic, longitudinal axis images of **(A)** autosomal dominant polycystic kidney disease (ADPKD), **(B)** autosomal recessive polycystic kidney disease (ARPKD), **(C)** familial juvenile nephronophthisis (NPHP), **(D)** glomerular cystic kidney disease (GCKD), **(E)** medullary cystic kidney disease (MCKD), and **(F)** tuberous sclerosis complex (TSC). The bottom panels show the same sequence of renal cystic disorders using either magnetic resonance imaging (MRI) or computed tomographic (CT) imaging: **(G)** a coronal MRI of early stage ADPKD, **(H)** an axial CT image of ARPKD, **(I)** a coronal MRI of NPHP, **(J)** an axial CT image of GCKD, **(K)** an axial CT image of MCKD, and **(L)** a coronal MRI of TSC.

16.2 Diagnostic Criteria for Autosomal Dominant Polycystic Kidney Disease

Age	PKD1	PKD2	Unknown ADPKD Gene Type
Diagnosis			
30–39 years	≥3 cysts[a] PPV = 100% SEN = 96.6%	PPV = 100% SEN = 94.9%	PPV = 100% SEN = 95.5%
40–59 years	≥2 cysts in each kidney PPV = 100% SEN = 92.6%	PPV = 100% SEN = 88.8%	PPV = 100% SEN = 90%
Exclusion			
30–39 years	≤1 cyst NPV = 100% SPEC = 96%	NPV = 96.8% SPEC = 93.8%	NPV = 98.3% SPEC = 94.8%
40–59 years	≤1 cyst NPV = 100% SPEC = 93.9%	NPV = 100% SPEC = 93.7%	NPV = 100% SPEC = 94.8%

[a]Unilateral or bilateral.
All values presented are mean estimates.
ADPKD, autosomal polycystic kidney disease; PPV, positive predictive value; SEN, sensitivity; SPEC, specificity; NPV, negative predictive value.
Derived from Pei Y, Obaji J, Dupuis A, et al. Unified criteria for ultrasonographic diagnosis of ADPKD. J Am Soc Nephrol. 2009;20(1):205–212.

78%, respectively). This is particularly a problem when evaluating potential young related kidney transplant donors, where the exclusion of ADPKD is important.

Based on this experience, Pei and colleagues[33] are now able to provide a unified age-based criteria for a diagnosis of ADPKD using ultrasound imaging for both PKD1 and PKD2 individuals (Table 16.2). This modification from the original Ravine criteria increases the age from 30 to 40 years for screening purposes. The presence of at least three (unilateral or bilateral) renal cysts and two cysts in each kidney are sufficient for a diagnosis of both at-risk individuals and those without a family history of ADPKD aged 15 to 39 years and 40 to 59 years, respectively. The requirement of three or more cysts (unilateral or bilateral) has a positive predictive value of 100% in the younger age group and minimizes false–positive diagnoses, because 2.1% and 0.7% of unaffected healthy individuals younger than 30 years have one and two renal cysts, respectively. In those 30 to 39 years old, both the original (two cysts in each kidney) and the revised (three cysts, unilateral or bilateral) criteria have a positive predictive value of 100%. Finally, for at-risk individuals aged greater than 60 years, four or more cysts in each kidney are required. Even with these criteria in place, there are still exceptions where ultrasound screening is not sufficient, usually when either a family history for ADPKD is absent and the clinical presentation is atypical, or when clinical suspicion for a positive diagnosis is high and evidence for renal cystic disease by ultrasound is lacking.

Although a minimum number of renal cysts are required for a diagnosis of ADPKD, other renal cystic diseases may also meet the requisite cyst number criteria to qualify for a diagnosis of ADPKD (Fig. 16.1). Additionally, given that approximately 15% of ADPKD individuals develop polycystic kidney disease (PKD) spontaneously and have unaffected biologic parents, other features of the clinical presentation are important to consider beyond simply the number of renal cysts identified. For example, the distribution and size of cysts can be informative. Cysts occurring predominantly in the medullary space with relatively small size are found in medullary cystic disease and familial juvenile nephronophthisis in the setting of normal or small kidney size and can be used to distinguish these from ADPKD. Angiomyolipomas are typically present in the kidneys of patients with tuberous sclerosis complex. Glomerular cystic disease is associated with relatively small widely distributed discrete cysts found predominantly in the cortex in the setting of normal kidney size.

In contrast to many other hereditary renal cystic diseases, ADPKD is characterized by significant renal enlargement in the setting of normal kidney function. Although renal enlargement is a feature of ARPKD, particularly in those diagnosed in utero or at birth, significant renal insufficiency usually accompanies this feature. The cysts in ARPKD tend to be diffuse, small, and relatively homogeneous and are more commonly described as fusiform and ectactic dilatations rather than discrete macrocysts. Significant renal enlargement is not present in other hereditary kidney diseases including von Hippel Lindau disease, nephronophthisis, and medullary cystic disease. Renal enlargement with significant renal cystic burden in the setting of normal kidney function, often with early onset, can be seen in specific individuals who have contiguous gene deletion mutations involving both the PKD1 and TSC2 genes.[34] This contiguous gene syndrome usually requires further genetic testing for accurate diagnosis. In addition to the diagnostic value of kidney enlargement in the setting of normal kidney function in ADPKD, the presence of radiographically visible liver cystic disease, when present, is also a unique and diagnostically useful feature of ADPKD. No other hereditary renal cystic disease is accompanied by polycystic liver disease with the exception of some instances of familial juvenile nephronophthisis. Importantly, familial instances of liver cystic disease indistinguishable from that seen in ADPKD but lacking kidney cysts is a genetically distinct disorder.[35]

Genetic testing may be required to confirm or exclude a diagnosis of ADPKD. Genetic testing is reserved for patients with renal cystic disease without a family history and with an uncertain presentation of ADPKD, or those with a negative ultrasound who are at risk for ADPKD but who need a confirmatory diagnosis for the purposes of living related kidney donation, family planning, or for occupational safety. Direct sequencing of the PKD1 and PKD2 genes is the most reliable approach to a genetic diagnosis.[36–38] A curated database of PKD1 and PKD2 mutations is available at http://pkdb.mayo.edu/. Mutation detection is successful in up to 85% of cases in research laboratories. Destructive mutations (i.e., those predicted to result in truncated proteins due to premature termination codons, aberrant splicing, or insertion-deletions resulting in frame shifting) are readily identifiable as pathogenic. The same is not true for mutations due to nonsynonymous amino acid substitutions, which may account for up to 30% of mutations in PKD1 and a significantly lower percentage of PKD2. The pathogenicity of missense sequence variations often need to be confirmed with segregation studies in other affected family members before a diagnosis can be confirmed. A genetic diagnosis is further complicated by the lack of commonly recurring mutations that have been identified in other diseases such as cystic fibrosis. As a result, most families have private mutations requiring the relatively expensive whole gene sequencing approach for detection that nonetheless yields a mutation detection rate (highest detection rate, 85%) lower than the rate of cyst detection by age-appropriate ultrasound (lowest detection rate, 99%). As a result, this approach is reserved in the clinical setting for a limited group of patients meeting the previous criteria.

PATHOLOGY OF POLYCYSTIC KIDNEY DISEASE

The kidneys of patients with polycystic disease gradually enlarge and attain an enormous size due to the growth of hundreds of cysts. Kidneys measuring 40 × 25 × 20 cm and weighing 7 to 8 kg have been reported. Usually, these greatly enlarged kidneys are seen in patients with ESRD undergoing

nephrectomy or at autopsy. These end-stage kidneys contain hundreds of fluid-filled cysts of widely differing sizes. The cyst walls can be thin and transparent, but calcification of cyst walls is also common.[39] The renal capsule may be thickened around infected cysts, and the kidney may be attached to adjacent abdominal organs such as the spleen and the adrenal glands by fibrous tissue.

Cut sections demonstrate cysts throughout the renal parenchyma. Islands of normal-appearing renal parenchyma can usually be found only in kidneys from young, nonazotemic patients. The cysts vary in size from 1 mm to 10 cm or more in diameter. Cysts in ADPKD arise from all segments of the nephron, and some cysts (~11%) retain the morphologic characteristics of proximal or distal tubules or collecting ducts. However, most (84%) are lined by a single layer of poorly differentiated columnar or cuboidal epithelium.[40,41] Approximately 5% of cysts are lined by a markedly hyperplastic epithelium, forming polyps and microadenomas.[40,42] This hyperproliferative epithelium typically has no signs of dysplasia or premalignant features. The cysts are surrounded by a fibrous stroma, which may contain bundles of smooth musclelike cells, likely transformed myofibroblasts. Inflammatory interstitial infiltrates are seen, and in advanced cases, the renal interstitium is replaced by fibrosis. Marked arteriosclerosis and arteriolosclerosis are found in nephrectomy specimens, evidence that ischemic injury and damage from hypertension contribute to tubular atrophy and glomerulosclerosis.[43]

Microdissection studies of human kidneys suggest that only 1% to 2% of nephrons are cystic.[40] These studies also have shown that cysts begin as focal dilatations of tubular segments.[44] When these dilatations exceed approximately 2 mm in diameter, they typically disconnect from the parent tubule; at least 73% of the cysts have no tubular openings when evaluated by scanning electron microscopy.[40] The cysts lining epithelial cells are joined together by junctional complexes like those seen in normal proximal tubules or by tight junctions typical of the distal renal epithelium.[41] Only a few microvilli are seen on the luminal surface and a few mitochondria in the cytoplasm. Some cells have prominent cilia, and different types of cells are found in some cysts. Occasional infoldings of the plasma membranes may be found on the basal surface. The basement membrane of most cysts is strikingly abnormal. There is pronounced splitting, duplication, thickening, and lamination of the basal lamina.

The osmolality of cyst fluids is similar to that of plasma, but sodium and nonsodium osmolyte concentrations vary significantly.[45–47] Sodium concentrations can vary between 3 and 207 mEq per liter, but often are either less than 60 mEq per liter or more than 75 mEq per liter.[46] Therefore, a distinction was made between low sodium and high sodium cysts. The high sodium cysts have sodium concentrations similar to plasma and therefore are also called nongradient cysts, whereas the low sodium cysts are gradient cysts because they are able to maintain steep concentration gradients not only for sodium but for protons, potassium, chloride, phosphates, and other ions.[48] Morphologically, the gradient cysts have long tight junctions (zonulae occludens depth >500 μm), making them impermeable to ions, whereas the nongradient cysts have short tight junctions (<500 μm), making them leaky for solutes and water.[46] These characteristics suggested that gradient cysts were derived from collecting ducts and nongradient cysts from proximal tubules. However, most nongradient cysts are lined by a poorly differentiated epithelium with few microvilli and few mitochondria, which does not resemble the proximal tubular epithelium.[46]

More recent studies have assessed the distribution of aquaporin-1 and -2 in ADPKD cysts. In normal kidneys, aquaporin-1 is expressed in proximal tubules and thin descending limbs of the Henle loop, whereas aquaporin-2 is expressed on the apical surfaces of the collecting duct epithelia. In ADPKD kidneys, approximately 30% of cysts stain positive for aquaporin-1, another 30% are positive for aquaporin-2, and the rest are negative for both aquaporin-1 and -2.[49,50] The aquaporin-1–positive cysts presumably are derived from proximal tubules or thin descending limbs, the aquaporin-2–positive cysts are from collecting ducts, and the negative cysts are from nephron segments that do not express these water channels (i.e., the ascending limb of the Henle loop and distal convoluted tubules). These results also imply that the expression of water channels is not a prerequisite for cyst expansion. Moreover, the aquaporins appear to retain their segment-specific expression in ADPKD even though the morphologic characteristics of proximal and distal tubules are lost.

In addition to electrolytes and water, cyst fluids also contain amino acids, glucose, urea; idiogenic osmoles such as sorbitol, betaine, and glycerophosphorylcholine; and proteins, such as β_2-microglobulin, erythropoietin, renin, and albumin.[47,48] Cytokines, specifically interleukin (IL)-1β, IL-2, and tumor necrosis factor (TNF)-α, growth factors (epidermal growth factor [EGF], hepatocyte growth factor, endothelins), and a nonpolar lipid cyst activating factor, are present in cyst fluids as well and likely play a significant role in the pathophysiology of ADPKD.[51–56]

Therefore, the cysts of polycystic kidneys are not simply impermeable cul-de-sacs that collect and store urine from more proximal nephron segments. They are complex structures that proliferate and undergo apoptosis; that synthesize or transport various proteins, hormones, and cytokines; and that actively secrete chloride and water. Under certain conditions, they also may be able to absorb solutes and water.[45] Most cysts are permeable to small solutes, but some are highly impermeable. Although most cysts are lined by morphologically undifferentiated epithelium, the differential expression of water channels is maintained.

CLINICAL CHARACTERISTICS OF AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Although ADPKD derives its name from the kidney, it is a systemic disorder with extrarenal manifestations that are unique to ADPKD.[3,57,58] Renal manifestations of ADPKD are

the most common and include the presence of renal cysts, renal enlargement, a decreased renal concentrating ability, polyuria, nocturia, and increased thirst.[59,60] In addition, renal complications of ADPKD include flank or abdominal pain, gross hematuria, hypertension, urinary tract infections, and nephrolithiasis.[13,61,62] Extrarenal manifestations are common in ADPKD and involve the cardiovascular, gastrointestinal, male and female reproductive systems, and the thyroid, subarachnoid, pericardial, and bronchial spaces.[63–67]

Although ADPKD is a hereditary renal disease, patients are relatively oligosymptomatic until the second or third decade of life. Renal complications are the most common and occur with increasing frequency with age. Pain is the most common complication, followed by hypertension and gross hematuria. The age-dependent presentation of these manifestations relate closely to kidney size or total kidney volume.[62] By the third decade of life, less than 10% of all ADPKD patients are complication free, even though the mean age of diagnosis of ADPKD is 27 years.[13] Patient-centered outcome reporting demonstrates that thirst, pain, and urinary frequency are the most common patient concerns.[68] However, close attention to other renal complications is important, given their contribution to progressive renal insufficiency and ESRD. Not surprisingly, renal complications are associated with poorer renal and patient outcomes.

Pain is the most common clinical manifestation of ADPKD and is responsible for the majority of presentations for symptomatic diagnosis.[69,70] Pre-ESRD patients completing quality of life questionnaires demonstrate lower scores on the physical component summary suggesting that symptoms of discomfort significantly impact their quality of life. Focus groups determining the most common patient-reported outcomes find that pain along with thirst and polyuria are the most important. Pain can be managed effectively in most patients, but in a minority, chronic pain limits individuals' ability to function, resulting in sleep deprivation, fatigue, anxiety, and a decreased quality of life.[71] Acute and chronic pain in ADPKD is due to different causes. Acute pain syndromes in ADPKD are most often associated with cyst rupture, hemorrhage, renal infections, or nephrolithiasis. Chronic pain is a more complex and less defined problem. ADPKD patients report pain located in the back (71%), abdomen (61%), head (49%), chest (30%), and legs (27%).[72] Renal and nonrenal sources of pain not related to cystic disease should be considered including diverticulitis, ovarian cyst rupture, aortic or iliac aneurysms, or incarcerated hernias.

Chronic pain management related to polycystic kidneys requires a staged approach beginning with nonpharmacologic interventions including ice, heat, whirlpool, massage, and physical therapy as well as exercises to improve vertebral and abdominal wall support. When these approaches are not successful, other therapies including intermittent transcutaneous electrical nerve stimulation (TENS) unit and nonopioid analgesics, such as acetaminophen, can improve the level of pain in polycystic patients. There is less objective information regarding the benefits of other treatments including short- and long-term opioid medications, tramadol (Ultram), clonidine, gabapentin, or pregabalin. Nontraditional complementary medical approaches such as acupuncture may be helpful, although this may involve a placebo effect. Surgical approaches to pain in ADPKD patients are reserved for those who have systematically attempted all nonmedical and medical therapies over a reasonable period of time. The least invasive approach is percutaneous cyst aspiration with alcohol injection, typically done in patients with symptoms that can be matched locally to candidate cysts identified using CT or MRI. This can be done in interventional radiology suites as an outpatient procedure. Multiple cyst fenestrations or deroofing procedures (Rovsing procedures) can be done in more severe and complicated cases. Prospective studies report an immediate improvement in 85% to 90% of individuals with close to two thirds maintaining a benefit up to 2 years after treatment.[73–76] More recently, renal denervation procedures both abdominally and thoracoscopically with and without nephropexy have demonstrated early short-term pain relief.[77,78] Whether there are long-term benefits resulting from these interventions is not yet clear. Finally, partial or full nephrectomy or volume reducing procedures, including transcatheter arterial embolization, have been used with success in small numbers of patients with intractable pain.

Hypertension

Hypertension is common in ADPKD and, unlike in other tubulointerstitial diseases, it occurs in the majority of patients prior to the loss of kidney function.[79–81] The average age of onset is 29 years, and men are more often hypertensive than women early in the course of disease.[11,80] Evidence suggests that carotid and left and right ventricular structure are abnormal in asymptomatic ADPKD patients early in the course of disease prior to the development of hypertension. This is manifest by increases in carotid intimal wall thickness, reduced end-diastolic relaxation, decreased aortic relaxation, increased left ventricular mass, and left ventricular hypertrophy.[82–84] Hypertension is common in children with ADPKD, affecting 10% to 25% of individuals,[85–87] and it is associated with evidence of end-organ damage including increased left ventricular mass index and left ventricular hypertrophy. Whether primary cardiovascular abnormalities or increased systemic blood pressure are the primary hemodynamic abnormality to develop in ADPKD and how they relate to each other is unclear. A recent study suggested that an early intervention in ADPKD, particularly with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, may decrease the occurrence of left ventricular hypertrophy and has the potential to decrease cardiovascular mortality.[88]

Total kidney volume (TKV) is greater in hypertensive ADPKD adults and children with normal kidney function when compared to the respective normotensive ADPKD controls.[89–91] The increased cyst burden found in hypertensive ADPKD individuals is associated with evidence of systemic activation of the RAAS. Vascular imaging and MR-based quantification of renal blood flow demonstrate attenuated renal vasculature and reduced renal blood flow,

both of which occur early and are associated with hypertension and increased TKV.[92,93] Activation of the RAAS in ADPKD is most likely due to increased intrarenal ischemia secondary to cyst formation and expansion. Distortion of the renal vasculature due to increased cyst burden results in decreased renal nitric oxide production, increased reactive oxygen species formation, and further activation of the intrarenal RAAS.[94] Currently two large randomized clinical trials are under way to determine the impact of inhibition of the RAAS and the value of rigorous blood pressure control in disease progression in ADPKD.[95] Results of these trials will be available in 2014.

Gross Hematuria

Gross hematuria is a common initial clinical presentation in ADPKD, often presenting prior to the onset of hypertension. Although not prospectively established, gross hematuria tends to associate with rapid cyst expansion, increased physical activity, and cyst wall calcifications. Gross hematuria is significantly associated with increased kidney size and a poorer renal prognosis.[62,96,97] Gross hematuria may or may not be associated with renal pain. In patients with gross hematuria who are asymptomatic, cyst rupture into the urinary collecting system is the most likely cause. Renal imaging is encouraged to rule out other treatable causes of gross hematuria. In patients in whom symptoms develop, localized pain, fever, and dysuria are common. When these clinical signs and symptoms occur, it is important to rule out cyst infection, nephrolithiasis, pyelonephritis, or lower urinary tract infections.

Gross hematuria secondary to cyst rupture is typically self-limited and usually lasts 2 to 5 days. Increased hydration with oral fluid intake and bed rest with close monitoring of blood pressure is indicated given the increased risk for acute reversible kidney injury in the setting of antihypertensive medication intake, particularly angiotensin-receptor blocking agents and angiotensin-converting enzyme inhibitors.[98] Often, it is advised to temporarily discontinue these agents until the episode of gross hematuria resolves. It is important to monitor blood pressure closely with home blood pressure monitoring devices during this time.

Urinary Tract Infections

Urinary tract infections are common in ADPKD and occur more often in women as compared to men.[99] Unlike hypertension and gross hematuria, it is not well established whether urinary tract infections are associated with progressive renal injury. Given that lower urinary tract infections are relatively common in the general population, their occurrence in ADPKD may or may not be disease related. Differentiation between lower and upper urinary tract infections can be difficult, further complicating the discovery of any link between urinary tract infections and disease severity. Upper urinary tract infections in ADPKD may be due to cyst infections, nephrolithiasis, or pyelonephritis and require careful evaluation.[100,101] Therapy for cyst infections requires different antibiotic treatment than those recommended to treat pyelonephritis in the general population. Antibiotics that provide adequate cyst fluid concentrations are necessary.[102] In addition, a more prolonged course of therapy is needed to ensure successful eradication of the infection. Current recommendations for the treatment of cyst infections include a 2-week course of an oral quinolone or possibly trimethoprim-sulfamethoxazole.

The diagnosis of a cyst infection is often difficult. Clinical presentations vary ranging from local tenderness, fever, leukocytosis, and leukocyturia with positive urine cultures to diffuse abdominal discomfort or pain, absence of a fever, and negative urine cultures.[103] Importantly, blood cultures may more often provide evidence of the infecting organism than urine cultures given that many infected cysts do not directly communicate with the urinary collecting system. Occasionally, cyst infections do not respond to appropriate oral antibiotic therapy. Typically, this occurs in larger cysts (>5 cm in diameter) or when intracystic antibiotic levels are inadequate. It may be necessary to administer parenteral antibiotics, conduct imaging studies to rule out other causes of fever and pain (including nephrolithiasis), and to consider percutaneous cyst aspiration to obtain cultures or to decompress the large infected space.[104] In rare circumstances, frank pyonephritis may develop associated with sever malaise, sepsis, and shock and may necessitate partial or total nephrectomy.

Nephrolithiasis

Kidney stones are tenfold more common in ADPKD patients than the general population, occurring in approximately 25% of affected individuals.[105] Symptomatic nephrolithiasis typically occurs later than other renal complications in ADPKD.[96] Nephrolithiasis associates with increased TKV in ADPKD patients with normal kidney function. All types of kidney stones can occur in ADPKD; however, urate nephrolithiasis is more common than other types of kidney stones.[106] ADPKD patients develop hypocitraturia, even prior to a loss of renal function, and this may contribute to the increased frequency of urate nephrolithiasis. Whether the hypocitraturia associated with ADPKD is due to abnormalities in renal ammonia generation or other tubular defects is unknown. Of note, urinary biochemical parameters in ADPKD patients uniquely demonstrate normal urinary calcium excretion with increased oxaluria. Patients with nephrolithiasis typically present with unilateral flank pain, with or without radiation, and may have micro- (or rarely, macro-) hematuria. Those with nephrolithiasis diagnosed incidentally during renal imaging more commonly report lower unilateral back pain. Importantly, fevers and chills may occur in the setting of nephrolithiasis. This constellation of signs and symptoms overlap significantly with cyst infections and cyst hemorrhage. An evaluation of nephrolithiasis almost always requires renal imaging—most often, noncontrast CT imaging.[107] Ultrasound has a reduced sensitivity for the detection of kidney stones as compared to CT imaging

in ADPKD individuals. Excretory urography, abdominal flat plate X-rays, and ultrasound can all be used; however, the localization and detection of renal stones is achieved best with CT imaging. The differentiation of renal cyst wall calcification and nephrolithiasis is important and can be easily done when CT imaging is performed. Cyst wall calcifications are more common in ADPKD patients who demonstrate nephrolithiasis than those who do not.

The approach to the management of nephrolithiasis in ADPKD patients should involve a biochemical analysis of the urine and stone using crystallography if possible. Estimates of daily fluid intake and dietary intake of stone-forming elements should be established. Both of these evaluations can be determined from a single 24-hour urine collection. Urinary biochemical analysis should include calcium, urate, oxalate, citrate, and pH.[108] For the majority of stones formed in ADPKD, increases in fluid intake are the cornerstone of therapy. A minimum of 3 L per day of fluid intake should be established using home monitoring coupled with monthly 24-hour urine collections. The addition of bicarbonate or citrate is also helpful for those patients with urate nephrolithiasis to decrease urinary acidification and to increase potential stone dissolution. Dietary education is also helpful with regard to dietary intake of urate, calcium, and oxalate. For patients with calcium oxalate stones, the addition of thiazide diuretics will help to reduce urinary calcium excretion and, coupled with increased fluid intake to greater than 3 L per day, will reduce the concentration of urinary calcium and inhibit initial stone formation.

The most complicated stone in ADPKD patients is the struvite stone, or staghorn calculus. These stones are a constant nidus for infection, which can recur shortly after each treatment course and must be removed to avoid complications. These stones are a nidus for infection, which recurs after each treatment course, and must be removed to avoid complications. Collaboration with the urologic specialists is essential for the management of these patients. Depending of the size of the stone and its location, retrograde lithotripsy, extracorporeal shock wave lithotripsy (EWAL) therapy, or percutaneous stone removal may be necessary.

EXTRARENAL MANIFESTATIONS IN AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Polycystic Liver Disease

Liver cyst formation is the most common extrarenal manifestation in ADPKD. Polycystic liver disease is due to the presence of multiple scattered cysts of biliary origin in the liver parenchyma. Among the hereditary renal cystic disorders, it is only found in ADPKD and, when present, is a useful adjunct in securing the diagnosis. In individuals with kidney cysts and no family history of ADPKD, the presence of liver cystic disease provides confirmation of the clinical diagnosis. Liver cystic disease occurs in over 85% of PKD1 patients by the age of 30.[109] An MRI analysis performed as part of the Consortium for the Radiographic Imaging Studies of Polycystic Kidney Disease (CRISP) study demonstrated that the prevalence of liver cysts increases with age, occurring in 58%, 85%, and 94% of affected individuals age 15 to 24, 25 to 34, and 35 to 46 years, respectively. The severity of cystic liver disease appears to parallel the severity of cystic kidney disease.[110,111] Liver cystic disease varies from a few cysts to massive cystic liver enlargement. Importantly, liver parenchyma and liver function are normal even in the setting of massive polycystic liver disease, and portal hypertension does not occur. Biochemically, the only liver function abnormalities found are mild elevations in the alkaline phosphatase and bilirubin. In contrast to renal cystic disease, polycystic liver disease occurs earlier and is more likely to be severe in women than in men and is influenced dramatically by estrogen exposure.[110] Liver cysts develop within specific segments of the liver, and there is no predictable segment sparing.

The signs and symptoms of polycystic liver disease include increased abdominal girth, increased clothing size, shortness of breath, early satiety, abdominal pain, and umbilical herniation. Morphologic studies of liver cysts demonstrate that they originate from biliary microhamartomas that arise from biliary ductules and peribiliary glands. As in the kidney, as liver cysts expand and enlarge, they become detached from their biliary tree of origin.[112] Similarly to polycystic kidney disease, cyst expansion is the result of multiple effects of proliferation of cyst-lining epithelia, fluid secretion, remodeling of the extracellular matrix, and neovascularization.[112] The genetic and molecular signaling mechanisms found in renal cystic epithelia have also been found in liver cystic disease in ADPKD, suggesting that the underlying disease biology in both organs are closely related.

Isolated Polycystic Liver Disease

Isolated autosomal dominant polycystic liver disease (ADPLD; MIM 177060, 608648) is an autosomal-dominant familial disease with significant genetic heterogeneity.[35,113] It is relatively rare, with an estimated incidence of $< 0.01\%$ of the population. This may be related to the low rate of clinical symptoms; autopsy studies suggest a rate of occurrence that is only slightly lower than that of ADPKD.[114] Although isolated ADPLD was reported as early as 1906,[115] it was not until 2003 that linkage analysis in eight Finnish families confirmed that isolated ADPLD is a disease genetically distinct from polycystic kidney disease. Subsequent gene discovery studies in patient families showed that ADPLD is genetically heterogeneous, with a subset of affected families having heterozygous mutations in PRKCSH or SEC63 in the setting of clinically indistinguishable clinical presentations.[116–118] Further genetic heterogeneity is suggested by the finding that only approximately 30% of ADPLD families have mutations in either of these two genes.[119] As a result, DNA testing in ADPLD patients has limited use because the mutated genes responsible for ADPLD have not been identified for the majority of families.

The natural history of ADPLD is relatively oligosymptomatic, characterized by associated symptoms in less than 30% of individuals. Those with symptomatic ADPLD complain of abdominal distention, fullness, discomfort, early satiety, and dyspnea and back pain. Individuals with ADPLD also demonstrate mild elevations in serum alkaline phosphatase as well as total bilirubin associated with lower total cholesterol and triglyceride levels. As in ADPKD, ADPLD women show a tendency toward significantly more liver cystic burden than men. As compared to unrelated and related unaffected individuals, mitral leaflet abnormalities may be more common, and other vascular malformations including intracranial aneurysms, carotid artery dissections, and ectatic cavernous arteries have been seen.[35] The differential diagnosis of ADPLD includes simple liver cysts and liver cysts resulting from other diseases, including ADPKD. Because simple liver cysts are common in the general population and occur with increasing frequency with increasing age, at least four liver cysts visible by ultrasonography are required for the diagnosis of ADPLD in individuals over the age of 40.

Intracranial Aneurysms and Other Vascular Abnormalities

The frequency of intracranial aneurysms (ICAs) is increased in ADPKD. A recent meta-analysis of 645 ADPKD patients with ICA demonstrated a 6.6-fold increased likelihood of an ICA developing compared to the general population.[120] This represents a frequency of 5.8% in selected ADPKD populations (as compared to 2.8% in the general population) and a 12% frequency in ADPKD patients with a positive family history of an ICA. ICAs tend to cluster in a small number of ADPKD families, and a positive family history of ICA is the only established risk factor associated with ICA in ADPKD. Gender, age, smoking exposures, hypertension, and race do not contribute to the risk of ICA formation in ADPKD. Mutations in the PKD1 gene tend to be closer to the 5′ end of the gene in families with intracranial aneurysms[121] and a common PKD1 mutation has been reported in individuals with a variety of vascular malformations including ICA,[122] but the genetic basis of ICA beyond the tendency to cluster in certain families is not well understood.

As compared to the general population, ICAs are more often found in the anterior circulation (84%) and rupture at an earlier age in ADPKD, but they do not differ in size at the time of rupture. As with all ICAs, the risk of rupture increases significantly once size reaches 10 mm in diameter. Given the serious consequences of an ICA rupture with permanent morbidity and mortality in excess of 40%, preventative screening and management are important aspects to patient care. Given that aneurysms are relatively rare, selective screening should be considered. Multiple studies of asymptomatic ADPKD patients demonstrate that only a positive family history associates with an ICA.[123,124] Repeat screening in individuals following an initial negative screen provided a very low yield of 2.4% in 76 individuals over 10 years.[20] Two longitudinal imaging studies of ADPKD individuals with documented small intact ICAs demonstrated a low frequency (8 out of 65) of increases in diameter over 243 patient years with the occurrence of six de novo aneurysms.[125,126] Taken together, these data suggest that the presence of ICAs in ADPKD patients is reflective of an initial expansion at the time of formation, perhaps with a higher risk of rupture. If the initial screening does not show vascular abnormalities, further imaging is not required unless individuals are symptomatic. Specific subgroups of ADPKD patients in addition to those with a positive family history of ICA, such as those considering organ donation or receipt, commercial pilots, or those with considerable personal burden due to concern about their status should undergo an initial screening for ICA.

Potential imaging modalities to assess the intracerebral vasculature include CT angiography, four vessel arteriography, or MRI. All modalities have excellent resolution, accuracy, and reliability. CTs and angiographies are associated with increased radiation exposure and potential complications. Therefore, MR angiography is the imaging modality of choice for screening. MRs with and without gadolinium can be used to clearly outline the cerebral vasculature. The management of ICAs in ADPKD patients relate primarily to the size of the ICA but also depend on location and whether they are asymptomatic. Typically, ICAs less than 5 mm in diameter are at low risk of rupture. In symptomatic individuals or those with ICAs greater than 7 mm, either surgical ablation or coil ablation or thrombosis can be used, depending on the size and location of the ICA. Complications related to surgical intervention are low (< 1%), but when they occur, they have significant morbidity, particularly with procedures performed in the posterior circulation of the circle of Willis. Therefore, patients with ICAs are advised to carefully review the risks of rupture and complications of treatment before moving forward with surgical or endovascular interventions.

Fertility in Autosomal Dominant Polycystic Kidney Disease

Women with ADPKD demonstrate fertility rates similar to the general population. However, an increased rate of ectopic pregnancy[127] has been reported that is potentially associated with abnormalities in fallopian tube function or ciliary motility. Importantly, seminal vesicle cysts are common in men and can be detected by transrectal ultrasonography in up to 40% of male ADPKD patients.[128] Abnormal sperm motility occurs in the majority of men with ADPKD, and although this has not been shown to directly relate to fertility, it may play a role in the increased occurrence of azoospermia reported in men with ADPKD.[129] Although women with ADPKD demonstrate a normal ability to become pregnant, the course of pregnancy is associated with increased maternal and fetal complications. In general, the likelihood of a successful pregnancy in ADPKD is similar to the general population,[127,130] but there are subgroups of patients, such as those with preexisting hypertension or with established renal insufficiency, who are at an increased risk for fetal loss.

Premature delivery, small for gestational age babies, and congenital abnormalities occur in a small percent of offspring

born to women with ADPKD, typically those older than 30 years or with preexisting hypertension.[127] In a large series of 605 pregnancies in 235 women with ADPKD, only 2 individuals had serum creatinine concentrations greater than 1.2 mg per deciliter prior to becoming pregnant. This is in large part due to the typically delayed occurrence of renal insufficiency in the fourth to sixth decades of life in ADPKD individuals. Given that renal function is usually intact in ADPKD individuals during their reproductive years, the typical complications of polyhydramnios and preterm labor that are associated with pregnancy in women with established renal insufficiency are not typical features of pregnancy management in ADPKD. Maternal complications occurred in 35% of women with ADPKD who become pregnant, including new-onset hypertension, worsening hypertension, preeclampsia, and acute kidney injury. These complications tend to be relatively mild and resulted in uncomplicated pregnancies in the majority of women with ADPKD.

In women with ADPKD who are planning a pregnancy, proactive management before and during pregnancy is critical. For women with hypertension planning to become pregnant, all inhibitors of the RAAS should be stopped prior to pregnancy given the untoward effects on the fetus even with first trimester exposure to this class of drugs. Once pregnant, women with ADPKD should be seen by a high-risk obstetrician and a nephrologist beginning in the middle of the second trimester, particularly if prepregnancy renal function is not normal. Monthly screening for the development of new or worsening hypertension should be conducted. Patients should also check their blood pressure in their home environment on a regular basis. Patients should have their urine reviewed for the presence of new or increased proteinuria, which is a potential sign for the development of preeclampsia. Blood pressure management during pregnancy should include using antihypertensive therapies approved for use in pregnancy including aldomet, hydralazine, clonidine, labetalol, or a dihydropyridine. Immediately postdelivery, women with ADPKD should be monitored closely for signs of worsening hypertension and should have their level of kidney function and blood pressure established approximately 6 weeks after delivery. Longitudinal studies of risk factors for the progression to renal failure have suggested that pregnancy number (particularly for those with more than three pregnancies) is an independent risk factor for the development of ESRD in ADPKD.[131] This association is weak compared to other risk factors such as the presence of hypertension or total kidney volume. The association with pregnancy number or use of estrogen/progesterone agents use is much stronger for liver cyst burden.[132]

THE PKD GENES AND THEIR PROTEIN PRODUCTS

The evolving understanding of the pathogenesis of polycystic kidney diseases has been punctuated by several critical discoveries. The most fundamental of these advances came with the identification of the genes and the respective protein products that are mutated in families with these diseases.[116–118,133–137] At the time of their discovery, the genes for ADPKD (and ARPKD) were completely novel and did not readily fit into in any known biologic pathways. The initial clues regarding their putative roles had to come from the predicted structure of the respective protein products and the knowledge that their functions are expected to intersect at the level of clinical human disease phenotype manifested as the dysregulated nephron tubule structure. This section will review the current state of knowledge regarding the protein products of the various genes associated with human polycystic kidney and liver disease.

PKD1 and Polycystin-1

PKD1 is located on chromosome 16p13.3.[133–135,138] The structure of the gene locus is complicated by the fact that the 5′ two-thirds of the gene is duplicated multiple times with very high sequence fidelity in pseudogenes located on more proximal regions of chromosome 16.[139–142] The need to resolve sequence variants occurring in the PKD1 gene itself as opposed to its homologs for purposes of mutation detection has complicated genetic testing in ADPKD, although current sequence–based technologies are able to address this complication. The protein encoded by PKD1 is called PC-1. PC-1 is a large, low abundance, polytopic integral membrane protein with complex domain structure suggestive of receptor function that undergoes multiple proteolytic cleavage processes (Fig. 16.2). This constellation of features coupled with the absence of direct biochemical and cell biologic assays for its function has made deciphering the mechanisms of ADPKD challenging despite the successful identification of the genes almost 2 decades ago.

Human PC1 is comprised of 4302 amino acids with a 3074 amino acid extracellular NH_2-terminus, 11 transmembrane domains, and a 198 amino acid cytosolic COOH-terminus (Fig. 16.2).[143] The extracellular NH_2-terminal domain contains a number of protein motifs including leucine-rich repeats, a WSC homology domain, C-type lectin domain, a low density lipoprotein (LDL)-A related domain, 16 immunoglobinlike PKD repeats,[134,144,145] a receptor egg jelly (REJ) module,[146] and a G-protein–coupled receptor (GPCR) proteolytic site (GPS).[147] The Ig-like polycystic kidney disease (PKD) domains occupy 40% of the extracellular portion of PC1 and contain a distinct β-sandwich fold structure[148] that is resistant to unfolding under mechanical force.[149–151] The stability of these PKD domains is altered by naturally occurring mutations in PKD patients.[152] The REJ module is comprised of four fibronectin type III β-sheet domains.[153] The first intracellular loop contains a highly conserved polycystin-1, lipoxygenase, alpha-toxin (PLAT) domain that may be involved in protein interactions.[154] The extracellular loop between the sixth and seventh transmembrane domains contains a highly conserved domain that is common to both PC-1 and PC-2 family members and is not found in any other protein families.[155] The region of the last six transmembrane domains of PC1 share sequence similarity with

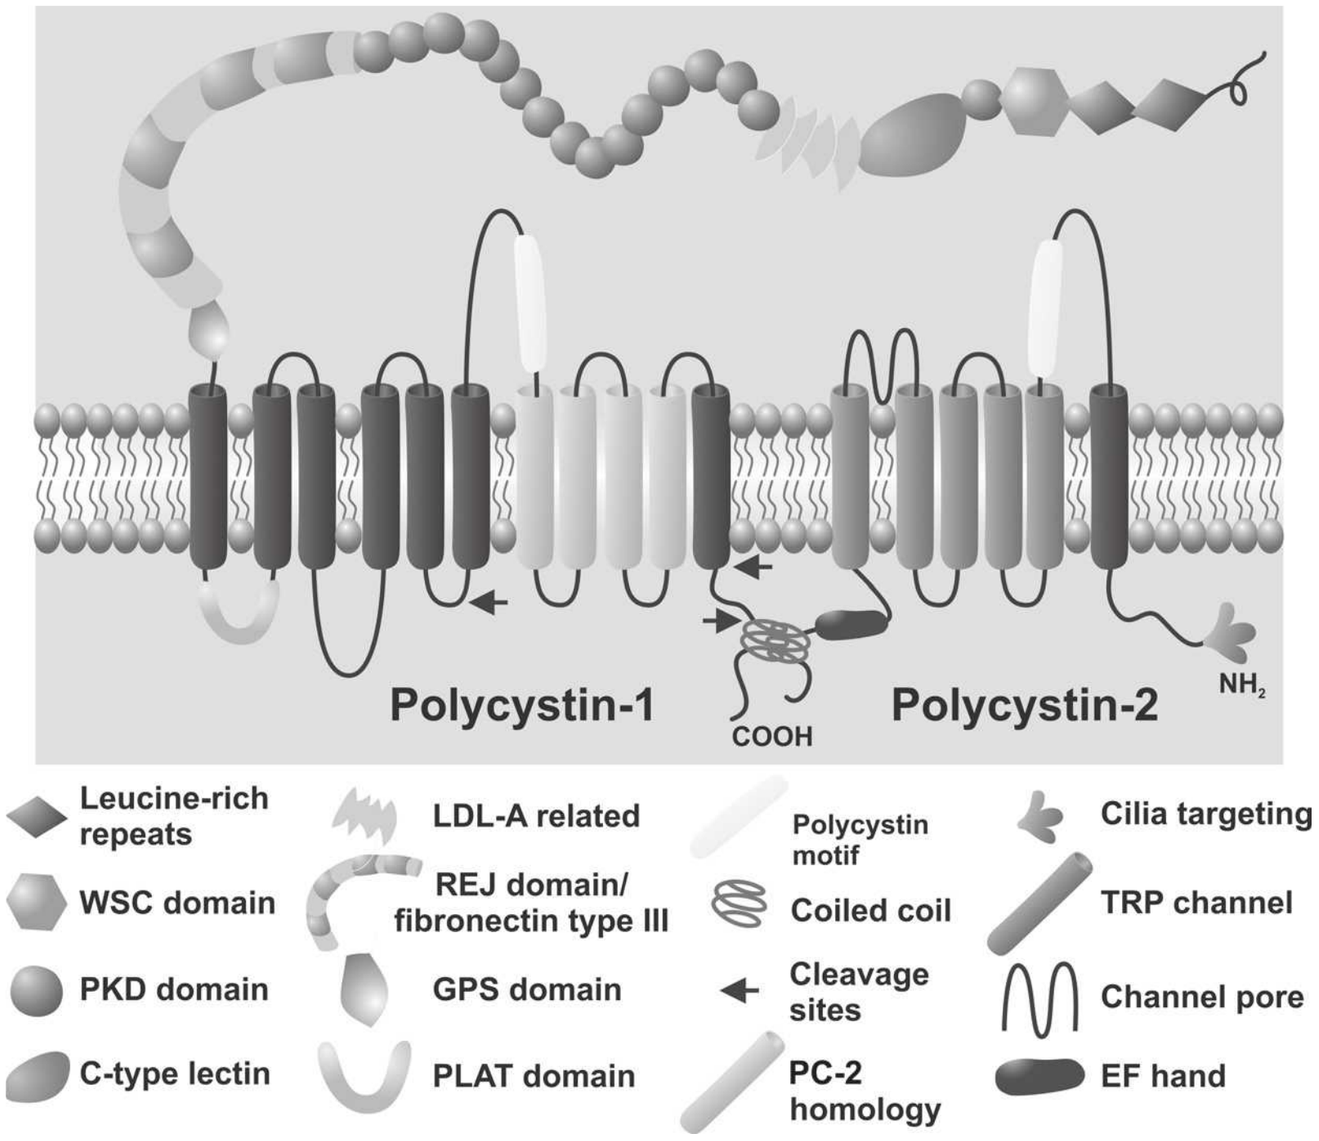

FIGURE 16.2 The protein products of the autosomal dominant polycystic kidney disease (ADPKD) genes *PKD1* and *PKD2*. The schematic drawing highlights the predicted domain structure of polycystin-1 (PC-1) and polycystin-2 (PC-2). PC-1 and PC-2 interact via coiled coil domains in their respective cytoplasmic carboxy (COOH)-termini to form a predicted receptor-channel complex; the most likely stoichiometry is three PC-2 molecules (only one is shown) and one PC-1 molecule. The extensive extracellular NH_2-terminal domain of PC-1 is cleaved at the G-protein–coupled receptor proteolytic site (GPS) in the endoplasmic reticulum (ER) but remains noncovalently associated with the intramembranous COOH-terminal PC-1 fragment. Additional putative cleavage sites are indicated by *arrows*. See the text for further discussion of the structural features of both proteins. PKD, polycystic kidney disease; LDL-A, low density lipoprotein-A; REJ, receptor egg jelly; PLAT, polycystin-1, lipoxygenase, alpha-toxin; TRP, transient receptor potential. (See Color Plate.)

PC-2 but lack critical residues suggesting that PC1 does not have the channel activity associated with PC-2 (see the following). The COOH terminus of PC1 contains a coiled coil domain that is necessary for interaction with PC-2.[156–158] In addition to the repeated partial PKD1 sequences on chromosome 16, there are four homologous protein products in the PKD1 gene family: PKD1L1, PKD1L2, PKD1L3, and PKDREJ. A complex of PKD1L3 protein with the PKD2 homolog, PKD2L1, has been assigned chemosensory function in sour taste and pH sensation,[159,160] although studies with Pkd1L3 knockout mice have called this into question.[161] PKD1L1, but not PKD1, has been implicated in left–right axis determination in mammals.[162]

Several functional cleavage processes have been defined for PC1. The best characterized of these is the autoproteolytic cleavage within the sequence HL↓T[3049] at the GPS in a process that requires an intact REJ module.[163,164] The GPS cleavage process occurs early in the secretory pathway, most likely in the endoplasmic reticulum (ER), and requires N-glycan attachment.[164] The resultant extracellular NH_2-terminal fragment and the intramembranous COOH-terminal fragment remain noncovalently associated with each other.[163] Although the GPS site is conserved in all PC1 homologs within and across species, at least two homologs, PKDREJ and the sea urchin protein SuREJ2, do not undergo GPS cleavage.[165,166] Experimental evidence for the functional importance of GPS cleavage in PC-1 comes from findings that pathogenic patient mutations in the REJ abrogate GPS cleavage, that cleavage deficient PC-1 does not support tubulogenesis and STAT1 activation in a cell culture assay, and that a GPS cleavage mutant knockin functions as a hypomorphic allele in mice.[163,167] GPS cleavage appears to promote cell surface expression of PC-1.[168] Cleaved PC-1 has been identified in urinary exosome–like vesicles, raising the possibility of a signaling function for shed polycystins.[169]

Additional cleavage products of PC-1 have been identified, although these are less well understood than the GPS cleavage. P100, a second intramembranous cleavage product of PC-1 encompassing the last six transmembrane domains, has been shown to diminish store-operated calcium entry by altering the translocation of the ER calcium sensor protein STIM1 to the cell periphery.[170] Two cleavages liberating different fragments of the cytoplasmic tail of PC-1 have also been identified. The first yields a 35 kDa fragment that translocates to the nucleus following cleavage step that is dependent on the presence of functional PC-2.[171,172] This fragment is released by gamma-secretase–mediated cleavage and regulates the Wnt and C/EBP homologous protein (CHOP) pathways by binding to respective transcription factors (TCF) and CHOP, thereby disrupting their interaction with a common transcriptional coactivator p300.[173,174] The second proposed COOH terminal cleavage product is a 15 kDa fragment that interacts with the transcriptional activator STAT6 and the coactivator p100 in a process that is enhanced by the cessation of flow-induced mechanical stimuli.[175] Inhibition of STAT6 in a Pkd1 mouse model results in the slowing of cyst growth.[176]

PKD2 and Polycystin-2

PKD2 encodes PC2, a 968 amino acid integral membrane protein with six transmembrane spans and intracellular NH_2 and COOH termini (Fig. 16.2).[135,177,178] It is a member of the transient receptor potential (TRP) family of cation channels and is also known as TRPP2.[179–182] Two mammalian homologs of PKD2, PKD2L1 (TRPP3) and PKD2L2 (TRPP5), have been identified. The TRP channel family is comprised of

28 different gene products, which function in diverse, mostly sensory, cellular processes including sensation of pain, temperature (hot and cold), taste, pressure, and vision.[183] The last five transmembrane spans of PC-2 have the greatest structural similarity with other TRP channels, with the region between the fifth and sixth transmembrane domains comprising the ion selectivity pore. An RVxP motif in the NH_2 terminus of PC-2 is necessary for its localization in cilia, and PC-2 can traffic to cilia independently of PC-1 (see the following).[184] Phosphorylation at serine 812 in the COOH terminus of PC-2 affects the channel properties[185] and trafficking[186,187] of the protein. The subcellular immunolocalization of PC-2 has been controversial. There is general consensus that PC-2 is abundantly expressed in the ER[177,179,188] and the primary cilium.[189,190] COOH truncated forms of PC-2 readily traffic to the plasma membrane,[177,184] and it has been suggested that coassembly with PC-1 is required for trafficking of full-length PC-2 to the generalized plasma membrane.[180] PC-2 has also been reported associated with centrosomes[191] and the mitotic spindles of dividing cells.[192]

The cellular mechanisms for trafficking PC-2 to the cilium and the somatic plasma membrane are divergent.[193] Trafficking begins with a coat protein complex II (COPII)-dependent process that delivers PC-2 from the ER to the cis side of the Golgi. From there, the bulk of PC-2 is returned to the ER in a process dependent on a 34 amino acid retrieval signal in the COOH terminus of PC-2. A minority of PC-2 enters a vesicular transport process directly from the cis part of the Golgi that delivers the protein to the cilium in a process that depends on Rab8a as well as the RVxP motif. If PC-2 is also to be delivered to the somatic plasma membrane (e.g., by truncation of the COOH terminus retrieval signal), this process traverses the Golgi in the conventional manner of other integral membrane and secreted proteins. PC-2, like PC-1 and the ARPKD (PKHD1) gene product fibrocystin, is a prominent component in urinary exosomeslike vesicles that are produced by the multivesicular body sorting pathway.[169] The PKD-related proteins and the exosomes that contain them may play a role in novel urinary signaling pathways in the kidney.

The COOH terminus of PC-2 contains EF hand[135,194,195] and coiled domains[156–158,195,196] and has been the subject of several biophysical and biochemical studies. The EF hand binds calcium[194] and may have a role in modulating channel activation and inhibition. The coiled coil domain is responsible for homo- and hetero-multimerization of PC-2 with itself and with PC-1, respectively. The structural data are most consistent with a complex consisting of three PC-2 molecules and one PC-1 molecule interacting through their respective coiled coil domains.[157,197] Critical residues in both proteins that weaken these interactions have been identified and should prove useful in modulating activity of the polycystins in experimental systems.[158,196] In addition to interacting with each other, PC-2 and to a lesser but still significant extent, PC-1, have acquired an extensive list of interacting proteins primarily associated with their respective COOH termini.[58] Although many of these interactions have shown functional effects in a variety of biologic systems, a direct role in the pathogenesis of ADPKD is lacking in most of them. This may in fact highlight the likelihood that PC-1 and PC-2 serve additional cellular and tissue functions that may not be directly related to their role in PKD. Identifying the roles specific to ADPKD remains a challenge especially in light of the fact that those roles might be subsumed by the minute fraction of each protein that appears in the primary cilium (see the following).

The Genes for Autosomal Dominant Polycystic Liver Disease

The two known genes for ADPLD, PRKCSH [116,117] and SEC63,[118] respectively encode the noncatalytic beta subunit of glucosidase II (GIIβ)[198,199] and SEC63p. These proteins work at the level of the ER to ensure the proper biogenesis of integral membrane and secreted proteins (Fig. 16.3). As such, their client proteins include up to one-third of the cellular proteome. GII is an ER luminal enzyme involved in glucose trimming of N-glycan moieties in the calnexin–calreticulin cycle. GII activity is necessary for proper folding and quality control of proteins passing through the ER translocon.[200] The ADPLD-associated GIIβ subunit contains an ER luminal retention signal and is required for the function of the GII holoenzyme.[201] SEC63p, an integral protein of the ER membrane, works upstream of GIIβ in concert with the SEC61 translocon pore and BiP, the major Hsp70 chaperone in the ER to effect the cotranslational targeting of precursor proteins with NH_2-terminal cleavable or noncleavable signal peptides.[202–205] SEC63p has a DnaJ-like domain located in the ER lumen, which recruits BiP to the translocon complex. BiP and SEC63p form a molecular ratchet that is responsible for the ATP-dependent vectorial movement of polypeptides into the ER lumen.[206] In contrast to the still incompletely understood functions of the polycystins, it is fairly clear that the two ADPLD gene products work together to facilitate cotranslational translocation across the ER membrane and the proper folding of nascent peptides destined to become either secreted or membrane-inserted proteins. Recent studies have elucidated the interrelationship of this function with polycystic kidney disease (see the following).

PKHD1 and Fibrocystin/Polyductin

A single gene, PKHD1, is known to be mutated in human ARPKD. Heterozygous carrier parents are typically asymptomatic, although a recent report has suggested that they have a predisposition to polycystic liver disease and increased renal medullary echogenicity by ultrasound,[207] whereas affected offspring show bile duct proliferation associated with fibrosis in the liver and relatively homogeneous fusiform dilation of collecting duct segments in the kidney. The protein product of PKHD1 is a 4074 amino acid type I integral membrane protein with a 3858 amino acid extracellular NH_2-terminus, a single transmembrane domain, and a 192 amino acid cytoplasmic tail called fibrocystin/polyductin

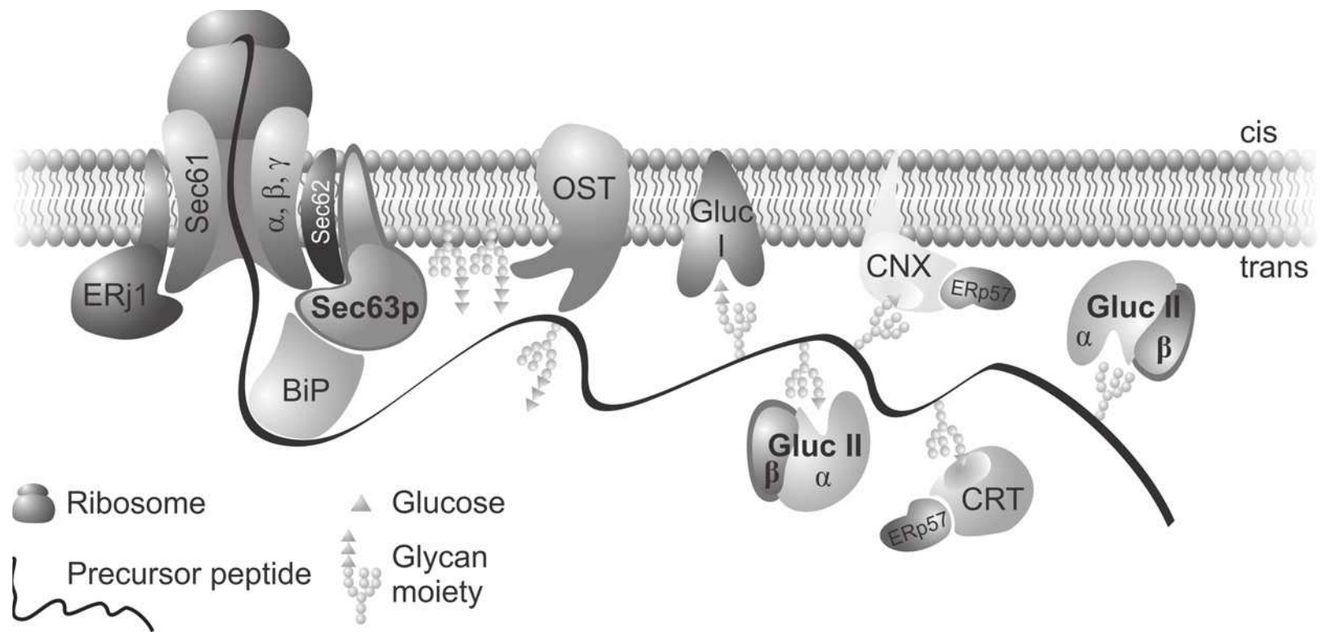

FIGURE 16.3 The functional pathway for isolated polycystic liver disease genes, *SEC63* and *PRKCSH*. The respective products Sec63p and glucosidase IIβ (Gluc IIβ) are resident endoplasmic reticulum (ER) proteins that function in the biogenetic pathway for integral membrane and secreted proteins. The ribosome and precursor polypeptide docks with its receptor comprised of the Sec61α,β,γ/Sec62 complex on the cytoplasmic (*cis*) aspect of the ER membrane. The ER luminal Hsp70-type chaperone protein BiP, acting in concert with the Hsp40 type cochaperones, Sec63p and ERj1, facilitates the cotranslational translocation of nascent peptides with cleavable or noncleavable NH_2-terminal signal peptides. The J domain of Sec63p recruits BiP to the translocation pore complex and activates it by converting its low substrate affinity ATP-bound form to its high affinity ADP-bound form. BiP binds the nascent peptide and acts as a molecular ratchet, facilitating translocation. Oligosaccharyl transferase (OST) catalyzes the attachment of the core glycan moiety to asparagine residues (*N*-glycosylation). Gluc I removes the terminal glucose from the glycan and Gluc II, comprised of α and β subunits, removes the second glucose. This allows the nascent peptide to complex with the chaperone proteins calnexin (CNX) and calreticulin (CRT), both of which associate with thiol-disulfide oxidoreductase ERp57 and promote proper folding and quality control of the precursor polypeptides. Gluc II removes the third glucose from the *N*-linked glycan once the peptide is properly folded. Proteins failing to fold properly are targeted for ER-associated degradation (ERAD) by retro-translocation through the translocon complex followed by proteasomal degradation in the cytoplasmic compartment (not shown).

(FPC).[136,137,208] FPC undergoes "notchlike" proteolytic processing that leads to the shedding of the extracellular domain and the release of the intracellular COOH-terminal fragment through regulated intramembranous proteolysis.[209] FPC, like PC-1 and PC-2, has been found in urine and bile in exosomelike vesicles (ELV),[169] with a recent study suggesting that the majority of mature FPCs are targeted to ELVs.[210] ELV components may have a role in noncell autonomous signaling along the nephron.

MOLECULAR GENETICS OF AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

The discovery of the genes for ADPKD, ADPLD, and ARPKD has enabled an emerging understanding of the increasingly complex molecular bases for cyst formation. Elucidation of these mechanisms is essential for the future development and validation of therapies for ADPKD. The discovery of the genes for ADPKD demonstrated that the preponderance of human disease mutations in both PKD1 and PKD2 were heterozygous loss-of-function variants. This made it unlikely that ADPKD occurred by a true dominant or gain-of-function mechanism, leaving the paradox of an apparent disconnect between germline heterozygous mutations that affect all cells in the body and the focal nature of cyst formation affecting discrete points in a small subset of nephrons. Studies using human material and mouse models of ADPKD and related diseases have implicated a complex interplay between multiplicity of factors, all related to germline mutations in PKD1 or PKD2, giving rise to cyst formation. Over the past decade, advances in the field have defined the occurrence and timing of somatic second hit mutations, the dosage of PKD genes, and most specifically, of PKD1. The effects of noncell autonomous factors including kidney injury, inflammation, and as yet undefined local signals all play a central role in determining the severity and progression of polycystic kidney disease.

The "Two-Hit" Mechanism

A preponderance of evidence supports the notion that homozygous inactivation of either PKD gene during kidney development or adult life is sufficient to result in cysts. Such a cellular recessive mechanism proposes that the critical cyst-initiating event in an affected heterozygous individual occurs when a somatic mutation inactivates the remaining normal copy a PKD gene in an epithelial cell(s) along the nephron. Such a cell undergoes a change in phenotype manifest through increased proliferation coupled with other processes such as a change to a secretory phenotype that, over time, give rise to the focally derived cysts that predominate in ADPKD (Fig. 16.4A). Direct experimental evidence of such a mechanism was first described using human polycystic kidneys from which cells lining individual cysts were

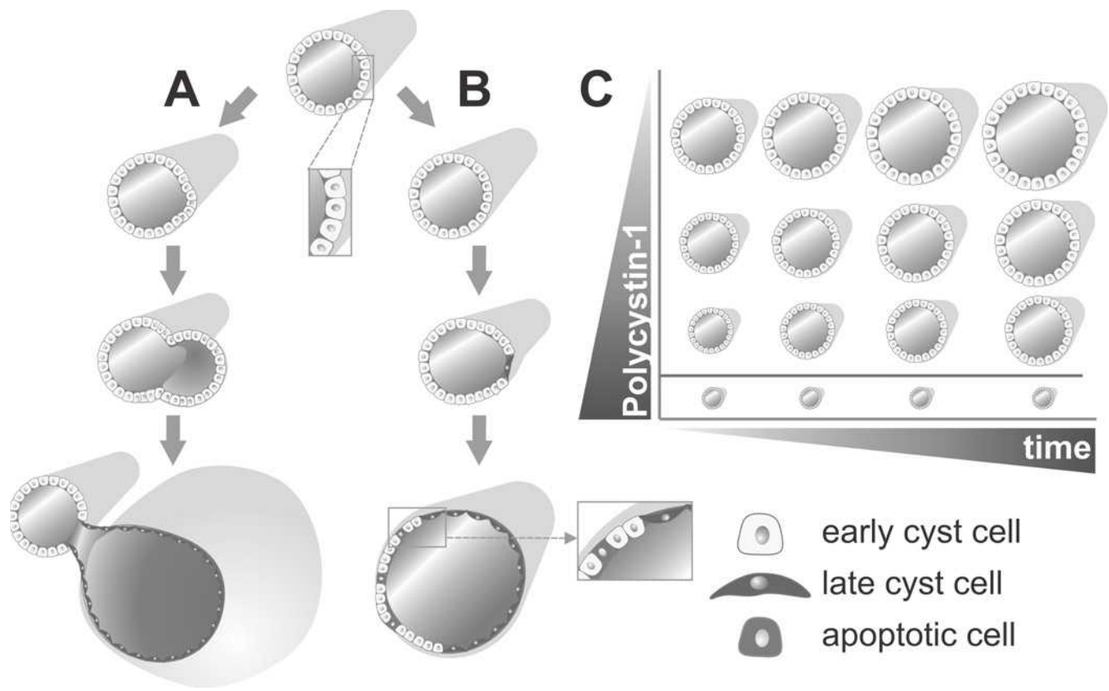

FIGURE 16.4 Mechanisms of cyst formation. **A**. Individual tubular cells undergo a somatic second hit mutation of the normal allele (early cyst cell) and these cells proliferate, forming a focal out-pouching from the tubule that progressively enlarges and eventually loses its connection with the tubule of origin. **B**. Additionally, as the early cyst cell mass expands following the second hit, non–cell autonomous processes can contribute to apoptosis in surrounding cells and to expansion of the tubule to form mosaic cysts comprised of normal tubule cells as well as early and late cyst cells. **C**. Cyst formation can occur as a function of reduced polycystin (PC)-1 dosage and time. When there is sufficient PC-1 (below the *line*), tubules maintain normal structure. Once PC-1 levels fall below the critical threshold (above the *line*), progressive cyst formation ensues. The *vertical axis* illustrates the concept that the lower the dose of residual PC-1, the more quickly cyst growth occurs. The *horizontal axis* illustrates that at each level of reduced PC-1 dosage, cyst growth is progressive over time.

isolated and examined for a loss of heterozygosity (LOH) as a marker for the loss of the normal PKD1 allele.[211] Several subsequent studies confirmed the occurrence of LOH in a subset of cysts in both the kidney and liver due to mutations in either PKD1 or PKD2.[212–214] Together, these studies demonstrate an association between LOH and cysts and support the hypothesis that individual cysts represented clonal expansions of cells that had undergone somatic second hits.

Dynamic evidence of the two-hit mechanism of cyst formation was initially provided by a mouse model of Pkd2 in which the gene-targeting event resulted in a serendipitous allele, $Pkd2^{WS25}$, which undergoes spontaneous inter- or intragenic recombination resulting in conversion to a null allele or reversion to the wild-type allele.[215] This model spontaneously develops cysts over time that result from stochastic gene inactivation events that most closely models the human disease. Subsequently, the principle that second hit mutations are sufficient for cyst formation has been demonstrated in a multitude of knockout mouse models in which conditional alleles produced by flanking loxP sites in the mouse orthologs of Pkd1 or Pkd2 are inactivated by transgenically expressed Cre recombinase enzyme.[211,216–223] The expression of the Cre recombinase can be controlled spatially by tissue and nephron segment–specific promoters and temporally by using inducible forms of the Cre recombinase. The past decade has seen extensive use of these animal models to define additional mechanisms of cyst formation and to evaluate candidate target pathways in preclinical evaluations of therapy.[224–226]

Studies comparing the number and rate of growth of cysts in human PKD1 and PKD2 show that the relatively slower progression of disease in PKD2 patients is associated with a reduced number of cysts, but not with differences in the rate of growth of PKD1 and PKD2 cysts.[227] PKD2 patients also have the same spectrum of extrarenal manifestations as PKD1 patients. These data are most consistent with the interpretation that the rate of somatic second step mutations is lower for the much smaller protein coding region in the PKD2 gene, resulting in a reduced rate of cyst initiation and, therefore, a smaller number of cysts. Biologically, once either PKD gene is lost, they appear to be functionally equivalent as indicated by similar rates of PKD1 and PKD2 cyst growth in humans, similar cystic phenotypes in knockout mouse kidneys,[217,228] and the interchangeability of a mating defect observed in male Caenorhabditis elegans nematodes with inactivation of either gene's ortholog.[229]

Conditional and inducible gene inactivation models in the mouse have also played a critical role in defining the importance of cilia to the pathogenesis of PKD. The intraflagellar transport proteins and their associated motor proteins are necessary for the formation and maintenance of intact primary cilia in renal tubular epithelial cells. Inactivation of these genes in the mouse kidney results in cyst formation that is reminiscent of the cysts formed following the inactivation of Pkd1 and Pkd2.[230–232] These and related findings have solidified the link between the primary cilium in the pathogenesis of PKD (see the following). In addition, kidney-specific inactivation in mice has defined an in vivo system by which candidate genes whose function is thought to be central to maintaining normal tubular structure can be evaluated to determine whether or not they are associated with cyst formation. Because work with mouse models is both time

consuming and costly, the discovery that the inactivation of cilia and PKD-related genes in the vertebrate genetic model organism zebrafish can model cystic diseases[233] has permitted more rapid discovery and validation of important genetic components in the cyst formation process.

The Timing of Gene Inactivation

Taking advantage of the ability to temporally control activity of the Cre recombinase, and therefore of the timing of the inactivation of the mouse orthologs of Pkd1 or Pkd2, investigators set out to determine the differential effects of inactivation of the respective genes during and after kidney development. Inactivation of Pkd1 during kidney growth and development resulted in explosive cyst growth,[220,223] whereas inactivation in the postdevelopmental adult kidney resulted in a much slower, indolent progression of cystic disease.[220] These differences based on timing of gene inactivation were also seen with inactivation of Ift88,[231] an intraflagellar transport protein, and Kif3a,[234] a component of the heterotrimeric kinesin II motor protein complex required for integrity of cilia. These findings have raised questions regarding the timing of second step mutations in human ADPKD. Computational models based on the measured rate of cyst growth observed by volumetric MRI in human subjects suggest a disconnect between cyst size and the simple two-hit model beginning with single cells that can be reconciled if the bulk of the second hits take place in utero and are associated with extraordinary prenatal cyst growth.[235] An alternative explanation may be that cyst formation entails additional factors beyond the simple two-hit model beginning with a single cell.

The Role of Noncell Autonomous Factors in Cyst Progression

Studies in both heterozygous and knockout animal models of PKD orthologous genes or genes related to cilia structures have shown that acute injury promotes accelerated cyst growth in mice. Injury models using ischemia reperfusion,[234,236–238] nephrotoxins,[239] and compensatory hypertrophy following unilateral nephrectomy[240] resulted in marked acceleration of cyst progression in Pkd1 and Pkd2 heterozygotes, and Pkd1, Kif3a, or Ift88 adult knockout models. These findings have led to the proposal that environmental "third hits" are an essential part of disease progression in human ADPKD.[241] This effect is presumably related to the induction of a proliferative response following kidney injury because cells with reduced or absent polycystin expression or cells lacking cilia have a greater proliferative potential. It is likely that instances of acute kidney injury or perhaps subclinical injury in patients with ADPKD have deleterious effects on the progression of polycystic disease. Nonetheless, it should be kept in mind that cyst formation occurs, albeit at a slower pace, following adult second hit mutations without the requirement for third hits.[220,242,243] Therefore, the clinical significance of the contributions from kidney injury to cyst progression in the majority of ADPKD patients remains uncertain.

An intriguing study using chimeric mice produced by aggregation of $Pkd1^{-/-}$ pluripotent embryonic stem cells and wild-type morulae showed that cysts can be mosaic (i.e., comprised of both $Pkd1^{-/-}$ and $Pkd1^{+/+}$ cells).[244] The wild-type $Pkd1^{+/+}$ morulae were derived from mice that express lacZ ubiquitously so that cells from the wild-type lineage could be stained blue by adding substrate for β-galactosidase. The $Pkd1^{-/-}$ cells did not express lacZ and so could be distinguished from cells of wild-type origin throughout the life of the animals. The degree of cyst formation correlated with the extent of chimerism in this model; the greater the contribution from $Pkd1^{-/-}$ cells, the greater the cyst burden. Individual cysts were mosaic, comprised of both wild-type cells that could be stained blue and that retained their cuboidal epithelial shape as well as $Pkd1^{-/-}$ cells that did not stain blue and that had a squamoid shape typical of Pkd1 knockout cyst cells. Over time, the $Pkd1^{-/-}$ cells induced apoptosis in surrounding wild-type cells by a c-Jun N-terminal kinase (JNK)–dependent pathway.[244] This constellation of findings raises the possibility that noncell autonomous processes are active in cyst formation and that cystic disease progression and tissue remodeling in ADPKD involves proliferative expansion of the $Pkd1^{-/-}$ cells' mass coupled with either inclusion or programmed cell death of surrounding wild-type cells (Fig. 16.4B).

Inflammatory and fibrotic processes have long been identified in human ADPKD tissues. In most cases, this has involved late stage cystic kidneys that have undergone a lifetime of cyst infection and hemorrhage as well as systemic damage from hypertension and other factors. Proinflammatory cytokines such as IL-1β, TNF-α, and IL-2 have been identified in cyst fluid samples from human kidneys.[56] Monocyte chemoattractant protein-1 (MCP1) has been found in the urine of ADPKD patients.[245] Expression of MCP1 and macrophage infiltration was found in the nonorthologous Han:SPRD polycystic rat model,[246] and a transcriptome analysis revealed a strong innate immune response signature in another nonorthologous model, the cpk mouse.[247] Most recently, studies using early onset orthologous gene models based on Pkd1 and Pkd2 showed infiltration by an abnormally large number of alternatively activated macrophages in cystic mouse kidneys.[248] Therapeutic depletion of these macrophages resulted in decreased cyst formation, decreased proliferation of cyst cells, and improved preservation of renal function, suggesting that macrophage infiltration and differentiation may be another factor promoting progression of polycystic kidney disease.

Gene Dosage Effects

There is growing evidence to support the role of threshold dosage variation in both the initiation of cysts and the progression of PKD. The absence of pervasive cyst formation along the entire nephron in human ADPKD and in

heterozygous animal models indicates that a 50% reduction of PKD1 or PKD2 gene dosage resulting from the heterozygous germline state in ADPKD is not sufficient for clinical cyst growth. An analysis of individual human cysts identified some with transheterozygous mutations (i.e., mutations affecting one copy of PKD1 and one copy of PKD2 in the same cyst).[249] Subsequent studies in a unique family with a bilineal inheritance of PKD1 and PKD2[250] as well as transheterozygous mouse lines[218] showed that compound transheterozygous mutations in PKD1 in PKD2 are also not sufficient for cyst initiation. The two individuals in the family with bilineal inheritance who had mutations in both genes manifested severe but not explosive PKD with the onset of ESRD in their late 40s.[250] Transheterozygous mice developed more severe cystic disease than would be expected from a simple additive effect of second hits on both Pkd1 and Pkd2, but nonetheless showed that the transheterozygous state is not sufficient for cyst formation.[218] The extra additive effect on cyst formation in the transheterozygous mice suggested a possible threshold effect whereby second hit mutations producing hypomorphic alleles that normally would result in very slow or absent cyst formation can result in more active proliferation when there is haploinsufficiency of both PKD genes.[218]

More severe reductions in gene dosage, particularly of PKD1, have subsequently been associated with graded increases in the severity of cystic response, with a complete loss of polycystins leading to the most severe disease. The importance of dosage is apparent from animal models with mutant Pkd1 alleles that express reduced rather than absent functional PC-1. Mice homozygous for two such hypomorphic alleles develop polycystic kidneys.[251,252] Another example of cyst formation resulting from a reduced dosage of polycystin is seen following inactivation of the RNA-binding protein bicaudal C.[253] Bicaudal C normally antagonizes the inhibitory effect of the microRNA miR–17 on expression of PC-2, and the markedly reduced expression of PC-2 in the absence of bicaudal C is thought underlie cyst formation in this model.

The most compelling experimental data for the centrality of gene dosage come from a study that combined orthologous gene models of isolated ADPLD (Prkcsh, Sec63) with models of ADPKD (Pkd1, Pkd2) and ARPKD (Pkhd1) showing that PC-1 dosage is the central determinant of kidney cyst progression in all of these diseases.[254] The study showed that conditional inactivation of either Prkcsh or Sec63 in the kidney resulted in PKD. This finding extended the phenotypic interrelationship between ADPLD and ADPKD to include the kidney and showed that ADPLD likely occurs via a cellular recessive second hit mechanism similar to ADPKD.[255] The study went on to show that reducing the dosage of PC-1 or PC-2 further exacerbated the kidney cysts in the ADPLD knockout mice. Conversely, increasing the expression of PC-1 (but not PC-2) by transgenic expression ameliorated the kidney cystic disease. The ADPLD genes affected cyst formation by significantly reducing the steady-state levels of PC-1 due to defective biogenesis (Fig. 16.3). The ability to worsen and improve kidney cysts following ADPLD gene inactivation by either reducing or increasing the PC-1 dosage, respectively, indicates that PC-1 is the rate limiting component in this process. The rescue of the ADPLD cysts by overexpression of PC-1 was durable but not permanent, indicating that the time required for cyst formation is inversely related to the degree of reduction of PC-1 dosage. Taken together, these findings indicate that a combination of PC-1 dosage and time are key determinants of cystic progression (Fig. 16.4C). Furthermore, reduced PC-1 dosage resulted in worsened cyst formation following homozygous inactivation of the ARPKD gene, Pkhd1, suggesting that at least in mouse models the expressivity of the ARPKD phenotype in the kidney is modulated by functional PC-1 dosage.[254,256] In aggregate, this study defines dosage- and time-dependent interrelationships between ADPKD, ARPKD, and ADPLD in orthologous mouse models and establishes PC-1 activity as the central determinant of the phenotypes in all three disease models.

Genotype–Phenotype Correlations and Genetic Modifiers

Genotype–phenotype correlations are variations in disease progression (the phenotype) based on different mutations (the genotype) in the primary gene underlying a human Mendelian disease. The major genetic determinant of severity in ADPKD is the underlying disease gene locus effect—PKD1 mutations result in ADPKD with mean age of ESRD almost 2 decades earlier than PKD2.[10,227] In clinical studies, 85% of ADPKD families have PKD1 mutations and only 15% have PKD2 mutations. The milder phenotype has likely caused underascertainment of PKD2 families in these studies, and population-based ascertainment suggests that 29% of ADPKD families have PKD2.[13] In the group of individuals entering ESRD after age 65, 50% are PKD2 families.[257] Within the PKD1 population, a small subset of patients with mutations resulting in a contiguous gene deletion syndrome affecting the tuberous sclerosis complex 2 gene, TSC2, have severe PKD, often presenting in early childhood.[258,259]

Human ADPKD families with recessive inheritance of nonsynonymous amino acid substitution mutations in PKD1 have recently been described[260] and have been found to mimic ARPKD.[261] Although fetuses homozygous for complete loss-of-function PKD gene alleles are presumed to be nonviable, these recessively inherited hypomorphic PKD1 alleles have reduced function, allowing for live-born progeny. They develop early onset cystic disease with cysts that are homogeneous in size and distribution. This is in contrast to the usual heterogeneous and focal cyst population seen in typical ADPKD and are more reminiscent of ARPKD. Similar findings have been described in an individual homozygous for a PKD2 missense mutation due to uniparental disomy (two copies of part of a chromosome from one parent and none from the other).[262] A weak modifier effect resulting in

greater severity of ADPKD from PKD1 mutations in the 5′ end of the gene compared to the 3′ end has been reported.[263] Recently, a dominantly inherited heterozygous missense variant in PKD1 was identified in a family segregating a mild form of ADPKD that was clinically similar to PKD2-based disease.[264] This finding suggests that hypomorphic alleles in the heterozygous state in PKD1 can also result in disease that is clinically milder.

Genetic variations at loci other than the primary disease gene can modify disease severity. Because all affected individuals in a given family have the same germline mutation in either PKD1 or PKD2, the high degree of intrafamilial variability observed in the severity of ADPKD has been taken to suggest that genetic modifiers and environmental factors influence the progression of ADPKD. This conclusion should be tempered in light of the fact that the timing and extent of somatic second hit mutations will also contribute to intrafamilial variability. Although no strong genomewide genetic modifier effects have been identified in ADPKD, several lines of evidence support the hypothesis that such modifiers exist and should be discoverable. The observation that a variation in age at ESRD among siblings is significantly greater than the variation in genetically identical twin pairs is likely attributable to the existence of genetic modifier effects.[265] Similarly, the occurrence of severe neonatal PKD in the progeny of parents with very mild ADPKD due to PKD2 mutations suggests that genetic modifiers at non-PKD gene loci may impact disease progression.[266] Two studies[267,268] used variance component analysis to determine heritability in ADPKD (i.e., the proportion of phenotypic variance explained by modifier genes). They found that between 32% and 42% of the variance in creatinine clearance and 43% to 78% of the variance in age at ESRD were heritable.

The existence of genetic modifiers has been directly demonstrated in selected cases of ADPKD. A report identified severely affected ADPKD patients in whom heterozygous mutations in PKD1 were accompanied by heterozygous mutations in the transcription factor hepatocyte nuclear factor-1β (HNF-1β).[269] Recessively inherited mutations in HNF-1β result in glomerulocystic disease in maturity onset diabetes of the young type 5 (MODY5) and HNF-1β regulates transcription of several PKD genes, including PKD1.[270–272] This suggests that the severity of ADPKD may be modified by mutations that indirectly affect expression of PKD genes. A directed genetic association study analyzing 173 biologic candidate genes in 794 ADPKD patients from 227 families identified Dickkopf 3 (DKK3) as a possible genetic modifier for disease severity in ADPKD.[273] DKK3 antagonizes Wnt/β-catenin signaling, a pathway that has been implicated in cyst growth (see the following).

CILIA AND CYSTIC KIDNEY DISEASE

Following the discovery of the genes responsible for ADPKD, the next major quantum of advancement in the field arose from the understanding that the structure and function of the primary cilium is central to the pathogenesis of polycystic diseases.[274,275] All cells in the kidney tubule with the possible exception of intercalated cells have a single primary cilium extending from the apical surface into the tubule lumen. Primary cilia differ from motile cilia in that they have nine pairs of radially arrayed microtubule bundles but lack the central pair, hence they are called 9+0 cilia (Fig. 16.5). Cilia comprise a unique cellular compartment that is devoid of intracellular components such as membrane-bound vesicles and ribosomes.[276] As a consequence, all the protein components of cilia must be synthesized in the cell body

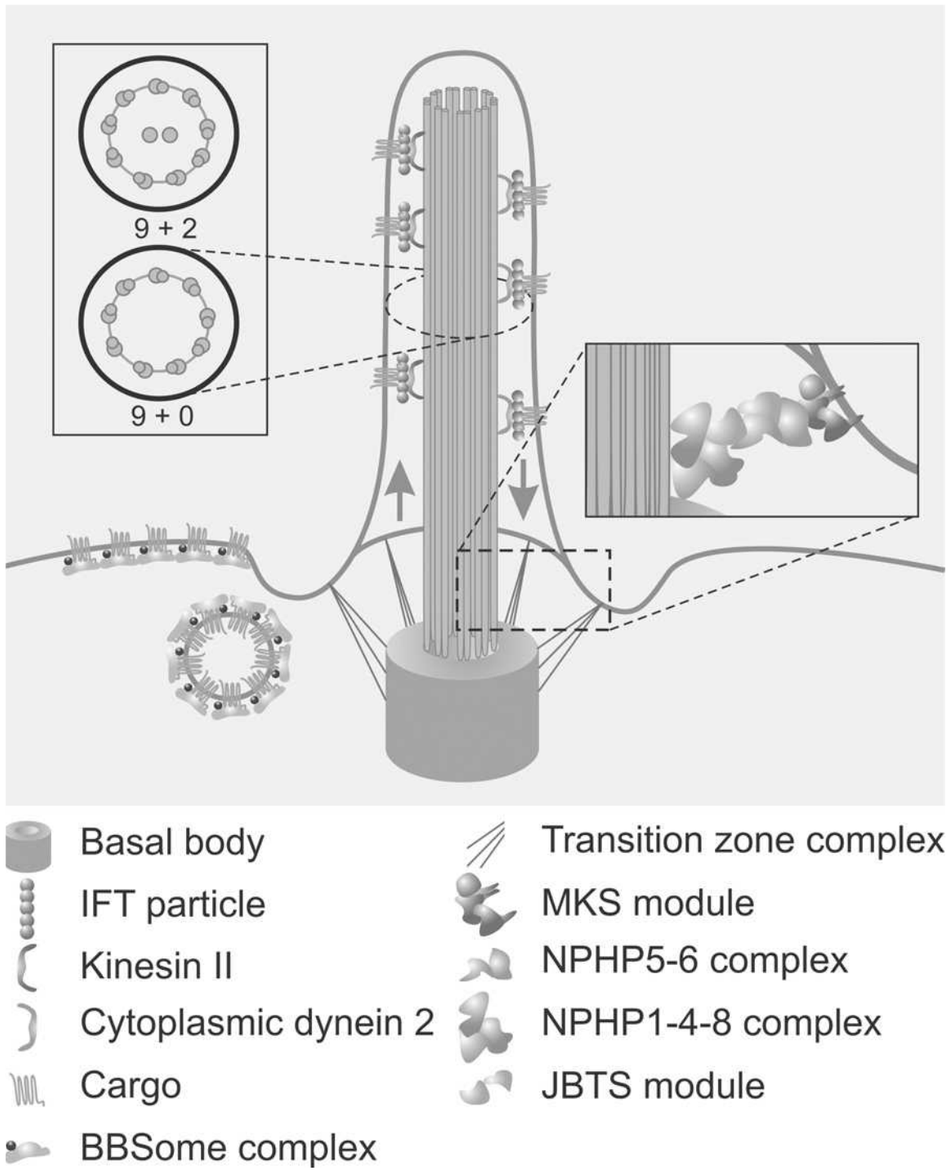

FIGURE 16.5 Cilia structure and function. Primary cilia are structured on nine pairs of radially arrayed microtubules without the central pair found in motile cilia. The ciliary axoneme emanates from the basal body, and the cilia compartment is separated from the body of the cell by the transition zone complex. The delivery of integral membrane proteins likely occurs by targeted exocytosis near the base of the cilia. The sorting of specific proteins destined for cilia may be mediated by the BBSome coat complex, which contains several of the gene products associated with Bardet-Biedl syndrome (BBS). The protein-sorting process is regulated by the transition zone complex, which has associated with it the protein products of the ciliopathy genes. The membrane proximal component of this complex is primarily composed of Meckel Gruber syndrome (MKS) proteins. Two nephronophthisis (NPHP) complexes, respectively based on NPHP5/6 and NPHP1/4/8 and in association with Joubert syndrome (JBTS) gene products, have also been identified. Within the cilium, cargo proteins are transported on IFT particles with kinesin II motor proteins responsible for anterograde transport away from the cell body and cytoplasmic dynein motor proteins responsible for retrograde transport back toward the cell body. (See Color Plate.)

and transported to cilia; similarly, the turnover of cilia components requires retrograde transport to the cell body. These transport processes are collectively referred to as intraflagellar transport (IFT). IFT particles are protein complexes necessary for bidirectional transport of cilia components that are moved along the microtubular ciliary axoneme by molecular motors.[276,277] The cilium is nucleated on the apical surface of epithelial cells by the basal body complex comprised of the centrioles in nondividing cells. The base of the cilium has a transition zone that serves as a sorting complex to regulate the trafficking of proteins into and out of the cilia.[278–280] Primary cilia subsume a broad array of sensory functions in different tissues and cell types.[281,282] As sensory organelles, cilia make use of their specialized structural features and the restricted access of cellular components to uniquely integrate signals from the cell's surroundings.

Several convergent lines of evidence support the connection between cilia function and the group of renal cystic disorders that include ADPKD and ARPKD as well as for a broader group of recessively inherited "ciliopathy diseases" such as NPHP, BBS, Joubert syndrome (JBTS), and MKS (Table 16.1). The early evidence for a connection between cilia and PDK came indirectly from findings in model organisms. The first gene identified for a recessive polycystic kidney phenotype in the mouse, Tg737,[283,284] was subsequently shown to be Ift88, an IFT complex B component.[285] Independently, the C. elegans homolog of PKD1, called lov–1, was found expressed in sensory neuronal cilia in male nematodes.[286] More direct evidence for the central role of cilia in ADPKD was obtained when PC-2 and PC-1 were localized to cilia in cells and tissues.[189,190] These findings led to a prospective study showing that kidney-selective inactivation of Kif3a, a component of the heterotrimeric kinesin-2 motor complex, resulted in the loss of cilia along the nephron, which recapitulated a polycystic kidney phenotype.[230] An unbiased phenotype-driven forward genetic screen for recessive loss-of-function alleles resulting in pronephric cysts in zebrafish identified 10 genes promoting cyst formation.[233] These included Pkd2 and Hnf-1β, IFT-related genes, and novel cilia-related genes, thus solidifying the connection between cilia structure and function and kidney cyst formation in vertebrates. Finally, human gene cloning for an extensive series of diseases that shared fibrocystic kidney phenotypes (e.g., NPHP, JBTS, MKS, and BBS) found that the respective protein products of these disease genes were mostly expressed in the cilia-basal body complex (Table 16.1).[275,287]

Polycystins have been localized to cellular compartments other than cilia.[288] Although it is widely believed that the function of polycystins in cilia is central to the pathogenesis of ADPKD, the contributions of polycystins expressed in other subcellular locations is uncertain. PC-1 has been localized to the basolateral membrane,[289] at sites of cell matrix adhesion[290] and intercellular adhesion,[291] and at desmosomes.[292] There is universal agreement that PC-2 shows its most abundant expression in the ER in cells[177] and in kidney tissues.[179] The localization of PC-2 to the generalized plasma membrane outside of cilia has been controversial.[177,185] The surface expression of PC-2 has been proposed as requiring coassembly with PC-1,[180] although PC-2 is able to traffic to cilia independently of PC-1.[184] The expression of PC-1 has shown developmental regulation with higher levels early in development and a reduced level of expression in adult tissues.[293,294] Similar changes in the expression of PC-2 with developmental stage have not been reported.

Ciliopathies

The recessive ciliopathy disorders (e.g., NPHP, JBTS, MKS, and BBS) have both clinical and genetic overlap amongst each other. The clinical overlap involves the range of tissues in which cilia function plays a central role.[275,282,295] For example, the outer segment of the retina represents a modified cilium, and retinal degeneration is seen in the Senior Loken variant of NPHP, as well as in JBTS, MKS, and BBS.[296] Cilia are also essential to Hedgehog signaling, which is important for patterning of the digits, and MKS, BBS, and another ciliopathy, such as orofacial digital syndrome, show digital defects.[282] Other manifestations associated with recessive cilia mutations include left–right asymmetry defects and associated cardiac heterotaxy syndromes,[297–299] central nervous system (CNS) malformations with developmental delay,[296] obesity,[231] anosmia,[300] and skeletal defects.[301] Genetic overlap among the ciliopathies occurs because mutations in the same gene can give rise to different diseases along this phenotypic spectrum (e.g., mutations in MKS3 can cause both MKS and JBTS; mutations in CEP290 can cause NPHP, JBTS, MKS, and BBS; and mutations in TMEM216 cause MKS and JBTS).[302,303]

The ciliopathy disease gene products have been segregated into distinct functional complexes within cilia (Fig. 16.5). Several of the BBS gene products comprise the functional BBSome that is central to the selective delivery of integral membrane proteins into cilia.[304–306] The gene products associated with NPHP, JBTS, and MKS comprise part of the transition zone gatekeeper complex at the base of cilia.[276,278,307] Within this transition zone complex, there are at least three functional subcomplexes.[307] NPHP gene products are active in apical organization and centriole/cilia integrity, MKS gene products are associated with Hh signaling,[307] and JBTS-MKS complex proteins regulate ciliary membrane composition.[278] Although functionally interrelated, the IFT, BBSome, and NPHP-JBTS-MKS complexes do not appear to interact physically, and only components of the latter two are associated with human diseases. It is possible that the absence of human disease resulting from recessive IFT mutants is due to lethality.

Relationship of Polycystic Diseases to Ciliopathies

Although it is tempting to categorize ADPKD as part of the ciliopathy spectrum of disorders, there are some important distinctions that support keeping ADPKD and diseases with close functional relation to it (ADPLD and ARPKD) in a conceptually and biologically distinct compartment. From a genetic

standpoint, the ciliopathies are all recessively inherited. It is likely that somatic second hits are affecting the normal copies of the ciliopathy genes in heterozygous carrier parents, yet these individuals do not develop clinical cystic phenotypes. This is in stark contrast to ADPLD, in which heterozygous patients still form liver cysts following second hit mutations in genes whose products only indirectly affect PC-1 and PC-2 activity.[254,255] The genetic evidence suggests that ciliopathy genes really have limited or absent functional interaction with the polycystins. These findings are also consistent with the view that the ciliopathy disorders are primarily developmental diseases with less of a role in structural homeostasis of the adult kidney than the ADPKD gene products. From a biochemical standpoint, PC-1, PC-2, and FPC are all integral membrane proteins and are notably absent from any of the complexes described for the other ciliopathy genes. Conceptually, the ciliopathy gene products function in establishing and maintaining the structural integrity and the unique molecular composition of cilia. PC-1 and PC-2 (and FPC) are part of that unique composition and form a receptor-channel signaling complex that subsumes a specific sensory signaling function within the primary cilium. The genetic and functional dichotomy between ciliopathies and polycystic diseases should raise a cautionary note in extrapolating molecular pathways defined in terms of defects in the cilia structure and function based on IFT, the transitional zone, and the BBSome mutations to disease pathogenesis in ADPKD, ADPLD, and ARPKD.

PATHOGENESIS: CELLULAR PATHWAYS AFFECTED BY THE POLYCYSTINS

Cellular Sensory Reception

The polycystins are integral membrane proteins expressed on a sensory organelle, the primary cilium. PC-1 has a structure suggestive of receptor function, and PC-2 is a member of the TRP nonselective cation on the channel family that largely serves as receptor-gated sensory signaling channels.[308] These features have been taken to indicate that PC-1 and PC-2 function as a sensory receptor-channel signaling complex, but the specific nature of the signal that the polycystins "sense" has remained elusive. The predominant hypothesis is that the polycystins comprise a mechanosensory complex within the cilia that detect luminal fluid flow or shear stress. The data to support this role come from laminar shear stress experiments performed on ciliated monolayers of cells in culture, which showed a global cytosolic calcium response that was dependent on the bending of intact cilia[309,310] and the presence of active PC-1 and PC-2.[311] Indirect in vivo evidence supporting this function came from a study examining defects in lateralized, flow-dependent calcium signaling in the embryonic node in mice.[299] The formation of the vertebrate left–right body axis requires leftward vectorial fluid flow generated by motile cilia in a transitory embryonic structure referred to as the embryonic node. Pkd2 knockout animals, which have a randomization of the left–right axis,[297] show a failure to initiate normal calcium transients along the left side of the node presumably due to the failure to sense the flow signal.[299] This flow sensor hypothesis suggests that renal tubular luminal flow per se is required for the normal homeostatic structural maintenance of the kidney, something that has not yet been directly demonstrated.

The alternative hypothesis that unknown ligands are involved in polycystin signaling remains plausible because the effects of flow or shear stress may be difficult to separate from the effects of signaling ligands that are delivered by flow. Recent evidence has shown that polycystins and FPCs are shed into the luminal space, and the ELVs in which they appear adhere to the surface of cilia.[169,210] These ELVs may be the vehicles carrying signals important in PKD. Earlier biochemical evidence supports homotypic interactions involving the extracellular domains of PC-1,[312] further posing the possible involvement of ligand binding in polycystin signaling. In the instance of flow-dependent embryonic node signaling in left–right asymmetry, shed vesicles carrying signaling molecules such as Sonic Hedgehog and retinoic acid have been shown to be essential in generating lateralized calcium signals, mentioned previously.[313] The PC-2–dependent cellular calcium response to flow stimulus was subsequently shown to require a heteromeric complex between PC-2 and transient receptor potential cation channel subfamily V member 4 (TRPV4).[314] Loss of TRPV4 abolishes the cellular calcium in response to flow in vitro yet does not result in cyst formation in the zebrafish model in vivo. This puts into question whether calcium transients resulting from ciliary flow sensing in vitro are a fundamental mechanism of cyst formation in vivo.[314] It is noteworthy that, to date, it has not been possible to document changes in local calcium within cilia in response to flow. A recent study linking the cilia-mediated flow response to regulation of the mammalian target of rapamycin (mTOR) signaling and cell size regulation showed that this was a function of the master kinase Lkb1 in cilia and specifically excluded PC-2 as the cilia sensor.[315] Finally, evidence that polycystin complex signaling is dynamically regulated by PC-1 dosage and not a binary on/off process[254] can be extrapolated to suggest that the signal sensed by PC-1 is also dynamically regulated. This should give pause to the notion that flow alone serves as the primary signal for determining kidney tubule lumen diameter. The increasing application of proteomic technologies to the analysis of signaling molecules in the urine may uncover novel signaling molecules and lead to improved understanding of the interrelationship between flow, ligands, and polycystin signaling.

Effector Pathways

A multitude of effector pathways have been proposed for the renal tubule cell response to a loss of polycystins.[58,316,317] Nonetheless, the molecular mechanism linking PC-1/PC-2 function in cilia to the extensive array of candidate cellular effector pathways has been elusive beyond a hypothesized role for calcium ions (Fig. 16.6).[58] The potential complexity of what is unknown in cilia-based signaling downstream of polycystins is best illustrated by what is known of Hedgehog

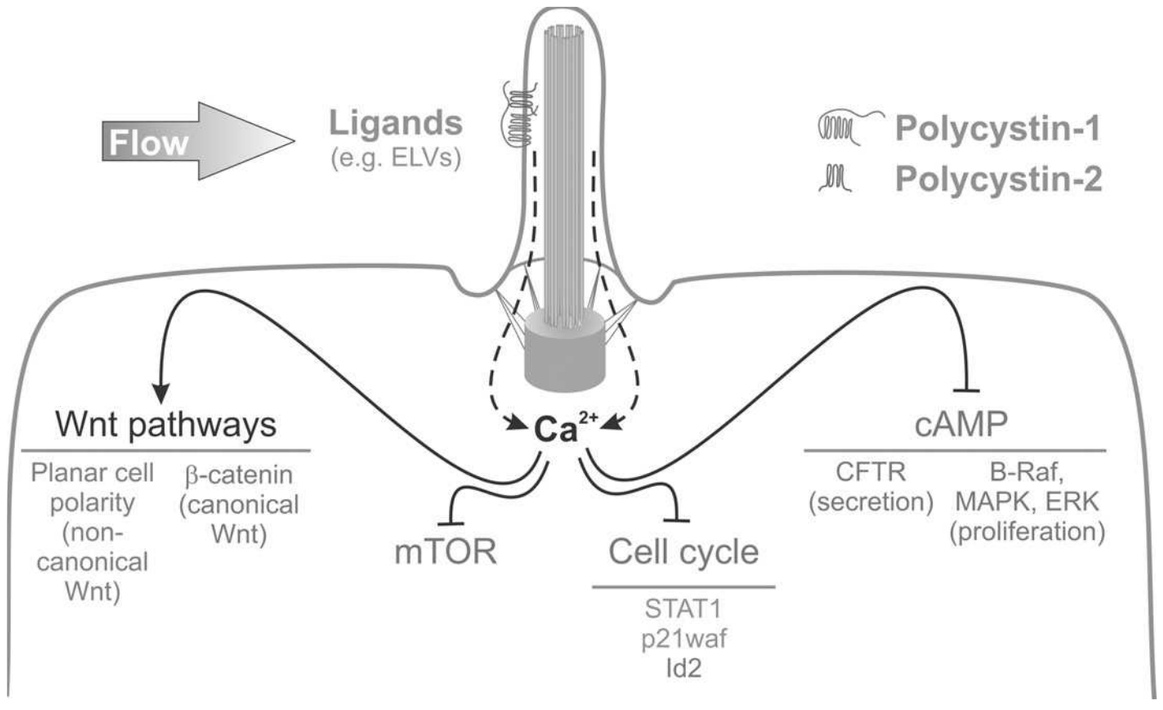

FIGURE 16.6 Polycystin (PC) signaling effector pathways. The PC-1/PC-2 receptor channel sensory complex on apical cilia on the renal tubular epithelium is activated by flow and potential ligands carried by the flow (exosome-like vesicles [ELVs]). This is thought to result in a rise in local and cellular calcium, which mediates signals to a number of effector pathways. Pathways or components shown in *blue* are activated by normal polycystin signaling, whereas those shown in *red* are inhibited by intact polycystin signals. A loss of PCs results in increased cyclic adenosine monophosphate (cAMP) production, which may increase apical secretion and the proliferation in cyst cells. The loss of PCs also increases the progression of the cell cycle, and may activate mammalian target of rapamycin (mTOR) signaling and may favor β-catenin-dependent Wnt signaling. STAT1, signal transducers and activators of transcription 1; CFTR, cystic fibrosis transmembrane conductance regulator; MAPK/ERK, mitogen-activated protein kinase/extracellular regulated kinase. (See Color Plate.)

(Hh) signaling in cilia.[281] In the absence of Hh ligand, the receptor Patched (Ptch) resides in cilia and inhibits the entry of the seven transmembrane receptor protein Smoothened (Smo) into cilia. In this state, the transcriptional repressor Gli3R inhibits Hh-responsive gene transcription, whereas the transcriptional activator Gli2 is sequestered in cilia by binding of Suppressor of Fused (SuFu). Upon binding of the Hh ligand, Ptch translocates out of cilia, thereby allowing Smo to enter the cilium. This in turn alleviates Gli3R repressor activity and promotes translocation of transcription activators Gli1 and Gli2 to the nucleus. All of the aforementioned components of the Hh signaling pathway have been found in cilia.[318,319] The lack of a comparable mechanistic understanding of polycystin signaling leaves open the possibility that many of the effector pathways identified to date represent secondary processes removed from the immediate molecular events of polycystin signaling. These secondary processes may contribute substantially to disease progression and therefore merit investigation and evaluation as potential targets for clinical therapy. In parallel, continued basic studies to identify the less understood, more proximate polycystin signaling events is essential to achieve the goal of identifying novel and specific therapeutic targets for ADPKD.

Planar Cell Polarity and Wnt Signaling

Cyst formation has been attributed to defects in a tissue organization process defined by planar cell polarity (PCP). In the case of the kidney, the developing nephron grows in the direction oriented in parallel with the lumen while not growing in the dimension perpendicular to the lumen. This asymmetric orientation of growth within the plane of the tubule epithelium is reflective of PCP (Fig. 16.7). "Convergent

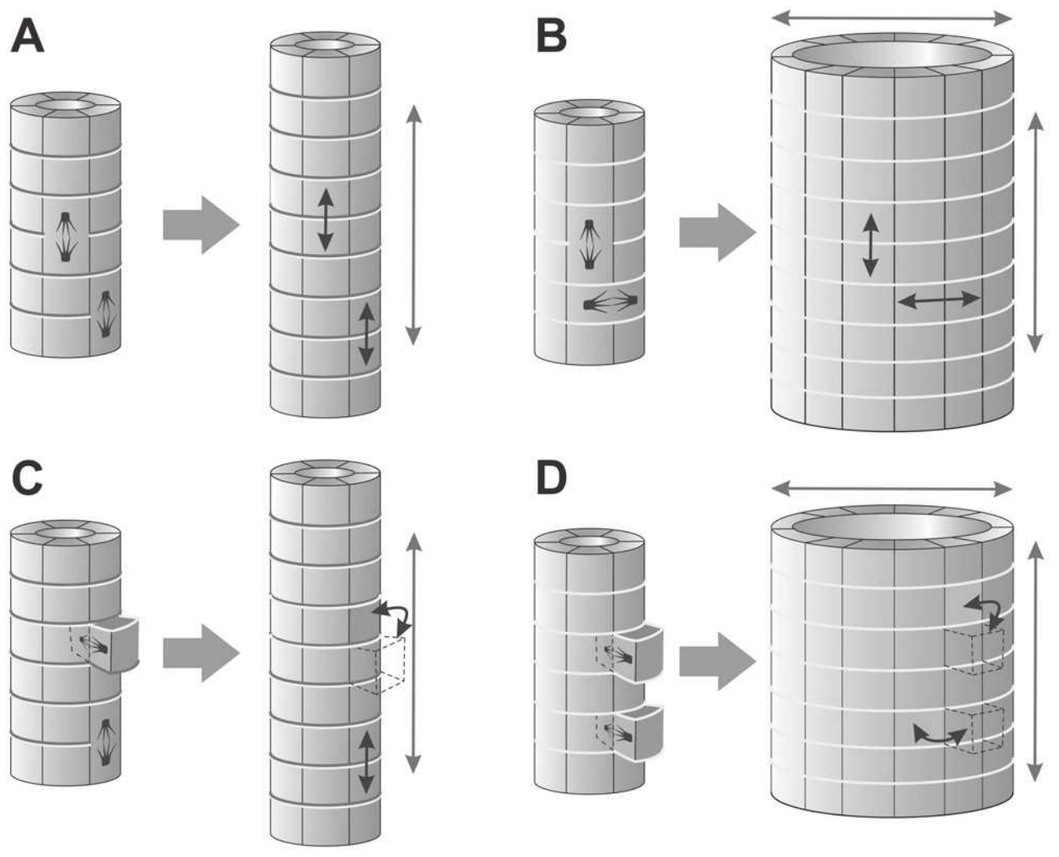

FIGURE 16.7 Planar cell polarity in the kidney. **A**: The postnatal elongating nephron shows oriented cell division (OCD) with mitotic spindle poles aligned with the long axis of the tubule within the plane of the epithelium. **B**: Randomization of the mitotic spindle axis, as may occur in recessive ciliopathies, can interfere with normal tubular elongation and give rise to dilated or cystic tubules. **C**: Planar cell polarity is also mediated by convergent extension movements whereby cells move toward a midline axis and along its length. In this schematic, a cell dividing out of the plane of the epithelium is shown entering that plane along the longitudinal axis. **D**: A loss of convergent extension movements can also result in impaired tissue polarity.

extension" movements, in which cells move toward a midline in one dimension and extend along that midline in a perpendicular direction, are one component of PCP. Another PCP component, oriented cell division (OCD), occurs when the axis of the mitotic spindle poles in anaphase and telophase align in parallel to the tubule lumen leading to cell division that is parallel to the axis of elongation and in the plane of the epithelium. Evidence linking cilia functions to PCP[320,321] has been provided by the association of Ift88 mutations with defective planar polarization of actin-based stereocilia in the inner ear[322] and by the roles in PCP processes of recessive ciliopathy genes for nephronophthisis (inversin)[323] and BBS.[324]

It has been proposed that a loss of OCD in elongating kidney tubules results in randomized orientation of mitoses, which replaces the directional tubule elongation process with cyst formation (Fig. 16.7).[325] Experimental studies have confirmed that elongating tubules in the postnatal mouse or rat kidney show OCD with mitotic spindles oriented parallel to the long axis of the tubule.[326,327] Consistent with the hypothesized pathogenic role of PCP defects in cyst formation, mice with mutations in Hnf-1β and rats with mutation in Pkhd1 show a loss of OCD in advance of the cyst formation.[326] Similarly, postnatal Ift20 mutant kidneys and injured adult Kif3a mutant kidneys, both of which have structural defects in cilia formation, also show a loss of OCD followed by cyst formation.[234,328] Finally, a loss of the PCP-related protocadherin Fat4 can result in cystic kidneys, a phenotype worsened by a reduced dosage of the core PCP protein Vangl2.[329] Although OCD is the predominant PCP mechanism in the postnatal elongating nephron in mice, convergent extension movements predominate during the embryonic phase of kidney development.[327] BBS genes (e.g., Bbs1, Bbs4, Bbs6) are required for PCP-associated convergent extension movements in zebrafish,[330] but a role for the human PKD genes (e.g., Pkhd1, Pkd1, Pkd2) in convergent extension movements has not yet been reported.

The previous data suggest that PCP-related processes are linked to cilia structure and function and are important in kidney development. The disruption of PCP processes during development can result in cyst formation. Despite this connection, the relationship of disruption of PCP to the pathogenesis of human ADPKD and ARPKD is less clear. Two mouse models of ARPKD that do not show a cystic phenotype in the collecting duct nonetheless show a loss of OCD in that segment in the postnatal kidney.[331] The same study also found that precystic tubules that had lost either PC-1 or PC-2 expression did not show a loss of OCD yet went on to form cysts.[331] The finding that mutations in Pkhd1 disrupt OCD during tubule elongation but do not lead to cysts calls into question whether a loss of OCD is sufficient for kidney cyst formation. The finding that a loss of PC-1/PC-2 can initiate cysts without the loss of OCD suggests that PCP defects are not necessary for cyst formation in ADPKD. One interpretation of these apparently discrepant results is that the mechanisms of kidney cyst formation in human ADPKD and ARPKD differ from those associated with the recessive ciliopathy diseases.

PCP is mediated by components of the noncanonical Wnt signaling pathway. Modulation of canonical Wnt signaling, which regulates cellular proliferation and differentiation, has also been associated with cystic diseases (Fig. 16.6).[332] Wnts are secreted glycoproteins that bind to Frizzled receptors, which signal through Dishevelled inside the cell. Downstream of Dishevelled, the canonical and noncanonical pathways diverge with β-catenin–dependent gene expression acting as the major effector of the canonical Wnt pathway. The nephronophthisis gene inversin modulates Dishevelled levels to determine the balance between canonical and noncanonical Wnt signaling.[323] Similarly, BBS genes are required for PCP-associated convergent extension movements in zebrafish, but suppression of these transcripts results in the activation of canonical Wnt signaling through stabilization of β-catenin.[330] These findings have led to the emergence of the concept that several ciliopathy genes function to regulate the balance between canonical and noncanonical Wnt signals. Implicit in such a hypothesis is the idea that cyst formation following the disruption of PCP pathways is fostered by the associated increase in canonical Wnt signaling.

The role of canonical Wnt signaling in cyst formation has been explored directly. The product of the JBTS gene Ahi1 supports canonical Wnt signaling by facilitating β-catenin accumulation and consequent transcriptional activation in the nucleus.[333] Loss of Ahi1 impairs the canonical Wnt response to kidney injury and results in cyst formation. Although cilia-related proteins may function in Wnt pathways, a direct role for cilia in Wnt signaling remains controversial given conflicting evidence that cilia inhibit canonical Wnt signaling[330,334] or have no role in it.[335,336] The data on the role of Wnt/β-catenin signaling in cyst formation in ADPKD is also confounded. Initial support for a role for canonical Wnt signaling in cyst formation came from studies showing that transgenic overexpression of a constitutively active β-catenin or kidney specific inactivation of the APC gene (which normally inhibits β-catenin signaling) results in cyst formation.[337,338] On the other hand, the study of Wnt9b-deficient mice that supported the role of noncanonical Wnt signaling/PCP in cyst formation did not find any evidence for β-catenin–dependent canonical Wnt signaling in the process.[339] The activity of COOH-terminal fragments of PC-1 in canonical Wnt signaling have been implicated in both activation[340–342] and repression[173,343] of the canonical Wnt pathway; the latter was also reported for PC-2.[344] Finally, a recent study using embryonic Pkd1 and adult Pkd2 mouse models of polycystic kidney disease in combination with a canonical Wnt activity reporter transgene failed to show evidence of β-catenin transcriptional activation in kidney cysts in vivo.[345] Although the absence of transgenic reporter activation in these mice does not entirely exclude a role for canonical Wnt signaling in cyst formation, it does pose a significant challenge to the model. In aggregate, the data suggest involvement of both canonical and noncanonical Wnt signaling in cystic processes, but this relationship is not universal and the direct relevance to human ADPKD remains uncertain.

Mitogen Activated Protein Kinase/ Extracellular Regulated Kinase

The mitogen activated protein kinase (MAPK)/extracellular regulated kinase (ERK) pathway is a kinase phosphorylation cascade that integrates extracellular signals received through receptor tyrosine kinases, G-protein-coupled receptors, and integrins. MAPK/ERK signaling is modulated by cAMP, protein kinase A (PKA), protein kinase C (PKC), and regulates a spectrum of cellular activities including cell cycle, gene transcription, protein translation, and epithelial morphogenesis (Fig. 16.6). Activation of the MAPK/ERK pathway is seen in cell culture models based on human ADPKD cyst lining cells that lack PC-1.[346,347] PC-2 has been implicated in providing tonic suppression of MAPK/ERK signaling.[348] MAPK/ERK activation occurs in vivo in mouse models based on nonorthologous[346,349,350] and orthologous ADPKD genes.[223] In human ADPKD cell culture models, the activation of the MAPK/ERK cascade is dependent on activation of B-Raf by cAMP—a paradoxical effect unique to PKD cells or in conditions of calcium deprivation.[346,347] Evidence for a similar mechanism of activation in vivo is lacking.[223] The presence of dysregulated MAPK/ERK activation associated with proliferation in both in vitro and in vivo models of ADPKD have identified this pathway as a potential target for therapy. To date, preclinical evaluations of inhibitors of this pathway have given mixed results. The MAPK/ERK blockade in a mouse model of NPHP reduced cyst formation,[350] but it had no effect in an early onset model of ADPKD.[223] It remains possible that an evaluation of additional agents targeting the ERK pathway in refined orthologous gene mouse models of ADPKD will identify agents suitable for human studies.

Mammalian Target of Rapamycin

The mTOR pathway integrates signaling input and nutrient availability to regulate a diverse set of processes including cell size, proliferation, metabolism, and survival. It has been implicated as an effector pathway in PKD (Fig. 16.6),[351,352] and mTOR inhibitors were evaluated in the first major randomized clinical trials for ADPKD (see the following). The earliest indication of a potential role for this pathway in PKD came from the observation that severe juvenile ADPKD was often the result of a contiguous gene deletion syndrome involving PKD1 and TSC2.[258,259] Mutations in TSC2 and TSC1 result in tuberous sclerosis complex. Together, their respective gene products have GTPase activity that inhibits Rheb, which is a master activator of the mTORC1 pathway. Experimental evidence for mTOR activation in PKD came from immunohistochemical studies showing phosphorylation of the mTORC1 target P70 ribosomal S6 kinase (S6K) in cells lining some, but not all, cysts; S6K phosphorylation was also observed in normal tubular epithelial cells in polycystic mouse models.[225,353,354]

Although there is evidence of activation of the mTOR pathway in PKD, as with the other putative effector pathways, the mechanisms of PC-1 or PC-2 to this mTOR activity remains incompletely understood. There has been a suggestion that the C-terminal tail of PC-1 interacts directly with TSC2 but the specificity of this putative interaction is uncertain given that no studies using the full-length PC-1 have been reported.[225] A functional interaction between PC-1 and mTORC1 has been suggested in cell-based studies where there was overexpression of PC-1–inhibited mTORC1 signaling, whereas cells lacking Pkd1 showed increased mTORC1 activation.[355] PC-1 inhibition of the mTORC1 cascade was dependent on its inhibition of ERK1/2 phosphorylation acting through TSC2. The mechanism of PC-1/mTOR interdependence remains unsettled because another study using just the COOH–terminus of PC-1 suggested that sequestration of TSC2 is the mechanism of mTOR repression,[356] whereas a third study found no evidence for constitutive activation of mTORC1 in cells lacking PC-1.[357] Throughout these studies, mTOR has been separately connected with cilia[315,357] and with polycystins,[225,355] but not with polycystins in cilia. In fact, a recent study of cilia-dependent Lkb1 regulation of mTOR actually excluded regulation by PC-2 signaling.[315] Given this uncertainty in the preclinical data and two negative clinical studies (see the following), consideration of the use of mTOR inhibitors in ADPKD requires further investigation.[358]

Cyclic Adenosine Monophosphate (cAMP)

Elevated levels of intracellular cAMP in polycystic kidneys are believed to promote cyst growth and disease progression (Fig. 16.6).[359,360] cAMP levels are regulated by the balance of adenylate cyclase (AC) synthetic activity and phosphodiesterase (PDE) degradation. AC activation occurs following ligand interaction with heterotrimeric GPCRs. A subset of ACs and PDEs are calcium responsive, resulting in the refinement of cAMP activity by local subcellular calcium levels. Increases in cAMP levels above a threshold results in the activation of PKA, which acts as an effector for cAMP signaling. Finally, the subcellular microdomain localization of cAMP signals is achieved by the scaffolding activity of A kinase anchoring proteins (AKAPs), which confine PKAs to regions in close proximity to AC and its GPCR receptor, as well as PDE.

Elevated cAMP levels have been found in animal models of ADPKD.[224,361] The mechanisms underlying the elevated cAMP levels are uncertain. Increased levels of circulating vasopressin as well as of the vasopressin type 2 GPCR (V2R) in the collecting duct in polycystic kidneys have been hypothesized to enhance cAMP production.[362] It is notable in this regard that the largest number and size cysts in ADPKD appear to be derived from collecting duct segments that express V2R.[224,363] In addition, the hypothesized reduction in cellular calcium resulting from the loss of the activity of the PC-1/PC-2 channel complex may result in increased activity of calcium inhibitable ACs and decreased activity of calcium-activated PDEs. Recent work may have shed additional light on the mechanistic relationship of polycystins and cilia to cAMP activity. Cilia contain an interacting protein complex comprised

of adenylate cyclase 5 (AC5), A kinase anchor protein 150 (AKAP150), phosphodiesterase-4C, and PC-2.[364,365] PC-2 is required for the ciliary location of AC5/6, which are calcium inhibitable, and the loss of either Pkd2 or of cilia through Kif3a mutation results in elevated cAMP perhaps due to the loss of AC5/6 inhibition.[364] Although the GPCR associated with this complex is unknown, V2R has been found in the cilia.[366] cAMP has also been implicated in determining cilia length and functioning in a negative feedback loop whereby longer cilia produce reduced responses to flow, which in turn decreases intracellular cAMP. This flow-mediated adaptive response is lost in the absence of polycystins.[367]

Several mechanisms have been proposed by which increased cellular cAMP fosters progression in ADPKD. In vitro, cAMP inhibits the proliferation of normal kidney epithelial cells but paradoxically increases the proliferation of ADPKD cyst cells. The latter occurs by a Ca^{2+}-dependent activation of the B-Raf/MAPK/ERK pathway.[347,368] cAMP-dependent activation of PKA and the consequent activation of the cystic fibrosis transmembrane regulator (CFTR) chloride channel is thought to be responsible for the chloride-dependent transepithelial fluid secretion that drives cyst enlargement.[369–371] In support of this, Pkd1 mutant kidney explants treated with cAMP analogs develop cysts, and this process can be blocked by inhibitors of CFTR.[372] CFTR inhibitors have also shown some efficacy in a mouse model based on Pkd1.[373] V2R antagonists that were effective in preclinical trials[224,361] and that are currently in human clinical trials are thought to act by reducing intracellular cAMP levels. The reduction of both cAMP production and cAMP-dependent fluid secretion remain attractive targets for therapeutic trials in ADPKD.

Calcium Signaling

The importance of calcium signaling in PKD was initially suggested by the identification of PC-2 as a nonselective calcium-permeable cation channel of the TRP family and by evidence that point mutations that abrogate PC-2 channel activity are pathogenic in human ADPKD.[135,179,180,374] This association was bolstered by the finding that the mechanical deflection of primary cilia result in cellular calcium transients[310,375] that are dependent on normal expression of PC-1 and PC-2 (Fig. 16.6).[311] The molecular mechanisms underlying these whole cell calcium changes have been challenging to define in large part because the local calcium effects in cilia have not been directly measured. In addition, the whole cell calcium results are confounded by the function of PC-2 as an ER calcium channel[188,311] and perhaps as a channel on the cell surface.[376,377] It has been difficult to define the precise disease-associated signaling processes because it is not known whether the polycystin-dependent calcium effects relevant to ADPKD are very localized (e.g., in cilia), or generalized in the whole cell.

A direct demonstration of the role of calcium in most of the putative ADPKD-effector signaling pathways has also been elusive. Some effector pathways have shown a response to fluid flow, and fluid flow has been associated with cellular calcium transients; therefore, a role for calcium has been inferred but not shown. For example, fluid flow in ciliated cells was implicated in modulating inversin levels, which in turn determine the balance between canonical and noncanonical Wnt signaling.[323] The inference that flow induced calcium transients in mediating inversin action remains speculative. The role of calcium in the regulation of cAMP levels through calcium-dependent AC and PDE as discussed in the previous section has remained inferential. The activation of MAPK/ERK attributed to changes in cAMP levels are linked to cellular calcium homeostasis by in vitro studies.[368] The limitations of these indirect associations are illustrated by the case of cilia and flow-dependent mTORC1 signaling in which PC-2–dependent calcium transients were specifically excluded, whereas a novel role for ciliary Lkb1/AMPK was identified.[315]

Aside from calcium changes following mechanosensitive activation of PC-1/PC-2 receptor channel complex, PC-2 functions as a calcium-activated intracellular calcium release channel.[179] The calcium sensitivity of PC-2 activity is modulated by phosphorylation at serine 812. PC-2 and PC-1 interact with and modulate the activity of the major epithelial ER calcium release channel, the inositol 1,4,5-triphosphate receptor (IP_3R).[378–380] PC-2 also regulates calcium signaling by the other major ER calcium release channel, the ryanodine receptor.[381] The ER t-SNARE protein syntaxin-5 interacts with the COOH-terminus of PC-2 and inactivates the channel to prevent calcium leak from ER stores.[188] PC-2 has also been proposed as a GPCR or receptor tyrosine kinase (RTK)–operated cell surface channel. An epidermal growth factor (EGF) treatment of epithelial cells stimulates PC-2–dependent increases in cellular calcium.[376] This response is augmented by an overexpression of PC-2 and is attenuated by the siRNA knockdown of PC-2. It has also been suggested that PC-2 is activated downstream of GPCR and PLC signaling.[377] This activity requires heterotrimeric channel formation between PC-2 and TRPC1 and is independent of PC-1.

There is compelling evidence based on the structure, function, and mutations in PC-2 that calcium ions play a central role in the pathogenesis of ADPKD. There is a general consensus that the channel activity of the polycystin complex in cilia is related to the pathogenesis of ADPKD. The relevance of polycystin channel activity in the ER and plasma membranes to the disease pathogenesis remains less certain. The difficulty in discovering the detailed mechanistic role of calcium signaling in ADPKD may rest with the fact that the bulk of PC-2 channel activity occurs at sites other than the cilia, yet it is the minute portion of the signal occurring in cilia that is central to disease progression.

Regulation of the Cell Cycle

The profound increase in the cystic cell mass in ADPKD suggests that proliferation is a central feature of the disease phenotype (Fig. 16.6). Whether this proliferative response is primarily connected to polycystin signaling or is secondary

to the multitude of changes occurring as the tissue remodels in response to the loss of polycystins is an area of active investigation. Interfering with the expansion of cystic cell mass has the potential to slow the progression of PKD. The first study to directly address the role of polycystins in cellular proliferation showed that the overexpression of full-length PC-1 in MDCK cells resulted in cell cycle arrest at the G0/G1 phase.[242] PC-1 was proposed to interact with JAK2, which increased STAT1 expression, which in turn upregulated $p21^{wafl}$ to inhibit cell cycle progression. This process is dependent on the ability of PC-1 to interact with PC-2. Although these studies were cell based, in vivo support was provided by the demonstration of the altered expression of STAT1 and $p21^{wafl}$ in $Pkd1^{-/-}$ embryos.[242] PC-2 has been proposed to interact with and sequester Id2 in the cytosol, thereby preventing translocation of the latter to the nucleus where it can stimulate proliferation.[382] The extension of this mechanism to PC-1 was suggested by the increased nuclear localization of Id2 in $Pkd1^{-/-}$ mice and by the ability of RNAi knockdown of Id2 to decrease proliferation in $Pkd1^{-/-}$ cells in culture. $Pkd2^{-/-}$ cells in culture also exhibit increased proliferation and increased propensity toward branching morphogenesis in a three-dimensional culture.[348] Additional proliferative effects from the loss of polycystins may be mediated through the activation of either the MAPK/ERK or the mTOR pathways, as discussed previously.

The proliferative response in kidney tubule cells following the loss of polycystins is likely to be highly context dependent. As discussed, the early inactivation of polycystins during postnatal development in vivo results in rapid cystic expansion, whereas adult inactivation of polycystins results in the more indolent progression of cystic disease.[220] The proliferation of cyst cells in vivo likely results from a combination of cell autonomous effects due to reduced or absent polycystin function coupled with noncell autonomous effects that can foster an enhanced proliferative milieu. The latter can result from ongoing development,[220] acute injury and regeneration,[234,236–238] or stimulation by mediators of inflammation entering the kidney.[248] The most specific agents for therapy targeting proliferation in ADPKD would be directed at the earliest cell autonomous changes resulting from the loss of polycystins. On the other hand, the earliest available therapies may in fact be targeted toward the noncell autonomous secondary processes that foster the enhanced growth of cyst lining cells and the progression of PKD.

KIDNEY DISEASE PROGRESSION AND TOTAL KIDNEY VOLUME IN AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is characterized by the development and expansion of renal cysts, resulting in increased kidney size and TKV. Combined kidney weights can exceed 10 kg once ESRD is reached. The initiation and growth of cysts over time cause increased kidney size, compression, and remodeling of normal renal architecture and vasculature resulting in inflammation, interstitial fibrosis, and renal failure.[43] Although cyst expansion results in total organ enlargement, the initiation of cyst formation and growth is restrictive and focal in nature. Microdissection studies of early stage ADPKD kidneys showed focal cyst formation involving less than 5% of nephrons and a minor subset of cells within individual tubules.[44] The increase in TKV in ADPKD can be seen in utero, is a consistent finding during childhood, and is predominant throughout adult life. ADPKD is the only hereditary cystic kidney disorder associated with an inexorable increase in kidney size. Although ARPKD is associated with increases in TKV, this is typically greatest during the early postnatal period and either plateaus or diminishes over time as renal function declines.

A striking feature of ADPKD is the prolonged oligosymptomatic period typically spanning 4 decades, during which cyst mass is expanding with an increase in TKV while kidney function remains relatively intact when measured by the glomerular filtration rate (Fig. 16.8). During this phase, all of the common signs and symptoms related to progression in ADPKD, including hypertension, chronic pain or heaviness in the flank or abdomen, hematuria and cyst hemorrhage, urinary tract infections, and nephrolithiasis occur and are directly associated with increased TKV.[62] Despite the preservation of kidney function, the size of kidneys increases from a normal size (150 to 200 mL each) in childhood to

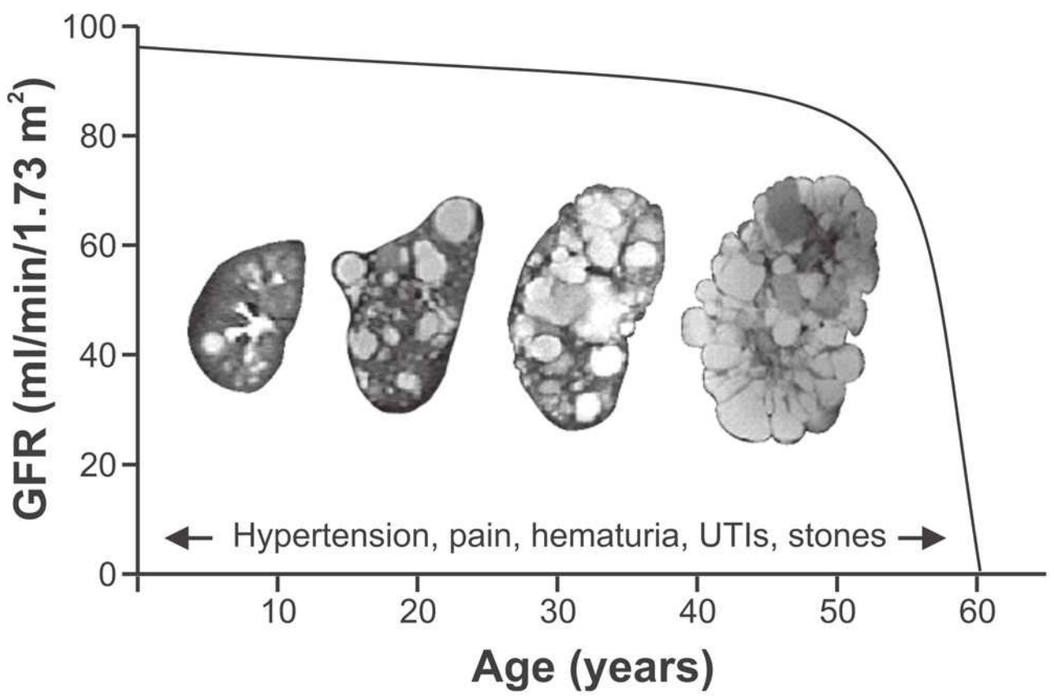

FIGURE 16.8 A proposed relationship between renal cyst burden, age, and renal function in autosomal dominant polycystic kidney disease (ADPKD). Coronal magnetic resonance imaging (MRI) of four ADPKD individuals age 9, 20, 21, and 40 with normal renal function are overlaid on a plot of glomerular filtration rate (GFR) as a function of age in ADPKD patients. Although hypertension, pain, hematuria, urinary tract infections (UTIs), and nephrolithiasis occur throughout the course of ADPKD, renal function remains largely intact until total kidney volume reaches a size where renal reserve no longer can compensate. Thereafter, renal function inexorably declines to end-stage renal disease. (Adapted with permission from Torres V, Scheinman S. Polycystic kidney diseases. *NephSAP*, Jan 2004;3(1):22.)

greater than 1500 mL by the third to fourth decade.[383] The relentless expansion of TKV due to the growth of cysts is the hallmark of ADPKD and leads inexorably to deformation of normal renal and vasculature architecture, inflammation, interstitial fibrosis, tubular atrophy, and finally, progressive kidney dysfunction.

Measurement methods using ultrasound, CT, and MRI have been developed to quantify TKV in ADPKD. Ultrasound imaging uses the formula for a modified ellipse to determine TKV [4/3π × ½(anterior–posterior diameter + width) × ½(length)].[31,384] Obtaining accurate longitudinal, axial, and depth measurements requires significant training and appropriate alignment through the cystic kidney. Ultrasound measurements are accurate in individuals with relatively small kidneys, which can be measured in a single imaging window. Significant variability occurs in individuals with extremely large kidneys, or in those with concomitant significant polycystic liver disease. Additional variability is introduced with different operators, motion artifact, and respiratory variation. Ultrasound determinations of TKV tend to underestimate TKV measurements obtained by MRI by approximately 25% in healthy controls.[384] Despite these limitations, ultrasound ellipsoid-based and MR-based stereology estimates of TKV are highly correlated (r = 0.89). The reproducibility or the coefficient of variation differs greatly with ultrasound (21% to 35%) compared to MRI (2.1% to 2.5%).[384] Importantly, kidney length is the most reproducible measurement using ultrasound. These observations indicate that ultrasound is not an appropriate imaging tool for short-term longitudinal monitoring in ADPKD, but may have a screening role for risk stratification in young individuals or could be used in individuals followed over long periods (more than 5- to 7-year intervals).

Recently, the National Institutes of Health (NIH)–sponsored CRISP has evaluated the relationship between GFR progression and TKV expansion in ADPKD. MRI acquisition methods that can accurately, reproducibly, and reliably determine TKV in ADPKD individuals have now been developed. Using both T2- and T1-weighted MRIs, interobserver and intraobserver variability, as well as day-to-day variability of TKV measurements, are all less than 2.5%.[385] Both gadolinium-enhanced and non–gadolinium-based MR measures of TKV are accurate, with a slightly greater TKV (1% to 6%) measurement seen in postgadolinium studies.[386] Given the previous reports of systemic nephrogenic fibrosis related to gadolinium exposure, CRISP no longer uses gadolinium contrast agents during image acquisition. Total cyst volume measurements in CRISP are more variable than TKV measurements, but they remain highly correlated with TKV (r = 0.99), indicating that renal cystic expansion accounts for the overwhelming majority of the increase in TKV seen in ADPKD. CRISP has now had the opportunity to prospectively follow 241 nonazotemic patients for 8 years with MRI examinations to measure the progression of kidney and cyst volumes.[385,387] The mean rate of increase in TKV over 3 and 8 years was 5.3% and 5.2% per year, respectively, which is consistent with an independent cohort from the SUISSE pre-randomization studies (5.8% per year). On average, CRISP participants increased their TKV 55% from baseline at the end of 8 years of follow-up. This rate of change is roughly equivalent to a 75 to 90 mL per year increase in TKV, which is equivalent to half of a normal adult kidney size and which is easily detectable by current imaging methodologies.

In CRISP, the overwhelming majority of ADPKD individuals demonstrated detectable increases in TKV over relatively short (6- to 12-month) periods (Fig. 16.9).[387] Men had higher rates of kidney and cyst growth than women. These differences diminish when TKV is indexed for measures of body size, including height (htTKV). In the CRISP study, baseline TKV correlated with a subsequent rate of increase in TKV, and an initial TKV above 1500 mL (approximately 5 times greater than normal) was the primary predictor of declining glomerular filtration rate in the first 3 years of study. Importantly, receiver operator characteristic curves

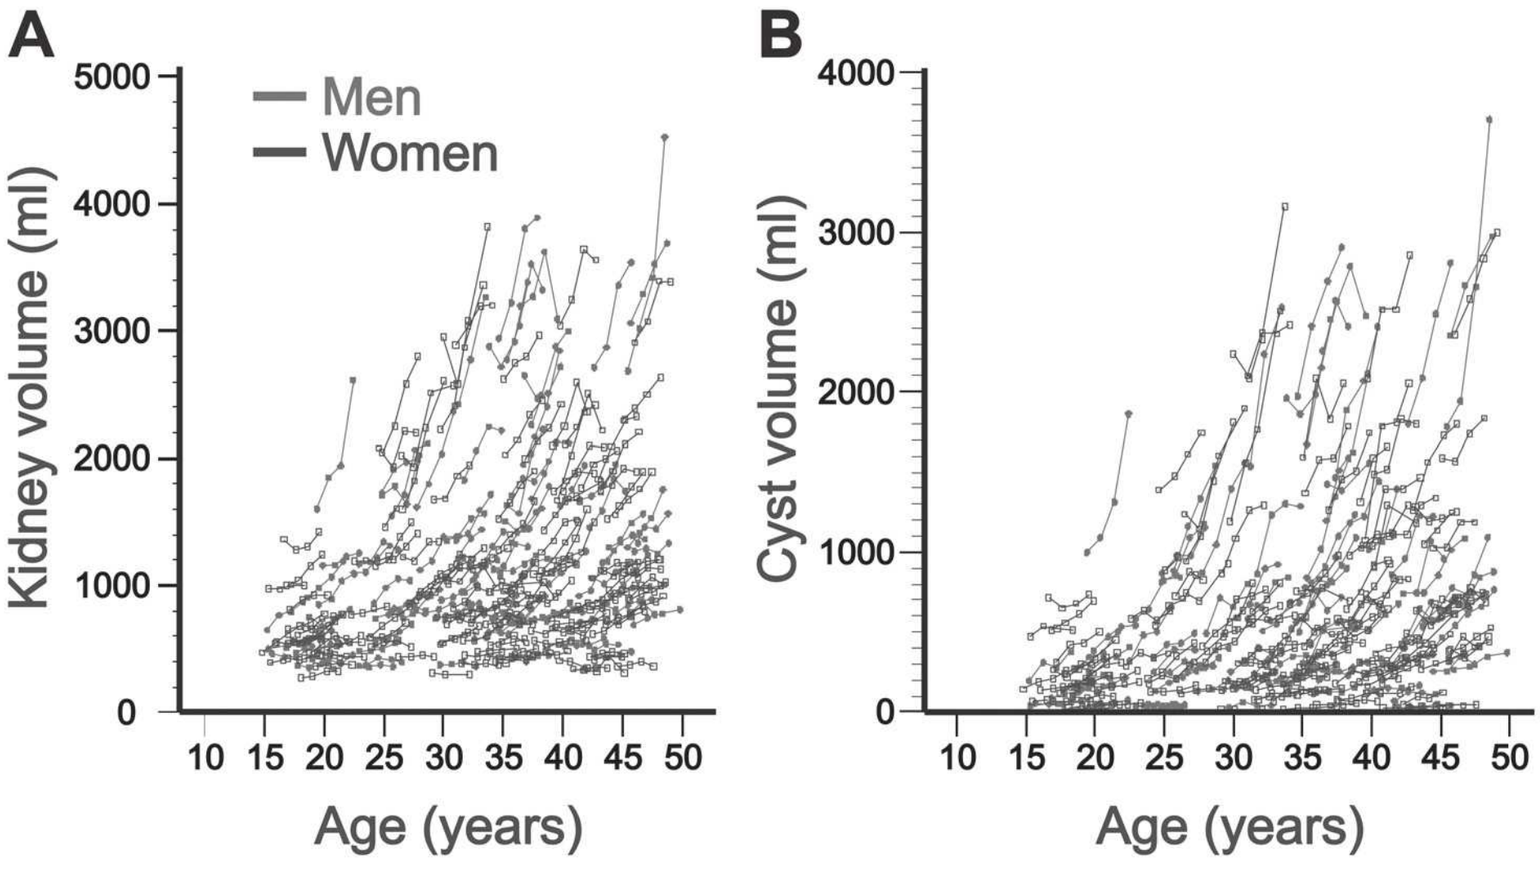

FIGURE 16.9 Total kidney volume **(A)** and total cyst volume **(B)** in relation to age in women (*blue*) and men (*red*) imaged annually over 3 years during participation in the Consortium for Radiologic Imaging studies in Polycystic Kidney Disease (CRISP). (From Grantham JJ, Torres VE, Chapman AB, et al. Volume progression in polycystic kidney disease. *N Engl J Med.* 2006;354:2122–2130. Copyright (c) 2006 Massachusetts Medical Society.) (See Color Plate.)

(ROC) demonstrated that htTKV reliably and accurately predicts the development of chronic kidney disease (CKD) stage 3 within 8 years of measurement with a cut point of 600 mL per meter (equivalent to a TKV of approximately 1200 mL). The htTKV-based prediction of CKD stage 3 was independent of variables known to associate with renal insufficiency in ADPKD, including genotype, gender, race, and age. A multivariate analysis further indicated that for each 100 mL increment of htTKV at baseline, the odds of reaching a CKD stage 3 end point within 7.9 years increases 1.48-fold.

PKD2 participants in CRISP demonstrated significantly smaller TKVs than PKD1 participants, but nonetheless showed similar rates of increase in TKV.[227] Mathematical modeling of TKV data from CRISP participants to estimate TKV at age 18 were accurate, indicating a relatively constant rate of increase in TKVs accounting for the observed exponential rate of kidney size growth.[388] Computational modeling integrating cyst surface area, volume, and an assumed overall constant rate of cyst growth (assuming variability across cysts within an individual) as shown by TKV change in the CRISP study suggested that cysts that developed early in life were the main contributors to TKV.[388] These inferred data were interpreted as showing that there are periods of accelerated cyst growth and/or that the initiation of cyst burden is mostly established by the time of birth.

The relationship between clinical symptoms of ADPKD and GFR is highly variable, which is likely due to the striking dissociation between the expansion of TKV and GFR observed early in the course of the disease. A significant time lag between the increase in TKV and the decline in GFR and an increasingly negative correlation between baseline TKV and GFR measured in subsequent years was demonstrated in CRISP.[389] The stability of GFR results from hyperfiltration of the surviving nephrons. The finding of stable GFR when ADPKD kidneys are dramatically enlarged, distorted by multiple cysts, and fibrotic provides false reassurance as to the stability of the disease progression. Once GFR begins to decline the progression is inexorable, with an average rate of decrease of approximately 4.4 to 5.9 mL per minute per year, a faster rate than in other types of progressive renal disease.[390] Currently, changes in GFR (frequently estimated from changes in serum creatinine) are considered the gold standard for quantifying the progression rate in most chronic renal diseases. However, given that these changes are seen only once the kidney architecture has been grossly and irreversibly distorted, GFR may not be suitable as a primary end point for clinical studies testing early interventions in ADPKD.[383] Risk factors associated with a worse prognosis in addition to TKV include male gender, a first episode of hematuria before the age of 30, PKD1 genotype, the onset of hypertension before the age of 35, dipstick-positive proteinuria, elevated low density lipoprotein (LDL), decreased high density lipoprotein (HDL), increased dietary sodium intake, and decreased renal blood flow.[391,392] All of these variables, with the exception of sodium intake and dyslipidemia, are specifically related to TKV. The CRISP study has shown that kidney and cyst volumes are the strongest predictors of renal functional decline,[389] and it is anticipated that this measurement will find its way into clinical practice.

RANDOMIZED CLINICAL TRIALS IN AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

The availability of an extensive array of orthologous and nonorthologous animal models for PKD has permitted the preclinical evaluation of a broad spectrum of potential therapeutic agents. Many of these agents have shown promising results in one or more rodent models, but only a handful have been deemed sufficiently promising to enter human clinical trials.

Vasopressin V2 Receptor Antagonists

Arginine vasopressin (AVP) increases cAMP levels in the collecting duct, and evidence for the role of cAMP in cystogenesis has provided the rationale for preclinical trials of V2R antagonists in a variety of hereditary renal cystic diseases. Inhibition of the AVP V2 receptor and the subsequent decrease in adenylyl cyclase activity may help to compensate for alterations in intracellular calcium homeostasis and may affect the normalization of intracellular cAMP levels, thereby reducing the proliferative phenotype of cystic epithelium.[393] The V2R antagonists OPC-31260 and OPC-41061 (Tolvaptan) reduce renal levels of cAMP and markedly ameliorate cyst development in models of ARPKD (pck rat), NPHP (pcy mouse), and ADPKD ($Pkd2^{WS25/-}$).[224,394] High water intake by itself, possibly by suppressing the release of vasopressin, has demonstrated a protective effect on the development of PKD in pck rats.[395] The genetic deletion of the vasopressin gene in pck rats by intercrossing them with Brattleboro rats leads to lower renal cAMP levels and an almost complete inhibition of cystogenesis.[396] The cystic phenotype can be recovered following the administration of the exogenous V2 receptor agonist, desmopressin (dDAVP). Activation of the predominant endothelin receptor subtype in the collecting tubules, the endothelin-1 endothelin B (ETB) receptor, inhibits AVP action. An antagonist of this receptor increases renal cAMP levels and aggravates renal cystic disease in a mouse model of ADPKD, presumably by interfering with the inhibition of AVP activity.[397] In aggregate, the data support the hypothesis that the pharmacologic inhibition of the V2R pathway is a logical strategy to inhibit the development and expansion of renal cysts in ADPKD.

Based on these preclinical studies, the Tolvaptan Efficacy and Safety in Management of PKD and Outcomes (TEMPO) program was initiated. Tolvaptan is an orally effective, relatively short-acting, nonpeptide arginine vasopressin V2 receptor antagonist. It is currently approved in the United States and the European Union for the treatment of hyponatremia associated with hypervolemic states (e.g., cirrhosis, congestive heart failure) and euvolemic syndrome of inappropriate

antidiuretic hormone (SIADH) states, and in Japan for the treatment of cardiac edema that is resistant to diuretics. Tolvaptan is also being studied in the United States and in Europe as an adjunct therapy for volume overload in patients with heart failure. A phase IIa dose ranging study to determine the response to increasing doses of tolvaptan in patients with normal renal function has been completed.[398,399] An international phase III clinical trial for the treatment of ADPKD is ongoing at the time of this writing (Table 16.3). A primary therapy study to delay the progression of ADPKD (NCT00428948) has enrolled over 1400 relatively young (< 50 years) ADPKD patients with preserved kidney function (creatinine clearance > 60 mL per minute) but with TKVs greater than 750 mL as measured by MRI. Based on this enrollment, regardless of the final study outcome, this trial will leave open the question of the potential role for V2R antagonists in patients with more advanced kidney disease and the potential efficacy of these drugs at lower doses, which are associated with reduced side effects of polyuria and nocturia and with improved tolerance.

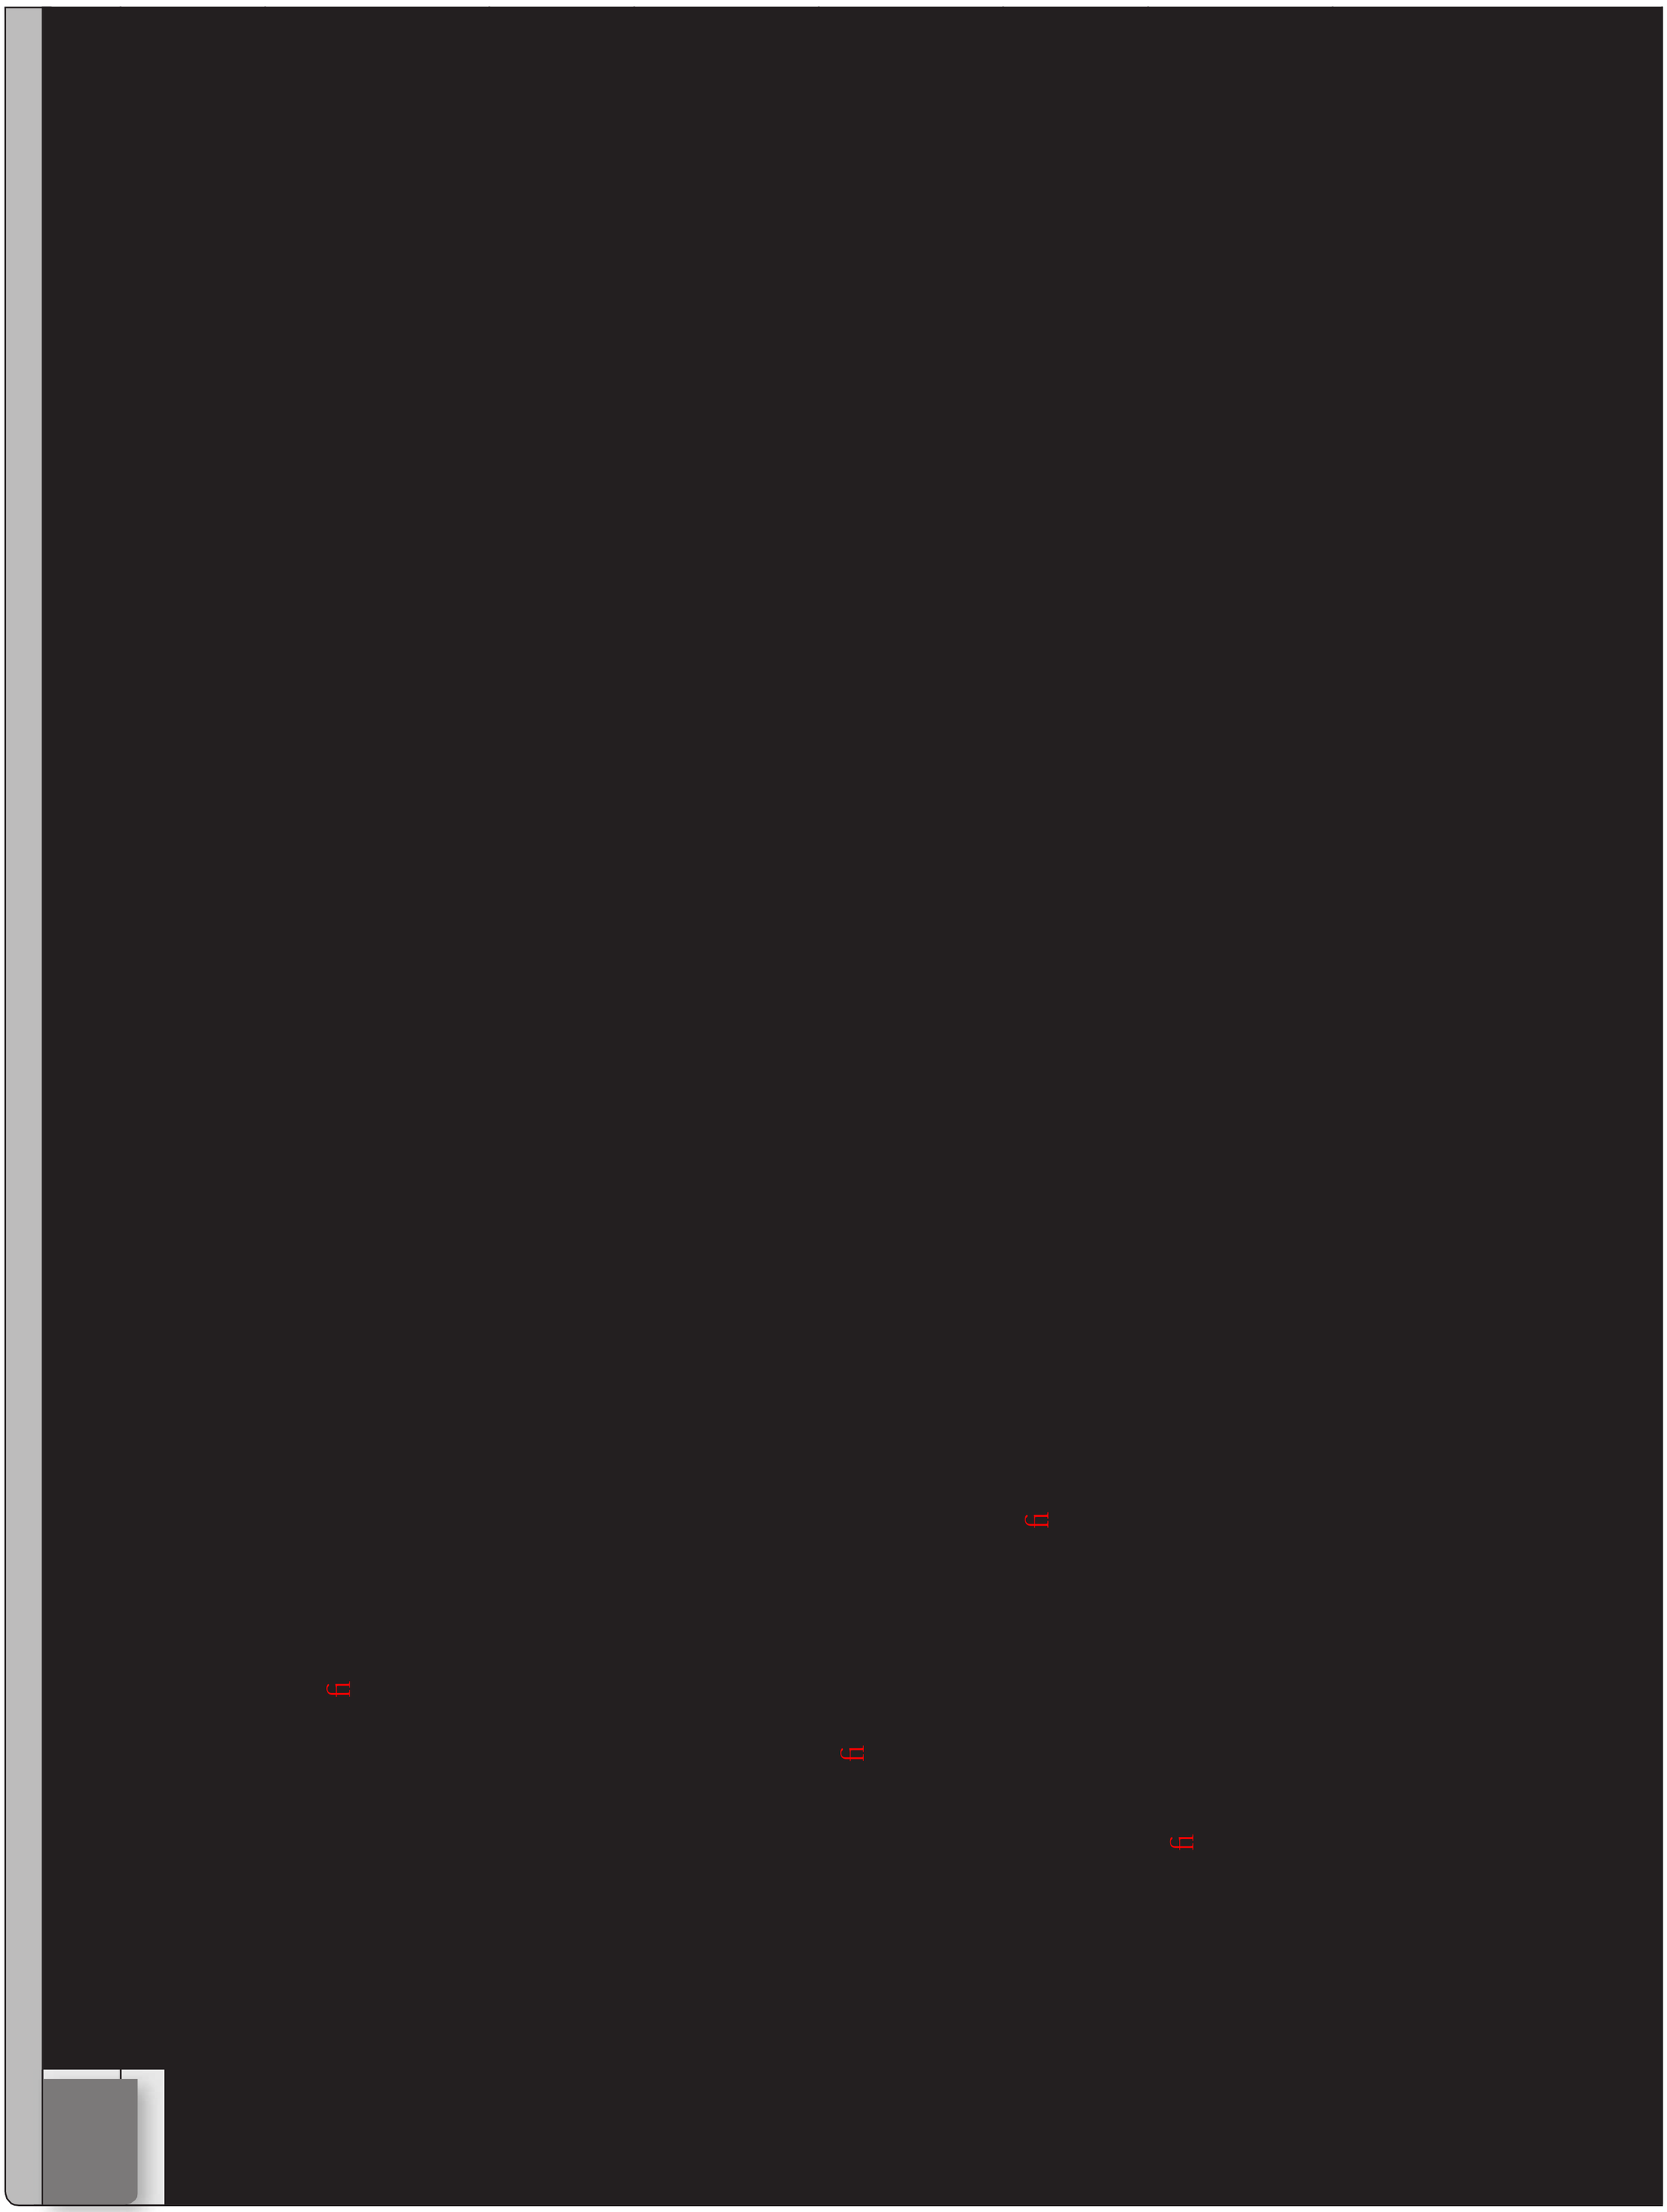
Somatostatin Analogs

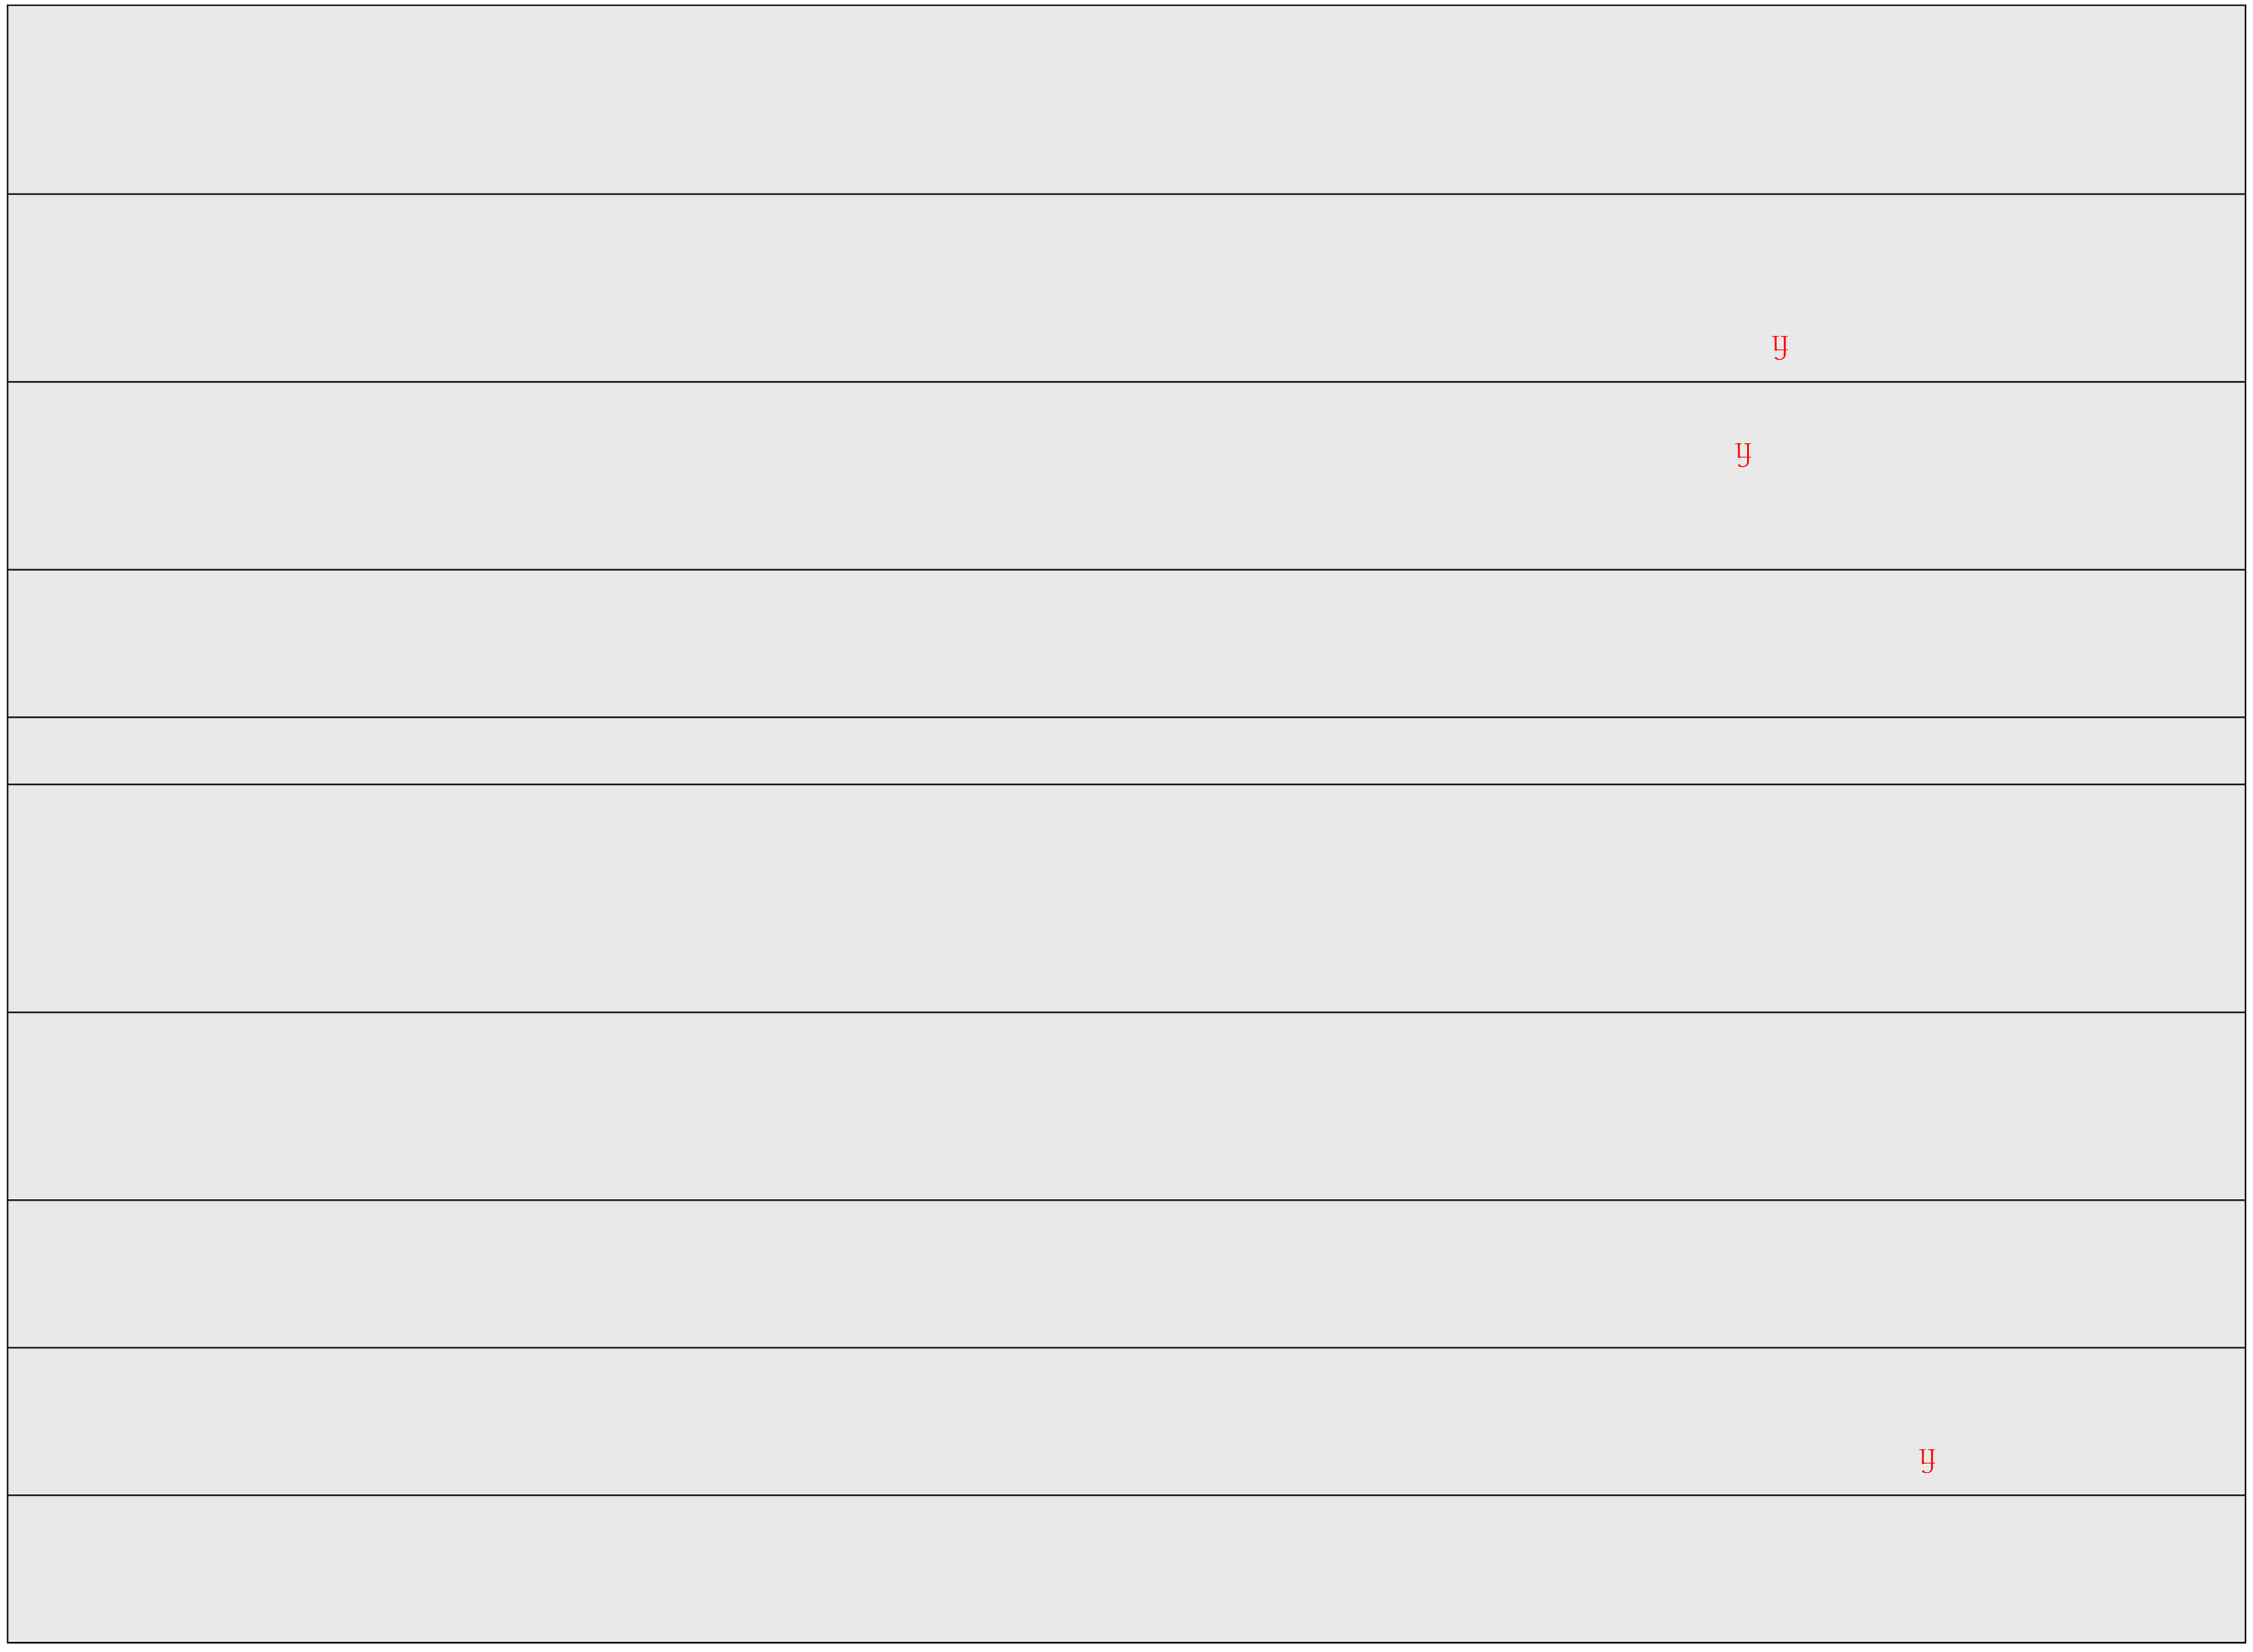
A similar pharmacologic inhibition of cAMP accumulation has been established with the administration of somatostatin, which acts on somatostatin receptor 2 (SST2) receptors in the kidney and liver.[400] Octreotide, a metabolically stable somatostatin analog, halted the expansion of hepatic and renal cysts in ARPKD model pck rats. These observations are consistent with the reduction in total kidney volume in a pilot study of long-acting octreotide for human ADPKD. Presently, there are a number of ongoing clinical trials of octreotide and lanreotide for PKD and liver disease (NCT00309283, NCT00426153, and NCT00565097). Pilot studies evaluating the feasibility of increasing the fluid intake in the form of water have also begun in ADPKD patients.[401] These are based on the assumption that decreasing the urinary osmolality to less than 300 mOsm per kilogram in the steady state will result in the deactivation or inhibition of the V2R. The tolerability of increasing fluid intake is reasonable; however, long-term compliance and 24-hour monitoring of urinary osmolality is a potential concern. Measures of disease progression under these conditions have not yet taken place.

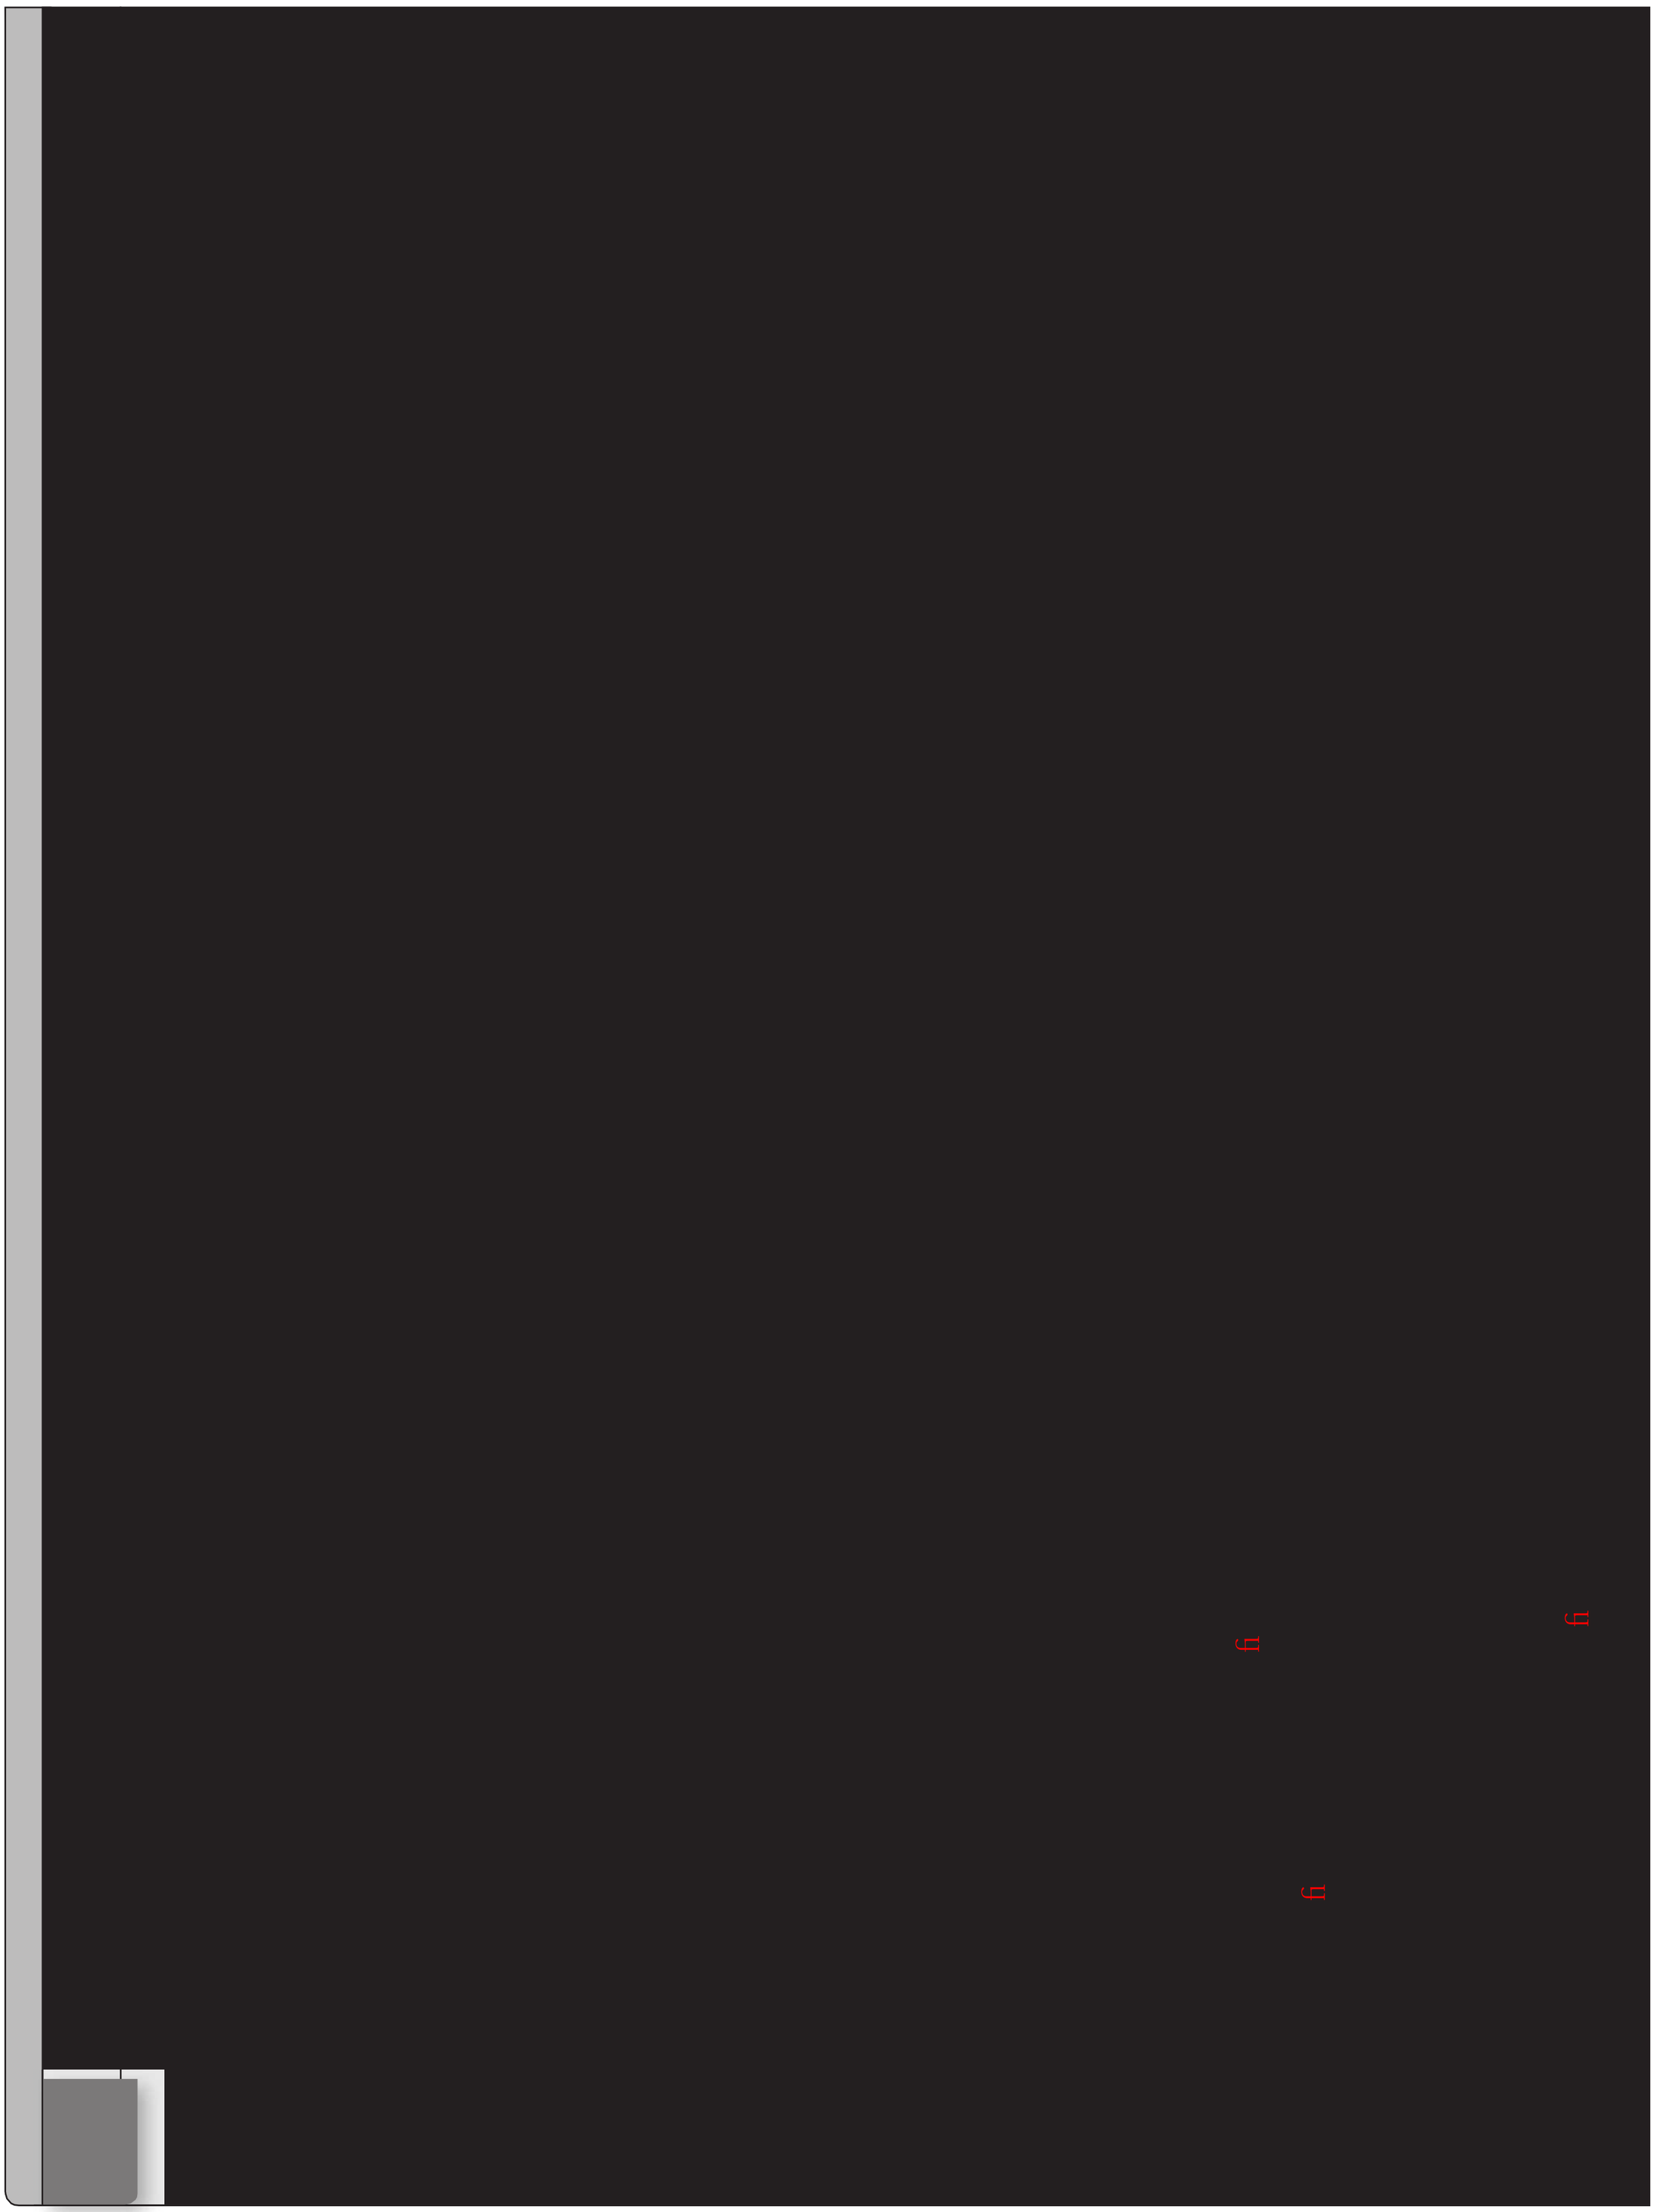
Inhibition of the Mammalian Target of Rapamycin

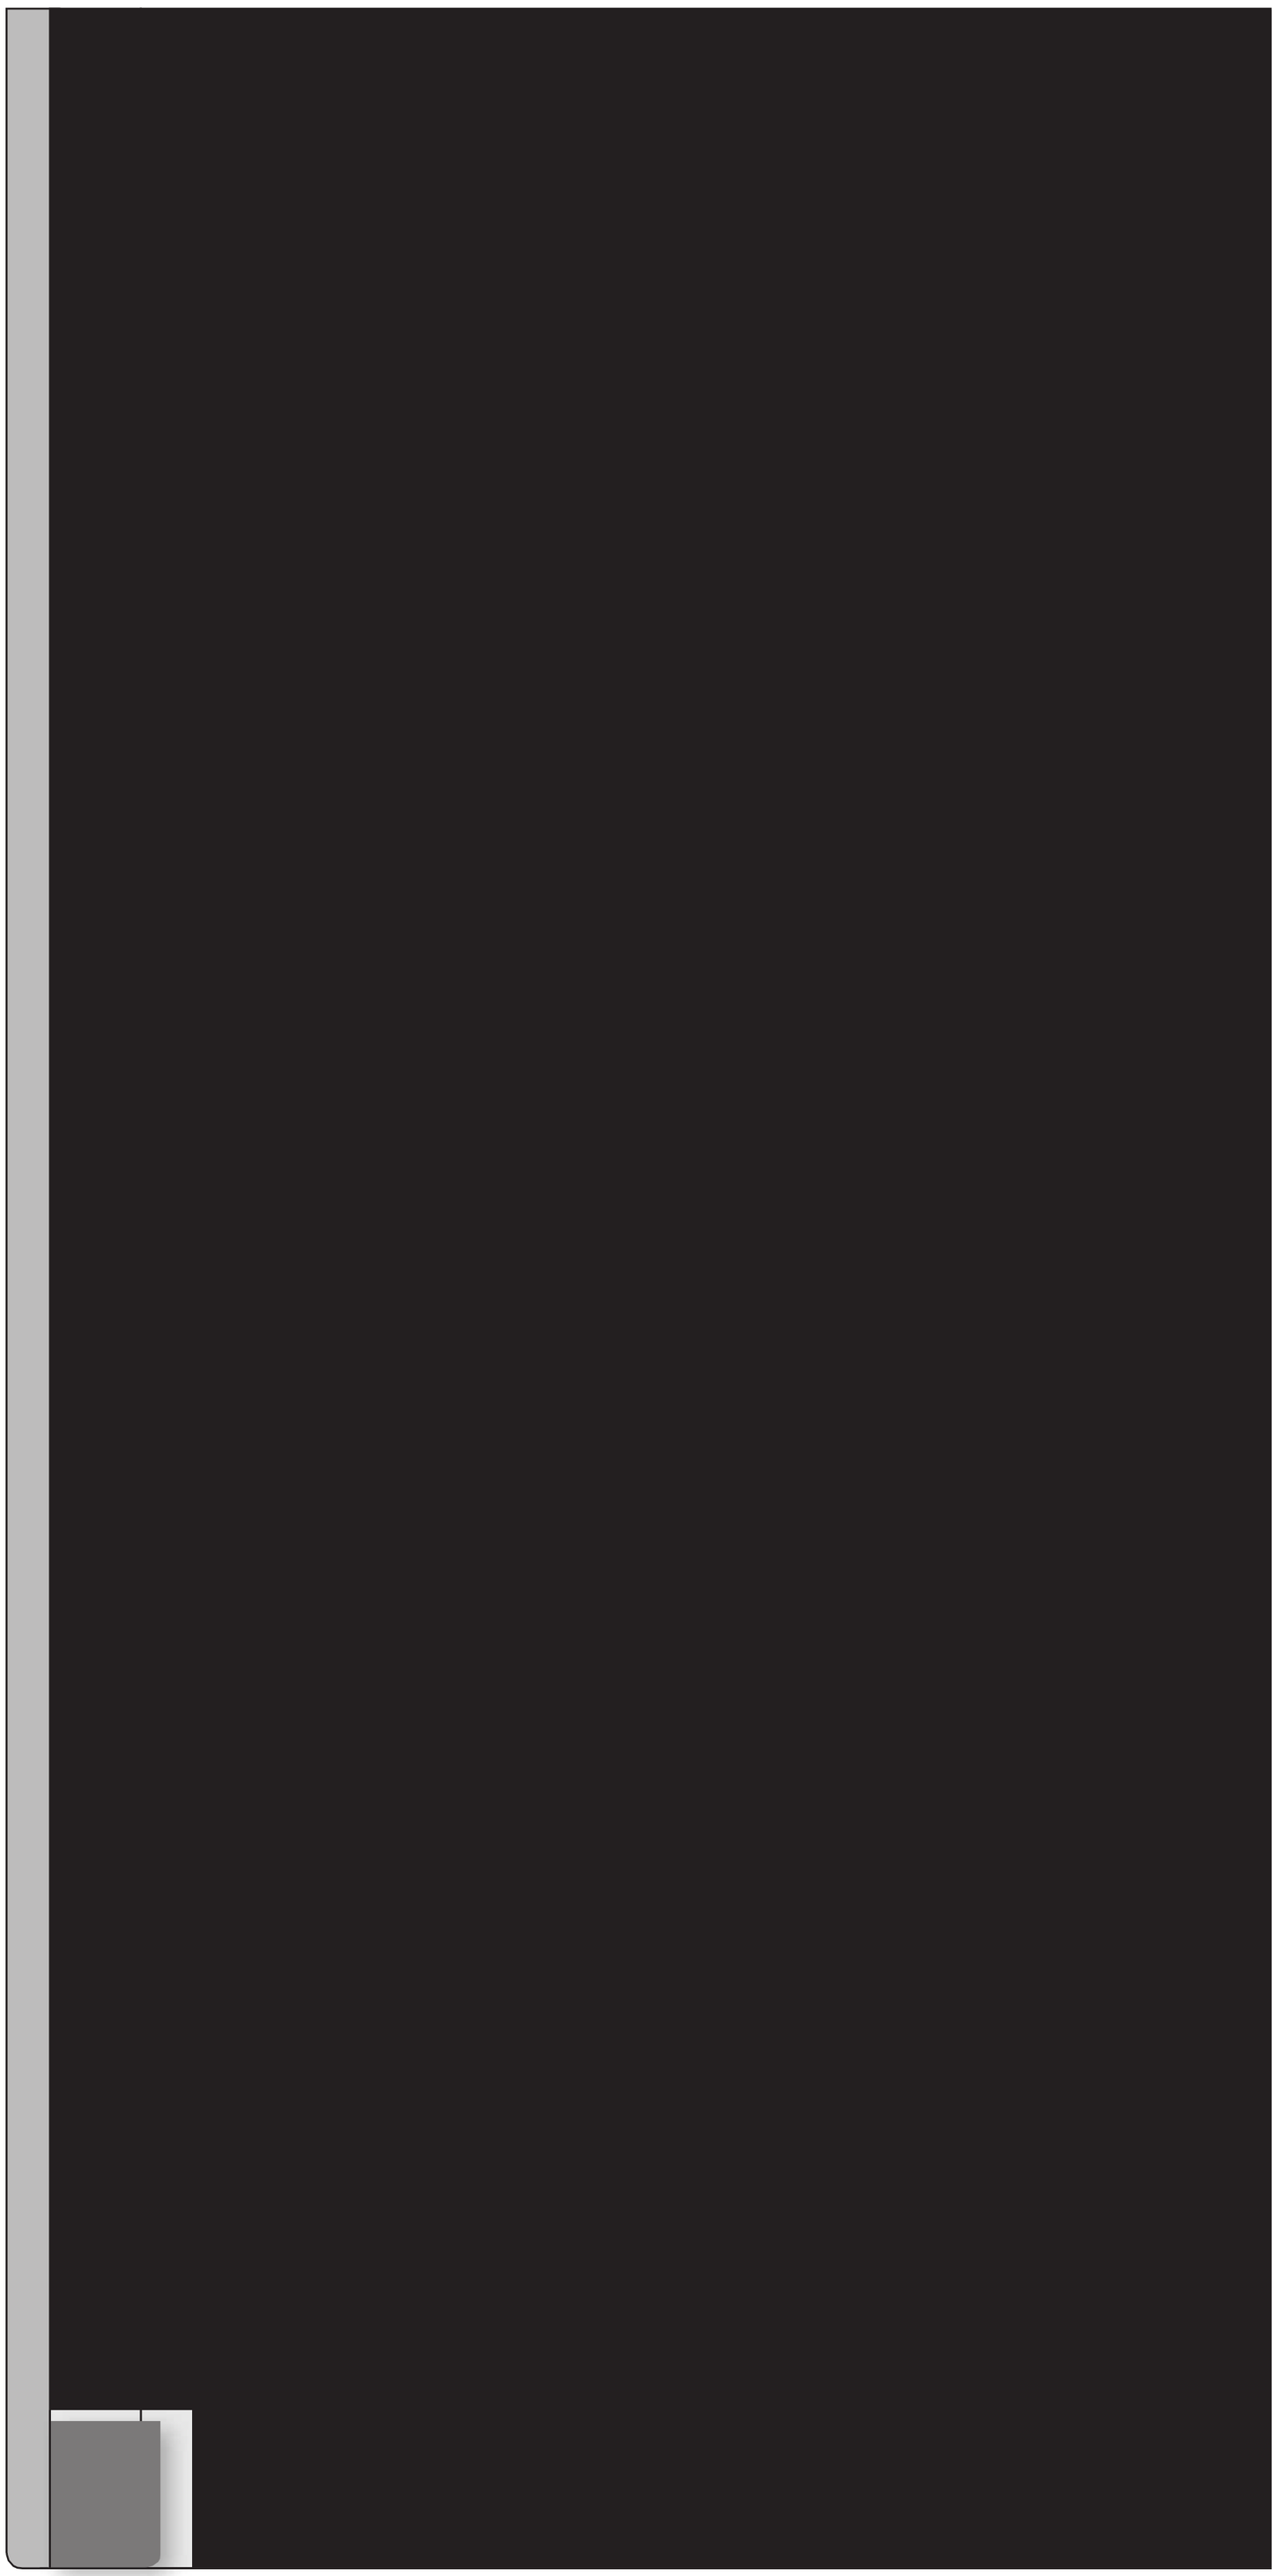
mTOR, a serine-threonine kinase that is involved in the coordination of cell growth and proliferation, is inappropriately activated in cysts lining the epithelial cells of kidneys from mice and humans with ADPKD (see previous).[225,402,403] Studies in animal models of cystic kidney disease have shown that mTOR inhibition suppresses cyst growth. Sirolimus or everolimus significantly reduced kidney volume growth in the nonorthologous Han:SPRD rat model by reducing cyst expansion with a sustained effect with prolonged treatment.[404,405] Sirolimus also had some effect in an animal model of NPHP and in an orthologous mouse model with the conditional inactivation of Pkd1.[354,406] These studies used higher doses of mTOR inhibitors than can be achieved in humans and only tested their preclinical potential in early onset, rapidly progressive orthologous gene mouse models of Pkd1.[354] A small scale, 6-month, randomized trial comparing eight patients on sirolimus with eight control patients showed reduced kidney volume growth in the sirolimus-treated group.[407] Collectively, these preclinical and clinical observations offered a rationale for clinical trials of mTOR inhibitors in ADPKD.

Two major prospective randomized clinical trials using sirolimus or everolimus have since been completed (Table 16.3). The studies differed with respect to patient number, subject characteristics, and dose range. The two studies reported negative results. Walz et al.[408] randomly assigned 433 patients aged 18 to 65 years with ADPKD and an estimated GFR > 30 mL per min per 1.73 square meter (chronic kidney disease stage II/III) to receive either placebo or the mTOR inhibitor everolimus (2.5 mg twice daily) for 2 years. Everolimus treatment was associated with a marginal slowing of the increase in TKV, reaching statistical significance at 1 year and marginal significance at 2 years. The finding that increases in TKV were persistently lower in the everolimus group suggests that everolimus may be able to limit the growth of cysts in patients with ADPKD. The perceived lack of a positive effect on glomerular filtration rate and the progression of chronic kidney disease may be due to the reduced power of the trial resulting from the fact that approximately one-third of the patients dropped out, largely because of drug-related adverse effects. In a complementary trial, the SUISSE ADPKD study treated 100 patients aged 18 to 40 years with preserved renal function with sirolimus (2 mg per day) for 18 months.[409] At the end of the study period, the median increase in TKV was similar in the placebo group to the sirolimus group (97 mL versus 99 mL, respectively). The study used a relatively low target dose of sirolimus, and the dose delivered was approximately 25% lower than the intended dose because of adverse effects. The average sirolimus dose normalized by mean patient body weight was approximately 0.020 mg per kilogram. ROC curve analyses of dose finding studies identified 0.049 mg per kilogram of body weight as the cut-off threshold for sirolimus dosage that predicted a reduction or reversal of total cyst volume growth. The negative findings from these studies contrast the positive results from preclinical studies and the results from smaller clinical studies of shorter duration.[407] Taken together, mTOR inhibitors require further investigation to determine any potential to favorably impact changes in TKV in ADPKD individuals. Efficacy is limited by their toxicity, and the impact of mTOR inhibitors appears to be greatest during the most proliferative stages of disease type. It remains to be seen if this class of agent can still be used in patients during the more aggressive phases of cyst growth and expansion, potentially in concert with other disease modifying agents.









3-Hydroxy-3-Methyl-Glutaryl-CoA (HMG-CoA) Reductase Inhibitors

Lovastatin therapy in the heterozygous male (but not the female) Han:SPRD rats resulted in decreased cystic kidney size and improved renal function.[410] These effects may be due to the decreased formation of farnesyl pyrophosphate, an intermediate in the conversion of acetyl-coenzyme A (CoA) to cholesterol that is also required for the activation of Ras, which in turn may be an important factor in cell proliferation. Three clinical trials of statins lasting from 4 weeks to 2 years in small numbers of ADPKD patients have shown improved renal hemodynamics, including increased GFR and effective renal plasma flow, improved endothelial function, and longer term kidney function and urinary protein excretion.[411–413] Currently, a phase III randomized trial comparing pravastatin to placebo over 5 years is under way in 107 children and young adults aged 8 to 22 years and treated with angiotensin-converting enzyme inhibitors. The end points in this trial include TKV, renal function, and urinary protein excretion levels.[414]

Triptolide

Triptolide is a natural compound derived from the Chinese herb Thunder God Vine. It is a potent inhibitor of nuclear factor-kappa B (NF-κB) and nuclear factor of activated T cells (NFAT)-mediated transcription, which thereby decreases inflammatory and proliferative cellular responses. Triptolide also promotes increased PC-2–mediated calcium release and reduces cyst formation in Pkd1 mouse models.[415–417] Current clinical trials using triptolide are under way in approximately 300 patients at the University of Nanjing to evaluate its effects on kidney function and TKV.

Epidermal Growth Factor Receptors and Src Inhibitors

Epidermal growth factor receptor (EGFR) inactivation has been shown to slow cyst growth in nonorthologous recessive models of polycystic kidney disease,[418,419] but not in a rat model orthologous to human ARPKD.[224] EGFR tyrosine kinase inhibitors, one of which is an Src inhibitor, play an intermediary role in cAMP pathways.[420] Src activity has been shown to be associated with the progression of disease in bpk mice and pck rats.[421] A truncated EGFR-like protein, Bosutinib, which is a Src inhibitor, has been valuable in treating breast cancer.[422] Most of the EGF receptor tyrosine kinase inhibitors are relatively nonspecific and have significant side effects, which suggest that long-term use at normal antineoplastic doses will not be feasible in ADPKD individuals. However, they may be extremely useful at a reduced dosage level with other disease modifying agents in appropriate subsets of ADPKD individuals. A clinical trial of 400 ADPKD individuals is under way using the receptor kinase inhibitor Bosutinib SKI606 (NCT01233869). This trial is designed to inhibit Src and to increase MAPK activation. Both renal function and TKVs are being evaluated in this study.

HALT Polycystic Kidney Disease

Substantial evidence has implicated the RAAS in the pathogenesis of ADPKD and associated hypertension. However, evidence that treatments inhibiting the RAAS are superior to other treatment strategies or are at all beneficial are, to date, inconclusive. Limitations of previous studies due to small sample size, short periods of follow-up, and the study of patients at relatively late stages of the disease without a complete blockade of the RAAS have hampered the development of evidence-based guidelines for the treatment of hypertension in ADPKD. Because of the importance of hypertension in ADPKD and the uncertainties surrounding its treatment, the NIH/National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) has funded two distinct, multicenter, double-blind, randomized clinical trials adequately powered to assess the effect of RAAS blockade on renal progression in early and late stages of the disease (NCT00283686). HALT PKD consists of two ongoing randomized trials with the largest cohort of systematically studied patients with ADPKD to date. Study A is designed to compare the combined treatment with an angiotensin-converting inhibitor and receptor blocker to the inhibitor alone at standard compared to low blood pressure targets. There are 558 ADPKD early stage patients with an eGFR over 60 mL per min per 1.73 square meters. Study B is comparing angiotensin-converting enzyme inhibitors and receptor blockers to the inhibitor alone at standard blood pressure level in 486 patients with more progressive renal disease and an eGFR between 25 and 60 mL per minute per 1.73 square meters. An initial evaluation of this study population[95,423] demonstrates a significant association between eGFR, urinary albumin excretion, body surface area, and TKV. These studies are due to be completed in 2014.

CHAPTER

17 Alport Syndrome, Fabry Disease, and Nail-Patella Syndrome

Godela M. Brosnahan • Martin Gregory • Imed Halal • Berenice Y. Reed

Hereditary glomerular diseases have diverse and often covert patterns of inheritance and varied clinical presentations. They are more common than is generally appreciated. Vigilance and awareness of these subtleties are important for prompt and accurate diagnoses, which allow for optimal management and timely genetic counseling.

ALPORT SYNDROME

Alport syndrome (AS), formerly called hereditary nephritis, is a disorder characterized by hematuria, proteinuria, progressive renal failure, variable sensorineural hearing loss, and ocular abnormalities. On a histologic examination, irregularities of the glomerular basement membrane (GBM) constitute the primary disease feature. Cecil Alport's archetypal kindred[1] had dominantly inherited kidney disease that was characterized in both sexes by hematuria and urinary erythrocyte casts, variable proteinuria, and by hearing loss and renal failure in males. Affected males died in adolescence of uremia, whereas females lived to old age.

The Present Definition of Alport Syndrome and the Molecular Defect Definition

For this chapter, AS will be defined as progressive, hereditary, hematuric, nonimmune glomerulonephritis that is characterized ultrastructurally by progressive irregular thickening, thinning, and lamellation of the GBM and genetically by a mutation in COL4A3, COL4A4, or COL4A5.

The Genetic Classification of Alport Syndrome

Between 2% and 5% of males with end-stage renal disease (ESRD) and probably less than 1% of females have AS. Various estimates place the gene frequency between 1:5,000 and 1:53,000, respectively.[2] The true prevalence may be higher because affected patients with subtle hearing loss are easily overlooked. There are three main genetic types of AS: X-linked Alport syndrome (XL-AS), autosomal recessive Alport syndrome (AR-AS), and autosomal dominant Alport syndrome (AD-AS), which are classified based on the mode of inheritance as described in Table 17.1. The severity of symptoms varies from person to person and with age and gender. Large kindreds show modes of inheritance and kindred-specific phenotypes that clearly reflect the genetic heterogeneity of AS. Thus, although the demonstration of a family history of glomerulonephritis among affected persons within a kindred may be helpful to ascertain, demonstration of a causative mutation remains the gold standard for genetic diagnosis.

X-Linked Alport Syndrome Caused by a Mutation in *COL4A5* (OMIM 301050)[3]

XL-AS is the most common form of AS, accounting for 80% of cases. XL-AS results from a mutation in the COL4A5 gene located at Xq22.3, which encodes the α_5 chain of type IV collagen (α_5[IV]). Hematuria from birth occurs in 100% of hemizygous males[4,5,6] and 90% to 100% of heterozygous female carriers of XL-AS.[5,7,8] Disease expression is phenotypically very heterogeneous. ESRD is inevitable in males but occurs at widely different ages in different families. The age of ESRD tends to run true within a family, but even within a family there can be quite wide variability. Knowing the mean age of ESRD in males in a family is useful from a prognostic standpoint. Moreover, extrarenal manifestations, such as hearing loss and ocular defects, tend to occur more commonly, more severely, and at an earlier age in kindreds whose males develop ESRD early.[4]

Because they are late symptoms, it is unwise to equate chronic renal failure and ESRD with Alport gene penetrance. We define penetrance of ESRD as the fraction of a population at risk in whom ESRD eventually develops. For males in each Alport kindred, ESRD penetrance generally coincides with hematuria penetrance. In Figures 17.1 and 17.2, representations of the probability of ESRD and hearing loss in boys and girls with XL-AS are shown. Inactivation of the X chromosome likely explains both incomplete hematuria penetrance among females heterozygous for XL-AS and their low probability of ESRD and hearing loss.[9] Jais et al.[7] found a cumulative prevalence of ESRD of 12% in female carriers of XL-AS by the age of 40 years.

17.1 Genetic Classification of Alport Syndrome

Description	OMIM	Gene	Comment
X-Linked Alport Syndrome	301050	COL4A5	Most common form of Alport syndrome accounting for 80% of cases. A heterogeneous condition with progressive renal insufficiency and timing of ESRD occurring between childhood and adult. Hearing loss and eye problems are common but severity is variable. More severe phenotype in affected males.
COL4A5 and Contiguous Gene Defects			
Alport Syndrome with Diffuse Leiomyomatosis	308940	COL4A5-COL4A6	Alport syndrome with diffuse leiomyomatosis.
Alport Syndrome, Mental Retardation, Midface Hypoplasia, Elliptocytosis (AMME)	300194/95	COL4A5 with FACL4/ AMMECRI	Contiguous gene deletion affecting genes located 3′ of the COL4A5 gene.
Autosomal Recessive Alport Syndrome (ARAS)	203780	COL4A3/COL4A4	This form of Alport syndrome accounts for 15% of cases. Most cases result in the early onset of ESRD. Hearing and eye problems are common, with both males and females being equally affected.
Autosomal Dominant Alport Syndrome (ADAS) without Hematologic Defects	104200	COL4A3 or COL4A4	A milder disease with the later onset of renal impairment, and a lower incidence of hearing loss and eye problems.
Familial Thin Basement Membrane Disease and Benign Familial Hematuria	141200	COL4A3 or COL4A4	A milder disease, with no hearing loss or occurrence of eye problems.

One consequence of X linkage is that twice as many females as males with a nephritis gene will be born if there are no prenatal effects and if reproductive fitness is independent of gender of the gene-carrying parent. In kindreds with XL-AS and early onset of ESRD, most affected children obtain the gene from their mothers, and the sex ratio of gene-carrying newborns approaches 1:1.

X-Linked Alport Syndrome Caused by a Deletion in *COL4A5* with Damage to Contiguous Genes (OMIM 308940 and 300194/5)

In this form, AS is associated with other features caused by an extension of the deletion outside COL4A5. Alport syndrome with diffuse leiomyomatosis (smooth muscle tumors) (Online Mendelian Inheritance in Man [OMIM] 308940)[3] stems from a deletion embracing the 5′ ends of COL4A5 and COL4A6.[2,10] The AMME syndrome (OMIM 300194/5)[3] consists of AS, midface hypoplasia, mental retardation, and elliptocytosis and has been described in several families with deletions of COL4A5 that extend beyond the 3′ end of the gene.[11–14]

Autosomal-Recessive Alport Syndrome Caused by Homozygous Mutations Mutations in *COL4A3* or *COL4A4* (AR-AS, OMIM 203780)

AR-AS is allelic with familial thin basement membrane nephropathy (TBMN). This form of AS accounts for 15% of

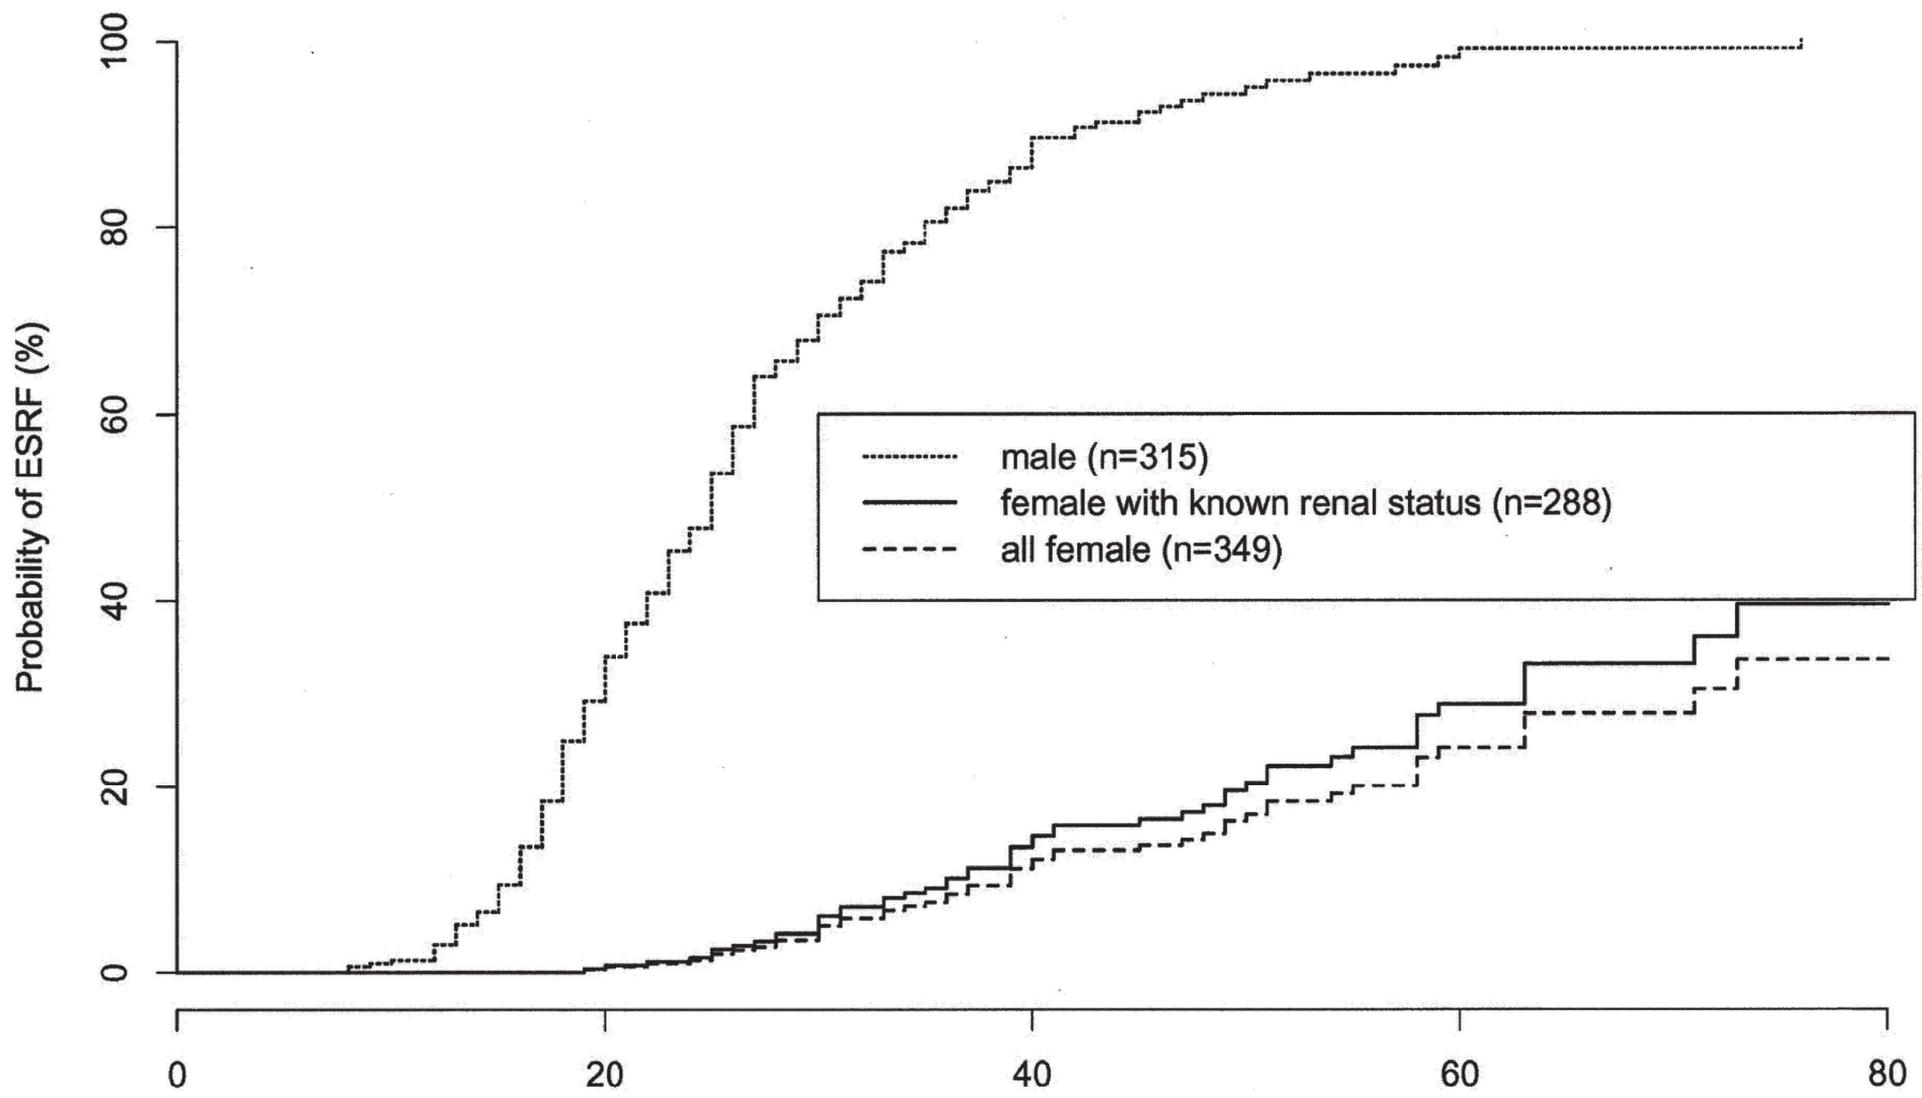

FIGURE 17.1 Probability of end-stage renal disease (ESRD) in 315 boys and men and 288 girls and women with the *COL4A5* mutation. In the third curve, girls and women with incomplete clinical data were added because they were not in ESRD at last follow-up. AS cases. AR-AS results from mutations affecting both alleles of the COL4A3 gene or the COL4A4 gene. To date, most examples of AR-AS syndrome have resulted in early ESRD, but this may reflect ascertainment bias.[15–17] Males and females are equally severely affected, and hearing and ocular defects are usual. It is not yet clear whether all AR-AS or all TBMN is caused by mutations of these genes.

Autosomal-Dominant Alport Syndrome without Hematologic Defects (AD-AS, OMIM 104200)

AD-AS is a relatively rare genetic form of AS. It is linked with a heterozygous mutation of either the COL4A3 gene or the COL4A4 gene. Only a few families have been described to date. One well described family had relatively mild renal impairment and no hearing loss, eye signs, platelet abnormalities, or leiomyomatosis.[18] The mutation in this family is a splice site mutation in COL4A3.[19] In a study of eight families with heterozygous mutations affecting the COL4A4 gene none had ocular problems, and a low incidence of hearing anomalies was observed.[20] Loss of renal function occurred at a later age than the X-linked form.

Familial Thin Basement Membrane Nephropathy or Benign Familial Hematuria (OMIM 141200)

In 1997, Lemmink et al.[21] linked the occurrence of heterozygous mutations in the COL4A3 and COL4A4 genes with familial TBMN. These conditions are associated with the maintenance of long-term normal renal function and the absence of hearing loss or ocular problems. More recently, Pierides et al.[22] described 11 large pedigrees in which heterozygous COL4A3/COL4A4 mutations were associated with microscopic hematuria before the age of 30 and late development of proteinuria and ESRD due to focal segmental glomerulosclerosis.

Genotype–Phenotype Correlation in Alport Syndrome

COL4A5 Mutations

XL-AS is both clinically and genetically heterogeneous. To date, more than 590 mutations and potential mutations have been described in the COL4A5 gene associated with XL-AS.[23,24] Among affected male patients, the age at ESRD typically ranges between the second and third decades of life. However, in milder cases, ESRD may be delayed until the fifth or sixth decade. Similarly, deafness occurs at variable ages and a wide variety of ocular abnormalities have been reported among patients.[2] Several large studies from Europe, the United States, and China have assessed a genotype–phenotype correlation in XL-AS.[2,4,25,26,27] The COL4A5 mutation type appears to be one factor associated with renal disease severity and extrarenal manifestations. In male-affected patients large deletions, non-sense, and frame shift mutations have been associated with more severe disease manifestations, such as earlier age at ESRD onset, hearing loss, and the occurrence of eye abnormalities compared to patients with missense mutations.[4,25,26] Early renal failure and retinopathy have also been reported to associate with the occurrence of certain specific mutations, including some missense mutations.[28] The position of the mutation and the affected domain of collagen α_5(IV) also appears to affect disease severity. An earlier age at onset of ESRD was shown to associate with a more 5′ gene location in one study.[26] The distance of the mutation from the NC1-domain was shown to affect severity.[25] Glycine substitutions occurring in exons 1 through 20 resulted in a less severe phenotype compared to those affecting exons 21 through 47.[25] This effect was attributed to the fact that the triple helix formation starts at the C-terminal of the NC1-domain and proceeds in a zipperlike manner to the N-terminal end.[29] Similar studies in affected women and girls have failed to demonstrate any genotype–phenotype correlation.[7] However, it should be stated that phenotypic variability is also common among affected family members of the same gender who carry the same germline mutation. This intrafamilial variability may be attributed to both the environment and the effect of other genes.

COL4A3 and COL\4A4 Mutations

To date, 71 mutations or potential disease-associated sequence variants have been described in the COL4A3 gene, and 56 have been described in the COL4A4 gene.[23] Although AR-AS associated with homozygous mutation in either COL4A3 or COL4A4 results in the early onset of ESRD with typical hearing loss and eye problems, heterozygous mutations in the COL4A3/COL4A4 genes are associated with the less severe phenotype associated with benign familial hematuria and familial TBMN. Due to the innate genetic complexity of these disorders, not surprisingly, no genotype–phenotype correlation has been described.

Clinical variability in disease expression has been described for both male and female patients with AD-AS who carry a heterozygous mutation in either COL4A3 or COL4A4. However, no significant genotype–phenotype correlations have been described in AD-AS.[20] This may relate to the small number of families that have been identified with this genetic form of AS.

Pathogenesis

Type IV collagen, a major constituent of basement membranes, is comprised of six chains: α_1(IV) through α_6(IV). The type IV collagen chains assemble into three different heterotrimers in the mammalian basement membrane: $\alpha_1,\alpha_1,\alpha_2$; $\alpha_3,\alpha_4,\alpha_5$; or $\alpha_5,\alpha_5,\alpha_6$, respectively. The $\alpha_3,\alpha_4,\alpha_5$ form is synthesized by the podocytes in the glomerulus, and this heterotrimer of type IV collagen is also the predominant form of collagen found in the basement membrane of the ears, eyes, and lungs.[30] Mutation affecting any of the corresponding genes—namely, COL4A3, COL4A4, or COL4A5—will have a consequential effect on the integrity of the type IV collagen. In the GBM in Alport syndrome, the normal $\alpha_3,\alpha_4,\alpha_5$ collagen network is replaced by the fetal $\alpha_1,\alpha_1,\alpha_2$ network, which

is less resistant to degradation, thus resulting in the gradual deterioration of the GBM and in the clinical features of AS.[31]

Pathology

Kidney

There are no pathognomonic lesions seen with light microscopy in AS.[32,33] Lipid-laden interstitial foam cells are seen in the cortex of some but not all biopsy specimens. Foam cells are typically absent from biopsies taken early in the disease process.[34,35] Direct immunofluorescence is initially negative, whereas a faint deposition of immunoglobulin (Ig)G, IgM, and/or C3 may be observed with the progression of the glomerular segmental lesions.[36] The most definitive diagnostic information is provided by electron microscopy (EM) and by differential immunostaining for collagen α(IV) chains with specific monoclonal antibodies, which is discussed further under immunopathology.

Electron microscopy. The classic ultrastructural lesion of AS is characterized by an irregular thinning and thickening of the GBM, splitting and lamellation of the GBM with the loss of the normal lamina densa, small granules within the GBM, and an irregular outer and inner contour of the GBM (Fig. 17.3).[36] Distortion of the lamina densa may be extreme at times, amounting to a basket weave appearance in which the lamellae branch and rejoin in a complex triangle.[37] Focal or diffuse foot process fusion is common. The ultrastructural changes are common to all variants of AS. However, the extent of GBM thickening and lamellation is gender and age dependent. Moreover, there is considerable variability between affected individuals regarding the presence of these characteristic ultrastructural findings and even between affected individuals from the same family.[36] It should be emphasized that GBM splitting with variable thickness and an irregular outer contour is not specific for AS; such changes may be seen with other renal injuries, as reviewed by Haas.[36] Therefore, the combined use of EM and immunohistology for the detection of the collagen α_3(IV), α_4(IV), and α_5(IV) chains increases the specificity for AS diagnosis. Use of these combined methods permits AS diagnosis in most cases.[36]

Immunopathology. Staining for α_3(IV), α_4(IV), and α_5(IV) collagen chains with monoclonal antibodies distinguishes between the various forms of AS including XL-AS, AR-AS, and TBMN as depicted in Table 17.2. In particular, the absence

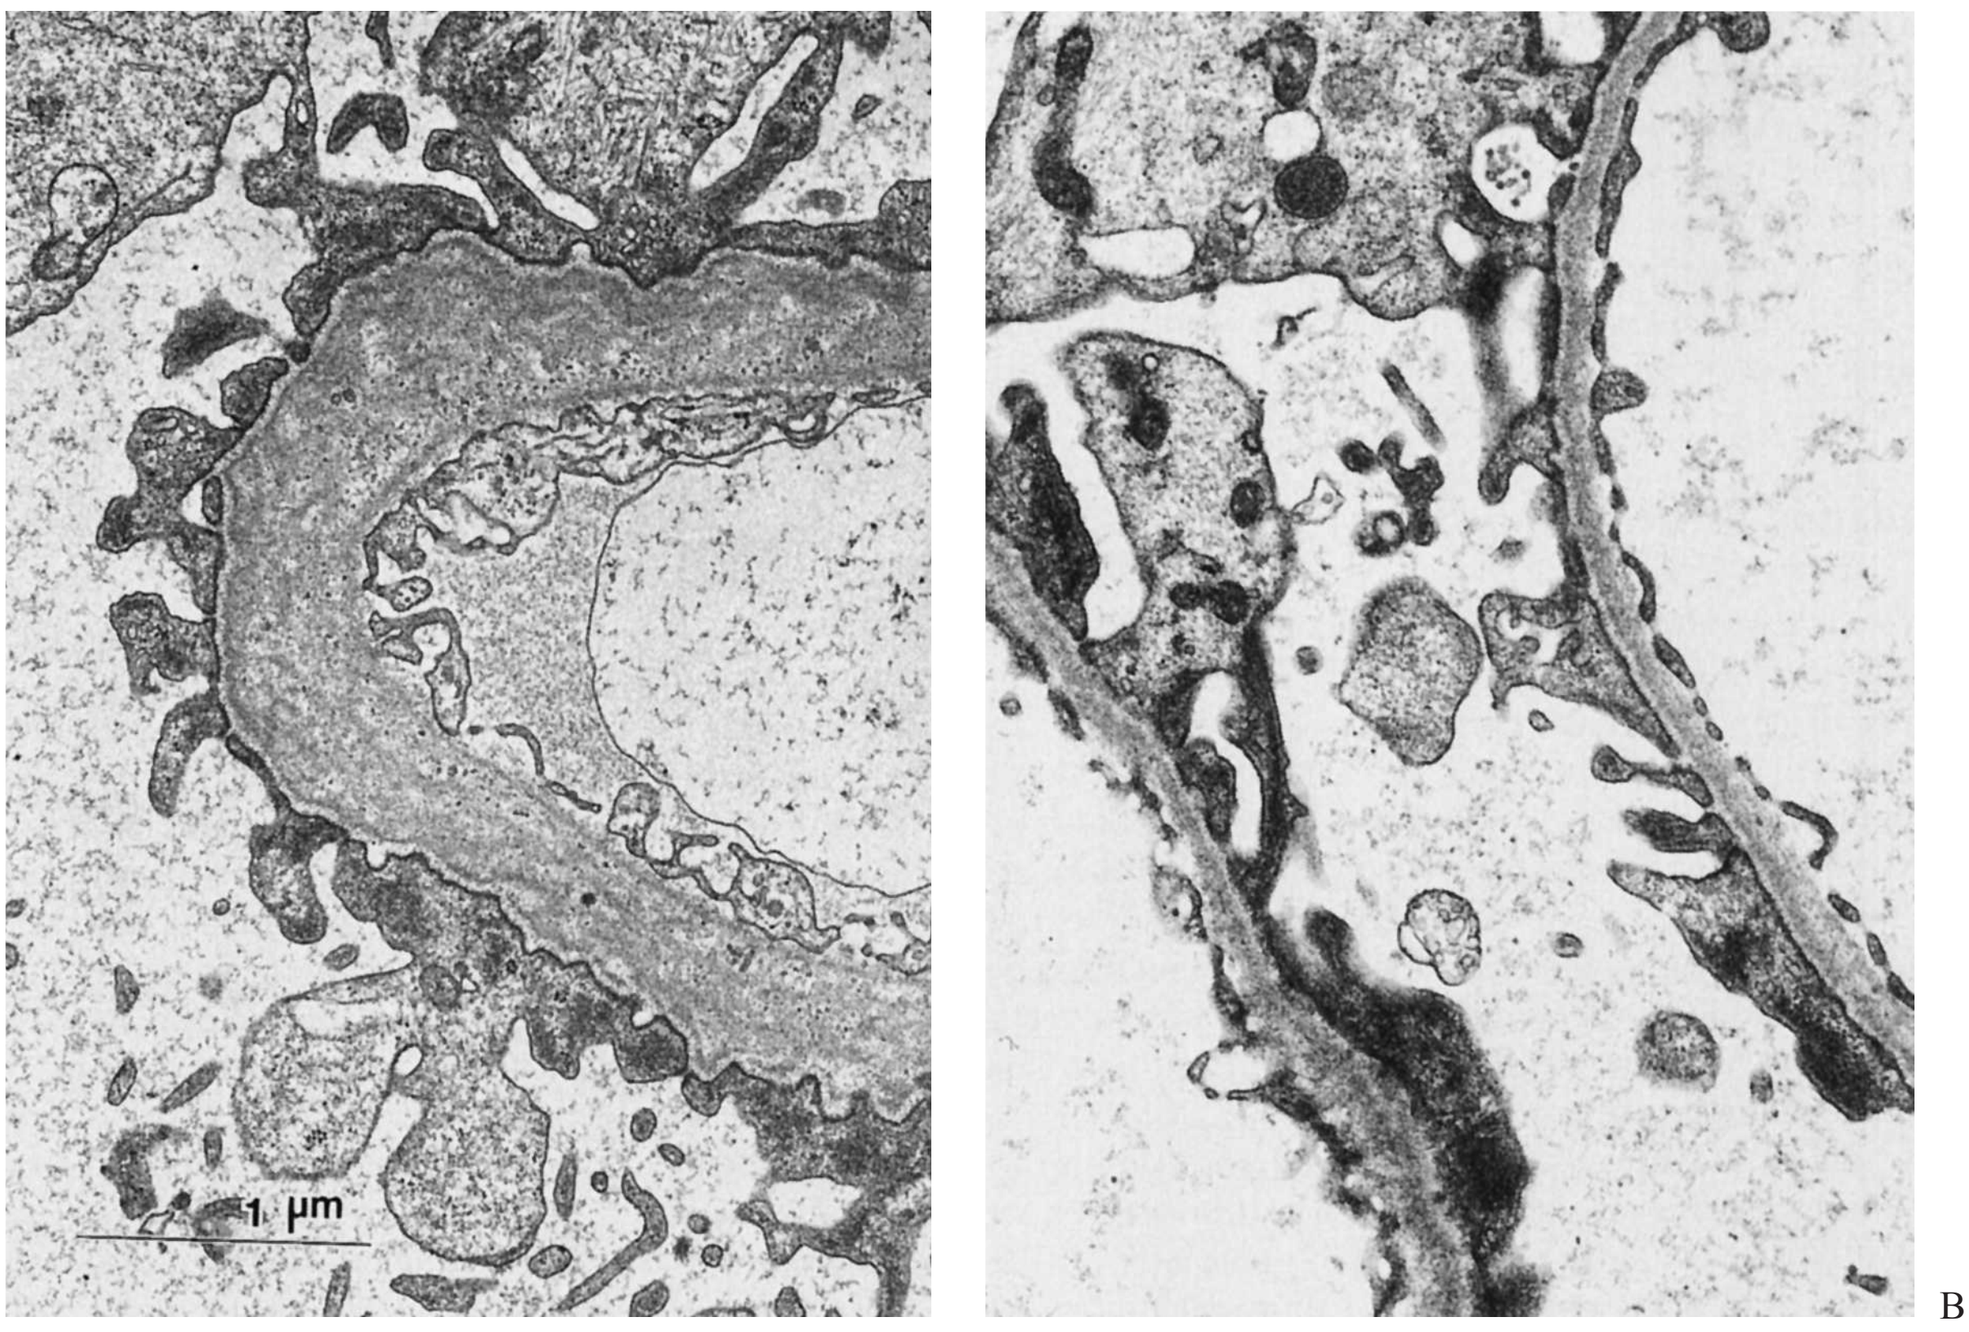

FIGURE 17.3 **A:** Glomerular ultrastructure in Alport syndrome. Electron micrograph of a renal biopsy specimen from a man in Utah kindred M, illustrating a widened lamina densa of the GBM (GBM). The lamina densa is split into several layers, between which may be seen numerous small electron-dense granules. **B:** Electron micrograph, at same magnification as **(A),** from an affected woman with familial thin GBM disease. The uniform thinning of the GBM can be appreciated by comparison with the width of the epithelial foot processes. (Electron micrographs courtesy of Dr. M.E. Hammond, University of Utah, Salt Lake City.)

17.2 Staining for α_3(IV) and α_5(IV) in Thin Basement Membrane Nephropathy (TBMN) and Alport Syndrome Variants

	α_3(IV)			α_5(IV)			
	GBM	BC	TBM	GBM	BC	TBM	EBM
Normal/TBMN	+	+	+	+	+	+	+
Alport variants[a]							
X-linked carrier (heterozygote)	Discont	Discont	Discont	Discont	Discont	Discont	Discont
X-linked male	–	–	–	–	–	–	–[b]
Autosomal recessive	–	–	–	–	+	+	+

[a]Infrequent exceptions to these patterns have been noted on renal biopsies.
[b]Up to approximately 50% of individuals in each of these categories will show normal staining for α_5(IV) on skin biopsy.
GBM, glomerular basement membrane; BC, Bowman capsule; TBM, distal tubular basement membrane; EBM, epidermal basement membrane; Discont, discontinuous staining (mosaic pattern).

of GBM staining for α_3(IV) and α_5(IV) is indicative of AS: either XL-AS in male subjects or AR-AS in both genders.[36] It should be noted that in 15% to 20% of XL-AS kindreds, α_3(IV) and α_5(IV) staining remains normal. This may result from the presence of certain missense mutations that cause only minimal disruption to the collagen chain structure. Both α_3(IV) and α_5(IV) are normally expressed in TBMN. Readers are referred to a comprehensive overview of differential α(IV) staining patterns for differentiation of the various forms of AS and TBMN by Haas.[36]

Skin

Skin biopsies are far less invasive than renal biopsies and may provide useful diagnostic information based on immunofluorescence analysis in certain patients. A normal epidermal basement membrane (EBM) contains α_5(IV) but not α_3(IV) or α_4(IV) chains. Thus, in AR-AS, α_5(IV) is present in EBM.[38] Absence of staining for α_5(IV) is highly specific of XL-AS in male patients. A pronounced pattern of discontinuous α_5(IV) staining is observed in some heterozygous carriers of XL-AS. However, it should be noted that a significant proportion of XL-AS patients, both male and female, retain a normal EBM staining of α_5(IV).[36] Thus, the diagnostic value of skin biopsies that demonstrate a positive staining for α_5(IV) is limited. Moreover, skin biopsy staining cannot be used for the diagnosis of AR-AS as expression of α_3(IV), and α_4(IV) is normally absent in EBM.

Cochlea

The inner ear is much less amenable to a histopathologic study than the kidney. Specific lesions in AS include a zone of separation between the basilar membrane and the overlying basement membrane of the organ of Corti and the presence of cells filling the tunnel of Corti and the extracellular spaces of Nuel.[39] Cellular infilling of the tunnel of Corti and spaces of Nuel likely represents a persistence of the fetal cochlear structure.[39]

Eye

In the anterior lenticonus, the basement membrane of the anterior lens capsule is thinned and more fibrillar than normal,[40,41] allowing for an anterior bulging of the cortex of the lens, most prominently in the pupillary region. The collagen α_3(IV), α_4(IV), and α_5(IV) chains may be present or lacking in the anterior lens capsule of AS patients.[42]

Another common ocular manifestation is perimacular "dot and fleck" retinopathy, which consists of whitish or yellowish flecks or granulations in a perimacular distribution.[43]

Smooth Muscle

In Alport-leiomyomatosis syndrome, the orderly hyperplasia of smooth muscle may involve the trachea and bronchi, all muscle layers of the esophagus, the clitoris, and the uterus. True leiomyomas, characterized by disorderly smooth muscle proliferation, have been found in the trachea and lungs, the esophagus, the upper part of the stomach, the clitoris, the vagina, the vulva, and the perineum.[10] Malignant transformation has not been observed. Ultrastructurally, basement membranes are normal in the esophageal tissue.[10]

Clinical Features of X-Linked and Autosomal Recessive Alport Syndrome

Renal Symptoms and Signs

Hematuria is the cardinal feature, persistent and present from birth, in 100% of affected males[4] and in 90% to 100%

of heterozygous females.[7] Hematuria is a sine qua non for the diagnosis of AS in males. Single or recurrent episodes of gross hematuria have been reported in 60% to 70% of males.[4] They may follow sore throats or other infections in children and may be the presenting symptom.[44]

Microscopy reveals dysmorphic red cells, renal tubular cells, and red cell casts in the urine. Urinary tract infections are no more frequent than in the general population. Proteinuria develops in 95% of affected males and in 75% of female heterozygous patients and is of variable degrees, ranging from barely detectable in early stages to nephrotic range[4] in some patients in advanced stages. As in other renal diseases, heavy or increasing proteinuria implies a worse prognosis.[4,44] Nephrotic syndrome may occur in severely affected patients. The serum complement concentration is normal.

Renal function initially remains normal for years and then wanes inexorably to renal failure. The age at which ESRD develops is very variable and spans from childhood or adolescence in families with severe (usually truncating) mutations to the fourth or fifth decade in some families with very mild (usually missense) mutations.[4,26] In the past, families in which ESRD developed in males at a mean age of 30 years or younger were classified as "juvenile" Alport families (about 70% of XL-AS), whereas others in which ESRD occurred at a mean age over 30 years were called "adult" Alport families (about 30% of XL-AS).[45] However, even within a family, the age of ESRD may be widely variable. As renal function declines, hypertension develops and worsens. Rarely, crescentic glomerulonephritis has been described and accompanied by rapidly progressive renal failure.[46]

In XL-AS, renal failure is inevitable for affected males, whereas only 30% to 40% of females develop ESRD, generally in later adulthood. In a European study of 195 XL-AS families, 12% of gene-carrying women developed ESRD by the age of 40 years, 30% developed ESRD by age 60, and 40% developed it by age 80 years (Fig. 17.1).[7] However, this may be an overestimate because in that study, about a third of gene-carrying women, possibly the less severely affected, were lost to follow-up. Many females remain asymptomatic carriers, only manifesting microscopic hematuria with or without low-grade proteinuria.[7,9] There is no correlation between the severity of the disease in women and men from the same family, and no genotype–phenotype correlations in women, which is likely due to the random inactivation of X-chromosomes in women.[7,9] The clinical manifestations of AR-AS are indistinguishable from XL-AS, with hematuria, proteinuria, and renal failure developing equally in males and females. ESRD occurs in all affected men and women, usually before the age of 30 years.[2,8]

Sensorineural Hearing Loss

Sensorineural hearing loss occurs in 50% to 80% of males with XL-AS and in 20% to 30% of heterozygous females, as shown in Figure 17.2.[4,7,8] It is never present at birth but starts to develop in childhood; initially, there is high-frequency hearing loss that is detectable only by audiometry, but it progresses and becomes clinically detectable in boys at an average age of 11 years.[2] Deafness develops at varying ages, often concurrently with the progression to ESRD, but in some cases 10 or more years later.[4,47] There is some correlation between the severity of the renal disease and the severity of hearing loss; families without hearing loss appear to have less severe renal disease than those with hearing loss.[44] However, there is also variability within AS families; while some affected family members develop hearing loss, other affected members may have apparently normal hearing even after ESRD.[47] Hearing loss generally occurs less frequently, less severely, and at an older age in carrier females (Fig. 17.2),[7,8,48] although some women and girls may have a profound loss. In the European study of XL-AS families, the risk of deafness by the age of 40 years was only 10% for women, but after the age of 60 years, 20% of the women had developed hearing loss.[7]

There is no anatomic abnormality of the tympanic membrane or ossicular chain; middle ear pressures are normal and air conduction is normal. Hearing loss is usually worse above 1,000 Hz, with an abnormal short increment sensitivity index, negligible tone decay, and normal brainstem auditory evoked responses,[48] thus proving cochlear rather than neural dysfunction. Caloric test results are normal, but more subtle testing reveals impaired vestibular function[48]; flat intensity function curves locate the lesion in the end organ itself. Hearing loss is thought to be due to structural lesions of the capillary basement membrane of the stria vascularis in the cochlea where the collagen α_3(IV), α_4(IV), and α_5(IV) chains are normally expressed.

Renal disease with hearing loss, even if familial, should not be equated with AS. Several genetic diseases affect the ear and the kidney, and chronic renal failure itself has been associated with impaired hearing. Hearing loss from the time of birth is unlikely to be due to AS.[4,47,49]

Ocular Features

A wide range of eye abnormalities have been reported, including anterior lenticonus, dot and fleck retinopathy, corneal endothelial vesicles (posterior polymorphous dystrophy) and erosions, macular holes, retinal detachment, and more recently, bull's eye and vitelliform maculopathy.[50] Eye abnormalities are usually not observed in children but develop in late adolescence and young adults. The most frequent are anterior lenticonus and dot and fleck retinopathy, which appear to be specific for AS.[2,28] The retinopathy consists of yellowish or whitish spots around the macula, sparing the fovea. Loss of the foveal reflex with alterations in macular pigmentation may be observed, as well as more peripheral pigmentary disturbances, either white or dark.[50] Visual acuity is unaffected by the presence of these retinal lesions. Their reported frequency varies and depends in part on whether a thorough eye exam is performed. In a smaller study, the retinopathy was found in 90% of affected males,[2] whereas other studies report it in 50% to 60% of men and in about 15% of women in XL-AS.[4,7,28]

Anterior lenticonus is a conical protrusion on the anterior aspect of the lens due to thinning of the lens capsule; it is less common than the dot and fleck maculopathy, occurring in 20% to 40% of men with XL-AS and is usually, but not invariably, bilateral. It is easy to recognize when it is fully developed. The red reflex is present, but it is impossible to see the fundus clearly because of the severe refractive error. Examination through a dilated pupil with a strong convex lens in the ophthalmoscope reveals an "oil drop" bulging the anterior surface of the lens. Lesser degrees of lenticonus may be difficult to diagnose even by slit-lamp examination.[51] Severe degrees of lenticonus cause grave visual impairment, are not correctable by glasses or contact lenses, and require lens replacement. Lenticonus is usually associated with early onset renal failure and more severe mutations in COL4A5.[4,28] It is rare in women with XL-AS.[7,8] Lenticonus is almost always accompanied by dot and fleck retinopathy,[52] but the retinopathy can be found in the absence of lenticonus. Ocular findings in AR-AS are similar to those seen in XL-AS men.[2] In one study, 91% of subjects with AR-AS had retinopathy and 82% had lenticonus.[8]

Autosomal Dominant Alport Syndrome

AD-AS is characterized by wide intra- and interfamilial variability in severity, but usually it is a milder disease.[2,19,20,53] It has been described in more detail in recent years, and causative heterozygous mutations have been shown in both COL4A3 and COL4A4 genes.[2,19,20,53] Although microhematuria is present in 95% to 100% of gene carriers, proteinuria is observed in about 50% of carriers at an age between 20 and 40 years, and ESRD is observed in 24% at a mean age of 51 years, but increases to 80% among patients older than 60 years.[20] ESRD has not been documented before the age of 31 years, and the overwhelming majority (93%) occurs after the age of 40 years.[20] Manifestations are similar in men and women. Hearing loss occurs in about 20%, with the onset usually after the age of 40 years. Ocular lesions have so far not been observed in AD-AS.[20]

Esophageal and Genital Leiomyomatosis

In several kindreds and in isolated patients, hematuric nephropathy was associated with striking muscular hypertrophy or leiomyomas of the esophagus.[54–57] In females, there was also hypertrophy of the clitoris, vulva, and adjacent structures. Hearing loss and cataracts were common, and anterior lenticonus was occasionally present.[57] Cataracts, which are not a feature of AS alone, were frequently severe and of early onset, and were sometimes congenital. Alport-leiomyomatosis syndrome has been comprehensively reviewed.[55,57]

Inheritance is X-linked dominant with deletions having been shown in the adjacent 5′ ends of COL4A5 and COL4A6.[56,58–60] In cases examined by electron microscopy, lamellation and granulation were seen in renal but not in esophageal basement membranes.[55] Clinically, affected patients suffer from dysphagia, odynophagia, regurgitation with respiratory symptoms, and bleeding. Occasionally, esophageal leiomyomatosis may be asymptomatic. The renal disease is similar to that in XL-AS men or women.[55]

Aortic Abnormalities

Aside from isolated case reports of aortic disease in males with AS, recently five males with a severe form of XL-AS were described who manifested thoracic aortic dissection at ages 25 and 32 years (two cases), ascending aortic aneurysm with rupture at age 32 (one case), aortic insufficiency requiring a replacement of the aortic root and valve at age 23 (one case), or asymptomatic dilatation of the ascending and descending aorta at age 21 years.[61] All five patients had ESRD by age 20 years, three had sensorineural deafness, and two had anterior lenticonus. Supporting the contention that aortic disease is a manifestation of AS was the finding of absence of collagen α_5(IV) from the aortic media in transgenic mice with XL-AS. A ruptured abdominal aortic aneurysm at age 36 and a ruptured intracranial aneurysm at age 14 years had been previously reported in two males with XL-AS.

Rare or Chance Associations

Many strange associations with AS have been described. Often, the diagnosis of AS was insecure, and in others, a coincidence noted on a few cases was not confirmed in larger studies. Further examples are needed to confirm these associations.

Diagnosis

The path to the correct diagnosis lies through a carefully collected, extended family history and a personal examination of the urinary sediment, specifically for hematuria. The proband will often be a child with unexplained hematuria or an adolescent to middle-aged male with ESRD with a vague history of kidney disease in brothers or relatives on the maternal side. A systematic urinalyses may reveal several relatives with hematuria.

There are several points to remember:

Microscopy of urine sediment—do it yourself!

Family history—extend to as many generations and collaterals as possible.

Age of ESRD in males helps to clarify the phenotype.

Female gene carriers—look for hematuria, although not all carriers have it.

When a member on the line of descent in a well-studied kindred is found to have hematuria, a renal biopsy is generally superfluous. The poorer the family history and the more remote the nearest affected relative, the stronger the case for a biopsy. Typical extrarenal features, specifically anterior lenticonus or retinal pigmentary changes in the patient or family, strengthen the presumption of AS and diminish the need for a biopsy. Linkage studies can identify gene carriers with near certainty in large families, but this is frequently

not practical for routine diagnosis due to the need to study several affected family members. About 15% of XL-AS cases are due to new mutations and, therefore, the family history will be negative.[2,62] In these patients, AS is diagnosed or suspected based on a renal biopsy performed for unexplained hematuria with or without proteinuria.

Molecular genetic testing is now generally available for mutation detection in the COL4A5, COL4A4, and COL4A3 genes. Acceptable samples for analysis include buccal swabs or blood samples. Detection of COL4A5 mutations by targeted mutation panel screening identifies the most commonly occurring mutations in this gene with almost 100% detection efficiency.[62] In addition, whole gene sequence analysis is available and has an efficiency of approximately 80% for mutation detection. Detection of large COL4A5 deletions or duplications requires more complex testing, which is offered by specialized clinical laboratories. Carrier testing and prenatal diagnosis may be performed once a mutation has been identified. Molecular genetic screening of both COL4A3 and COL4A4 genes by direct sequence analysis is likewise currently available through several clinical laboratories with an estimated efficiency of 80% for mutation identification. Screening for large deletions/duplications in these genes is less readily available outside of research laboratories.

Treatment

Kidney Disease

No specific treatment is known to affect the underlying pathologic process or to alter the clinical course of kidney disease. One uncontrolled series reported a surprising benefit of cyclosporine[63]; however, this was not confirmed in other studies. Despite a reduction of proteinuria with cyclosporine, renal function deteriorated and significant lesions of cyclosporine nephrotoxicity were seen on repeated renal biopsies.[64,65] Angiotensin converting enzyme inhibitors (ACEI) have been used in both hypertensive and non-hypertensive Alport children with proteinuria.[66,67] They variably reduced proteinuria and appeared to stabilize the decline of GFR. Although there is no proof of efficacy of these agents in AS, they are being widely used to suppress proteinuria in AS children.[68] Control of hypertension is necessary on general grounds and should follow the guidelines for children with renal disease. Patients with deteriorating renal function are monitored and treated as the general population with chronic kidney disease. When ESRD occurs, dialysis and transplantation pose no particular problems.

Transplantation is the treatment of choice for these young and otherwise healthy patients and has had excellent outcomes. Recurrent disease does not occur, but a small proportion of males (3% to 5%) developed de novo anti-GBM glomerulonephritis, which usually does not respond to plasmapheresis and cyclophosphamide and results in graft loss in 90% of cases.[69–71] The autoantibodies are directed against the collagen α_3(IV) and/or α_5(IV) chains, which are missing in the native kidneys. Why anti-GBM disease develops only in a minority of transplanted patients is unknown, but may depend on the specific mutation. It is not possible to predict which patients will develop this complication, but once this has occurred, the risk of recurrence in a subsequent transplant is very high.[71]

Hearing and Vision

Great care should be taken to avoid adding insults from drug cytotoxicity to the advancing aural injury. Improvement or stabilization of hearing loss in AS patients has occasionally been noted after transplantation[44,72]; others noted no benefit.[73] An interpretation of these findings is difficult because dialysis and the uremic state have been associated with reversible hearing loss. There is fair success with hearing aids. When hearing loss worsens, the patient will become more dependent on lip reading and other visual cues. Visual acuity should be monitored at intervals in those with or at risk of lenticonus, and consideration should be given to early lens extraction and intraocular lens implantation. Steroid doses should be kept low after transplantation, and patients should be monitored regularly for cataracts; poor vision is a disproportionate handicap to the deaf.

Genetic Counseling

Inheritance is X-linked dominant in 80% to 85% of families, is autosomal recessive in about 15%, and is autosomal dominant in 1% to 5%.[62] As a group, men with AS have about 30% fewer children than do men without AS; many men with more severe disease will sire no offspring.

An incomplete penetrance of AS in females must always be kept in mind.[74] In kindreds with X linkage, daughters of affected males will all be gene carriers regardless of their urinalysis results. Each clinically normal daughter of dominant gene carriers (mothers in kindreds with X linkage, and parents of either sex in kindreds with autosomal dominance) has a 50% chance of having an undetected Alport gene. Information from genetic tests or from urinalyses of the next generation may help decide whether these females have inherited a gene.

Differential Diagnosis

Conditions with Hearing Loss

Many conditions affect both the ear and the kidney, perhaps because of simultaneous embryogenesis or because of structural and physiologic homology.[75] For instance, hearing loss and proteinuria with a histologic picture of focal segmental glomerulosclerosis (FSGS) have been described in patients with mitochondrial cytopathies.[76] Here we discuss the most important hereditary conditions that might be confused with AS.

Autosomal-Dominant Alport-Like Syndrome Caused by Mutations in *MYH9*

Epstein and colleagues[77] first described a syndrome (OMIM 153650) that looked like a variant of AS with nephropathy,

sensorineural hearing loss, thrombocytopenia, and giant platelets. Subsequently, several kindreds have been described. When there were inclusions in leukocytes and cataracts in addition to nephropathy, deafness, and giant platelets, the term Fechtner syndrome (OMIM 153640) was used.[78] Other families had giant platelets, thrombocytopenia, and leukocyte inclusions but no nephropathy or deafness; this disorder was called May-Hegglin anomaly after the first descriptions in 1909 and 1945 (OMIM 155100). Other families have autosomal dominant hereditary hearing loss without any other manifestations (DFNA 17, OMIM 603622). All of these seemingly different disorders are caused by mutations in the MYH9 gene on chromosome 22q11-13, which encodes for the nonmuscle myosin heavy chain IIA (NMMHC-IIA), and are therefore variable expressions of the same disease.[79,80] Mutations in the motor domain of NMMHC-IIA are associated with a severe phenotype with severe thrombocytopenia and a high risk of glomerulopathy, ESRD, and deafness before the age of 40 years, whereas mutations in the tail domain are milder and often cause only giant platelets with mild thrombocytopenia, with a low risk of developing cataracts or hearing loss late in life.[79,80] However, as in other genetic disorders, there is significant intrafamilial variability in the severity of manifestations, possibly mediated by modifying genes or environmental factors.[80]

Clinical and Laboratory Features of MYH9 Disorders

The hallmark of this disease is macrothrombocytopenia from birth; all patients also have neutrophilic inclusions, although in some cases they are small and difficult to see on routine peripheral blood smears. The bleeding tendency is generally mild and depends on the degree of thrombocytopenia; platelet counts are usually between 25,000 and 100,000 per microliter. Bleeding times may be normal or substantially prolonged.

Glomerulopathy develops in 30% to 70% of patients with MYH9-related disorders at a mean age of 23 years.[80,81] Patients present with proteinuria, which is in the nephrotic range in more severe cases, and/or microhematuria, and often progress to ESRD before the age of 40 years.[80] When a renal biopsy was performed, it usually showed nonspecific light microscopic findings, including mesangial cell and matrix expansion, focal segmental, or global glomerulosclerosis and tubulointerstitial fibrosis.[80,82] Electron microscopy showed a focal and segmental effacement of foot processes and a loss of the interpodocyte slit diaphragm, as well as irregular thickening, splitting, thinning, and even a basket weave appearance of the GBM,[80] which may lead to confusion with AS. A renal biopsy is not necessary for the diagnosis of an MYH9-related disorder.

Sensorineural hearing loss and, sometimes, cataracts usually develop in parallel with the renal disease in patients with severe mutations (in the motor domain or at position 702 of the NMMHC-IIA gene), similar to AS.[79] The differentiation is made clinically by the finding of giant platelets, thrombocytopenia, and autosomal dominant inheritance. Individuals from families with milder mutations (in the tail domain of the gene) may develop presenile cataracts and hearing loss later in life.

Treatment

The treatment or prevention of bleeding complications is with platelet transfusions, with or without adjunctive desmopressin (DDAVP). Corticosteroids, intravenous immunoglobulin, and splenectomies have no role because this is not an autoimmune-mediated disease. The management of the renal disease is nonspecific; drugs that block the renin-angiotensin system are used for patients with hypertension and proteinuria. Drugs that are potentially harmful to the inner ear, lens, or kidneys must be avoided. Subjects who progress to ESRD are good candidates for renal transplantation.

Hereditary Interstitial Nephritis with Hearing Loss

One large kindred with autosomal-dominant inheritance of high-tone hearing loss, proteinuria, casts, and pyuria, but without hematuria, has been described.[83] Biopsy findings in four siblings were interpreted as interstitial nephritis. Renal impairment was generally mild, although renal failure supervened late in life in four men and in one woman. Familial reflux nephropathy was not excluded as a possible cause of this disorder.

Conditions with Normal Hearing

Familial Thin Basement Membrane Nephropathy (Benign Familial Hematuria, OMIM 141200)

Familial hematuria does not always have an ominous prognosis, and large families in which renal impairment never occurred have been described. Rogers and colleagues[84] delineated an entity characterized by uniform thinning of the GBM and prolonged survival without the deterioration of renal function. Familial TBMN is the best name for this condition, which occurs in about 1% of the general population.[36,85,86] In several reports, about 40% of cases have been shown to result from heterozygous mutations in the COL4A3 or COL4A4 genes.[21,85–88] It is not clear whether other genes can cause TBMN or whether the failure to detect mutations in these genes in some families resulted from incomplete penetrance, concurrent conditions causing hematuria, or the limitations of mutation analysis.

TBMN displays autosomal-dominant inheritance[89,90] and represents the carrier state for AR-AS.[22,36,85,86] Clinically, it manifests hematuria from childhood, usually microscopic and continuous, but it may be punctuated by episodes of visible hematuria, particularly during or after an upper respiratory tract infection. Hearing is normal and ocular lesions do not occur. In most individuals, there is no or only minimal proteinuria, blood pressure is normal, and renal

function remains normal.[84,85,91] Flank pain occurs in some patients,[85,91] and TBMN appears to be one of the causes of the so-called loin pain–hematuria syndrome.[92,93] Although familial TBMN does not lead to ESRD in most cases, a few families have been reported in whom significant proteinuria, hypertension, and ESRD developed in older individuals (>50 to 60 years of age), without hearing loss or ocular manifestations.[22,94,95] Because these cases of late onset ESRD were also caused by COL4A3 and COL4A4 mutations, these observations blur the line between benign familial hematuria and AD-AS, in which hearing loss occurs in only some individuals late in life and ocular changes are not seen.[20,36,53] Moreover, recently, five families with a clinical diagnosis of benign familial hematuria have been found to carry a heterozygous missense mutation in the COL4A5 gene, whereas that same mutation caused AS with late onset ESRD in other families,[96] possibly due to the effect of other modifier genes.

In classical TBMN, renal biopsy specimens, apart from the presence of erythrocytes in the Bowman space and in tubules, appear normal by light microscopy.[36,84] Immunofluorescence examinations also reveal normal findings.[84] The characteristic ultrastructural finding is uniform with diffuse thinning of the lamina densa of the GBM. The overall width of the GBM is reduced from 300 to 400 nm to approximately 200 nm.[36,84] Breaks may be seen in the GBM through which red cells can cross.[84] There is no widespread splitting or lamellation of the GBM, although very localized (<5% of GBM length) splitting may be observed.[36]

Even with adequate material for high-resolution electron microscopy, the distinction from AS is not always clear. Biopsies in early stages of AS can show uniform thinning while lacking abnormally thick areas and lamellation, which develop later in the course of the disease.[36,62] In these cases, immunofluorescence staining for α_3(IV) and α_5(IV) may allow the differentiation. These chains are absent from the GBM in about 80% of AS but are always present in TBMN, although at reduced levels.[36,62] Renal biopsies from individuals with late onset proteinuria and chronic renal failure have shown focal-segmental and global glomerulosclerosis in addition to diffusely thin GBM.[85,94,95]

In practice, in the absence of genetic testing, features that help distinguish TBMN from AS include male-to-male transmission, normal hearing and longevity of several affected family members, and characteristic biopsy findings in at least one member of the family. In small families or patients with new mutations, only long-term follow-up will allow for a precise diagnosis.

Familial Immune Glomerulonephritis

A familial incidence is occasionally noted in many forms of glomerulonephritis, including IgA nephropathy,[97] systemic lupus erythematosus, membranous nephropathy,[98] IgM mesangial proliferative glomerulonephritis,[99] focal segmental glomerulosclerosis,[100,101] membranoproliferative glomerulonephritis,[102] and partial lipodystrophy.[103] Congenital complement deficiencies, most commonly C3, predispose an individual to membranoproliferative nephritis.[104] The distinction from AS is evident on a renal biopsy, although the clinical features can be very similar in children or young adults presenting with hematuria with or without proteinuria.

Hereditary Interstitial Nephritides

Familial Juvenile Hyperuricemic Nephropathy (FJHN, OMIM 162000). This entity is a chronic interstitial kidney disease with autosomal dominant inheritance. It is characterized by decreased uric acid excretion, hyperuricemia in childhood and clinical gout beginning in adolescence, the development of chronic kidney disease in the third or fourth decade of life, and slow progression to ESRD by the fourth to seventh decade.[105,106] Besides hyperuricemia, decreased urine concentrating ability is observed early in life, and children may present with polyuria and enuresis.[105,106] Hypertension develops later, but proteinuria is absent or slight and the urine sediment is normal or contains only a few urate crystals or epithelial cells. Renal ultrasound shows normal size or small kidneys, sometimes with multiple small medullary cysts, in which case autosomal dominant medullary cystic kidney disease (MCKD) type 2 was diagnosed until advances in molecular genetics showed that both FJHN and MCKD type 2 are caused by mutations in the uromodulin gene on chromosome 16 and therefore are the same disease.[107] Chronic interstitial nephritis is histologically nonspecific. Sometimes intratubular crystal deposits and a thickening of the tubular basement membranes are seen. There is no specific treatment for this renal disease, but allopurinol will help prevent the development of progressive tophaceous gout.[106]

A similar autosomal dominant interstitial nephropathy with early onset hyperuricemia was recently found to be caused by mutations in the renin (REN) gene on chromosome 1 (OMIM 613092).[106,108] Individuals with REN mutations have decreased renin production, predisposing them to hypotension, hyperkalemia, and acute kidney injury, which is similar to patients receiving ACEI. Children with these mutations also suffer from anemia due to decreased renin and angiotensin production.[108] Gout is common in these families and is due to decreased urate excretion. The pathogenesis of both disorders involves the accumulation of abnormally produced uromodulin or renin in tubular cells, leading to tubular cell death and subsequent tubular atrophy.

There is a third form of autosomal dominant chronic interstitial kidney disease with unknown mutations that is not associated with gout or anemia. Some of these families have been linked to chromosome 1, but REN mutations have not been found.[106]

FABRY DISEASE (OMIM 301500)

Fabry or Anderson–Fabry disease was identified over a century ago, in 1898. This inborn error (also called angiokeratoma corporis diffusum, ceramide trihexosidosis) is a rare

metabolic disorder that particularly affects vascular endothelium, leading to renal, cardiac, and cerebrovascular manifestations and early death. Fabry disease is the only known X-linked sphingolipid storage disease. Lack of α-galactosidase, a lysosomal hydrolase crucial in glycosphingolipid metabolism, causes an accumulation of neutral glycosphingolipids in many tissues.

Epidemiology

The disease is panethnic, and estimates of incidence range from about 1 in 40,000 to 60,000 males,[109,110] but may be higher.[111] Fabry disease affects males more severely than females, although many carrier (heterozygous) females also have symptoms and some have severe organ manifestations because of random X-chromosomal inactivation.[112,113]

Genetics

Inheritance is X-linked and the gene coding for α-galactosidase A (GLA) is situated at Xq22.1 on the long arm of the X chromosome, just centromeric to the AS locus. The GLA gene is a relatively small gene of ~12-kb containing seven exons. To date, over 600 mutations that cause Fabry disease have been identified, including missense, nonsense, small deletions and insertions, large gene rearrangements, and splice mutations.[23] The mutations are spread throughout the entire GLA gene, and most are "private," occurring in one or a few affected families. An analysis of data from the Fabry Outcome Survey (FOS) has suggested a correlation between genotype and clinical severity.[114] Most mutations result in the typical phenotype, but several missense mutations produced signs and symptoms confined to the heart, called "cardiac variant," or produced no symptoms at all.[115] A higher incidence of a splice mutation, IVS4-919G→A, has been reported in Japanese and Taiwanese patients with a late onset cardiac phenotype.[116,117] Moreover, patients carrying this splice mutation have recently been shown to also have a higher incidence of renal and ocular abnormalities, suggesting that the effects of this mutation are not restricted to the heart.[117]

Genotype–phenotype correlations are complex in Fabry disease because the same mutation can lead to both classic and atypical disease, even within the same family.[118,119] Patients with atypical variants of Fabry have been found to exhibit missense mutations that lead to a reduction but not an absence of α-galactosidase A activity.[120] In contrast, an increased incidence of GLA loss of function mutations has been demonstrated in children with ocular manifestations of disease.[121]

The complexity of genotype–phenotype interactions in Fabry disease is further complicated by the potential influence of modifier genes. Polymorphisms in the endothelial nitric oxide synthase gene (NOS3) have been associated with left posterior wall thickness of the heart in patients with Fabry disease and the cardiac phenotype.[122] Polymorphisms in the vitamin D receptor gene (VDR) have also been associated with variability in the Fabry phenotype.[123]

Pathogenesis

α-Galactosidase hydrolyzes neutral glycosphingolipids with terminal α-galactosyl residues. If the enzyme is defective, several glycosphingolipids, particularly globotriaosylceramide (GL-3, or ceramide trihexoside), will accumulate in many cell types, especially vascular endothelial and smooth muscle cells and also in cardiac myocytes, renal glomerular and tubular cells, and cardiac conduction fibers. Patients with a reduction in α-galactosidase A activity have a less extensive accumulation of GL-3 than patients with an absence of activity.

Pathology

Kidney

In early stages (children and adolescents), light microscopy may only show a vacuolization of podocytes and distal tubular epithelia.[124] As the lipids deposited in these cells are dissolved out with routine processing, the cells that contained them appear as foam cells (Fig.17.4). However, foam cells are not specific for Fabry disease and can be seen in other lysosomal storage diseases or in nephrotic syndrome. The accumulation of GL-3 starts in utero and affects all glomerular cell types but is greatest in podocytes.[125] Deposits can also be seen in distal and, to a lesser degree, proximal tubular epithelial cells, as well as in endothelial and vascular smooth muscle cells of arteries and arterioles.[124] In more advanced stages, light microscopy shows focal segmental and, later, global glomerulosclerosis with tubular atrophy and interstitial fibrosis, all of which are nonspecific findings.[124] However, electron microscopy reveals striking stacks or whorls of dense, flat, osmiophilic inclusions in the lysosomes of blood vessels and of glomerular and tubular epithelial cells with a periodicity of 35 to 50 Å (Fig. 17.5). These myelin bodies are 1 to 3 μm in diameter, showing a characteristic "zebra" or "onion-skin" appearance, and are strongly suggestive of a diagnosis of Fabry disease.[126,127]

Nonrenal Tissues

The most striking changes are in blood vessels and are similar to those just described for the kidney. Thromboses can occur in many organs, leading to tissue infarction, and seem to occur as a result of platelet aggregation on areas of sphingolipid accumulation in the endothelium and vascular smooth muscle cells. Aside from ischemic sequelae, the heart may show extensive glycosphingolipid deposition in myocytes and valvular fibrocytes. A left ventricular endomyocardial biopsy can reveal severe hypertrophy and a vacuolization of myocardial fibers, in some cases surrounding normal appearing arterioles.[128] On electron microscopy, lamellar inclusion bodies can be seen in vacuoles, similar to the zebra bodies in renal epithelial cells.[128] All four chambers of the heart may enlarge, the mitral and tricuspid valves thicken, and the mitral valve may prolapse. In advanced stages, prominent cardiac fibrosis develops. Cerebral vessels are strikingly involved, leading to stroke in young subjects. Glycosphingolipid accumulation in neural tissue is confined

to the perineurium of the peripheral nerves, autonomic neurons, dorsal root ganglia, and some primary somatic afferent neurons. Accumulation also occurs in the cornea.

Clinical Features and Course

Extrarenal Manifestations

In childhood and early adolescence, affected individuals experience agonizing pain in the limbs, more marked distally.[109] Pain can be chronic and/or acute, with episodic crises often precipitated by changes in temperature, exercise, or stress. They occur in 80% to 90% of male patients in the first decade and in about 10% to 70% of female patients, often in the later course of the disease.[129,130] A typical pattern of pain is acroparesthesia or burning sensations in the palms of the hands or soles of the feet. They become less intense or may even disappear in later life. In severe attacks, pain radiates proximally and may even simulate an acute abdomen. The pain is a result of damage to small nerve fibers caused by the accumulation of GL-3 in the nerve axons and dorsal root ganglia.

Hypohidrosis is a nearly constant feature, leading to heat and exercise intolerance. Some patients suffer from hyperhidrosis. Other common nonspecific complaints in children and adults are abdominal cramps and diarrhea, which are likely caused by autonomic neuropathy. Progressive sensorineural hearing loss, often associated with tinnitus or vertigo,

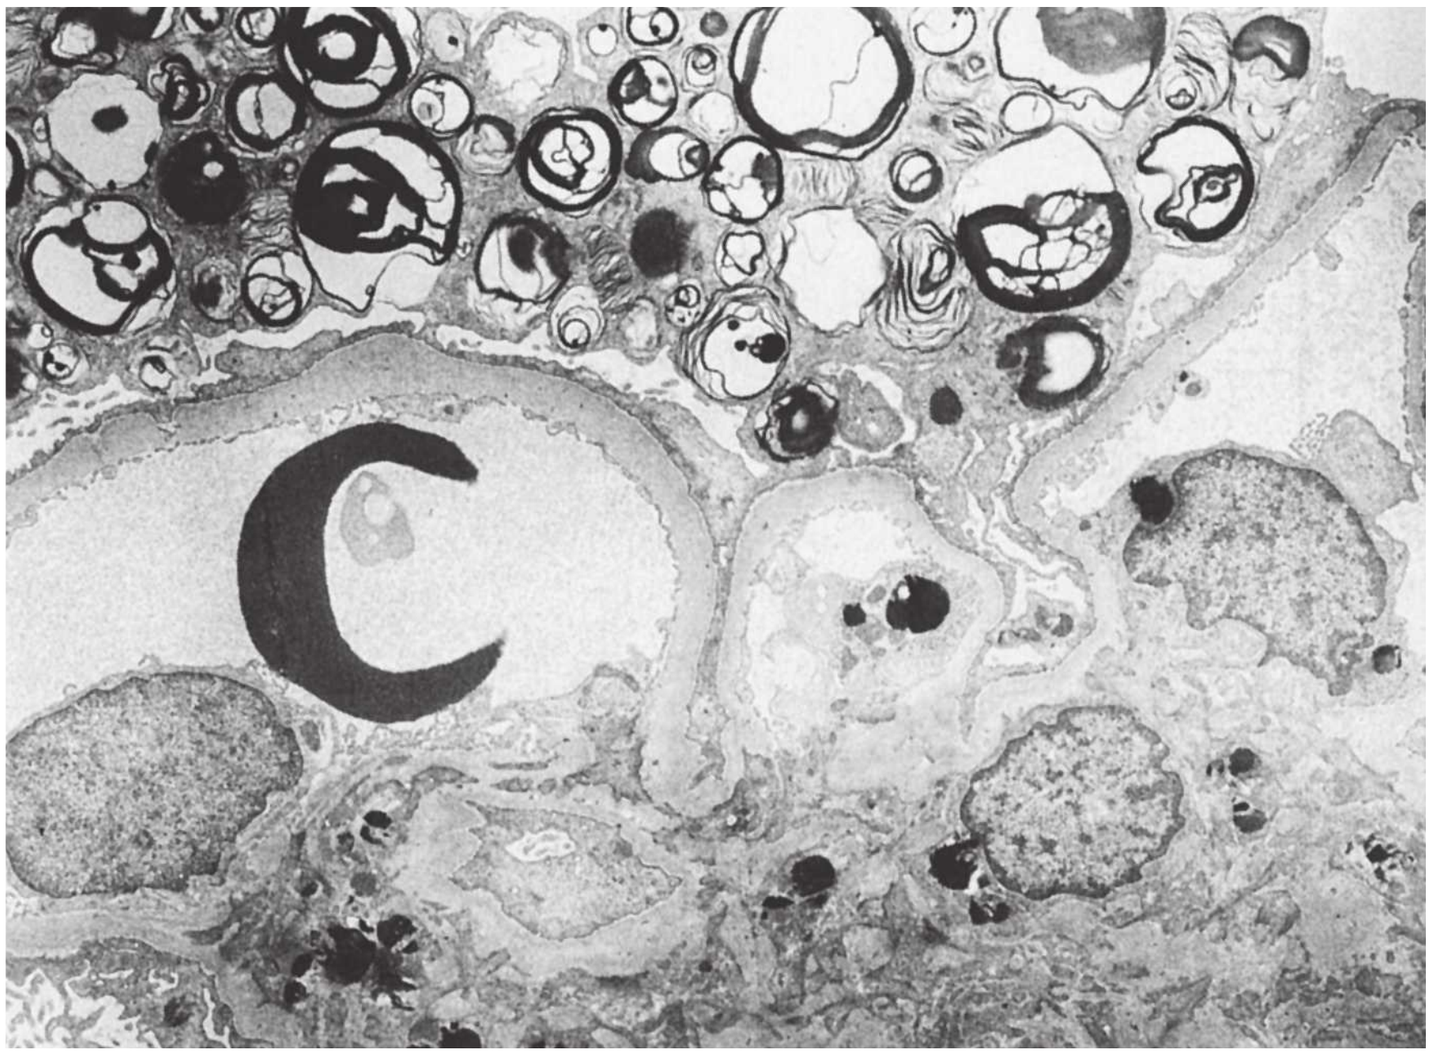

FIGURE 17.5 Myelin figures in Fabry disease. An electron micrograph of glomerular capillary loops with ultrastructural changes characteristic of Fabry disease. (Magnification ×5,500.) has also been reported to occur commonly in young male and female patients; its severity appears to be correlated with the peripheral nerve manifestations of the disease.[131,132]

Angiokeratomas, apparent as slightly raised, cherry red to black, nonblanching macules or maculopapules 1 to 3 mm in diameter, are small hyperkeratotic areas of dilated blood vessels. They appear in adolescence and progressively increase on the lower trunk and back, being particularly marked on the scrotum and bathing suit area (Fig. 17.6). Usually, they appear in groups or in generalized forms but they can be isolated. About 30% of carrier females have at least minimal angiokeratomas.[133] Angiokeratomas are not specific for Fabry disease because they also occur in other lipid storage diseases, and their absence does not rule out a diagnosis of Fabry disease.[134]

Cardiac involvement manifests as left ventricular hypertrophy, and some patients are erroneously diagnosed with idiopathic hypertrophic cardiomyopathy.[135] Left ventricular hypertrophy usually develops in the third and fourth decades of life and in the absence of significant hypertension.[113,135,136] In one echocardiographic study, left ventricular hypertrophy was found in 61% of men and in 18% of women who were older than 30 years of age.[135] Patients may present with congestive heart failure and/or severe mitral regurgitation.[134] The accumulation of glycosphingolipids in the cardiac conduction

FIGURE 17.6 Angiokeratomas of the anterior abdomen of a man hemizygous for Fabry disease.

system leads to arrhythmias or conduction defects requiring pacemaker and/or defibrillator implantation.[131] Cardiac and cerebral ischemic episodes can occur at an early age, in the third and fourth decades of life, often preceding the diagnosis of Fabry disease.[137] Therefore, Fabry disease is an important consideration in young patients with an unexplained stroke. One retrospective chart review of 447 Fabry patients reported that cardiac events, strokes, or transient ischemic attacks had occurred in 49% of males at a mean age of 36 years and in 35% of females at a mean age of 44 years.[131]

Cardiovascular events become more common in patients with ESRD. The Fabry registry, a voluntary international registry of 2,712 subjects with Fabry disease, reveals that after the onset of renal replacement therapy, 50% of men experienced a cardiac event or stroke (by a mean age of 48 years) compared with 20% of men without the need for renal replacement therapy (with a mean age of 36 years).[138] In this registry, there were significantly fewer women receiving renal replacement therapy (N = 27, versus 186 men), but 10 of them (37%) had a cardiac event or stroke by a mean age of 51 years. Cardiac involvement is the most common cause of death in both men and women.[139] In this recent study, the median age of death was 54.3 years for men and 62.0 years for women.[139]

Cornea verticillata is a distinctive whorled corneal opacity that is very similar to the opacities that can occur with prolonged chloroquine or amiodarone therapy.[140,141] It is the most common ocular manifestation of Fabry disease, occurring in about 70% of adult patients and 50% of child patients.[121] Opacities appear within the first few years of life and are generally asymptomatic; they are diagnostic of Fabry disease (unless the patient is on long-term treatment with chloroquine or amiodarone). Posterior radial cataracts eventually occur in 50% of patients but scarcely interfere with vision. Retinal vascular tortuosity is observed in about 50% of males, 22% of females, and 27% of children, but by itself it is not diagnostic of the disease.[121] Retinal vascular occlusion and ischemic optic atrophy may cause a visual loss.[142,143]

Female heterozygotes have very variable and often milder manifestations, but some are as severely affected as males. In the Fabry registry mentioned previously, 70% of the 1,077 enrolled females had symptoms and signs of Fabry disease with a median age at symptom onset of 13 years.[113] Twenty percent of females experience a major cerebrovascular, cardiac, or renal event at a mean age of 46 years. Although more severely affected women are more likely to have enrolled in the registry, these data clearly show that a significant number of affected women have serious disease manifestations.

Renal Manifestations

Urinary concentration defects may be the earliest functional manifestation of Fabry renal disease, leading to polyuria and nocturia. A nephrology referral is more typically initiated because of the development of proteinuria. Proteinuria may begin in the teenage years and becomes more frequent when patients reach their 20s and 30s, and may be in the nephrotic range.[144] Microscopy of the urine sediment may show red blood cells, renal tubular cells, casts, and lipids. Lipid droplets with their characteristic "Maltese cross" appearance under polarization microscopy may be found even when proteinuria is slight. Electron microscopy of the urine sediment may show "myelin bodies" morphologically identical to those seen in the lysosomes of renal tubular cells on renal biopsy specimens (Fig. 17.7). Renal ultrasound studies have revealed an increased incidence of renal sinus and parapelvic cysts compared to healthy controls; the pathophysiology is unclear.[145]

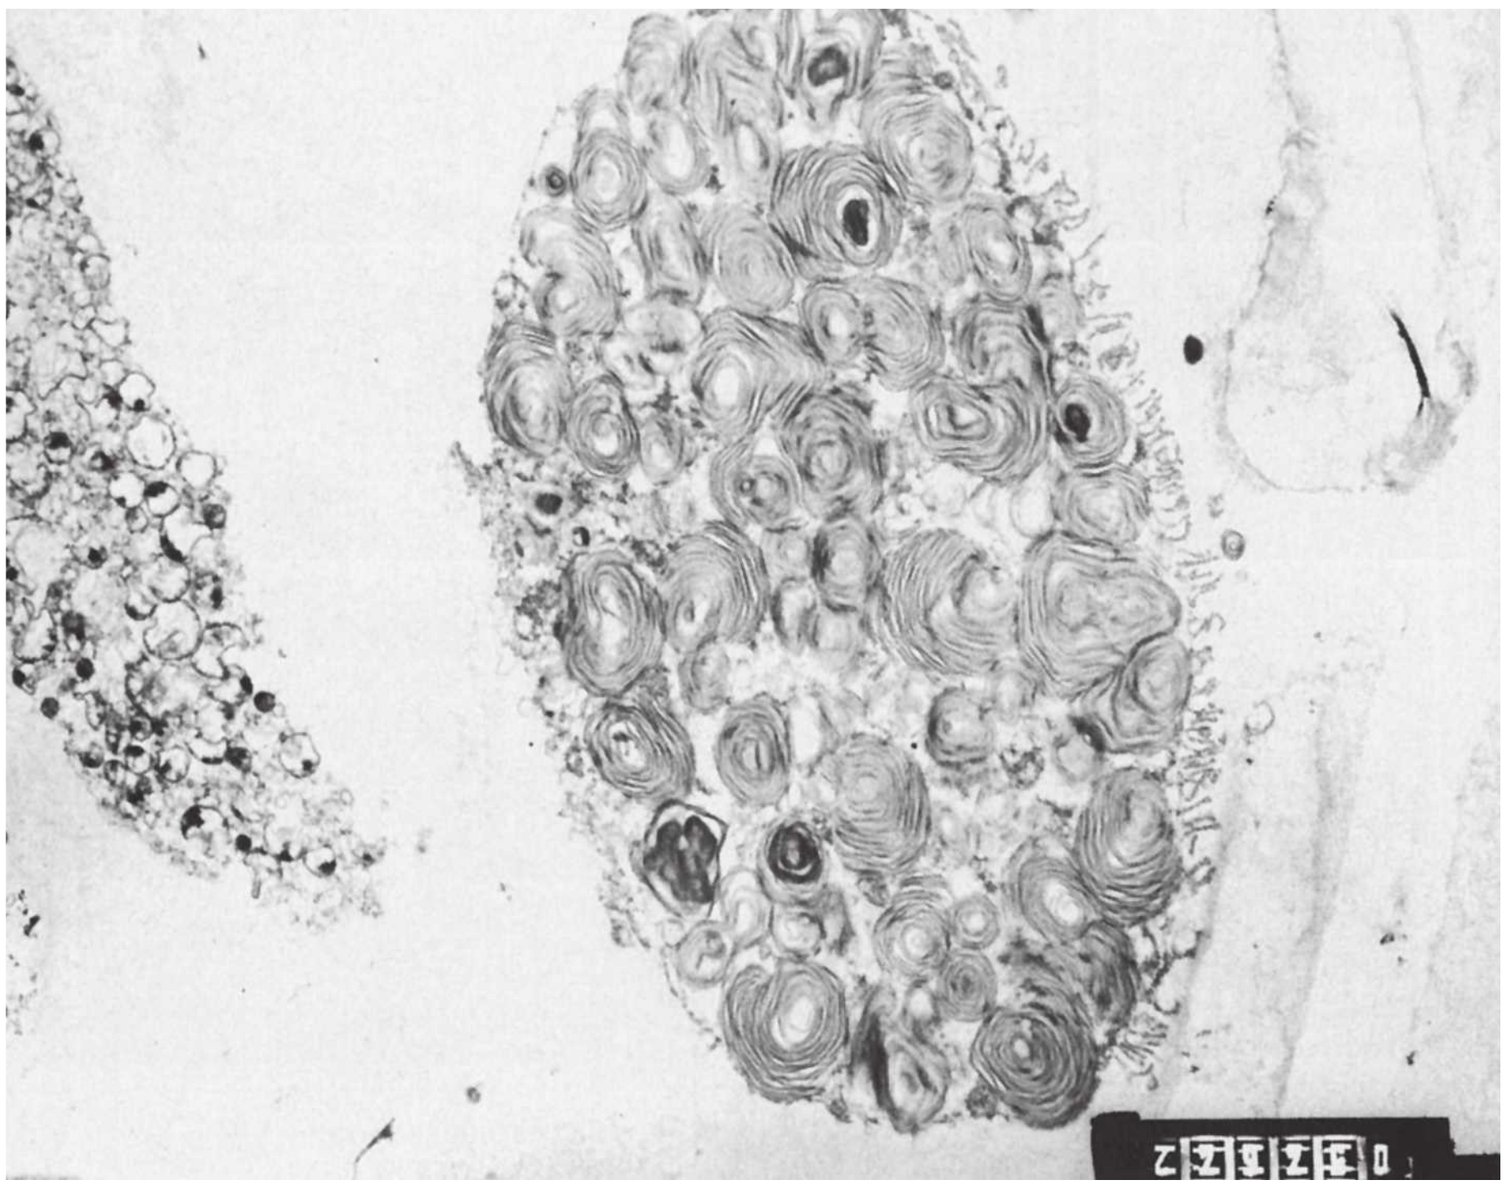

FIGURE 17.7 Urinary myelin bodies. An electron micrograph of a cell in the urine of a female heterozygous for Fabry disease. It is filled with myelin figures. The progression to ESRD is near universal in males in their third to sixth decade of life, but occasionally occurs in their teenage years.[144,146] The mean age at the onset of ESRD in a study of 105 males was 39 years, and all patients who survived to age 55 developed ESRD.[144] Fewer women develop ESRD, and often at an older age than males,[131,147,148] although some of them develop ESRD as early as men.[113] The strongest predictor for a more rapid decline in GFR is the degree of proteinuria. Data on the natural history (i.e., the disease course before enzyme replacement therapy) comes from the Fabry registry and shows that men with a urine protein to creatinine ratio of 1.5 or greater lose GFR at a rate of 5.6 mL/min/1.73 m^2 per year, compared to 1.3 mL/min/1.73 m^2 per year for those with lesser degrees of proteinuria.[148] In the same study women had a slower decline, averaging 1.3 mL/min/1.73 m^2 per year if their urine protein to creatinine ratio was greater than 1.2; women also were about 5 years older at enrollment, and fewer women exhibited the higher levels of proteinuria.[148] Hypertension is a late manifestation, usually developing after GFR starts to decline, and is also associated with faster GFR decline, at least in men.[144,148]

Diagnosis

The most important step is to consider the diagnosis of Fabry disease. The index patient in most families goes undiagnosed for years or decades. In affected males with fully expressed disease, the constellation of symptoms and signs is highly suggestive. The diagnosis is confirmed if there is low α-galactosidase A activity in plasma or leukocytes. The test in leukocytes is more sensitive and is therefore preferred. The enzyme activity in Fabry leukocytes is usually under 4% of normal, and often undetectable in men, but it may be normal in women.[113,131] Therefore, direct genetic analysis is often required to make the diagnosis in women. A biopsy of the skin or kidney that demonstrates the characteristic glycolipid deposits may establish the diagnosis if no other means is available. Sometimes a kidney biopsy is performed for the evaluation of proteinuria, and the finding of "zebra bodies" in glomerular cells leads to the diagnosis of Fabry disease.[149] In such cases, family screening should be done in order to identify additional gene carriers with or without symptoms who might benefit from therapy (see the text that follows).

Prenatal Diagnosis

The severity of Fabry disease in males and in a proportion of females is the principal motivation for prenatal diagnosis. An analysis of α-galactosidase A activity in fetal cells obtained from chorionic villous tissue can confirm the disease in a male fetus; genetic mutation analysis should also be done, particularly in female fetuses because they can have residual enzyme activity. A mutation analysis can be performed on chorionic villi or cultured amniocytes.[150]

Treatment

Until recently, Fabry disease management was limited to symptomatic and palliative treatment, but this has changed with the availability of the recombinant human α-galactosidase A enzyme, agalsidase. Two different intravenous agalsidase formulations have been obtained: one from human fibroblasts (agalsidase α), and one from Chinese hamster ovary cells (agalsidase β). Both preparations underwent clinical trials that documented the feasibility, efficacy, and safety of the treatment. Based on observations made during these trials, both agalsidase α (Replagal) (0.2 mg per kilogram every other week) and agalsidase β (Fabrazyme) (1.0 mg per kilogram every other week) have been approved in Europe, but only agalsidase β was approved in the United States.[151,152]

A recent review identified 48 prospective clinical studies of enzyme replacement therapy (ERT), 22 each for agalsidase α and β and 4 with pooled treatments.[132] The longest reported treatment duration and follow-up was 4.5 to 5 years.[132,153] Overall, these studies showed that treated patients had a sustained decrease in plasma GL-3 levels and sustained endothelial GL-3 clearance as seen on skin, kidney, or heart biopsies.[153,154] The safety profile was favorable. Neuropathic pain and quality of life usually improved, even in dialysis patients. However, no effect on the incidence of strokes could be demonstrated in any study.[132] The effect on renal disease progression depended on the stage at which ERT was begun. If patients had more than 1 g proteinuria per day and/or decreased GFR ($<$ 60 mL/min/1.73 m^2), ERT was usually unable to halt the progression.[136,147,153] However, there was long-term stabilization of renal function in patients who were treated before they developed significant proteinuria. Similarly, a reduction in left ventricular hypertrophy was achieved only in patients without significant cardiac fibrosis, arguing for an early initiation of ERT.[132] A point to keep in mind is that ERT is extremely expensive.

Supportive treatment is also important for patients with Fabry disease. The debilitating pain may be considerably eased by phenytoin or carbamazepine. Excess glycosphingolipids can be removed by plasmapheresis with a temporary symptomatic benefit.[155] Given the limited benefit of ERT in patients with proteinuria, aggressive antiproteinuric therapy with angiotensin converting enzyme inhibitors and/or angiotensin receptor blockers in addition to ERT is both feasible and recommended.[136,156] The goal is to reduce proteinuria to less than 500 mg per day and to reduce the rate of GFR decline to less than 1 mL/min/1.73 m^2 per year.

When ESRD supervenes, both hemodialysis and peritoneal dialysis can be carried out with no specific problems. In studies from both the United States and Europe, the 3-year survival of dialysis patients with Fabry disease was worse compared with nondiabetic dialysis patients of similar age.[157] Renal transplantation is the treatment of choice for Fabry patients. In the most recent study of 197 kidney transplant recipients with Fabry disease, 5-year graft survival was similar to that of a matched cohort of recipients with other causes of ESRD, but 5-year patient survival was worse (81% versus 90%).[158] The most common reported cause of death was myocardial infarction. Few patients, if any, in these reports had received ERT. Although ERT is safe in kidney transplant

recipients and small studies show symptomatic benefit, it is currently unknown whether ERT will improve the prognosis of Fabry patients with ESRD.[157] Graft loss due to recurrent Fabry nephropathy has so far not been documented.[157]

Variants and Diseases Related to Fabry Disease

Recently, a variant form of Fabry disease was identified with manifestations primarily limited to the heart[128,159]; these "cardiac variants" lack the classical disease symptoms, and present in the sixth or seventh decade of life with left ventricular hypertrophy (LVH) and/or cardiomyopathy. These patients may also have proteinuria, but their renal function is typically normal for age. Of note, cardiac variants have residual α-galactosidase A activity due to missense mutations and lack the systemic vascular endothelial glycosphingolipid deposition characteristic of classically affected patients. Screening of 230 consecutive Japanese male patients with LVH and 153 British male patients with hypertrophic cardiomyopathy by plasma α-galactosidase A assays revealed that 3% and 3.9%, respectively, were previously unrecognized cardiac variants.[128,159]

There is mounting evidence that renal disease with ESRD can also occur in the absence of other typical organ manifestations. Nakao et al.[160] screened 514 male Japanese hemodialysis patients and identified 6 with exclusively renal manifestations. Interestingly, these subjects had residual α-galactosidase A activity, but reached ESRD at an age similar to patients with full-blown disease. These may be examples of a renal variant.

Angiokeratoma corporis diffusum with glycopeptiduria is an autosomal-recessive disorder resulting from a deficiency of α-N-acetylgalactosaminidase.[161,162] Features are similar to Fabry disease, with angiokeratomas and peripheral neuropathy. Both a severe infantile onset and a milder adult onset form of the disease have been described.

Finally, renal ultrastructural lesions identical to those in Fabry disease have been described in patients on long-term treatment with hydroxychloroquine, chloroquine, and amiodarone.[163] These drugs can inhibit several lysosomal enzymes, including α-galactosidase A. This complication of drug therapy has been called iatrogenic phospholipidosis and seems to be limited to the kidney and cornea. After the removal of the offending agents, a variable improvement in renal parameters has been reported.[163]

NAIL-PATELLA SYNDROME (NPS) (OMIM 161200)

Nail-Patella syndrome (NPS) is a rare autosomal dominant disorder first described by Little in 1897, which is characterized by the tetrad of dysplastic nails, hypoplastic or absent patellae, iliac horns, and deformities of the elbow. Other names include hereditary onycho-osteodysplasia (HOOD), Fong's syndrome, Turner-Keiser syndrome, and Osterreicher-Turner syndrome. It shows wide variability in phenotypic expression and organ involvement within and between families. Renal involvement is observed in about 40% of cases and appears to cluster in certain families.[164,165] Renal failure has been reported to occur in 1% to 15% of patients.[164,165]

Epidemiology and Genetics

The incidence of NPS has been reported to approach 1 in 50,000 live births.[165–167] The condition was linked to the ABO blood group locus as early as 1955[168]; fine mapping established the locus at 9q34.1.[3,169,170] The gene was identified in 1998 as the LMX1B gene,[170] which codes for a transcription factor that is essential for a wide range of developmental processes including dorso-ventral patterning of the limb, differentiation of dopaminergic and serotonergic neurons, patterning of the skull, and normal development of the kidney and eye as recently reviewed by Dai et al.[171] These developmental processes apparently require the function of two normal LMX1B genes because a mutation in one of them results in NPS, which is likely due to haploinsufficiency.[172,173]

To date, over 160 mutations[23,81] have been reported in patients with NPS. In 10% to 15% of families, no mutation is found; about 12% of cases have no family history and may be either new mutations, subclinical disease in the parent, or due to somatic mosaicism of the parent.[165,174] Most negative studies attempting to demonstrate genotype–phenotype correlations in NPS have been small. One larger study of 106 subjects from 32 NPS families demonstrated that individuals with LMX1B mutations affecting the homeodomain had significantly more frequent and higher values of proteinuria compared to those individuals carrying LIM domain mutations.[164] The genetic basis for the wide inter- and intrafamilial phenotypic variability is unknown but may involve modifier genes or polymorphisms in the target genes of LMX1B.[165]

Renal Pathology

Light Microscopy of renal biopsy specimens is nonspecific and often demonstrates normal findings. The only consistent but nonspecific glomerular feature is focal GBM thickening.[175,176] In more advanced stages, when renal functional impairment is present, light microscopy findings include focal segmental glomerulosclerosis, proliferative glomerulonephritis with crescents, and hyalinization of glomeruli.[175–177]

Immunofluorescence microscopy is negative or shows presumably a nonspecific trapping of IgM and complement.[175] Staining of the GBM for collagen α_3(IV) and α_4(IV) chains, podocin, synaptopodin, CD2AP, α3 integrin, and nephrin is normal.[165]

Ultrastructural changes are characteristic and specific and have been found in all NPS patients. The GBM is irregularly thickened and contains lucent areas and areas of fluffy low-density material, giving the appearance of a "moth-eaten" basement membrane. Overlying pedicles are effaced.

FIGURE 17.8 Glomerular basement membrane (GBM) in nail-patella syndrome (NPS). A high resolution (magnification ×55,000) electron micrograph of the GBM showing fluffy lucencies expanding the GBM and blurring its endothelial margin. Several collagen fibrils are visibly embedded in the GBM. (Photograph courtesy of Dr. Daniel Terreros, Salt Lake City VA Medical Center, Salt Lake City, Utah.)

Patches of dense fibrillar material with a periodicity of collagen are scattered throughout the entire thickness of the GBM (Fig. 17.8).[175–178] The Bowman capsule and tubular basement membranes are not specifically affected, but the mesangium may show fibrillar collagen similar to that in the GBM and is usually accompanied by mesangial cell proliferation. Although similar mesangial lesions have been seen in other conditions such as diabetes, membranoproliferative glomerulonephritis, amyloidosis, and glomerulosclerosis, in these conditions the material is not collagen and can be distinguished by its relatively weak staining with phosphotungstic acid.

NPS has been associated with other glomerular lesions, including membranous nephropathy,[179] systemic vasculitis,[180] IgA nephropathy,[181] Goodpasture syndrome,[182] hemolytic-uremic syndrome,[183] and bilateral renal stones.[184] The significance of these associations is unknown, but perhaps the abnormal structure or abnormal immunogenicity renders the GBM more vulnerable to other insults.

Clinical Features and Course

Extrarenal Manifestations

Patients with NPS have a lean body mass, which is more apparent in adolescents and young adults. This decrease in muscle mass is more prominent in the dorsal parts of the upper arms and in the upper legs. Other abnormalities include lumbar lordosis and scoliosis. The classic tetrad of NPS consists of dystrophic nails (Fig. 17.9), patellar and lateral femoral condylar hypoplasia (Fig. 17.10), hypoplasia of the radial head and capitellum of the elbow (Fig. 17.11), and bilateral iliac horns (Fig. 17.12).

Nail dystrophy is present at birth in more than 90% of those affected and is the most constant feature of NPS.

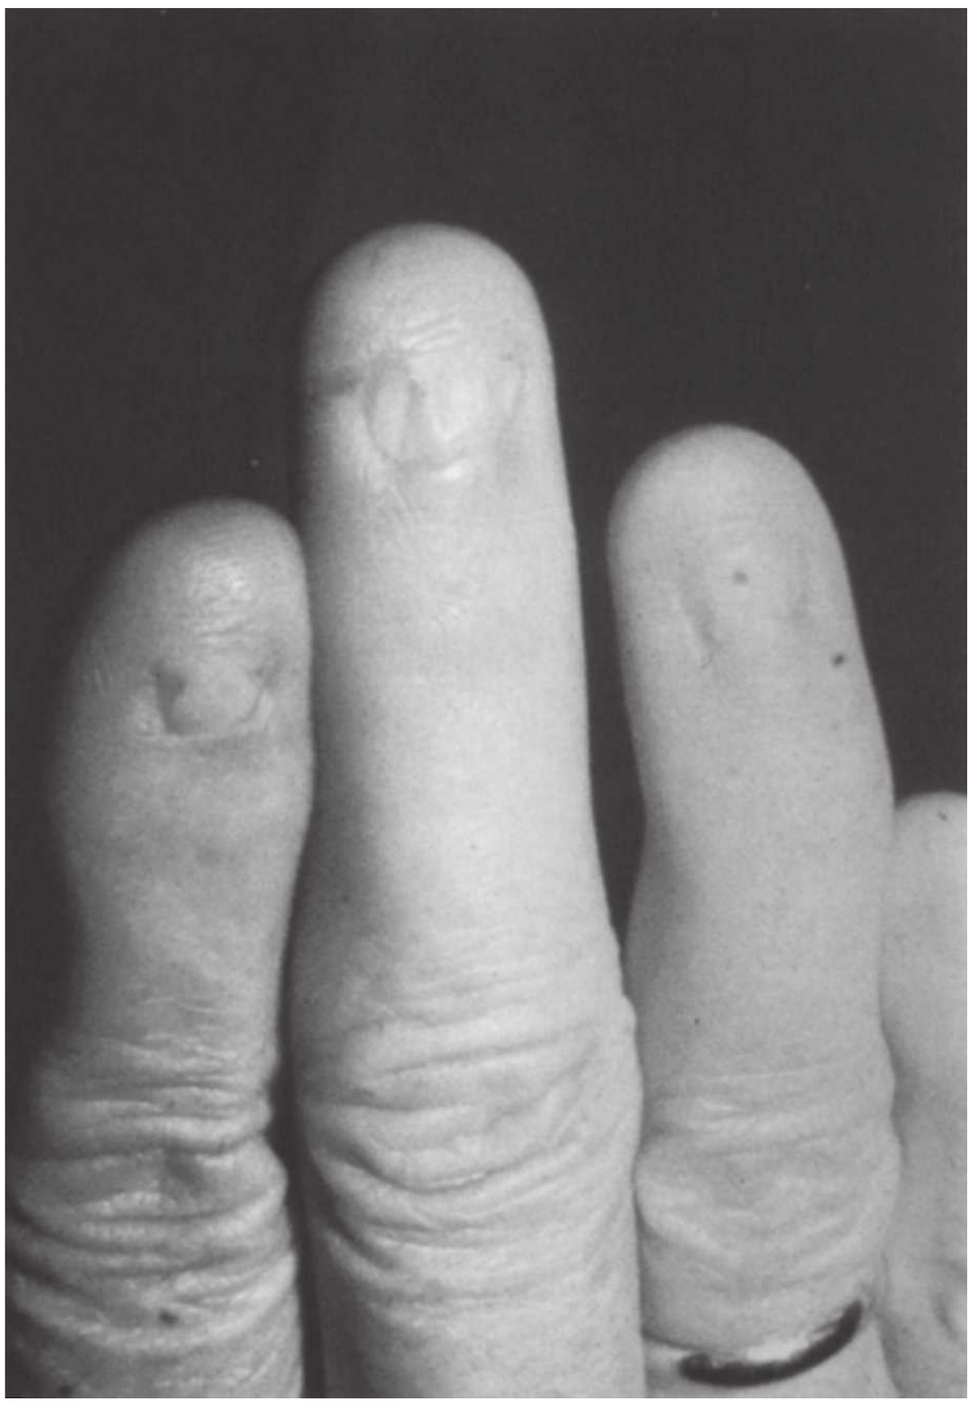

FIGURE 17.9 Characteristic nail changes of nail-patella syndrome (NPS). All the nails are small. The long finger shows the typical central triangular dystrophy with its base at the lunula. Usually, the changes are more marked toward the radial side of the hand.

FIGURE 17.10 An absence of patella in nail-patella syndrome (NPS). A radiograph of the left knee of a 19-year-old girl with NPS. The patella is congenitally absent and the lateral femoral condyle is hypoplastic.

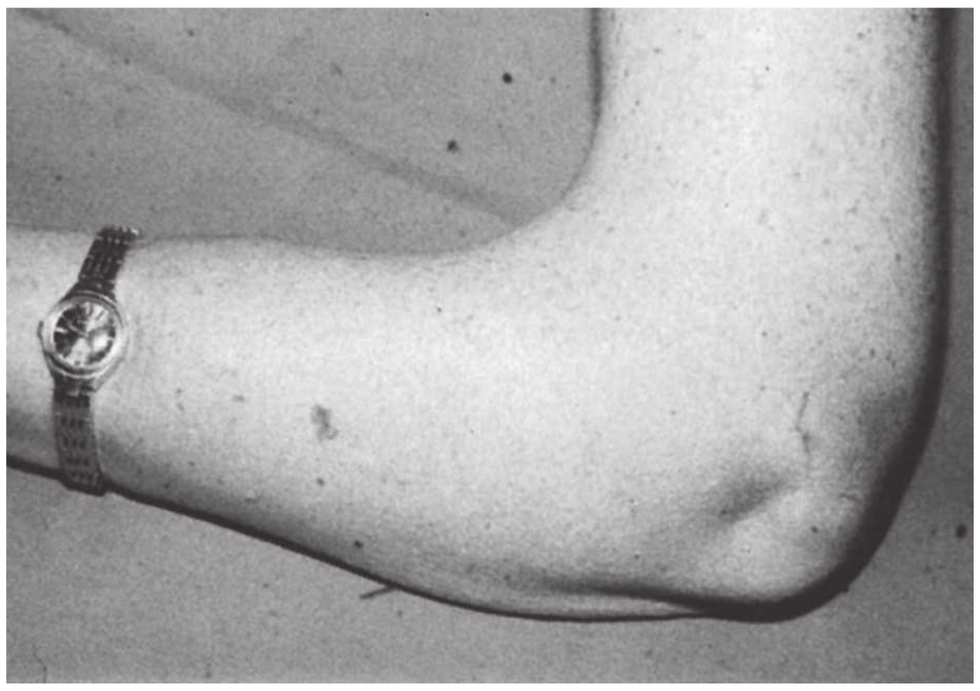

FIGURE 17.11 An elbow contracture in nail-patella syndrome (NPS). The left elbow of a 44-year-old woman with NPS and end-stage renal disease (ESRD) (same patient as in Fig. 17.9). She is holding her elbow as straight as possible. A web of soft tissue fills the antecubital fossa.

FIGURE 17.12 Iliac horns. A pelvic X-ray film of an 8-year-old girl with nail-patella syndrome (NPS) (same patient as in Fig. 17.10, but 11 years earlier). The *arrow* indicates the characteristic iliac horn, which is visible medial to the outer margin of the blade of the ileum. The radiograph incidentally shows a fusion defect and lumbarization of S1.

The presence of a triangular nail is a pathognomonic sign for NPS. The lunula appears stretched toward the free border of the nail, and the central portion of the nail is deformed. Commonly, affected nails are smaller than normal and may even be absent. Fingernails are more affected than toenails, and thumb and radial-side digits are more affected than ulnar-side digits. Furthermore, longitudinal ridging, splitting, spoon-shaped, and flaky nails have been associated with NPS.

The patella is small, misshapen, or absent in more than 90% of patients (Fig. 17.10). Concurrent hypoplasia of the lateral femoral condyle and poor development of the vastus medialis muscle may lead to recurrent subluxation or dislocation of the patella, knee instability, and knee pain complicated by patello-femoral arthrosis. Involvement of the elbow is almost as common, with hypoplasia of the radial head and capitellum being characteristic. This predisposes the patient to posterior subluxation of the radial head. Synechiae may lock the elbows in a permanent and disabling flexion (Fig. 17.11).

Conical bony horns projecting from the back of the blade of the ileum are seen in about 80% of patients and is considered pathognomonic of NPS. Often palpable in thin subjects, they are readily seen radiographically (Fig. 17.12).

Although not part of the classic tetrad, the most common presentations to orthopedists are foot or ankle deformities (club feet) and/or hip dysplasia.[164,185] Usually, these deformities require surgical correction.

More recently, ocular involvement and sensorineural hearing impairment have been described in patients with NPS. The most common pathologies are glaucoma, isolated glaucomatous alteration of the optic disk, and ocular hypertension, which are found in 35% of individuals in one study.[164] The mean age of these patients was 63 years, and glaucoma was rare under the age of 40 years. Cataracts were found in 8% of subjects,

including congenital cataracts in two siblings. Other anomalies were iris pigmentation (Lester sign) and corneal abnormalities. Unilateral or bilateral hearing impairment was detected by audiometric testing in 46% of patients at a mean age of 47 years.[164]

Renal Manifestations

It is the renal manifestations of NPS that influence mortality, occurring in 12% to 55% of the patients.[166] Between 5% and 14% develop ESRD.[166] The first and most typical sign of renal disease is moderate proteinuria with or without hematuria. Proteinuria may occur at any age and may resolve spontaneously, remain stable, or progress to renal failure at variable ages.[166] Nephrotic syndrome may also sometimes occur.[165,175]

The relationship between the somatic features of NPS, the clinical signs of nephropathy, and the GBM lesion is perplexing. There appear to be families with the somatic features in whom nephropathy does not develop, and other families with clinical renal disease and typical renal ultrastructural findings but no somatic manifestations. In a genotype–phenotype correlation study, Bongers et al.[164] presented evidence that the LMXB1 mutation position is involved with the risk of developing nephropathy. However, even families that clearly express the full spectrum of somatic and renal features, including proteinuria and the progression to ESRD, may have affected individuals without renal clinical manifestations. Other individual patients have shown musculoskeletal features and the typical renal ultrastructure but no clinical renal abnormalities.[177,178,186] Thus, the origins of variable phenotypic expression in NPS remain unclear.

Diagnosis

Typically, NPS is readily recognized clinically. If doubt remains, radiographs of the knees and pelvis usually show absent, rudimentary, or deformed patellae and bilateral iliac horns.

Renal biopsy is rarely required to make the diagnosis of NPS. It may be justified in patients with an atypical disease in whom another potentially treatable glomerulonephritis may coexist.

Prenatal Diagnosis

In families with a defined mutation, chorionic villous sampling can potentially be used for a mutation analysis[187]; in large families without an identified mutation, but with sufficient members to be informative, linkage could be sought with polymorphic markers near 9q34.[188] The typical renal ultrastructural features of NPS were found in an 18-week abortus,[189] and the diagnosis of NPS has been made by intrauterine kidney biopsy.[190] Skeletal anomalies may be recognized by fetal sonography.[191,192]

Treatment

As long as we cannot correct the molecular defect of NPS, treatment for all aspects is supportive. Orthopedic surgery to relieve contractures and to fuse or realign joints confers major benefits. Knee, ankle, and foot surgery is frequently helpful, whereas elbow surgery is rarely needed.[185] The treatment of renal disease is as in other patients with chronic kidney disease. ACEI may be of benefit in patients with proteinuria. Hemodialysis, peritoneal dialysis, and transplantation have been carried out successfully. In three patients who have had a biopsy of the allograft,[193,194] there was no evidence of recurrence of NPS lesions or of anti-GBM nephritis. Most intriguing, in a single patient,[194] nail lesions appeared to improve after transplantation.

Variants and Diseases Related to Nail-Patella Syndrome

More than 20 patients showing the renal ultrastructural features of NPS without the somatic findings have been described.[195–197] In seven families, inheritance appeared to be autosomal recessive. It is possible that these cases were examples of collagen III glomerulopathy, as previously described.[198] There is also some evidence for an autosomal dominant NPS-like syndrome without extrarenal symptoms.[199] These GBM diseases might be due to a partial expression of NPS or another type of hereditary glomerulopathy.[167]

A girl with a heterozygous complete deletion of the COL5A1 gene at 9q34 and underexpression of α_1(V) chains had dysplastic nails, normal patellae, but other mesenchymal and ectodermal features more suggestive of Goltz syndrome than of NPS.[200]

CHAPTER

18 Isolated Renal Tubular Disorders: Mechanisms and Clinical Expression

Thomas D. DuBose Jr. • Amanda K. Goode

Renal control of acid and base reabsorption and excretion is controlled by the proximal and distal tubules (see Chapter 6). Thus, it is likely that abnormalities in those mechanisms responsible for these processes will result in clinically significant disorders. The transporters for carbohydrates, amino acids, and ions are polarized to either the apical or basolateral membrane, and the clinical abnormalities of fluid, electrolyte, and acid-base balance regulated by these transporters either have a genetic basis or are the result of acquired abnormalities of specific transport proteins. In this chapter, we review the major tubular transport defects of carbohydrates, amino acids, and some of the ions (H^+, K^+, Na^+). We describe the clinical features of these disorders as they appear in humans and summarize some of the insights learned from experimental models.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA) is a clinical syndrome characterized, when fully expressed, by a chronic hyperchloremic nongap metabolic acidosis, which results from a defect in urinary acidification.[1] This defect can be localized to the nephron segment responsible for the pathophysiologic expression and may be inherited or, more commonly, acquired by specific diseases or by drug or toxin effects. An incomplete form of distal RTA may be exhibited in family members of patients with genetic abnormalities of specific transporters in this nephron segment. Examples of specific defects involved in the pathogenesis of proximal and classical distal RTA include acquired or inherited abnormalities of the basolateral electrogenic Na^+/HCO_3^- symporter, the apical Na^+/H^+ exchanger, NHE-3, or the enzyme carbonic anhydrase II in the proximal tubule, and the H^+-ATPase and the HCO_3^-/Cl^- exchanger in the distal tubule. Proximal RTA (type 2 RTA) and classical distal RTA (type 1 RTA) are both associated with chronic hypokalemia. In contrast, a more generalized abnormality in the distal nephron is associated with hyperkalemia. The diagnosis of "complete" RTA requires spontaneous nongap metabolic acidosis in association with either a less than maximal urine pH or low ammonium excretion. Incomplete RTA is seen without spontaneous metabolic acidosis, but with evidence of the inability to acidify urine maximally in response to an exogenous acid load. Most inherited forms cause growth retardation or short terminal stature. Both inherited and acquired forms of proximal and classical distal RTA are accompanied by hypokalemia, often sufficiently severe enough to cause periodic paralysis or even seizures.

DIFFERENTIAL DIAGNOSIS OF NONGAP (HYPERCHLOREMIC) METABOLIC ACIDOSIS

A nongap metabolic acidosis is recognized by a low plasma bicarbonate concentration (or total [CO_2]), low blood pH, and a normal anion gap (8 to 10 mEq per L). A compensatory decrease in PCO_2 is typical, indicating the presence of a pure, or simple, nongap metabolic acidosis. The differential diagnosis of a nongap metabolic acidosis includes both nonrenal and renal causes. The differential diagnosis of nongap acidosis is displayed in Table 18.1. The evaluation of a nongap or hyperchloremic metabolic acidosis requires one to appreciate the role of the kidney in the acid-base balance, and to determine whether the kidney is responding appropriately to the prevailing acidosis (Table 18.2), which is to increase ammonium (NH_4^+) production and excretion adaptively. In contrast, ammonium production and excretion are impaired with chronic renal insufficiency, hyperkalemia, and with all forms of nongap acidosis of renal origin, including all examples of renal tubular acidosis.

Loss of HCO_3^- from the Gastrointestinal Tract versus Renal Tubular Acidosis

Diarrhea is a common cause of hyperchloremic metabolic acidosis. Diarrheal stools contain a large amount of HCO_3^- and HCO_3^- decomposed by reaction with organic acids.[2] The HCO_3^- loss and the ensuing volume depletion cause hyperchloremic metabolic acidosis. Hypokalemia develops due to direct K^+ loss in the stool and increased renal K^+ secretion (in the cortical collecting tubule) due to a secondary increase

18.1 Differential Diagnosis of Nongap Acidosis

Extra-Renal Causes
Diarrhea or other GI losses of bicarbonate
    (e.g., tube drainage)
Posttreatment of ketoacidosis (dilutional)
    (occasional: initial DKA)

Renal Causes Not Due to Renal Tubular Acidosis
Ureteral diversion (e.g., ileal loop, ureterosigmoidostomy)
Progressive chronic kidney disease
Toluene ingestion (excretion of hippurate)
Drugs
    With associated hypokalemia
        Carbonic anhydrase inhibitors (acetazolamide and topiramate)
        Amphotericin B
    With associated hyperkalemia
        Amiloride
        Triamterene
        Spironolactone
        Trimethoprim
    With normal potassium
        $CaCl_2$, $MgSO_4$
        Cholestyramine
Exogenous acid loads (NH_4Cl, acidic amino acids, total parenteral nutrition, sulfur)
Posthypocapnic state

Renal Tubular Acidosis
Low $[K^+]_p$
    Type 1 (classical distal) RTA
    Type 2 (proximal) RTA
    Type 3 (mixed proximal and distal) RTA
        (carbonic anhydrase II deficiency)
High $[K^+]_p$
    Type 4 (generalized distal RTA)
        Hypoaldosteronism (hyporeninemic and isolated)
        Aldosterone resistance
        Voltage defect in collecting duct

DKA, diabetic ketoacidosis; GI, gastrointestinal; RTA, renal tubular acidosis.

18.2 Diagnostic Criteria for Causes of Nongap Acidosis

Nonrenal Etiology
    Nongap acidosis expect:
        Increase in NH_4^+ excretion
        Negative urine anion gap
        Acid urine pH (<5.5)—exceptions

Renal Etiology
    Nongap acidosis expect:
        Inability to increase NH_4^+ excretion
        Positive urine anion gap
        Urine pH typically >5.5 but variable in type 4

in elaboration of renin and aldosterone in response to volume depletion. Both hypokalemia and nonrenal metabolic acidosis increase renal NH_4^+ synthesis, which increases urinary buffering capacity and urinary pH. The presence of NH_4^+ in the urine can be used clinically to distinguish hyperchloremic metabolic acidosis due to diarrhea from renal tubular acidosis (Table 18.2). In the latter, NH_4^+ excretion is invariably low. Urine pH, although a time-honored method to distinguish these disorders, is less reliable because urinary ammonium excretion is augmented in chronic metabolic acidosis due to diarrhea, causing urine pH to increase over time.

Other Causes of Nongap Metabolic Acidosis

In addition to diarrhea and RTA there are other less common causes of hyperchloremic metabolic acidosis (Table 18.1). External pancreatic and biliary diversion may lead to the loss of HCO_3^--rich fluid and result in hyperchloremic metabolic acidosis. The excretion of sodium salts of ketones during the recovery phase of ketoacidosis represents the loss of potential HCO_3^- and may result in hyperchloremic metabolic acidosis. Ureteral diversion is commonly associated with hyperchloremic metabolic acidosis because the ileum and colon are both endowed with an apical Cl^-/HCO_3^- exchanger. When chloride from urine comes into contact with the gut, chloride is absorbed in exchange for bicarbonate leading to excretion of bicarbonate, absorption of chloride, and hyperchloremic metabolic acidosis.[3] The degree of acidosis is magnified by stasis and prolonged contact of urine with the HCO_3^-/Cl^- exchanger in the pouch. Because of bicarbonate secretion, potassium secretion is also stimulated and leads to hypokalemia. Finally, the administration of acid or acid equivalent (arginine HCl, lysine HCl, or NH_4Cl) or medications such as cholestyramine, calcium chloride, and magnesium sulfate are associated with hyperchloremic metabolic acidosis.[4] Dilutional acidosis occurs in conjunction with rapid infusion of isotonic saline. In these latter examples, the serum potassium is usually normal.

Progressive renal failure is associated with metabolic acidosis. Hyperchloremic metabolic acidosis is commonly seen when the glomerular filtration rate (GFR) is between 20 to 50 mL per min.[5] As renal failure progresses to a GFR of less than 10 to 15 mL per min, the acidosis converts to the typical high anion gap acidosis of "uremic" acidosis. The

principle defect in advanced renal failure is impaired ammoniagenesis and ammonium excretion.[5] The latter is a result of impaired medullary ammonium transport and trapping of NH_3/NH_4^+ in the outer and inner medulla.

In summary, the defect in renal acidification in RTA may be manifest by one of three clinical syndromes: (1) an acid urine pH and low urine anion gap (UAG) during metabolic acidosis or frank bicarbonaturia and hypokalemia during $NaHCO_3$ therapy (as in proximal RTA); (2) an inappropriately alkaline urine pH, hypokalemia, and a positive urine anion gap (classical distal RTA); or (3) hyperkalemia and a positive urine anion gap but variable pH with aldosterone deficiency, aldosterone resistance, or a "voltage" defect in the collecting tubule (generalized defect in distal nephron) (Table 18.2).

Clinical Laboratory Evaluation

Because the measurement of urinary NH_4^+ concentration may be problematic for the routine hospital clinical pathology laboratory, it is helpful to estimate the urine ammonium concentration by considering the electrolytes present in urine. Because NH_4^+ is a cation, its presence in urine, especially when in large amounts as expected in nonrenal forms of hyperchloremic metabolic acidosis, should be denoted by an increase in urinary anions (Cl^-) in excess of the usual cations ($Na^+ + K^+$). The urine anion gap (UAG) is calculated on a "spot" urine sample as follows (Table 18.3)[6]:

$$UAG = [Na^+ + K^+]_u - [Cl^-]_u \quad (1)$$

18.3 Clinical Application of Urine Anion Gap to Approximate Urine Ammonium Excretion

1. Spot urine electrolytes: $[Na^+, K^+, Cl^-]_u$ in a patient with hyperchloremic metabolic acidosis
2. Calculate urine anion gap:

$$UAG = (Na + K)_u - Cl_u$$

3. Interpretation:

$(Na + K)_u > Cl_u$: NH_4^+ low (ammonium excretion impaired)
$Cl_u > (Na + K)_u$: NH_4^+ adequate (nonrenal hyperchloremic acidosis)

4. Pitfalls: Unusual anions in the urine (perform urine osmolar gap)
   Ketones
   Toluene

18.4 Urine Osmolar Gap to Approximate Urine Ammonium Concentration

Urine Osmolar Gap = Measured Urine Osmolality − Calculated Urine Osmolality

Urine = U_{osm} $0.5[2\,(Na^+ + K^+)_u + \text{urea}/2.8 + \text{glucose}/18][NH_4^+]$

Interpretation: Urine ammonium = 75 mEq/L or > anticipated in acidosis with normal renal tubule function

NH_4^+ is assumed to be present in the urine if the sum of the major cations ($Na^+ + K^+$) is less than the concentration of the major anion (Cl^-). Therefore, a negative urine anion gap denotes the presence of ammonium in the urine and signals a "normal" renal response to acidosis of nonrenal origin (i.e., diarrhea). Hyperchloremic metabolic acidosis of renal origin (i.e., RTA) is supported by the presence of a positive urine anion gap. A positive urine anion gap confirms a deficiency of NH_4^+, and obtains when the sum of the major cations ($Na^+ + K^+$) in the urine exceeds the major urinary anion (Cl^-). A positive urine anion gap, therefore, denotes an "abnormal" renal response to acidosis and is consistent with a defect in net acid secretion. The presence of urinary anions other than chloride can invalidate the UAG. Examples of urinary anions which invalidate this shorthand method of estimating urinary ammonium concentrations include drug anions, ketones, and toxins such as toluene. If these constituents are suspected, urinary NH_4^+ may be estimated reliably by measuring urine osmolality (U_{osm}); the concentrations of $Na^+ + K^+$, urine urea, and glucose (Table 18.4); and calculating the urine anion gap. Urine ammonium (U_{NH4}^+) is calculated as:

$$U_{NH4}^+ = 0.5\,(U_{osm} - [2(Na^+ + K^+) + \text{urea} + \text{glucose}]) \text{ (all expressed in mmol/L)} \quad (2)$$

The fractional excretion of sodium may also be helpful to differentiate hyperchloremic metabolic acidosis due to diarrhea from RTA. The fractional excretion of sodium is typically low (<1%–2%) in patients with diarrhea compared to RTA (2%–3%).

PROXIMAL RENAL TUBULAR ACIDOSIS

Role of the Proximal Tubule in Bicarbonate Reabsorption and Urinary Acid Excretion

The kidney employs two fundamental mechanisms to maintain acid-base homeostasis: bicarbonate absorption and H^+ secretion. Of the 4,000 mEq of HCO_3^- filtered by the kidney

each day, 80% to 90% is reabsorbed in the proximal tubule. Effective HCO_3^- absorption in the proximal tubule is mediated by H^+ secretion. Even though the distal tubule is responsible for the secretion of 50 to 80 mEq of H^+ and final acidification of the urine, the vast majority of H^+ secretion obviously occurs in conjunction with HCO_3^+ reclamation in the proximal tubule.

Bicarbonate absorption is dependent on H^+ secretion across the apical membrane of the proximal tubule in exchange for Na^+ entry into the cell via the Na^+/H^+ exchanger (NHE-3; see Chapter 6).[7,8] A low intracellular Na^+ concentration is maintained by the active extrusion of Na^+ across the basolateral membrane via the Na^+,K^+-ATPase. The enzyme carbonic anhydrase present in the cytoplasm (type II) and on the apical and basolateral membrane (type IV) is critical to accelerate the reaction as indicated here:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O \quad (3)$$

The active secretion of H^+ into HCO_3^--rich glomerular filtrate by the NHE-3 results in the formation of H_2CO_3. Luminal carbonic anhydrase (type IV) facilitates the conversion of H_2CO_3 to CO_2 and H_2O. CO_2 freely diffuses through the luminal membrane and, under the influence of cytoplasmic carbonic anhydrase (type II), forms H_2CO_3 that dissociates rapidly to H^+ and HCO_3^-, which are transported, respectively, across the apical and basolateral membranes. Bicarbonate exits the cell via the electrogenic Na^+-3 HCO_3^- symporter (NBCe1; see Chapter 6). The negative cell potential is the primary driving force for this transport process. In addition to H^+ secretion via the Na^+/H^+ exchanger, an apical H^+-ATPase is also responsible for a small but significant fraction of bicarbonate reclamation in the proximal tubule.

Other Proximal Tubular Functions

In addition to its role in H^+ secretion and HCO_3^- absorption, the proximal tubule is the primary site for glucose, amino acid, phosphate, and organic anion reclamation. Each of these solutes is transported across the apical membrane via an Na^+-cotransport process. Sodium enters the apical membrane down its electrochemical gradient. Low intracellular Na^+ concentrations and the negative intracellular potential are maintained via the basolateral Na^+,K^+ ATPase. Once inside the cell, these solutes are either metabolized or diffuse passively across the basolateral membrane. Citrate is reabsorbed in the proximal tubule in parallel with Na^+- via the NaDC-1 (Na dicarboxylate cotransporter-1).[9] The metabolism of citrate within the cell leads to the generation of HC O_3^-. The presence of citrate in tubular fluid and urine has been shown to be protective in the prevention of calcium oxalate stones and nephrocalcinosis. In the presence of all forms of metabolic acidosis except proximal RTA, citrate is preferentially reabsorbed resulting in hypocitraturia and predisposing patients to nephrolithiasis. In proximal RTA, because this Na^+-coupled transport system is impaired, urinary citrate remains high, even with metabolic acidosis, and nephrolithiasis rarely, if ever, occurs.

Generalized and Isolated Proximal Tubular Transport Defects

Renal tubular acidosis involving the proximal tubule can be divided into two major categories: generalized disorders of proximal tubule reabsorption and isolated abnormalities in renal acidification (Table 18.5). Those potential abnormalities that have been documented to date include, in order of frequency, genetic defects in the basolateral Na^+-3HCO_3^-

18.5 Etiology of Proximal Renal Tubular Acidosis (Type 2) with or without Fanconi Syndrome

1. Primary disorders
   - Inherited—isolated pure bicarbonate wasting
     - Autosomal recessive: Mutations of NBCe1/SLC4A4 (several examples associated with ocular abnormalities)
     - Autosomal dominant: Mutation of NHE-3 with short stature (defect not determined)
   - Familial disorders associated with proximal RTA
     - Cystinosis
     - Tyrosinemia
     - Hereditary fructose intolerance
     - Galactosemia
     - Glycogen storage disease (type 1)
     - Wilson disease
     - Lowe syndrome
2. Acquired disorders
   - Multiple myeloma, amyloidosis, light chain nephropathy
   - Chemotherapeutic agents
     - Ifosfamide
   - Carbonic anhydrase inhibitors
     - Topiramate
     - Acetazolamide
     - Sulfamylon
   - Heavy metals
     - Lead, copper, cadmium, mercury
   - Renal transplantation
   - Paroxysmal nocturnal hemoglobinuria
3. Mixed proximal and distal RTA (type 3 RTA)
   - Carbonic anhydrase II deficiency: osteopetrosis and ocular abnormalities (Guibaud-Vainsel syndrome)

RTA, renal tubular acidosis.

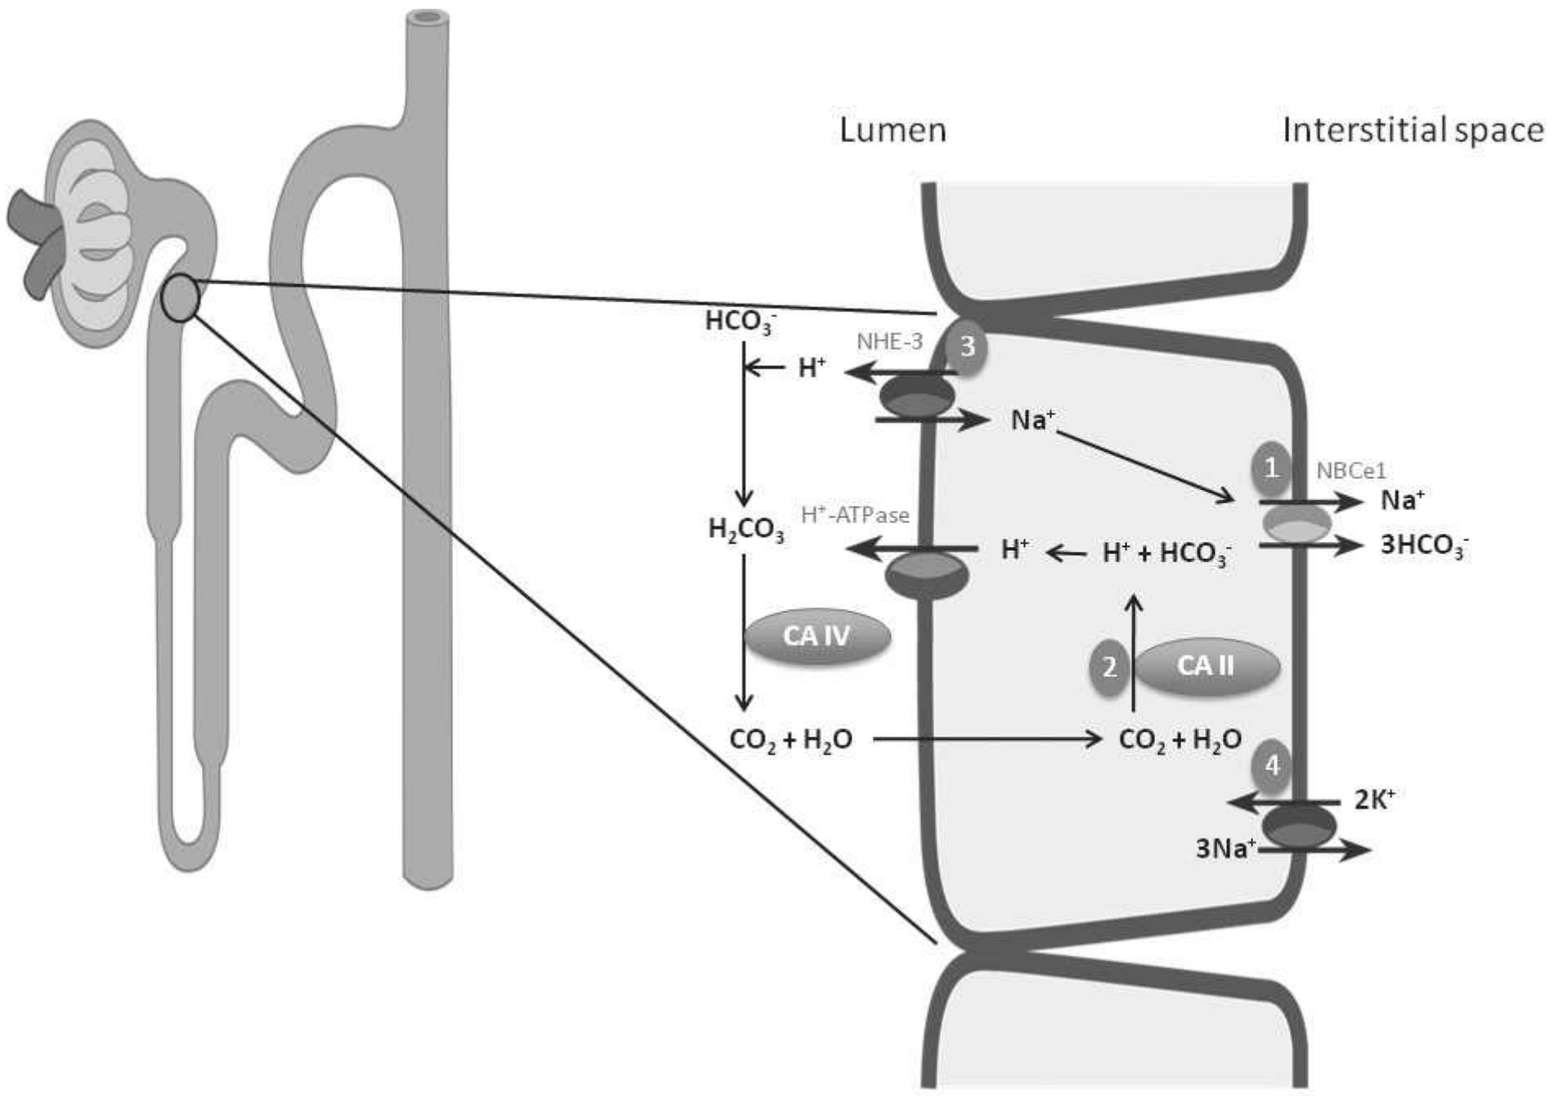

FIGURE 18.1 Pathogenesis of proximal renal tubular acidosis. Model of bicarbonate reabsorption in the proximal tubule showing described inherited defects of genes encoding proximal transport proteins that cause proximal renal tubular acidosis. *1*, defect of basolateral Na^+-HCO_3^- cotransporter; *2*, defect of carbonic anhydrase type 2; *3*, defect of Na^+/H^+ exchanger; 4, defect of Na^+,K^+ ATPase. See text for detail.

symporter or NBCe1, the enzymes carbonic anhydrase type II or IV, and the Na^+/H^+ exchanger (NHE-3) (Fig. 18.1).

Generalized Proximal Tubular Dysfunction

Generalized proximal tubular dysfunction is the more common of the two types of defects, and is appreciated by the co-occurrence of renal tubular acidosis (type 2 RTA), glycosuria, aminoaciduria, phosphaturia, and hypercitraturia. This constellation of symptoms is referred to collectively as "Fanconi" syndrome, which can be either hereditary or acquired. Excessive urinary excretion of glucose occurs, although plasma glucose concentration is normal, and is usually less than 10 g per day. A generalized aminoaciduria also occurs, but because it usually does not result in deficiencies, supplementation is not needed. Sodium and potassium losses occur, which may be massive, resulting in severe secondary hyperaldosteronism and even metabolic alkalosis.

The onset of Fanconi syndrome following an exposure to a triggering agent can vary widely, from minutes (as in the case of patients with hereditary fructose intolerance exposed to fructose[10]), to a few days (in galactosemic patients exposed to galactose[11,12]), to years (following exposure to cadmium[13]). Patients with hereditary fructose intolerance lack the enzyme fructose-1-aldolase, which results in sequestration of intracellular phosphate and is associated with ATP depletion.

Pathophysiologic Mechanisms of Fanconi Syndrome. Most studies suggest that the generalized defect and the defect in transcellular HCO_3^- absorption are due to depletion of intracellular ATP, with inhibition of the Na^+,K^+-ATPase (Fig. 18.1, number 4). Disruption of active HCO_3^-, amino acid, and solute absorption in the proximal tubule due to ATP depletion and inhibition of Na^+,K^+ ATPase has also been observed in an experimental model of cystinosis.[14] Generalized dysfunction of the proximal tubule could occur through three possible mechanisms: (1) an increase in paracellular permeability resulting in backleak of all reabsorbed solutes into the lumen; (2) a generalized defect in proximal tubule absorption, such as ATP depletion; and (3) a defect in basolateral Na^+,K^+-ATPase activity. The second mechanism is the most widely accepted to date.

Regarding paracellular permeability, enhanced efflux causes increased urinary electrolyte and solute excretion, as shown in studies using the maleic acid model (see below). Both mechanisms have been demonstrated in some studies using the maleic acid model of proximal renal tubule acidosis.[15,16] A generalized defect in proximal tubule absorption may be related to the brush-border membrane, such as an abnormality in the sodium-binding domain of the multiple heterogeneous carriers. Alternatively, there may be an abnormality in the way the different carriers are moved to the brush-border membrane. Finally, defects in basolateral Na^+,K^+-ATPase activity can result in abnormal energy generation, as Na^+,K^+-ATPase fuels transport in the proximal nephron. Hereditary fructose intolerance, galactosemia, and cadmium poisoning may result in Fanconi syndrome by reducing Na^+,K^+-ATPase activity. Thus, Fanconi syndrome may be best described as a defect in energy generation in the proximal tubule, with the most important cause being deficient Na^+,K^+-ATPase activity in the basolateral membrane, which decreases sodium-coupled reabsorption due to alterations in the sodium gradient across the luminal membrane. Most of the solutes lost in Fanconi syndrome are those

coupled to apical sodium reabsorption. Fanconi syndrome is also associated with distal nephron dysfunction in some patients. The mechanisms involved are not known, but the evidence suggests that there may be a defect in Na^+,K^+-ATPase throughout the nephron.

Experimental Models of Fanconi Syndrome. Maleic acid is a toxin, relatively specific for the proximal tubule, which results in the best characterized model of Fanconi syndrome. Animals (such as rodents) injected with maleic acid develop proximal RTA and exhibit symptoms similar to those seen in humans with Fanconi syndrome, including decreased activity and expression of Na^+,K^+-ATPase[16] and bicarbonaturia. Maleic acid given to rats also impairs vitamin D conversion.[17]

Because ifosfamide can cause Fanconi syndrome in human patients, it has been used to induce Fanconi syndrome in animals as well. However, the use of this agent in animals is mainly to determine if other agents given with ifosfamide can block the development of Fanconi syndrome without affecting ifosfamide's antitumor activity.[18–22] Heavy metals can also induce Fanconi syndrome in animals and humans. Cadmium, uranium, lead, and mercury all induce Fanconi syndrome in animals, although because cadmium-induced Fanconi syndrome reverses after cadmium administration ceases and because uranium and mercury affect GFR (which is unaffected in people with the syndrome), the study of heavy metal–induced Fanconi syndrome may not necessarily provide accurate information about mechanisms underlying the human disorder.

Dent Disease. Dent disease is a disorder of the proximal renal tubule caused by an X-linked genetic mutation in the CLCN5 gene. Symptoms include proteinuria, nephrocalcinosis, hypercalciuria, and slow progression of renal failure. Because it can also include phosphaturia, aminoaciduria, glycosuria, and rickets, it may be considered a form of Fanconi syndrome. Treatment for patients with Dent disease usually consists of vitamin D to manage rickets and recommendations to reduce hypercalciuria (e.g., thiazide diuretics and citrate supplementation) in order to limit or prevent progression of nephrocalcinosis.[23]

Isolated Proximal Tubule Bicarbonate Transport Abnormalities

Isolated abnormalities of proximal tubular renal acidification in the absence of Fanconi syndrome are less common, but may be associated with depolarization abnormalities or genetic mutations. One model, the infusion of L-lysine in dogs, results in marked bicarbonaturia due to inhibition of HCO_3^- absorption.[24] The presence of luminal L-lysine has been shown to depolarize proximal tubular cells, which could alkalinize the cell by decreasing HCO_3^- extrusion across the basolateral membrane. Mice, in which the gene encoding the renal Na^+/H^+ exchanger (NHE-3) has been knocked out, have metabolic acidosis with proximal RTA[25] (Fig. 18.1, number 3).

Sly et al.[26] have described a group of patients with inherited carbonic anhydrase II deficiency (Fig. 18.1, number 2). These patients develop osteopetrosis, cerebral calcification, and combined proximal and distal RTA.[26] This observation is not unexpected considering the role carbonic anhydrase plays in HCO_3^- reclamation.

Clinical Features of Proximal RTA

Patients with proximal renal tubular acidosis commonly present with hyperchloremic metabolic acidosis, an acid urine pH ($pH<5$) (when systemic acidosis prevails), and minimal HCO_3^- excretion. As bicarbonate is administered to correct the metabolic acidosis, bicarbonaturia occurs and the fractional excretion of HCO_3^- often exceeds 10% to 15% (bicarbonate wasting). This response to alkali therapy, the ensuing increase in potassium excretion in response to the bicarbonate leak into the distal tubule, and the difficulty with which the plasma bicarbonate is corrected are unique features of proximal RTA. Sebastian et al. demonstrated that the level of K^+ excretion correlates directly with HCO_3^- excretion.[27] Decreased NaCl absorption associated with proximal tubular dysfunction enhances K^+ excretion by increasing delivery of Na^+ to the distal nephron and the increase in aldosterone elaboration in response to volume depletion.

The most common causes of proximal RTA in children are acquired either from the administration and toxicity of ifosfamide or from cystinosis.[28,29] Most children present with Fanconi syndrome, but proximal RTA can be limited to an isolated impairment in proximal bicarbonate reabsorption. In contrast, the most common cause in adults is from multiple myeloma or light chain disease. The proximal tubular toxicity related to increased excretion of monoclonal immunoglobulin light chains in patients with multiple myeloma appear to induce a unique biochemical toxicity because of resistance to degradation by lysosomal proteases in proximal tubular cells.[30,31] Accumulation of the variable domain fragments is presumably responsible for the impairment in tubular function. Other causes of proximal RTA that lead to isolated bicarbonate wasting include acetazolamide or the administration of any carbonic anhydrase inhibitor. The most common offending agent currently is topiramate, which is a potent carbonic anhydrase inhibitor.

The majority of cases of proximal RTA are associated with generalized proximal tubule dysfunction (Fanconi syndrome) so that glycosuria, aminoaciduria, proteinuria, hyperphosphaturia, hypophosphatemia, hyperuricosuria, hypouricemia, and hypercitraturia are observed commonly. Table 18.5 lists several familial disorders that may be associated with proximal RTA that result when the abnormal product of metabolism impacts proximal tubule function. Hypercalciuria, a common feature of metabolic acidosis, is absent in

proximal RTA, presumably as a result of enhanced calcium absorption in the distal nephron in response to increased bicarbonate delivery. Rickets, a frequent manifestation of the Fanconi syndrome, is a result of phosphate wasting, not proximal RTA or acidosis. Of particular concern in children with proximal RTA is growth retardation, a direct consequence of acidosis. Because growth retardation will correct with alkali therapy, this complication becomes one of the major indications for correction of the serum bicarbonate concentration.

Isolated proximal RTA without features of the Fanconi syndrome can occur rarely in an autosomal recessive disorder affecting the gene SLC4A4 that encodes for the sodium bicarbonate cotransporter. In addition, a defect in the gene that encodes the Na^+/H^+ exchanger (NHE-3) on the apical membrane has been described in a single family as an autosomal dominant disease.

Management

The primary therapeutic objective in the management of patients with proximal renal tubular acidosis is to maintain a near normal serum HCO_3^- concentration and arterial pH. The bicarbonaturia associated with this disorder, which amplifies potassium excretion, requires administration of a mixture of sodium and potassium salts (e.g., K-Shohl's solution) (Table 18.6). A feature of proximal renal tubular acidosis is the large amount of HCO_3^- required to correct the acidosis, which, in turn, aggravates renal potassium excretion. As an adjunct, the administration of thiazide diuretics has been used to decrease GFR from chronic volume depletion. Sequelae of proximal RTA vary according to cause (generalized vs. isolated). Nevertheless, in children with isolated proximal RTA, stunted growth is normalized by correction of the acidosis. Additionally, the manifestations of isolated proximal RTA in children tend to improve with age, but alkali therapy is usually necessary throughout life.

18.6 Treatment of Proximal Renal Tubular Acidosis

Large amounts of alkali required to correct acidosis:
- 10–20 mEq/kg/day of alkali (typically enhances urinary K loss)

Preparations that include potassium:
- Potassium Shohl's Solution (K-Shohl's:
  - Polycitra-LC: Citric acid 334 mg, sodium citrate 500 mg, and potassium citrate 550 mg per 5 mL [480 mL] [alcohol free, sugar-free])

Thiazides (may be helpful)

DISTAL RENAL TUBULAR ACIDOSIS

Mechanism and Regulation of Distal Acidification (see also Chapter 6)

The role of the distal nephron in maintaining acid-base homeostasis occurs through HCO_3^- absorption and net acid secretion. As discussed previously, the proximal tubule absorbs approximately 90% of the filtered HCO_3^- load, with the distal nephron absorbing the remaining 10%. In addition, the distal nephron is responsible for secreting daily approximately 50 to 80 mEq of hydrogen ions, which matches daily net acid production from metabolism. Thus, excretion of net acid stoichiometrically replaces the bicarbonate lost in extracellular buffering of those acids gained from metabolism of dietary protein. Proton secretion in the distal nephron generates large pH gradients between blood and the lumen. The kidney utilizes an elaborate buffering system to avoid unsustainably large transepithelial H^+ concentration gradients and the ensuing tubular toxicity associated with the expected local acidity which would be necessary to secrete 50 to 80 mEq of H^+ per day without buffering. This buffering system is divided into two components: (1) ammonium and (2) titratable acids. Titratable acids in urine include phosphate, creatinine, and other miscellaneous buffers. Total net acid excretion (NAE) is represented by the sum of titratable acid (TA) and ammonium (NH_4^+) excretion (minus minimal HCO_3^- excretion, if any). Therefore, to maintain acid-base balance, net acid excretion must approximate net acid production.

The Pathophysiologic Basis of Classical Distal Renal Tubular Acidosis

Anatomic and Physiologic Segregation of the Collecting Duct

The collecting duct can be divided into three functional segments: the cortical collecting tubule (CCT), the outer medullary collecting tubule (OMCT), and the inner medullary collecting duct (IMCD). The CCT is a low capacity H^+ secretory segment where the rate of H^+ secretion is modulated by aldosterone, Na^+ and K^+ absorption, and systemic acid-base balance. The CCT has the capacity for both H^+ and HCO_3^- secretion.[32–35] The former function is accomplished by type A intercalated cells, and the latter by type B intercalated cells (Fig. 18.2). The OMCT, in contrast, has a high capacity for H^+ secretion, which is regulated by systemic acid-base homeostasis, the serum K^+ concentration, and aldosterone.[36] Finally, the IMCD is a low capacity proton secretory system. In this segment ammonium transport is regulated by acid-base homeostasis and the serum K^+ concentration.

In each segment of the distal nephron, HCO_3^- absorption is mediated by apical membrane H^+ secretion.[37,38] Because of the negative cell potential, H^+ secretion must occur by an active transport.[39–41] Two ATP-dependent proton pumps, the H^+-ATPase and the H^+,K^+ATPase, have been identified

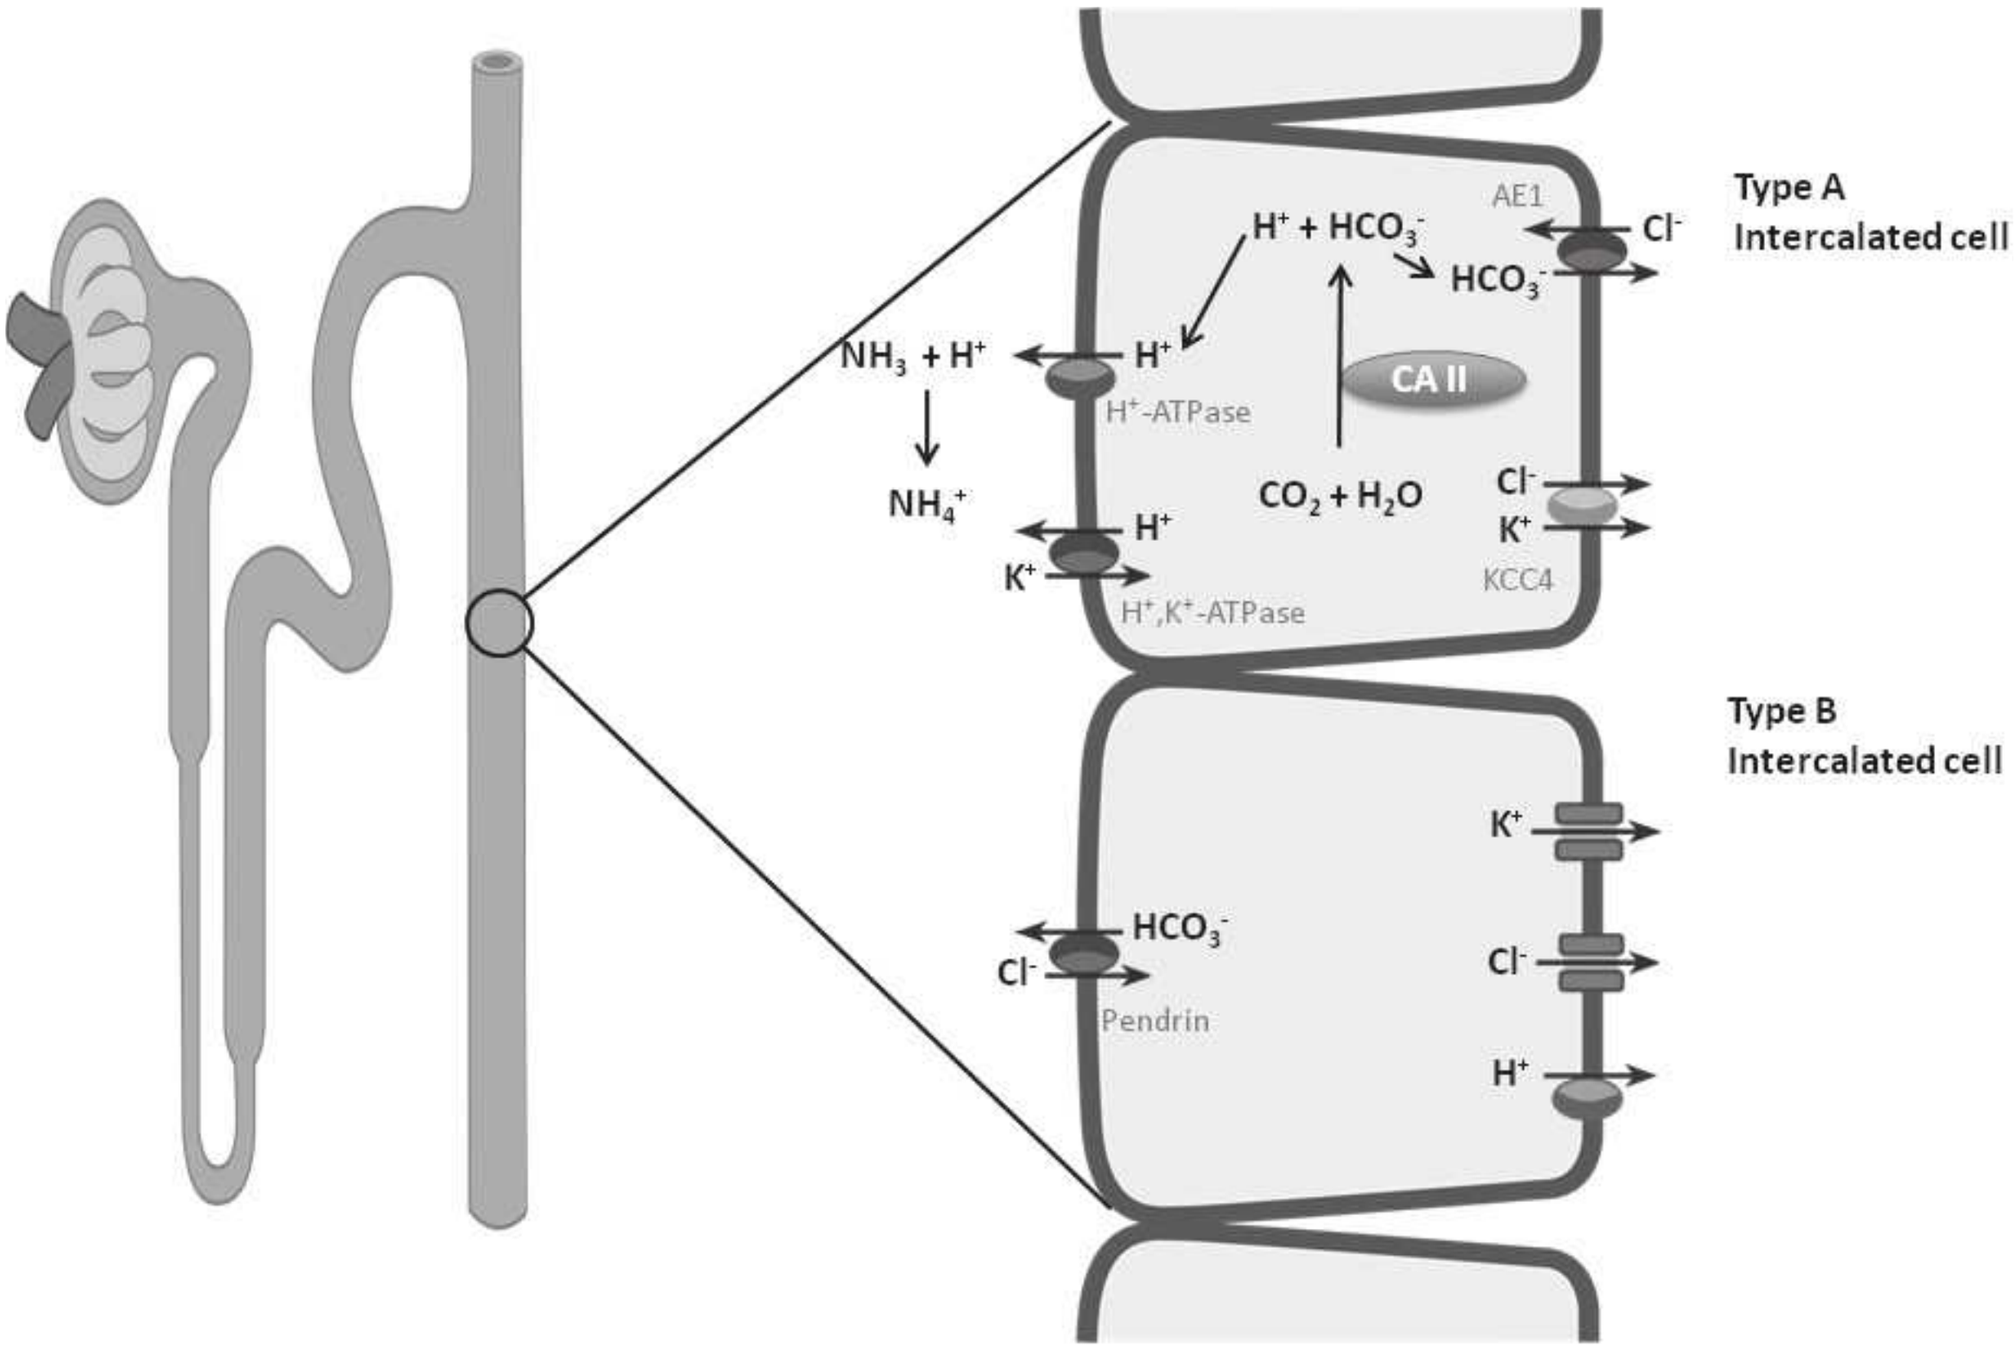

FIGURE 18.2 Type A and B intercalated cells of collecting duct. See text for detail.

in the distal nephron and together are responsible for H^+ secretion[42] (Fig. 18.2). Immunohistochemical studies have localized the H^+-ATPase to the apical membrane of acid secreting cells (type A intercalated cells) in the CCT and OMCT. Both the gastric and colonic H^+,K^+-ATPase subunits are expressed in intercalated cells of the cortical collecting duct and outer medullary collecting duct.[42] These two isoforms of H^+,K^+-ATPase have been designated as the $HK\alpha_1$ ("gastric") and $HK\alpha_2$ ("colonic") subunits. $HK\alpha_1$ is identical to the H^+,K^+-ATPase in gastric parietal cells, whereas $HK\alpha_2$ is homologous to the H^+,K^+-ATPase in distal colon. Several studies have demonstrated that $HK\alpha_2$ mRNA and protein (but not $HK\alpha_1$) are dramatically upregulated by chronic hypokalemia and chronic acidosis.[43] Furthermore, increased H^+,K^+-ATPase activity in the outer and inner medullary collecting duct results in enhanced HCO_3^- absorption.[44]

Apical proton secretion generates HCO_3^- intracellularly, which then exits the cell via the Cl^-/HCO_3^- exchanger (AE-1) present on the basolateral membrane (encoded by the gene SLC4A1).[45] Thus, these three transporters, the apical H^+-ATPase and H^+,K^+-ATPase, and the basolateral HCO_3^-/Cl^- exchanger could be involved, if defective, in the development of an acidification defect in the distal nephron (Fig. 18.3). The reader is referred to Chapter 6 for additional detail. Examples of genetic and acquired abnormalities of the H^+-ATPase and AE-1 have been described and are discussed later.

Additionally, defective net H^+ secretion could occur by the insertion of a "leak" pathway for H^+ into the collecting duct (Fig. 18.3). This abnormality, also referred to as a "gradient lesion," occurs most commonly with amphotericin B nephrotoxicity. Whether this latter abnormality accounts for acidification defects in other forms of inherited or acquired distal RTA has been described in case reports, but has not been established clearly.

Ammonium Production and Excretion

Although ammonium is secreted in several segments of the nephron, the majority of ammonium secretion occurs in the proximal tubule and is regulated by acid-base homeostasis (Fig. 18.4). Ammonium transport involves both ammonia (NH_3) diffusion and ammonium (NH_4^+) transport. NH_4^+ secretion into the proximal tubule lumen occurs via the apical membrane Na^+/H^+ exchanger (NHE-3) through substitution of NH_4^+ for H^+. Ammonium secretion is augmented dramatically by systemic metabolic acidosis. At physiologic pH, α ketoglutarate, a major metabolic product of ammoniagenesis, is converted to HCO_3^- ions, which are transported across the basolateral membrane to the extracellular fluid (ECF). This end product of ammoniagenesis therefore represents "new bicarbonate" when returned to systemic circulation via the renal vein. As mentioned previously, and

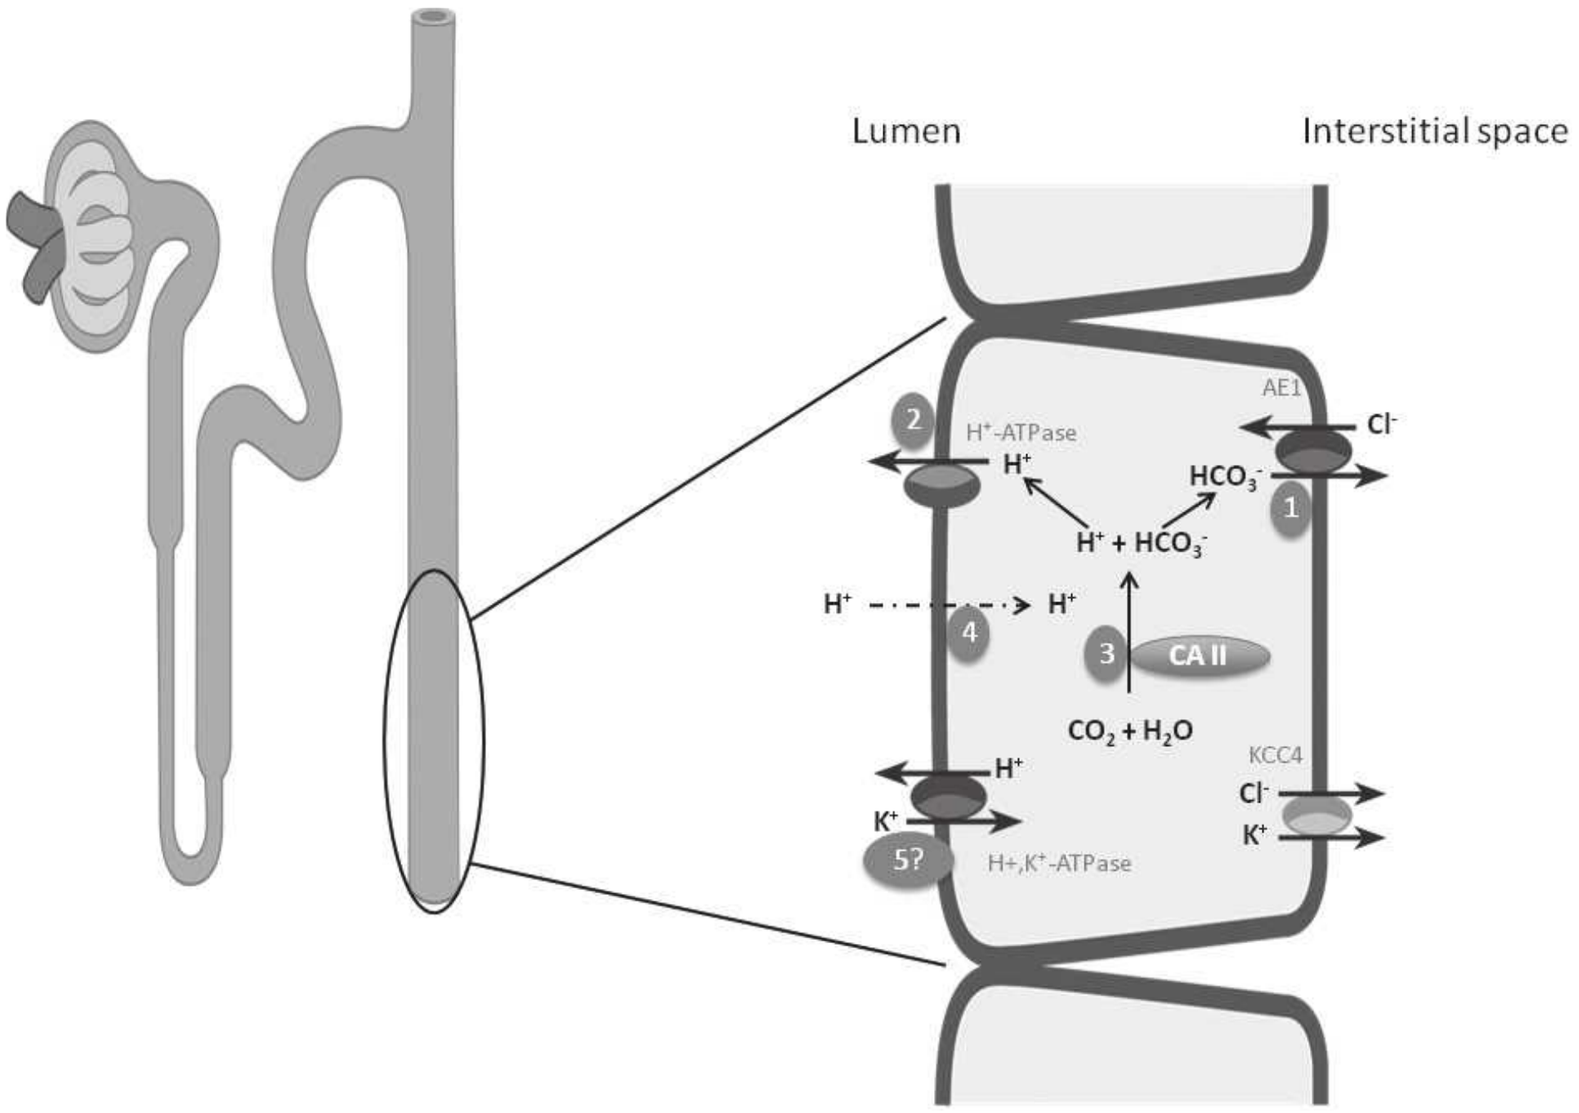

FIGURE 18.3 Pathogenesis of distal renal tubular acidosis (RTA). Model of type A intercalated cell in medullary collecting duct showing described inherited defects encoding distal transport proteins that cause classical distal RTA. *1*, defect of basolateral HCO_3^-/Cl^- exchanger; *2*, defect of specific subunits of H^+-ATPase; *3*, carbonic anhydrase II deficiency; *4*, backleak of H^+ or gradient lesion (amphotericin B and presumed rare inherited abnormalities); *5*, abnormality of H^+,K^+-ATPase (not verified, but may explain endemic [Northeastern Thailand] distal RTA with severe hypokalemia).

discussed in detail in Chapter 6, "new bicarbonate" restores the HCO_3^- lost in the ECF from buffering the acid products of metabolism.

After ammonium enters the proximal tubule lumen, an elaborate system exists to generate high medullary interstitial concentrations of ammonium[46] (Fig. 18.5). First, the HCO_3^- concentration and pH of tubular fluid increases progressively along the thin descending limb of the loop of Henle as a result of water abstraction.[47] This alkaline environment favors NH_3 diffusion out of the tubule lumen. In addition, direct uptake of NH_4^+ is accomplished via the apical Na^+-$2Cl^-$-K^+ cotransporter (through competition for the K^+ site) in the medullary thick ascending limb of the loop of Henle (TALH).[46] Ammonium absorption at this site is stimulated by acidosis and hypokalemia and is impaired by hyperkalemia.[48–52] NH_3 is capable of reentering the proximal straight tubule from the interstitium.[46] Active absorption of NH_4^+ in the TALH allows for trapping of NH_4^+ in the medullary countercurrent multiplication system.[53] The end result of this system is a medullary-to-cortical concentration gradient for ammonium with medullary concentrations exceeding cortical concentrations severalfold. This corticomedullary ammonium gradient is augmented by metabolic acidosis.[50] Ammonium is trapped in the medullary collecting duct by a combination of NH_3 diffusion from the interstitium and active H^+ secretion by the medullary collecting duct (H^+-ATPase and the H^+-K^+-ATPase).[50,54] This process generates high concentrations of ammonium in the final urine. Because NH_4^+ uptake by the TALH is accomplished by the Na^+-K^+-$2Cl^-$ cotransporter, competition between K^+ and NH_4^+ helps explain the association between hyperkalemia and metabolic acidosis.[55] Additional detail on ammonia/ammonium transporters and their regulation is provided in Chapter 6.

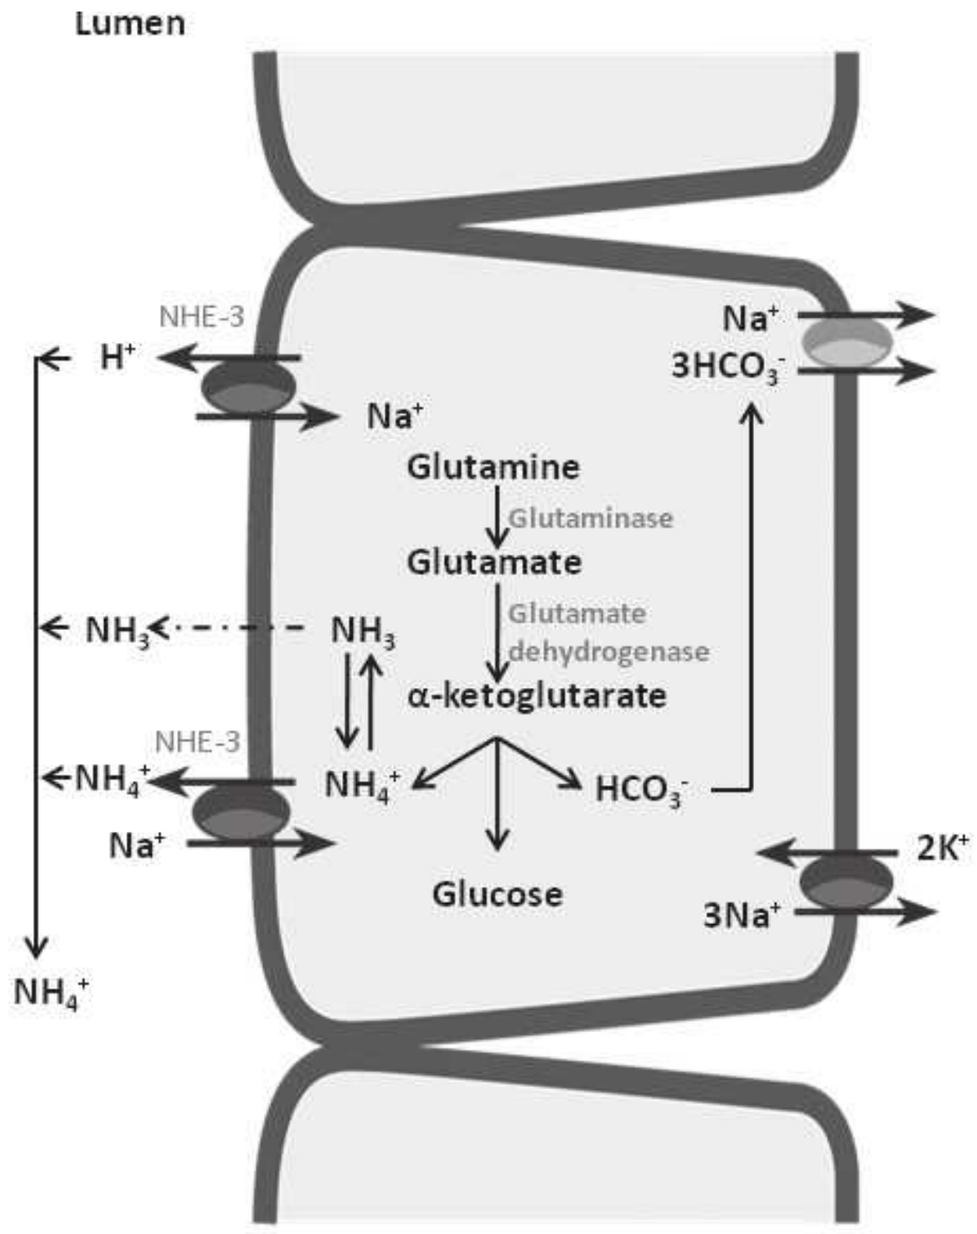

FIGURE 18.4 Ammoniagenesis and transport of ammonia/ammonium in the proximal tubule.

Regulation of Distal Acidification

Apical proton secretion and basolateral HCO_3^- transport together and regulate net HCO_3^- absorption in the distal nephron. The responsible transporters include the

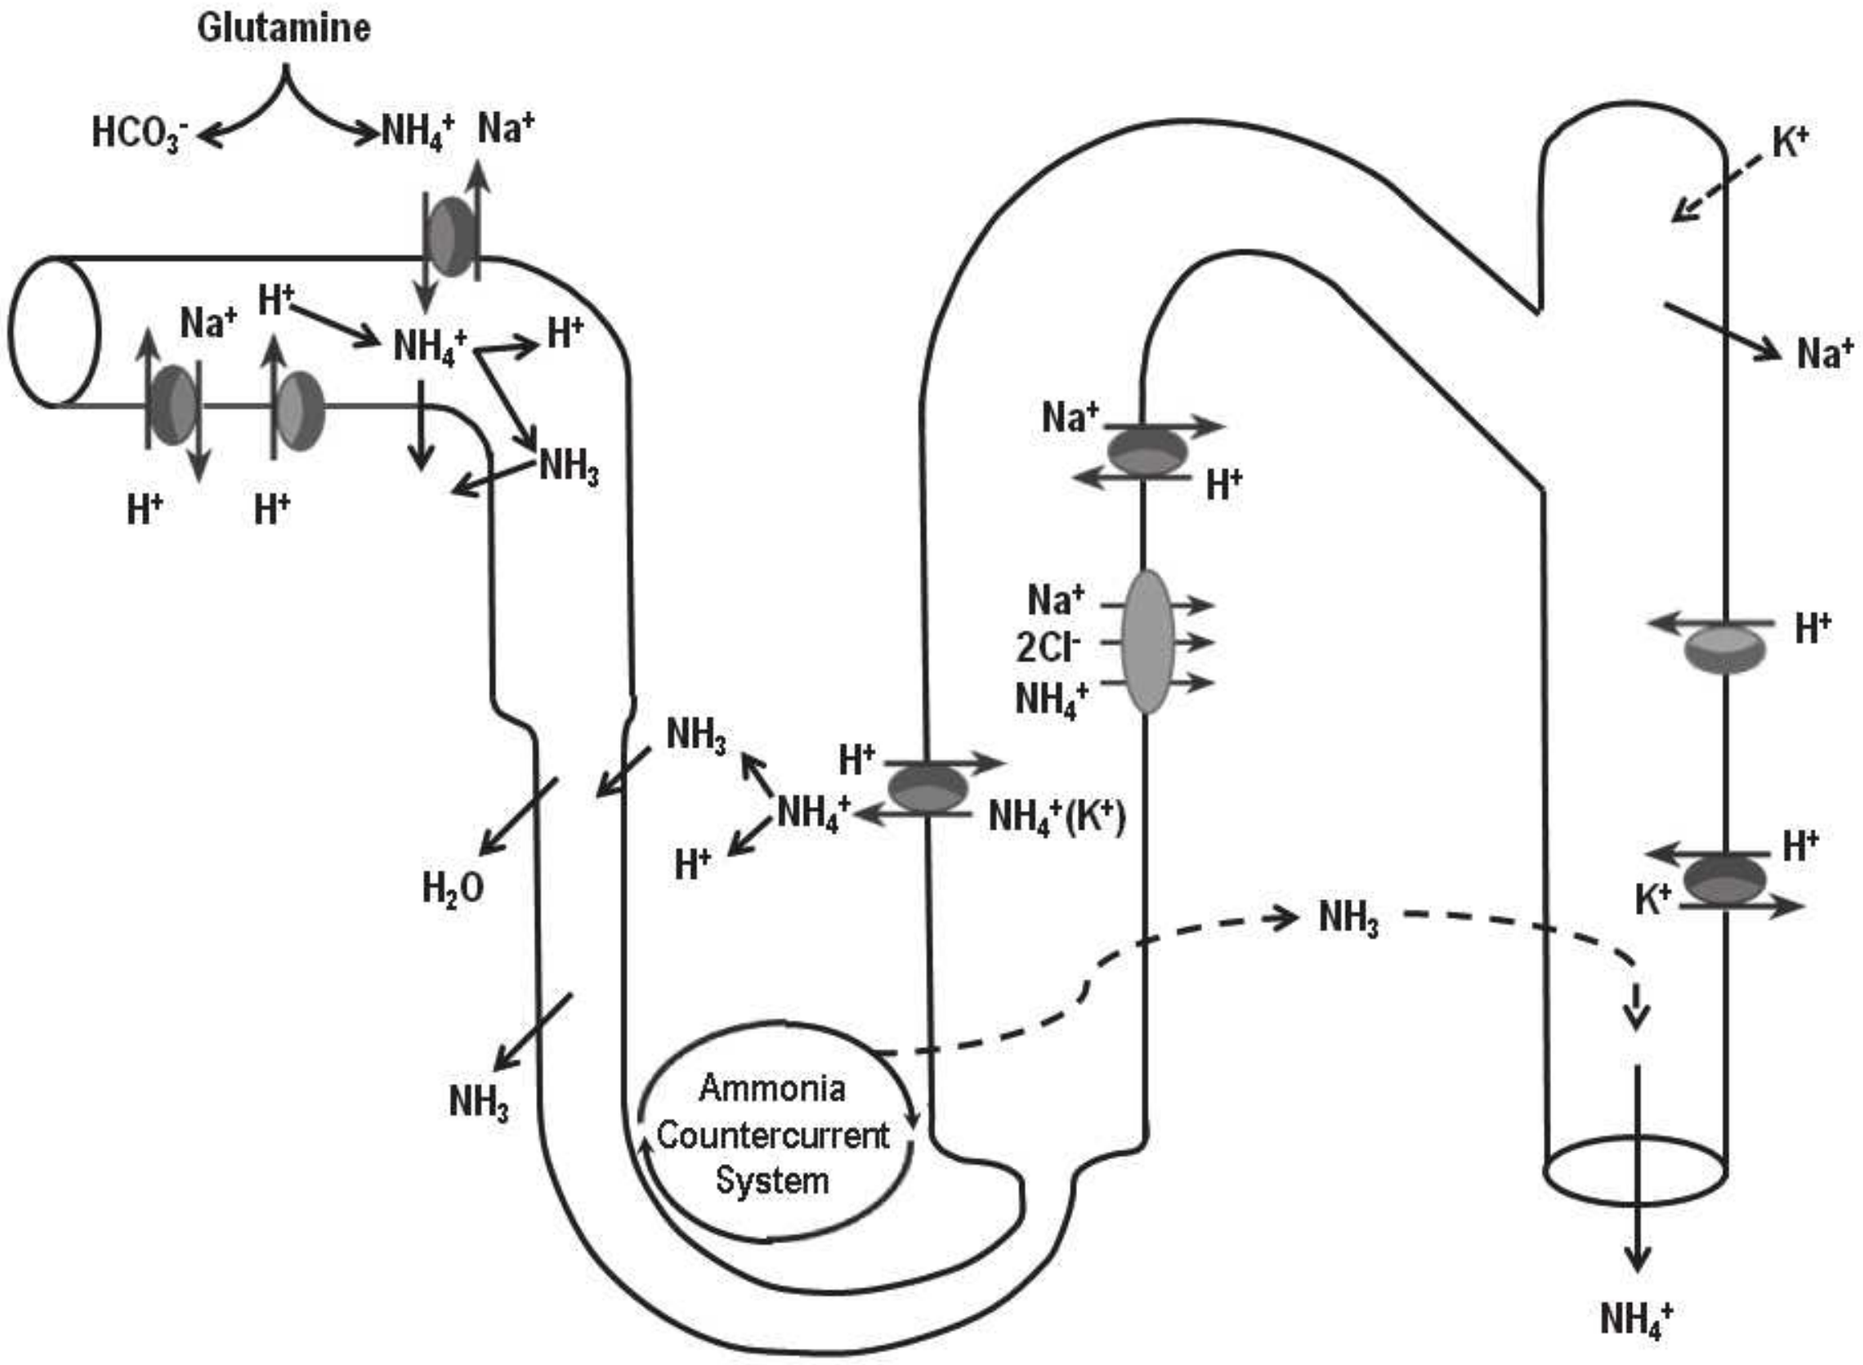

FIGURE 18.5 Summary of ammonia/ammonium transport pathways in the nephron. Possible defective ammoniagenesis and/or ammonium transport associated with distal renal tubular acidosis, discussed in text in detail.

electrogenic H^+-ATPase, the electroneutral H^+,K^+-ATPase on the apical membrane, and the HCO_3^-/Cl^- exchanger on the basolateral membrane (Fig. 18.6). Alteration in the negative transepithelial potential difference, which is dependent on the rate of Na^+ absorption, has a significant secondary impact on proton secretion by the electrogenic H^+-ATPase. Thus, a decline in Na^+ delivery or Na^+ acidity through either impairment of epithelial Na^+ channel (ENaC) function or through absence of mineralocorticoid will secondarily impair H^+ secretion. A defect in H^+ secretion in the CCT in response to a decline in Na^+-transport dependent transepithelial voltage has been termed a "voltage defect." Mineralocorticoids have been demonstrated to be a potent determinant of proton secretion. In the CCT, mineralocorticoids stimulate Na^+ absorption (ENaC) increasing the lumen negative transepithelial potential, which stimulates electrogenic proton secretion secondarily.[56] This early effect of aldosterone on ENaC is reinforced after several hours to upregulate the basolateral Na^+,K^+-ATPase as well. Taken together, mineralocorticoid increases the negative transepithelial potential, thus enhancing Na^+ absorption. Mineralocorticoids have also been shown to stimulate the H^+-ATPase in the cortical, outer, and inner medullary collecting tubules in the absence of Na^+.[40,57] Thus, in summary, both mineralocorticoids and Na^+ absorption in the CCT have important regulatory effects on net H^+ secretion in the collecting duct.

Potassium homeostasis also plays a significant role in the regulation of renal acidification. Clearance studies have suggested that potassium deficiency stimulates distal proton secretion. It has now been established that this regulatory response occurs, at least in part, through upregulation of the H^+,K^+-ATPase. Potassium status can also affect renal acidification indirectly. First, potassium is an important determinant of aldosterone, and as discussed previously, aldosterone is an important determinant of H^+ secretion. Potassium also affects ammonium synthesis and excretion.[52] Chronic hypokalemia stimulates ammonium production while hyperkalemia suppresses ammoniagenesis.[48] Alterations in ammonium production may also affect the medullary interstitial gradient and buffer availability. Hyperkalemia impairs ammonium absorption in the thick ascending limb, also decreasing medullary concentrations of total ammonia and secretion of NH_3 into the medullary collecting duct.[48,49,58]

Pathogenesis of Distal Renal Tubular Acidosis

Classical Hypokalemic Distal Renal Tubular Acidosis. The mechanisms involved in the pathogenesis of hypokalemic distal RTA (DRTA) are not yet completely resolved.

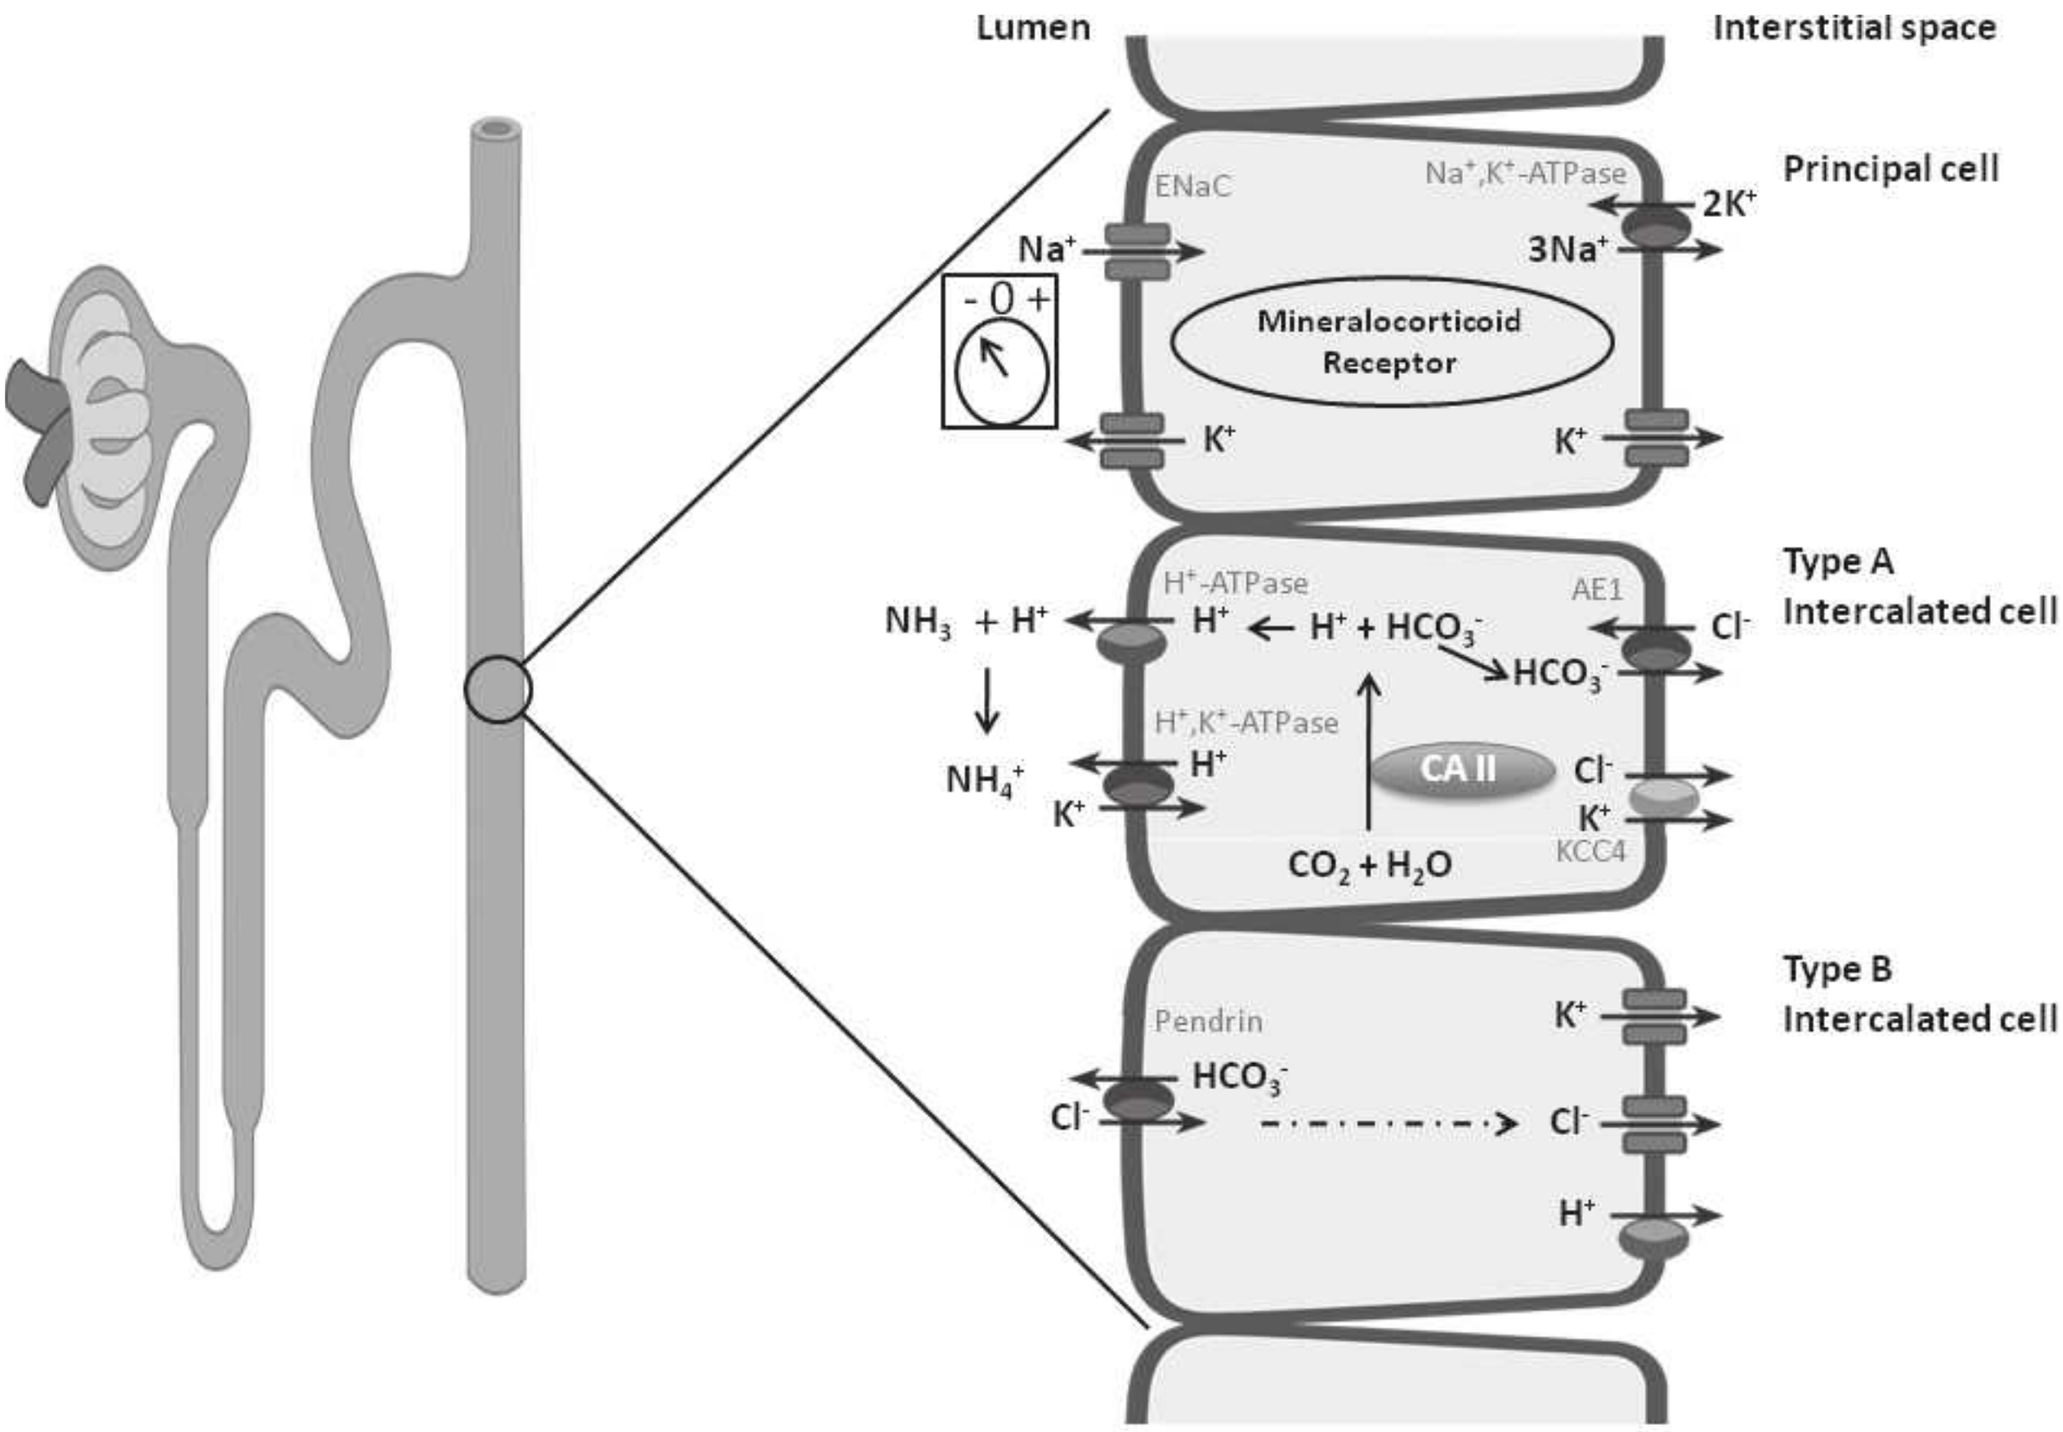

FIGURE 18.6 Three cell types in the collecting tubule: principal cell, and type A and type B intercalated cell. Mechanisms of transport discussed in text.

The occurrence of hypokalemia demonstrates that generalized CCT dysfunction or aldosterone deficiency is not causative. Initially the cause of classical hypokalemic DRTA was considered to be a "gradient lesion." Alternatively, a defect in proton secretion is the most widely accepted explanation for the inability to maximally acidify the urine,[59] in the majority of forms of classical DRTA (Fig. 18.3). The most notable exception of this mechanism is the defect induced by amphotericin B nephrotoxicity, for which insertion of a leak pathway in the apical membrane of the distal tubule by the antibiotic is causative (Fig. 18.3, number 4). An important feature in the determination of the pathogenesis of the acidification defect in these patients is the response of the urine PCO_2 to $NaHCO_3$ infusion. Infusion of $NaHCO_3$ to produce a high HCO_3^- excretion rate results normally in distal nephron hydrogen secretion and the generation of a high CO_2 tension in the urine. The magnitude of the urinary PCO_2 (referred to as the urine-minus-blood PCO_2, or U-B PCO_2) is quantitatively related to distal nephron hydrogen ion secretion.[38,60] A decrease in the rate of hydrogen ion secretion as a result of a defect of one of the H^+ transporters on the apical membrane (H^+- or H^+,K^+-ATPase) or the basolateral HCO_3^-/Cl^- exchanger will lead to a low U-B PCO_2. In contrast, a backleak of H^+, as occurs with a "gradient" defect, has been shown in experimental models to be associated with a normal U-B PCO_2. In patients with classical hypokalemic DRTA, the U-B PCO_2 is usually subnormal, except in amphotericin B-induced DRTA.[60–62] This finding supports the view that most patients with DRTA have a "rate" or "pump" defect (Fig. 18.3, number 1).

H^+-Secretory Defects. The rate of proton secretion could be affected by an abnormality in a specific transporter or mechanism involved in proton secretion. These include the apical H^+-ATPase or H^+-K^+-ATPase, and the basolateral Cl^-/HCO_3^- exchanger, AE-1 (Fig. 18.3, number 2). Impairment of the H^+-ATPase in classical DRTA has been documented in both acquired and inherited disorders. Acquired defects of H^+-ATPase have been demonstrated in renal biopsy specimens of patients with Sjögren syndrome with evidence of classical hypokalemic DRTA. These biopsy specimens revealed trapping of this transporter in intracellular compartments and an absence of H^+-ATPase protein in the apical membrane of type A cells. To further underscore the importance of H^+-ATPase in classical RTA, several

investigators have described autosomal dominant mutations in the ATP6V1B1 gene encoding the B-subunit of the H^+-ATPase in the kidney and cochlea, and these mutations are associated with sensorineural deafness. Another form of classical DRTA, inherited as an autosomal recessive defect, is associated with normal hearing and has been shown recently to be a mutation in the ATP6V0A4 gene that encodes for the A-subunit of this transporter.[63–65]

Alternatively, although abnormalities in the H^+,K^+-ATPase (Fig. 18.3) could result in both hypokalemia and metabolic acidosis, a defect in this transporter per se has not been described to date. An unusually high incidence of hypokalemic DRTA (endemic RTA) in Thailand may be the result of chronic hypokalemia and chronic tubulointerstitial disease, which could, in term, cause the acidification defect.[66] It would be logical to assume a role for chronic hypokalemia and subsequent tubulointerstitial disease in the development of some forms of classical DRTA through compromise of the H^+,K^+-ATPase.

Defects in the HCO_3^-/Cl^- Exchanger. Three groups have independently demonstrated an association between mutations in the AE-1 gene, which encodes the basolateral HCO_3^-/Cl^- exchanger (AE-1) in the collecting duct, and the occurrence of autosomal dominant classical DRTA (Fig. 18.3, number 3).[67–69] The typical clinical manifestations of classical DRTA were associated with heterozygosity for the AE1 point mutation, G1766A.[67–69] This mutation encodes an amino acid substitution, R598H, located at the cytoplasmic end of the AE1 protein in transmembrane span 6. Surprisingly, however, when these point mutations were expressed in vitro, abnormalities in HCO_3^-/Cl^- exchange were not observed. It was hypothesized that misdirection of the HCO_3^-/Cl^- exchanger to the apical, rather than the basolateral membrane might obtain in this disorder, resulting in impaired net H^+ secretion. If correct, enhanced HCO_3^-/Cl^- exchange on the apical membrane would increase rather than decrease urinary PCO_2 during bicarbonate infusion. That an increase in the U-B PCO_2 was demonstrated in patients with inherited classical DRTA supports this view.[70]

Therefore, in summary, genetic evidence exists for abnormalities in two subunits of the H^+-ATPase and misdirection of the HCO_3^-/Cl^- exchanger to the apical membrane as causes of inherited classical DRTA. Another rare mechanism for inherited DRTA includes carbonic anhydrase II deficiency which is associated with osteopetrosis and mental retardation. The diverse pathophysiology of the various inherited and acquired forms of classical DRTA are outlined in Table 18.7.

Impaired NH_4^+ Excretion

Patients with abnormalities in hydrogen ion secretion by the collecting duct in classical DRTA also exhibit uniformly low excretory rates of ammonium.[6,62] In the face of hyperchloremic metabolic acidosis, low ammonium excretion demonstrates that the kidney causes or perpetuates metabolic acidosis. Defective ammonium excretion may occur due to an inability to trap ammonium in the medullary collecting duct as a result of a higher than normal tubular fluid pH, as obtained when H^+ secretion is impaired (e.g., a defect in H^+-ATPase, H^+,K^+-ATPase, or the basolateral HCO_3^-/Cl^- exchanger) (Fig. 18.6). Moreover, urinary concentrating defects from the medullary interstitial disease is common in patients with classical DRTA, and may interfere with the medullary countercurrent multiplier and reduce the corticomedullary concentration gradient for ammonium and thereby reduce ammonium excretion.[50] Although the RhCG channel has been described in the distal nephron and has been shown to be important for ammonia/ammonium transport (see Chapter 6), there is no evidence to date that this transporter is involved in any form of RTA. Since classical DRTA is associated with hypokalemia, it would be anticipated that ammonium production and excretion would be enhanced. Nevertheless, ammonium excretion remains low for the prevailing systemic acidosis and urine pH, most likely as a result of failure of the corticomedullary countercurrent system.

Clinical Phenotype of Classical Distal Renal Tubular Acidosis

Classical hypokalemic DRTA is associated with positive acid balance, a nongap or hyperchloremic metabolic acidosis, and volume depletion with evidence of abnormal urine acidification for the prevailing acidosis (spontaneous or induced). Hyperchloremia is augmented by volume depletion. The positive acid balance and progressive acidosis causes calcium, magnesium, and phosphate wasting and may culminate in metabolic bone disease. Stunted growth is common in prepubertal children. A frequent association is nephrocalcinosis and nephrolithiasis, often with interstitial nephritis with susceptibility to pyelonephritis, which is difficult to eradicate. Both the hypercalciuria associated with DRTA and the hypocitraturia, which accompanies chronic metabolic acidosis, provide a favorable environment for urinary stone formation, chiefly calcium phosphate, and the development of nephrocalcinosis.[71] Nephrocalcinosis associated with nongap metabolic acidosis strongly implicates classical DRTA, because this does not occur with either proximal RTA or generalized distal nephron dysfunction with hyperkalemia.[72] Extra renal manifestations appear to be dependent, in part, on the gene mutated, and can include osteomalacia, rickets, osteopetrosis, deafness, ocular abnormalities, and cognitive dysfunction. The diagnostic features for classical DRTA are displayed in Table 18.8 and the systemic consequences in Table 18.9.

Classical Distal Renal Tubular Acidosis

Classical DRTA may occur as an autosomal dominant or autosomal recessive inherited defect (primary DRTA) or in association with a systemic illness (secondary DRTA). Overwhelmingly, the majority of patients with classical DRTA have secondary DRTA. The different etiologies of classical DRTA are displayed in Table 18.7.

18.7 Disorders Associated With Classical Hypokalemic Distal Renal Tubular Acidosis

Familial

1. Autosomal dominant
   a. Abnormality of the basolateral HCO_3^-/Cl^- exchanger (AE-1) due to SLC4A1 mutation
2. Autosomal recessive
   a. Deficiency or abnormality of the H^+-ATPase
      Autosomal recessive ATP6V1B1 mutation with deafness
      Autosomal recessive ATP6V0A4 mutation with or without deafness
   b. Carbonic anhydrase II deficiency – mixed PRTA-DRTA

Endemic

Northeastern Thailand

Acquired Defect of the H^+-ATPase

Sjögren syndrome

Secondary to Systemic Disorders

Autoimmune diseases
- Hyperglobulinemic purpura
- Cryoglobulinemia
- Sjögren's syndrome
- Thyroiditis
- HIV nephropathy
- Fibrosing alveolitis
- Chronic active hepatitis
- Primary biliary cirrhosis
- Polyarthritis nodosa

Hypercalciuria and nephrocalcinosis
- Primary hyperparathyroidism
- Hyperthyroidism
- Medullary sponge kidney
- Fabry disease
- X-linked hypophosphatemia
- Vitamin D intoxication
- Idiopathic hypercalciuria
- Wilson disease
- Hereditary fructose intolerance
- Hereditary sensorineural deafness

Drug- and toxin-induced disease
- Amphotericin B
- Mercury
- Vanadate
- Hepatic cirrhosis
- Ifosfamide
- Topiramate
- Cyclamate
- Lithium
- Classic analgesic nephropathy
- Foscarnet
- Acetazolamide

Tubulointerstitial diseases
- Balkan nephropathy
- Chronic pyelonephritis
- Obstructive uropathy
- Vesicoureteral reflux
- Renal transplantation
- Leprosy
- Jejunoileal bypass with hyperoxaluria

Associated with genetically transmitted diseases
- Ehlers-Danlos syndrome
- Sickle cell anemia
- Medullary cystic disease
- Hereditary sensorineural deafness
- Osteopetrosis with carbonic anhydrase II deficiency
- Hereditary elliptocytosis
- Marfan syndrome
- Jejunal bypass with hyperoxaluria
- Carnitine palmitoyltransferase I

PRTA-DRTA, proximal renal tubular acidosis–distal renal tubular acidosis.

18.8 Diagnostic Features of Classical Distal Renal Tubular Acidosis

Hypokalemia
Urine anion gap positive with induced or spontaneous metabolic acidosis
Abnormally low NH_4^+ excretion
Urine pH >5.5
Modest bicarbonaturia, <10% $FE_{HCO_3^-}$ >5%
Absence of Fanconi syndrome
Abnormal calcium metabolism (hypercalciuria, nephrocalcinosis, nephrolithiasis, bone disease)
Low urine citrate
Hyperglobulinemia

Inherited Classical Distal Renal Tubular Acidosis. Over 300 individuals from over 60 families have been identified with primary DRTA,[67,68,73,74] and the specific defects are either mutations of the H^+-ATPase (recessive inheritance), or of kAE1/SLC4A1 (dominant and recessive inheritance).[26,67,68,74] Most patients with inherited DRTA have associated hypercalciuria and hypocitraturia predisposing to nephrocalcinosis and bone disease.[1]

Autosomal Recessive Classical Distal Renal Tubular Acidosis Associated with Mutations of the H^+-ATPase. The features of autosomal recessive DRTA include severe metabolic acidosis, an inappropriately alkaline urine, growth failure, rickets, and renal calcification. This constellation of findings may occur with or without sensorineural deafness (see previous text and Table 18.9). Mutations in genes encoding isoforms of two subunits of the H^+-ATPase subunits include, respectively, the V_1 and V_0 domains. Over 20 mutations have been reported for ATP6V1B1 with deafness, all with a recessive inheritance pattern. Progressive bilateral hearing loss occurs with mutations in ATP6V1B1, encoding the B-subunit of the collecting duct apical electrogenic proton pump (H^+-ATPase) and the H^+-ATPase in the cochlea.[64] Over 28 mutations of ATP6V0A4 that encode the a4 subunit have been reported with variable deafness and are also transmitted as an autosomal recessive inheritance.[65]

Dominant and Recessive Distal Renal Tubular Acidosis with Mutations of kAE1/SLCA1**.** Approximately 20 family members with either recessive or dominant classical DRTA have been reported with mutations of SLC4A1/kAE1.[68,69,75] The normally configured kidney isoform of AE1 (kAE1) is a truncated product of the SLC4A/AE1 gene, whereas, in contrast, selective mutations cause DRTA. Dominant DRTA involving kAE1 result in either abnormal intracellular retention of kAE1, which prevents appropriate targeting, or a reversed polarity of the mutant kAE1. Recessive missense mutations of kAE1 encode an unstable protein that results in a null phenotype, such as severe hemolytic anemia, DRTA, and cardiovascular instability. Others have impaired urinary acidification but normal AE1 in red cells. The mutant kAE1, when expressed in kidney cells in culture, can be rescued with glycophorin A. Genetic models in mice ($AE1^{-/-}$) have severe hemolytic anemia, heart failure, and acidosis associated with growth abnormalities, spherocytosis, and poikilocytosis. Because this defect is often fatal, thorough studies have not been performed, but nephrocalcinosis has been reported.[7]

Accompanying Disorders of Distal Renal Tubular Acidosis: Hypokalemia, Nephrogenic Diabetes Insipidus, and Hypercalciuria (Table 18.9). Although the hypokalemia that frequently accompanies DRTA has been assumed to be secondary aldosteronism, more recent evidence implicates the BK Maxi-K channel (Slo1), which interestingly, exhibits pH sensitivity. Acid extracellular pH, presumably in the renal interstitium, may enhance K secretion.[76] However, there are other pH effects on other Na and K channels that may be offsetting and render this possible mechanism both complex and, as yet, not fully solved.

Calcium phosphate nephrolithiasis and nephrocalcinosis are very common in DRTA. The etiology has not been fully elucidated. The consensus has been that, with acidosis, calcium salts are leached from bone, thereby causing a high filtered load of calcium and thus hypercalciuria. However, pH-dependency of calcium handling by the distal nephron may participate. For example, TRPV5, the major mechanism of calcium reabsorption, is inhibited by an acid intracellular pH, a condition that likely prevails in the medullary interstitium of acidotic patients with DRTA.[77] Further work on this mechanism and a better understanding of the cellular basis of nephrocalcinosis is needed as are more effective therapies

18.9 Consequences of Classical Distal Renal Tubular Acidosis

Progression of chronic kidney disease
Bone disease (result of acidosis, hypercalciuria)
Nephrocalcinosis
Nephrolithiasis
    Hypercalciuria and hypocitraturia
        Acidosis leads to hypocitraturia
Progression of renal failure
Hypokalemia – may be severe
Pyelonephritis – difficult to eradicate
Stunted growth
Nephrogenic diabetes insipidus

for this devastating feature of DRTA. Nephrocalcinosis and interstitial fibrosis are a major cause of progressive kidney disease in these patients.

Endemic Distal Renal Tubular Acidosis. A high incidence of DRTA has been reported in northeast Thailand.[78,79] This disorder has a female to male ratio of 3:1 and patients range in age from 18 to 76 years. Associated features include severe hypokalemia resulting in profound muscle weakness, nephrocalcinosis, renal stones, hypocitraturia, osteomalacia, and nocturia. The hypokalemia and the accompanying features are more severe in the summer months and are most prevalent in impoverished groups whose diet consists almost entirely of rice. Therefore, dietary hypokalemia may be causative. Although the precise mechanism involved remains unclear, chronic tubulointerstitial renal disease as a result of chronic hypokalemia appears to be a better explanation than vanadate toxicity, as initially suggested.[80]

Secondary Distal Renal Tubular Acidosis. The disorders associated with acquired classical DRTA are outlined in Table 18.10. Hyperglobulinemia is commonly associated with acquired classical DRTA. Up to 50% of patients with Sjögren syndrome and hyperglobulinemic purpura eventually exhibit an acidification defect.[81–83] These patients may have profound hypokalemia at times. Other autoimmune and hyperglobulinemic states that are associated with DRTA include cryoglobulinemia, thyroiditis and Graves disease, primary biliary cirrhosis, chronic active hepatitis, systemic lupus erythematosus, and HIV nephropathy.[84–86] The co-occurrence of hypokalemic paralysis, a nongap metabolic acidosis and thyrotoxicosis, indicates DRTA rather than hypokalemic periodic paralysis.

18.10 Classification of Major Disorders Associated with Acquired Classical Distal Renal Tubular Acidosis

- Autoimmune disorders
  - Hyperglobulinemia- autoimmune diseases
    - Sjögren's, thyroiditis, primary biliary cirrhosis
- Hypercalciuria and nephrocalcinosis
  - Hypervitaminosis D, hyperparathyroidism, Graves disease
- Drug- or toxin-induced disease
  - Amphotericin B, ifosfamide, topiramate, lead, lithium, tetracycline, toluene
- Tubulointerstitial diseases
  - Minimal change disease, classical analgesic nephropathy

Abnormalities in calcium homeostasis, particularly when nephrocalcinosis is present, are commonly seen in patients with acquired DRTA. Examples of the co-occurrence of DRTA and nephrocalcinosis include: primary hyperparathyroidism, vitamin D intoxication, medullary sponge kidney, hyperthyroidism, idiopathic hypercalciuria, X-linked hypophosphatemia, and type 1 glycogen storage disease (Table 18.7).[87–93]

DRTA can also be caused by various drugs or toxins (Tables 18.7 and 18.10). Examples include amphotericin B,[94] carbonic anhydrase inhibitors (including the anticonvulsant topiramate), lithium carbonate,[95] analgesics,[96,97] ifosfamide, foscarnet,[98] and vanadate. DRTA occurs in the chronic rejection of renal transplantation.[99–101] DRTA with renal transplantation is attributed to defective ammonium excretion and generalized distal tubular malfunction.[100] Renal tubulointerstitial disease can be associated with DRTA. Prominent examples include hyperoxaluria,[102] obstructive uropathy,[103] vesicoureteral reflux,[104] lupus nephritis, leprosy, and pyelonephritis with nephrolithiasis.[105] DRTA is also associated with a variety of inherited disorders not discussed here, including Ehlers-Danlos syndrome, hereditary elliptocytosis, hereditary spherocytosis, sickle cell disease, medullary cystic disease, type I glycogen storage disease, and carnitine palmitoyltransferase I deficiency.[26,106–109]

Diagnosis of Classical Distal Renal Tubular Acidosis (Table 18.8)

The diagnosis of classical DRTA is most often made clinically in a patient with acquired forms of the disease (Table 18.10), indicating the importance of a thorough history and physical examination. These patients usually exhibit spontaneous and chronic nongap metabolic acidosis in association with chronic hypokalemia and an inappropriately alkaline urine pH (>5.5), and a positive urine anion gap, as mentioned previously. Hypokalemia may first bring the patient to medical attention, particularly if severe because it may be associated with flaccid paralysis. Additionally, patients may have a history of nephrolithiasis (calcium phosphate), variable degrees of nephrocalcinosis, or evidence of autoimmune disorders instead (Sjögren syndrome, thyroiditis, or primary biliary cirrhosis) (Table 18.10). Drugs and toxins may cause tubular effects or toxicity (Table 18.10). Conversely, other patients, usually members of families with known inherited classical DRTA, may have one or more of the disorders (e.g., nephrocalcinosis or nephrolithiasis) but not display evidence of chronic nongap acidosis. When such patients are challenged with an oral ammonium chloride load (0.1 gm per kg BW), urine pH does not decrease below 5.5 (as in nonaffected controls). This latter category of patients has what has been designated as "incomplete" classical DRTA. Patients with DRTA, in contrast to patients with proximal RTA, do not have a Fanconi syndrome and the fractional excretion of bicarbonate is lower (usually in the 5% range).

Finally, the urine to blood PCO_2 difference, or gradient, is typically lower than in normal subjects for both complete and incomplete DRTA. The U-B PCO_2, although not performed clinically in the majority of cases, remains the most sensitive diagnostic test for a secretory abnormality (i.e., abnormal H^+-ATPase in collecting tubule). In an alkaline urine, induced by an intravenous infusion of bicarbonate, the urinary PCO_2 typically increases 25 mm Hg above arterial PCO_2 levels. In patients with classical DRTA (as well as the generalized abnormality discussed later), the urine PCO_2 remains at or no more than 10 mm Hg above arterial levels (for review, see Chapter 6).[110]

Treatment of Classical Distal Renal Tubular Acidosis

The primary therapeutic objective for patients with classical DRTA is to correct the chronic metabolic acidosis. This can be achieved by administration of alkali in an amount sufficient to neutralize the daily acid load, or approximately 1 to 3 mEq/kg/day, and to return the plasma bicarbonate concentration to the normal range (Table 18.11). Shohl's solution (15 to 20 mL in water or juice, not as a syrup) may be more readily tolerated than $NaHCO_3$ tablets (325 or 650 mg or 3.9 and 7.8 mEq per tablet, respectively) in some patients. Compliance to either is often limited by taste fatigue with Shohl's solution and gastrointestinal discomfort with $NaHCO_3$ tablets. These and other choices are listed in Table 18.11. Correction of the acidosis reduces urinary potassium and sodium excretion, thus decreasing the need for potassium supplementation.[111,112] If required, potassium can be administered as potassium bicarbonate (K-Lyte 25 or 50 mEq), potassium citrate (Urocit K), or Polycitra (K-Shohl's).

Rarely, patients present with flaccid paralysis due to severe hypokalemia, metabolic acidosis, and hypocalcemia requiring immediate therapy. Because the hypokalemia may result in respiratory depression, increasing systemic pH with alkali therapy may worsen the hypokalemia. Therefore, immediate intravenous potassium replacement should be achieved prior to alkali administration.

Prognosis. The first goal of alkali therapy in DRTA is to normalize the serum bicarbonate and thereby prevent the relentless progression of chronic kidney disease. The GFR should be expected to stabilize with normalization of the serum bicarbonate (into 23 to 25 mEq per L range). This requires modest amounts (1 to 3 mEq/kg/day) of alkali therapy daily in divided doses. Hypercalciuria usually subsides on correction of the acidosis and urinary citrate excretion increases, thus reducing the incidence of urolithiasis. Although it is possible that nephrocalcinosis may improve over many years of alkali therapy, direct evidence for this view is lacking. Potassium homeostasis improves or normalizes in most adult patients and the renal phosphate clearance also improves. In children, growth is usually restored. Therefore, most if not all of the accompanying abnormalities are corrected with sustained correction of the serum bicarbonate.

18.11 Sources of Alkali for Therapy for Renal Tubular Acidosis

Shohl's solution (Na^+ citrate and citric acid)
- Sodium citrate 500 mg and citric acid 334 mg per 5 mL (480 mL)
- HCO_3^- equivalent 1 mEq/mL and Na^+ 1 mEq/mL

$NaHCO_3$ tablets
- 325 mg (3.8 mEq)
- 650 mg (7.6 mEq)

Baking soda (60 mEq/tsp)
K-Lyte (25 or 50 mEq/tablet)
Polycitra (K^+ Shohl's)
Granules, effervescent (Brioschi)

TYPE 3 RENAL TUBULAR ACIDOSIS: MIXED PROXIMAL AND DRTA

Carbonic anhydrase II deficiency is a very rare autosomal recessive abnormality characterized by osteopetrosis, RTA, and cerebral calcification.[26] Additional features that have been reported include severe mental retardation, stunted growth, microcephaly, dental malocclusion, high-arched palate, and broad thumbs. Reported patients with this syndrome have been predominantly from the Middle East and Mediterranean region. The evidence for both a proximal and distal cause of the RTA includes frank bicarbonate wasting consistent with proximal tubular dysfunction and an inability to acidify the urine during a sustained systemic acidosis, as well as a low urinary PCO_2 with bicarbonate loading—the latter two indicating DRTA.

RENAL TUBULAR ACIDOSIS ASSOCIATED WITH HYPERKALEMIA: GENERALIZED DISTAL NEPHRON DYSFUNCTION

The distinguishing features of generalized DRTA (type 4 RTA) are displayed in Table 18.12. This disorder occurs with hyperkalemia, whereas both proximal and classical DRTA occur with hypokalemia. A discussion of the unique pathophysiology, which localizes the nephron site of the abnormality, follows and is summarized in Table 18.13.

Pathophysiology of Voltage Defect

When a decrease in the negative transepithelial potential difference in the collecting tubule impairs proton secretion in

18.12 Distinguishing Features of Hyperkalemic (Generalized) Distal Renal Tubular Acidosis (Type 4)

1. Only variant associated with hyperkalemia
2. Collecting duct fails to secrete protons and potassium
3. Aldosterone is insufficient in quantity or activity or intrinsic (genetic) or acquired molecular defect in transport of Na^+, K^+, and H^+
4. Hyperkalemia contributes to acidosis by blunting NH_4^+ production and excretion

18.13 Pathophysiologic Basis of Hyperkalemic Acidosis and Generalized Distal Renal Tubular Acidosis (Type 4)

1. Abnormal CCD–MCD (intrinsic)
2. Primary decrease in mineralocorticoid (extrinsic)
3. Voltage defect—compromises H^+ and K^+ secretion
   a. Abnormal ENaC
   b. Chloride shunt

CCD, cortical collecting duct; MCD, medullary collecting duct.

this segment, it is referred to as a "voltage defect" (Fig. 18.7). Any process inhibiting sodium transport in the CCT would be expected to cause such a defect because translocation of the cation Na^+ from lumen to interstitium is the principal determinant of transepithelial voltage in the CCT. A decrease in negative voltage decreases the electrical gradient K^+ and H^+ secretion by the CCT. The traditional model of such a transport defect is that observed after amiloride administration. Amiloride occupies and interacts with the epithelial sodium channel (ENaC) on the apical membrane of the principal cell of the cortical collecting tubule inhibiting sodium transport, decreasing negative transepithelial voltage, and secondarily inhibiting both K^+ and H^+ secretion (the latter in Type A intercalated cells). Therefore, with a "voltage" lesion, both hyperkalemia and metabolic acidosis may develop. The mechanism for the generation of acidosis and hyperkalemia in patients receiving trimethoprim, pentamidine, and triamterene is similar in mechanism to that observed with amiloride.[55] Specific mutations in genes (SCNN1A, SCNN1B, SCNN1G) that encode the epithelial sodium channel (ENaC) have been shown to cause autosomal recessive pseudohypoaldosteronism type 1.[113] This defect in ENaC impairs Na^+ absorption, reduces transepithelial voltage, and subsequently impairs K^+ and H^+ transport. These mutations, by impairing ENaC and therefore Na^+ absorption, reduce the negative transepithelial voltage in the CCT, and result in a prototypical "voltage defect" in this segment. Therefore, autosomal recessive pseudohypoaldosteronism type 1 (PHA I) represents an example of an inherited "voltage" defect. This information is summarized in Figure 18.7.

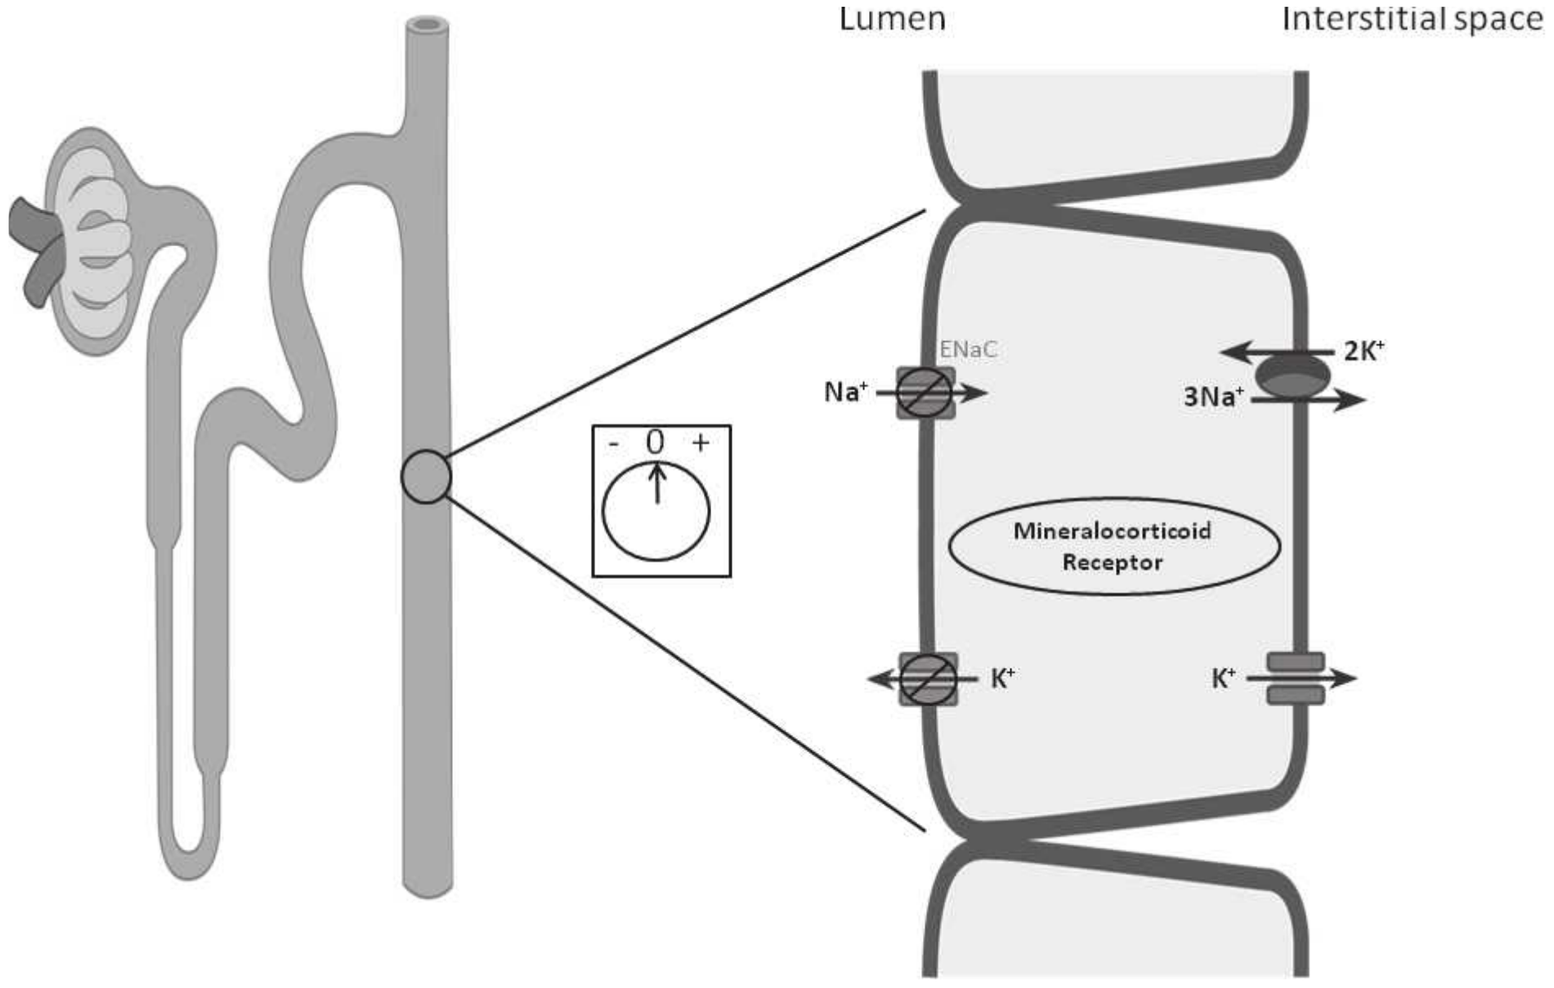

FIGURE 18.7 Model of principal cell in collecting tubule showing voltage defect. Example shows primary loss of function mutation of Na^+ channel (ENaC) or pseudohypoaldosteronism type 1 as example. Loss of function of ENaC causes a decrease in Na^+ absorption and loss of negative transepithelial voltage that secondarily causes decrease in K^+ secretion. Other examples of voltage defects are explained in the text.

Role of Aldosterone Deficiency in Generation of Hyperkalemic Acidosis

Aldosterone enhances the lumen negative transepithelial potential difference in the cortical collecting tubule through upregulation of Na^+ absorption. Initially, aldosterone upregulates ENaC, and subsequently the basolateral Na^+,K^+-ATPase, to stimulate Na^+ absorption, K^+ secretion, and H^+ secretion. Therefore, it is not surprising that aldosterone deficiency would result in the development of hyperkalemia and metabolic acidosis. In contrast to the CCT, aldosterone stimulates potassium and hydrogen ion secretion in the medullary collecting tubule, independent of sodium transport. Therefore, a relative decrease in the amount of aldosterone or decrease in responsiveness of the collecting tubule to aldosterone could result in a reduction in distal sodium absorption which would be expected to impair both potassium and hydrogen ion secretion. Aldosterone also plays a significant role in ammonium absorption and excretion by the inner medullary collecting duct.[57] Selective aldosterone deficiency in animal models has been reported to be associated with impaired ammonium excretion and reduced papillary PCO_2 during bicarbonate loading, verifying a defect in proton secretion. Both of these processes lead to a decrease in proton secretion, favoring the development of metabolic acidosis. The importance of mineralocorticoid in the regulation of net acid excretion has been documented in mineralocorticoid-deficient animals and man.[114] In patients who have undergone adrenalectomy, net acid excretion and plasma total CO_2 decline if mineralocorticoid is selectively discontinued, but increase with the reinitiation of mineralocorticoid.[115] The change in plasma total CO_2 correlated directly, in these studies, with changes in ammonium excretion and, inversely, with corresponding changes in potassium balance.

Role of Hyperkalemia in the Generation of Hyperchloremic Metabolic Acidosis

Hyperkalemia has an independent effect on net acid excretion through inhibition of renal ammoniagenesis. Hyperkalemia is associated, in addition, with a decrease in ammonium transport and, thereby, excretion. This contributes importantly to the development of metabolic acidosis.[58,116] DuBose et al. have shown that hyperkalemia decreases ammonium excretion and production in the proximal tubule.[52,57] Hyperkalemia markedly impairs ammonium absorption in the thick ascending limb, reducing inner medullary concentrations of total ammonia and decreasing secretion of NH_3 into the inner medullary collecting duct.[48,49,52,58] The mechanism for impaired absorption of NH_4^+ in the medullary thick ascending limb of Henle is competition between K^+ and NH_4^+ for the K^+ secretory site on the Na^+-$2Cl^-$-K^+ cotransporter. The importance of hyperkalemia as a cause of metabolic acidosis is underscored by the observation that correction of hyperkalemia is associated with a significant increase in net acid excretion and a parallel correction of the acidosis.

Clinical Examples of Mineralocorticoid Deficiency and Resistance

Hyperkalemic and hyperchloremic metabolic acidosis can occur as a result of one of three abnormalities: (1) deficiency of mineralocorticoid, (2) resistance to mineralocorticoid, or (3) renal tubular dysfunction. The causes of voltage defects (tubular dysfunction) and deficiency or resistance to mineralocorticoid are outlined in Table 18.14. Mineralocorticoid deficiency may occur in concert with general adrenal failure (Addison disease), where there is a decrease in elaboration of both glucocorticoid and mineralocorticoid. Addison disease can be caused by destruction of the adrenal cortex with hemorrhage, infection, invasion by tumors, or autoimmune disease. Patients have hypoglycemia, anorexia, weakness, hyperpigmentation, relative or frank hypotension, and a failure to respond to stress. Renal salt wasting, hyponatremia, hyperkalemia, and metabolic acidosis coexist.[117] Typically, serum aldosterone levels are low and the plasma renin high. Metabolic acidosis occurs because of a decrease in H^+ secretion in the collecting tubule from decreased H^+-ATPase number and function. Hyperkalemia further aggravates the acidosis by depression of ammonium production and excretion.

Selective or isolated hypoaldosteronism can occur in critically ill patients, particularly in the setting of sepsis or cardiogenic shock.[118] Heparin (either low molecular weight or unfractionated heparin), often administered in this setting, impairs aldosterone synthesis as a result of direct toxicity to the zona glomerulosa with direct inhibition of the enzyme aldosterone synthase.[119] Moreover, hypoxia and cytokines may contribute to aldosterone synthesis failure in the critically ill patient.[118,120]

One of the best examples of resistance to mineralocorticoid is autosomal dominant pseudohypoaldosteronism (PHA I). This disorder is clinically less severe than autosomal recessive PHA I (discussed later) and is associated with hyperkalemia, renal salt wasting, metabolic acidosis, elevated renin and aldosterone levels, and hypotension. The autosomal dominant disorder has been shown to be the result of a mutation in the intracellular mineralocorticoid receptor in the collecting tubule.[113] Unlike the autosomal recessive disorder, this defect is not expressed in organs other than the kidney, and becomes less severe with advancing age. Carbenoxolone raises the intracellular concentration of cortisol, overcoming the functional defect in the mutant receptor and improving mineralocorticoid resistance. Because the decrease in mineralocorticoid reduces apical Na^+ absorption and activity of ENaC, transepithelial potential difference declines and K^+ secretion is impaired.[121]

Clinical Examples of Voltage Defects in the Collecting Tubule (Table 18.14)

The prototype for a "voltage" defect is pseudohypoaldosteronism type 1 (PHA I). Most cases of autosomal dominant PHA I link to mutations in the mineralocorticoid receptor (MR). In general, patients with autosomal recessive PHA I

18.14 Generalized Abnormality of Distal Nephron with Hyperkalemia

MINERALOCORTICOID DEFICIENCY

Primary mineralocorticoid deficiency

Combined deficiency of aldosterone, desoxycorticosterone, and cortisol
- Addison disease
- Bilateral adrenalectomy
- Bilateral adrenal destruction
- Hemorrhage or carcinoma

Congenital enzymatic defects
- 21-Hydroxylase deficiency
- 3β-Hydroxy dehydrogenase deficiency
- Desmolase deficiency

Isolated (selective) aldosterone deficiency
- Chronic idiopathic hypoaldosteronism
- Heparin (unfractionated or LMW) in critically ill patient
- Familial hypoaldosteronism
  - Corticosterone methyl oxidase deficiency, types 1 and 2
- Primary zona glomerulosa defect
- Transient hypoaldosteronism of infancy
- Persistent hypotension and/or hypoxemia in critically ill patient

Angiotensin II–converting enzyme inhibition
- Endogenous
- ACE inhibitors and AT_1 receptor antagonists

Secondary mineralocorticoid deficiency

Hyporeninemic hypoaldosteronism
- Diabetic nephropathy
- Tubulointerstitial nephropathies
  - Nephrosclerosis
  - Nonsteroidal anti-inflammatory agents
  - Acquired immunodeficiency syndrome
  - Immunoglobulin M monoclonal gammopathy

MINERALOCORTICOID RESISTANCE

Pseudohypoaldosteronism type 1 (PHAI)—autosomal dominant

RENAL TUBULAR DYSFUNCTION (Voltage Defect)

Pseudohypoaldosteronism type 1 (PHAI)—autosomal recessive

Pseudohypoaldosteronism type 2 (PHAII)—autosomal recessive

Drugs that interfere with Na^+ channel function in CCT
- Amiloride
- Triamterene
- Trimethoprim
- Pentamidine

Calcineurin inhibitors (interfere with Na^+, K^+-ATPase in CCT)
- Cyclosporin A
- Tacrolimus

(continued)

18.14 Generalized Abnormality of Distal Nephron with Hyperkalemia (continued)

Drugs which inhibit aldosterone effect on CCT
- Spironolactone

Disorders associated with tubulointerstitial nephritis and renal insufficiency
- Lupus nephritis
- Methicillin nephrotoxicity
- Obstructive nephropathy
- Kidney transplant rejection
- Sickle cell disease
- Williams syndrome with uric acid nephrolithiasis

ACE, angiotensin-converting enzyme; CCT, cortical collecting tubule; LMW, low molecular weight.

as opposed to autosomal dominant PHA I have a more severe clinical phenotype and do not spontaneously improve during early childhood. Furthermore, given the generalized expression of ENaC in epithelial tissues, autosomal recessive PHA I associates with systemic manifestations, most notably recurrent pulmonary infections.[122–125] Children with autosomal recessive PHA I have severe hyperkalemia and renal salt wasting because of a functional block of sodium transport across the apical membrane through impairment of ENaC, which secondarily prevents potassium secretion and causes hyperkalemia. In addition, the hyperchloremic metabolic acidosis may be severe and is associated with hypotension and marked elevations of plasma renin and aldosterone. These children also present with vomiting, hyponatremia, failure to thrive, and respiratory distress. The latter is related to involvement of ENaC in the alveoli, preventing Na^+ and water absorption in the lungs, and increasing the frequency of infection. Patients with this disease respond to a high salt intake and correction of the hyperkalemia. Unlike the autosomal dominant form, autosomal recessive PHA I persists throughout life and is a more severe disease.

A "voltage defect" with a contrasting phenotype is pseudohypoaldosteronism type II (PHA II), or Gordon syndrome, first described in the 1960s (Table 18.14). This disorder occurs in adults and results in hyperkalemia, hyperchloremic metabolic acidosis, hypertension, mild volume expansion, and suppressed renin and aldosterone levels.[121,126] These patients typically respond to thiazide diuretics, suggesting a disorder of the distal tubule Na^+-Cl^- cotransporter. PHA II is transmitted in an autosomal dominant fashion and is caused by mutations in the WNK1 and WNK4 genes that interact with the Na-Cl cotransporter in the distal tubule, causing a gain of function (loss of degradation) of this transporter and resulting in salt retention and hypertension. The response of these patients to Na_2SO_4 infusion validates the presence of a voltage defect, perhaps as a result of preferential absorption ("shunting") of chloride in the collecting tubule beyond the site of the defect, the distal convoluted tubule.

In addition to inherited voltage defects, there are examples of acquired voltage defects due to drugs or tubulointerstitial disease (Table 18.14).[127,128] Examples of the former include amiloride and the structurally related compounds trimethoprim and pentamidine.[129–131] As discussed previously, this explains the occurrence of hyperkalemic hyperchloremic acidosis in patients receiving higher doses of these agents. Spironolactone and triamterene are more likely to cause hyperkalemia in patients with renal insufficiency or hyporeninemic hypoaldosteronism.[132,133] Those tubulointerstitial diseases, which may be associated with impairment or destruction of collecting duct function, include obstructive uropathy, lupus nephritis, sickle cell nephropathy, analgesic nephropathy, or multiple myeloma.[101,127,134,135]

Hyporeninemic-hypoaldosteronism

In hyporeninemic-hypoaldosteronism, both the metabolic acidosis and the hyperkalemia are out of proportion to the level of reduction in GFR. Many patients have congestive heart failure, diabetic nephropathy or tubulointerstitial renal disease, cardiac arrhythmias, and hypertension. Ammonium excretion is impaired because hyperkalemia inhibits both ammoniagenesis and ammonia/ammonium transport and excretion. Both ammoniagenesis and ammonia excretion improve with correction to normal plasma potassium. Many of these patients have progressive renal disease and at stage 4 or 5 chronic kidney disease develop the typical high anion gap acidosis of renal failure.

Identification and Treatment of Generalized Defect

The first priority in the treatment of hyperkalemic-hyperchloremic metabolic acidosis is identification of the underlying disorder. To this end obtaining a careful dietary and

drug history is critical and can identify unsuspected sources of exogenous K^+ intake. It is also important to identify contributing or precipitating factors that include low urine flow, decreased distal Na^+ delivery, superimposed acute renal failure, hyperglycemia, and hyperosmolality. The distinguishing diagnostic features are summarized in Table 18.12. The workup should consist of an evaluation of K^+ excretion by the (TTKG) or the fractional excretion of potassium, an estimate of renal ammonium excretion (urine anion gap), urine pH, the U-B PCO_2, and evaluation of PRA and aldosterone secretion. Aldosterone secretion, if evaluated, should be obtained under stimulated conditions with dietary salt restriction and/or furosemide-induced volume depletion. Drugs associated with hyperkalemia such as triamterene, spironolactone, amiloride, pentamidine, trimethoprim, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), or K^+ supplements should be discontinued. Salt substitutes and herbal preparations should be avoided and a diet low in potassium emphasized.

The severity of the hyperkalemia is the primary determinant in the decision to treat patients with this disorder and the therapy is summarized in Table 18.15. Patients with combined glucocorticoid and mineralocorticoid deficiency should receive both steroids in replacement dosages. Mineralocorticoids should be avoided in the face of hypertension or congestive heart failure. If supraphysiologic doses of mineralocorticoids are needed, patients should be monitored closely for volume overexpansion, hypertension, and hypokalemia. Effectively reducing the serum potassium with either cation-exchange resin (sodium polystyrene powder, 15 Gm dissolved in water not in sorbitol, daily) or loop diuretics will often improve the metabolic acidosis by increasing ammonium excretion. Volume depletion should be avoided unless the patient is volume overexpanded or hypertensive. Children with PHA I should receive NaCl supplement and adults with PHA II should receive thiazide diuretics. In summary, because hyperkalemia interferes with the kidney's response to metabolic acidosis, treatment consists of correction of hyperkalemia, restoration of euvolemia, alkali therapy, loop diuretics, and dietary potassium restriction. In severe hypoaldosteronism, the effect of loop diuretics can be enhanced by the addition of replacement mineralocorticoids.

18.15 Treatment of Generalized Dysfunction of the Nephron with Hyperkalemia

Alkali therapy
Loop diuretic (furosemide, bumetanide)
Sodium polystyrene sulfonate powder (Kayexalate 15 gm p.o. in water—not Sorbitol—three times a week)
Fludrocortisone (0.1–0.3 mg/day)
Avoid in hypertension, volume expansion, heart failure, chronic kidney disease
Combine with loop diuretic
Avoid drugs associated with hyperkalemia
In pseudohypoaldosteronism type I: add NaCl supplement

p.o., by mouth.

Summary

The diagnostic features and studies to distinguish the various types of RTA are displayed in Table 18.16.

BARTTER SYNDROME AND GITELMAN SYNDROME

Bartter and Gitelman syndromes are autosomal recessive inherited renal tubular transport disorders characterized by salt wasting and relative hypotension. Typical symptoms of both are severe hypokalemia, metabolic alkalosis with hyperaldosteronism, and hypertrophy and hyperplasia of the juxtaglomerular apparatus. Although the two syndromes are similar, Gitelman syndrome is uniquely associated with magnesium deficiency and hypocalciuria.

Both Bartter and Gitelman syndromes are caused by specific genetic mutations associated with salt transporters. Genetic abnormalities causing Bartter syndrome localize to transporters in the thick ascending limb of loop of Henle, whereas, in contrast, the defects in Gitelman syndrome reside in the distal convoluted tubule. There are three different specific types of Bartter syndrome. Type 1 is caused by a mutation of the Na^+-K^+-$2Cl^-$ cotransporter[136]; type 2 by mutations in the apical K^+ channel[137,138]; and type 3 (neonatal) by mutations in the basolateral Cl^- channel[139] (Fig. 18.8A). Gitelman syndrome is caused by mutations in the NaCl cotransporter in the distal tubule[140–142] (Fig. 18.8B). Gitelman syndrome is relatively common, affecting about 1% of the population.

The differential diagnoses for Bartter and Gitelman syndromes include chronic or surreptitious vomiting, laxative or diuretic abuse, or licorice ingestion. Daily treatment with 150 to 300 mEq of potassium along with amiloride, spironolactone, or triamterene is recommended. Although associated with relative hypotension, some patients respond when ACE inhibitors or ARBs are added, but with careful attention to blood pressure.

DISORDERS OF CARBOHYDRATE TRANSPORT

Mechanisms of Carbohydrate Reabsorption

The proximal tubule not only reabsorbs approximately 70% of the salt, bicarbonate, and water, but also all of the glucose and amino acids. The sodium-dependent glucose

18.16 Summary of Diagnostic Studies in Renal Tubular Acidosis

	Type of RTA		
Finding	**Proximal (II)**	**Classical Distal (I)**	**Generalized Distal Dysfunction (IV)**

[a]Except with Amphotericin B.
RTA, renal tubular acidosis; U-B, urine-minus-blood.

cotransporters (SGLT1 and SGLT2) are integral membrane proteins that mediate the transport of glucose across the plasma membrane by secondary active cotransport of glucose molecules and sodium ions. The lumen-to-cell sodium concentration gradient, maintained by the basolateral Na^+,K^+-ATPase, provides the energy for transport of sodium across the apical membrane, augmented by the lumen-negative potential difference in the early proximal tubule (−2 mV). The sodium-glucose transporters localize to the brush-border membranes of S_1 and S_3 segments. Most glucose is reabsorbed in the first 25% of the proximal tubule. Healthy kidneys reabsorb all filtered monosaccharides if their plasma concentrations are normal or low, but if plasma concentrations increase due to disease or a systemic infusion, sugar appears in the urine. A plot of the plasma concentration versus the urinary excretion rate allows the maximum rate of tubular reabsorption (T_{max}) to be obtained.[143]

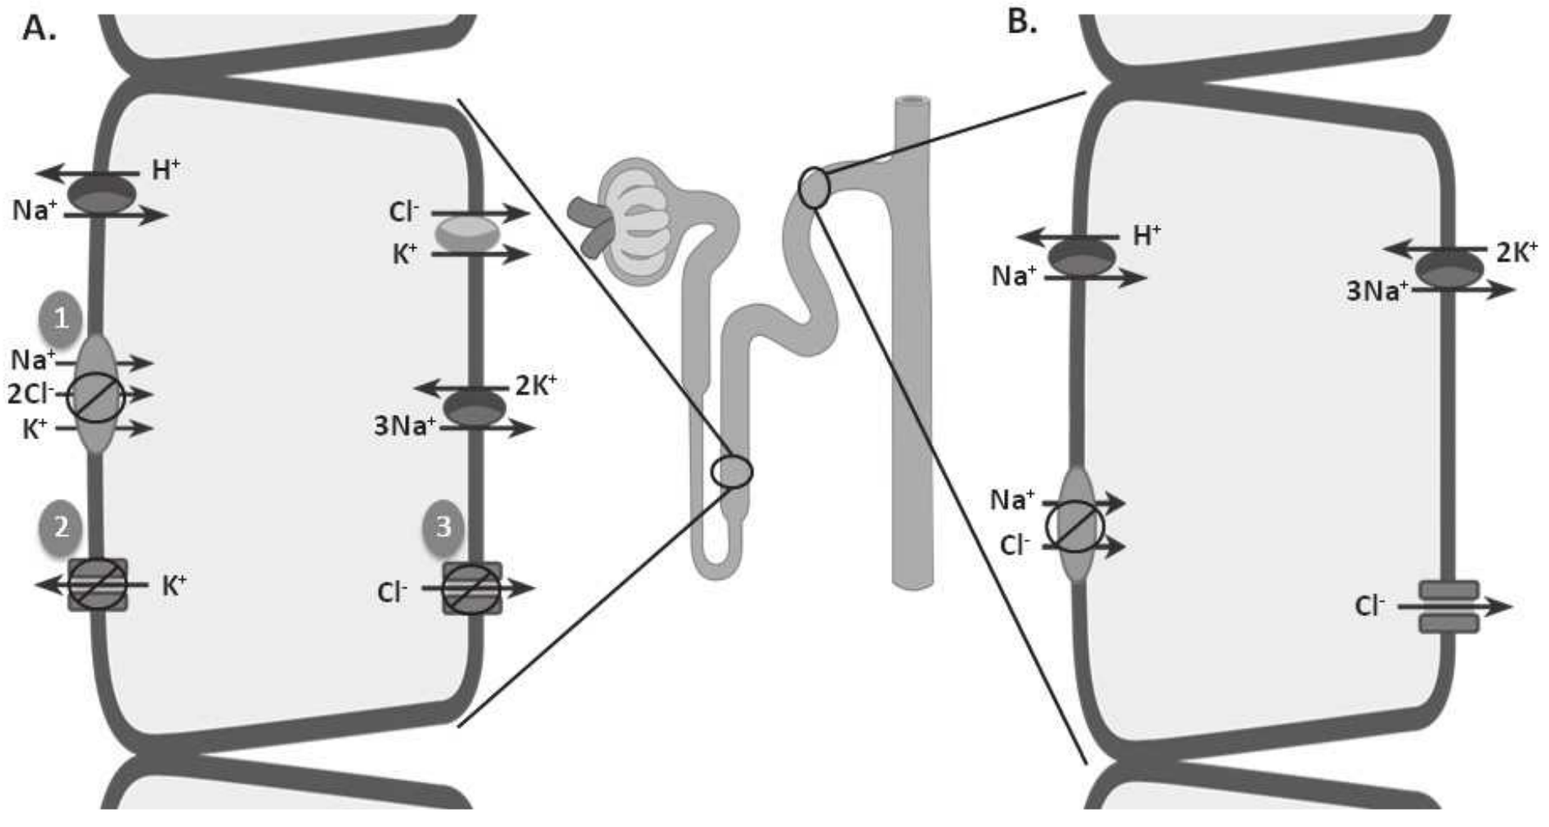

FIGURE 18.8 Inherited solute wasting disorders. **A:** Examples of three types of Bartter syndrome: type 1 Bartter, abnormality of apical Na^+-$2Cl^-$-K^+ tri-transporter; type 2 Bartter, abnormal apical K^+ conductance; and type 3 Bartter, abnormality of basolateral Cl^- channel. **B:** Distal convoluted tubule showing cause of Gitelman syndrome. See text for details.

Primary Renal Glycosuria

Primary renal glycosuria occurs when plasma glucose is normal but urinary glucose excretion is increased. GFR and intestinal absorption of carbohydrates are also normal. Although mechanisms underlying primary renal glucosuria are not fully appreciated, three types (A, B, and O) have been noted, based on glucose titration curves.[144] However, the genetic description of disorders of glucose transport have more recently elucidated the molecular basis for glycosuria.[145]

Congenital defects in SGLT2, located in the apical membrane of the S1 segment in proximal renal tubule cells, lead to a primary renal glucosuria. Patients with this disease have normal blood glucose levels, normal oral tolerance test results, and persistent glucosuria. In the most severe cases, a major portion of the filtered glucose is excreted.

The Fanconi-Bickel syndrome (FBS), a rare autosomal recessive inborn error of metabolism A, is the result of an inherited defect within the SLC2A2 gene and resembles type I glycogen storage disease. Thirty-four different GLUT2 mutations have been reported in 132 patients. Because GLUT2 is the predominant glucose transporter in hepatocytes, pancreatic beta cells, enterocytes, and renal tubular cells, a loss of GLUT2 leads to a typical combination of hepatorenal glycogen accumulation, glucose and galactose intolerance, fasting hypoglycemia, a proximal tubular nephropathy, and severely stunted growth.

The diagnostic criteria for the diagnosis of primary renal glycosuria includes glucosuria without hyperglycemia, which may increase during pregnancy; glucosuria independent of dietary intake, present after an overnight fast; a normal (or flat) glucose tolerance curve in the presence of normal plasma insulin, free fatty acids, and glycosylated hemoglobin; normal renal transport of other sugars; and normal carbohydrate utilization in affected subjects.

Glycosuria of Pregnancy

There are two reasons that glucose T_{max} could decrease during pregnancy: an increased GFR without parallel increases in glucose reabsorption, or a significant inhibition of reabsorption due to volume expansion. Glucose transport tends to normalize approximately 2 months after delivery. It does not appear that women with prenatal glucosuria are at higher risk for developing diabetes mellitus.

Disorders of Amino Acid Transport

Mechanisms of Amino Acid Transport. The kidney filters approximately 70% to 90% of the body's protein each day, mostly as small peptides and amino acids, with about 2% to 3% of amino acids being excreted in the urine and the remaining being reabsorbed by the proximal tubule for recirculation to the body. Sodium-dependent cotransport systems for many of the acidic and neutral amino acids have been identified,[146,147] which are energized by the basolateral Na^+,K^+-ATPase.[148–150] The nutritionally essential amino acids in adults are valine, leucine, isoleucine, threonine, methionine, phenylalanine, lysine, arginine, and histidine (taurine appears to be an essential amino acid for infants). There are at least six separate transport systems for the different types of amino acids: dicarboxylic amino acids glutamate and aspartate; dibasic amino acids lysine, arginine, ornithine, and cystine[36,37]; neutral amino acids glycine, valine, leucine, and isoleucine (and 13 other amino acids[146,151,152]; imino amino acids proline, hydroxyproline, and sarcosine (and other N-methyl amino acids); β-amino acids β-alanine, β-aminoisobutyric acid, β-aminobutyric acid, and taurine[153,154]; and cystine–cysteine.[146,152]

Specific Clinical Diseases Associated with Aminoaciduria. Genetic studies in patients with specific aminoacidurias, and phenotypic observations in knockout mice, have resulted in major contributions to a better understanding of amino acid transport in the kidney. The recognition of changes in individual amino acid levels in urine and plasma of patients with aminoaciduria has been behind much of the recent progress in this field. However, these recent advances, along with changes in nomenclature, have caused some consideration among renal physiologists and nephrologists as to classification, now based on specific solute carrier transporter types. The major classes of disorders include cystinuria A, cystinuria B, cystinuria AB, lysinuria, and Hartnup disease. Urinary amino acid screening has allowed identification of additional asymptomatic aminoacidurias, iminoglycinuria, and dicarboxylic aminoaciduria.[155]

Cystinurias. The overall incidence of cystinuria is approximately 1:7,000 births. Although the most evident consequence of this disease, cystine bladder stones, was first described almost two centuries ago, the proteins responsible were identified only recently. Alexander Garrod placed the clinical findings within the context of disordered amino acid metabolism, but it was not until 50 years ago that cystinuria was proposed to be an inborn error of dibasic amino acid transport. Charles Dent was the first to recognize that not only urinary cystine but also lysine and arginine were constantly elevated in patients with cystinuria.

SLC3A1 (rBAT) was the first protein related to epithelial amino acid transport to be identified. Interacting proteins have been identified as SLC7A9 ($b^{0,+}$AT) and SLC3A1 (rBAT). Both mediate dibasic amino acid and cystine transport across the apical membrane of renal tubule cells. These proteins can be localized to the brush border membranes of proximal tubules. By overexpression of SLC3A1 (rBAT) and SLC7A9 ($b^{0,+}$AT) in MDCK cells, both proteins were shown to colocalize in the apical membrane, whereas without expression of the heavy subunit SLC3A1 (rBAT), the light subunit SLC7A9 ($b^{0,+}$AT) was retained within the cell. Therefore, SLC3A1 (rBAT) is essential for proper cell surface expression of SLC7A9 ($b^{0,+}$AT). Together they exchange dibasic amino acids and cystine from the tubular lumen for intracellular neutral amino acids.

Mutations in either interacting subunit, SLC3A1 (rBAT) or SLC7A9 ($b^{0,+}AT$), cause cystinuria. Cystinuria due to mutations in SLC3A1 is an autosomal recessive trait, whereas mutations in SLC7A9 are autosomal dominant and lead to an abnormal pattern of urinary amino acid excretion in heterozygotes. The initial nomenclature, based on the excretion status of obligate heterozygotes (cystinuria types I, II [non-I], III [non-I]), has been replaced by a classification based on genotype. Accordingly, mutations in SLC3A1 cause cystinuria type A, mutations in SLC7A9 cause cystinuria type B, and mutations in both genes (compound heterozygotes) cause cystinuria type AB. The severity of disease appears similar in cystinuria types A and B. A mouse model develops stones and the overall phenotype resembles type B cystinuria. Animals develop massive hyperexcretion of cystine and dibasic amino acids, and cystine crystalluria, with 40% having cystine calculi in the urinary system. As in humans, oral treatment of this mouse model with D-penicillamine has been shown to reduce the size and number of calculi.[155]

Clinically, cystinuria presents during the second or third decade of life as renal colic and stone disease. Urinary tract obstruction, recurrent infection, and hypertension occur. The disease may progress and may require kidney transplantation. Commonly associated diseases include hyperuricemia, hemophilia, Down syndrome, hypotonia, retinitis pigmentosa, and pancreatitis. The intestinal absorption defects in cystinuria, however, do not appear to impair growth.

The diagnosis may be made with the urinary cyanide-nitroprusside test, in which the urine turns magenta red; characteristic cystine crystals may also be seen on microscopic urinalysis. Ion exchange chromatography reveals excretion of excess cystine and cationic amino acids with normal plasma levels.

Dietary control with low methionine intake and restriction of salt intake are only slightly effective.[156] Alkalinizing the urine to pH 7.5 is of no benefit because urinary cystine concentration is always greater than 0.8 mmol per L in affected subjects. Nevertheless, penicillamine (1 to 2 g per 24 hours) is the treatment of choice for dissolving stones and preventing further formation. The drug, however, may have serious side effects, including nephrotic syndrome, membranous nephropathy, serum sickness, fever, rash, and pancytopenia. As a result, its long-term use is quite limited. The compound α-mercaptoproprionyl glycine has also been used. This drug has a higher redox potential than penicillamine and is said to be less toxic. Even so, proteinuria, membranous glomerulonephritis, fever, rash, and positive antinuclear antibodies have been reported.[157] ACE inhibitors have been used in a few cases with beneficial results.[158] The mechanism of action appears to be related to the increased solubility of a cysteine–captopril complex excreted in the urine. Bladder irrigation using N-acetyl penicillamine, penicillamine, mercaptoproprionyl glycine, or trimethylamine has been attempted with some success. Cases in which the urinary tract is obstructed have been treated with lithotomy. Lithotripsy is of no benefit in this disorder because cystine stones are particularly refractory to extracorporeal shock waves. Use of this approach may result in substantial problems, including hematuria, infection, and renal parenchymal scarring. Fortunately if kidney transplantation is required, the disease does not appear to recur in the allograft.[159]

Lysinuria. The most widely appreciated disorder, lysinuria, is inherited as an autosomal recessive disorder more prevalent in Finland, Italy, and Spain.[159] Homozygotes are intolerant of a protein-rich diet. The mutations causing this autosomal recessive disorder have, in contrast to cystinuria, been identified in SLC7A7, which encodes a protein involved in transport of dibasic amino acids. Prenatal diagnosis is now possible. Patients show signs of failure to thrive, vomiting, hypotonia, and episodes of stupor or coma after consuming high amounts of dietary protein. Additional features include hepatomegaly, hyperammonemia, low blood urea nitrogen levels, and orotic aciduria. Osteoporosis is commonly seen and a severe interstitial lung disease may occur at any time during life. Intestinal absorption of three amino acids (lysine, ornithine, and arginine) is abnormal. Elevations of urinary dibasic amino acids lysine, arginine, and ornithine are diagnostic and more pronounced than in cystinuria; urinary cystine levels, in contrast to those of cystinuria, are almost normal.

Therapy consists of l-citrulline (0.5 mg per g) with dietary protein restriction (1.5 g per kg per day).[160] l-citrulline supplements improve tolerance for protein intake.

Type I hyperdibasic aminoaciduria is also an autosomal recessive disorder. Those affected appear to have an incomplete phenotype and modest aminoaciduria (lysine, ornithine, and arginine). It has a different ethnic distribution from that of the type II disorder in that cases are not clustered in one area. Although homozygotes have no hyperammonemia, mental retardation occasionally is observed.[161]

Iminoglycinuria. Iminoglycinuria is a benign autosomal recessive disorder that presents with elevated urinary glycine, proline, and hydroxyproline. It is important to analyze the fractional excretion of all amino acids to exclude urinary losses due to elevated plasma levels, as occurs in hyperprolinemia, where urine findings can mimic iminoglycinuria. Heterozygotes have glycinuria alone. The defect is thought to reside in the apical membrane amino acid transporter. It has been hypothesized that mutations in multiple genes, such as SLC36A1, SLC6A20, and SLC6A19, could be defective in iminoglycinuria. However, preliminary genetic studies[155] exclude SLC36A and SLC6A20.

Neutral Aminoaciduria (Hartnup Disease). Hartnup disease is one of the best described disorders of amino acid transport.[151] The neutral monocarboxylic amino acids—including tryptophan, phenylalanine, valine, leucine, isoleucine, alanine, serine, histidine, glutamine, asparagine, and threonine—are not absorbed normally and, subsequently, are excreted into the urine and stool in massive quantities. Elevated urinary neutral amino acids are the first means of

diagnosing the disorder, and must be differentiated from generalized aminoaciduria, the hallmark feature of the Fanconi syndrome.

The disorder occurs with an estimated incidence of 1 in 20,000 live births, but is multifactorial and depends on both diet and environment. Patients can present with signs and symptoms of pellagra (including light-sensitive dermatitis), intermittent cerebellar ataxia, and psychosislike symptoms. These symptoms are assumed to be the result of niacin deficiency, because tryptophan is a precursor of niacin and serotonin.

Mutations in SLC6A19, encoding the neutral amino acid transporter B^0AT1, which mediates neutral amino acid transport from the luminal compartment into the cells, are causative for autosomal recessive Hartnup disease. Therefore, a defect exists in the transporter(s) for the $^{\alpha}$-amino acids and the neutral amino acids in both the brush border of the renal tubule and the jejunum.

Treatment includes increasing protein intake and providing niacin (40 to 100 mg per day) to prevent or treat pellagralike symptoms.

Additional resources are available for the reader interested in a more in depth review of the genetic disorders of amino acid transporters in mammalian cells.[155,159,162–164]

CHAPTER

19

Urinary Tract Obstruction and Reflux Nephropathy

Ryan B. Pickens • Edward D. Kim

URINARY TRACT OBSTRUCTION

Introduction

Urinary tract obstruction is a common problem encountered by nephrologists, urologists, primary care physicians, hospitalists, and emergency medicine physicians. Obstruction can occur at any point in the urinary tract from the kidneys to the urethral meatus. It may develop secondary to calculi, tumors, strictures, anatomic abnormalities, or functional abnormalities.

Functionally, urinary tract obstruction can be divided into upper and lower urinary tract etiologies. The upper tract consists of the kidneys, the ureteropelvic junction (UPJ), ureters, and the ureterovesical junction (UVJ). The lower urinary tract consists of the bladder, the bladder neck, the urethra, the urethral meatus, and, in male patients, the prostatic urethra. Each entity has its own causes of urinary tract obstruction along with its own set of symptoms and treatments to relieve obstruction.

Obstructive uropathy can result in pain, urinary tract infection (UTI), a loss of renal function, sepsis, or death. Thus, suspected cases of urinary tract obstruction merit a consultation with a specialist for an evaluation. Because long-term obstruction can lead to irreversible damage to the function of the nephron, early detection is essential to preserving renal function. The principles of treatment are identification and a relief of the obstruction.

Incidence

The incidence of hydronephrosis reported by Bell[1] in a series of 32,360 autopsies was 3.8% (3.9% in males, 3.6% in females). The incidence of clinical manifestations of obstructive uropathy prior to death was not reported, and it is likely that hydronephrosis was an incidental autopsy finding in many of these patients. The incidence of hydronephrosis at autopsy is somewhat lower in children than in adults, at 2% in one series of 16,000 autopsies.[2] Over 80% of children with hydronephrosis at autopsy were less than 1 year old with the balance of childhood cases being distributed uniformly through the childhood years. In women, hydronephrosis is more likely to occur between the ages of 30 to 70 years secondary to pregnancy and gynecologic malignancies. In men, hydronephrosis is most likely to occur after the age of 60 secondary to prostatic obstruction from benign prostatic hyperplasia.[3]

Etiology

Urinary tract obstruction impedes the flow of urine from the kidney to the urethral meatus. This obstruction causes distention of the urinary tract proximal to the point of obstruction. This distention is caused by the increase in intraluminal pressure and can result in pain, which may be the first sign of obstruction. Distortion of the urinary tract and renal failure can develop from obstruction. The severity of damage depends on the degree and duration of obstruction. When the urinary tract is obstructed, urinary stasis develops predisposing the patient to acute or chronic renal failure, UTI, sepsis, or death.

Upper Urinary Tract Obstruction

Obstruction of the upper urinary tract can occur anywhere from the kidney down to the ureterovesical junction. Certain points along this path are more susceptible to obstruction. There are three main points of anatomic narrowing that urine must pass to get from the upper urinary tract to the lower urinary tract. These points are the ureteropelvic junction, the crossing of the ureter over the area of the pelvic brim as it runs anterior to the common iliac vessels, and the ureterovesical junction. The narrowest point among these three is the ureterovesical junction. The bladder itself can also cause a functional obstruction to the upper tract in cases of neurogenic bladder or severe bladder outlet obstruction.

The most common causes of upper tract obstruction are listed in Table 19.1. Intraluminal obstruction is most commonly caused by calculi, blood clots, tumors, or sloughed papilla. These obstructions tend to be acute in nature, leading to symptoms of severe renal colic with flank pain, hematuria, nausea, vomiting, and fever. Ureteral strictures tend to develop over time, causing chronic obstruction and renal atrophy. They can be caused by stone disease, cancer, maldevelopment, and iatrogenic injuries from ureteroscopy.

19.1 Urinary Tract Obstruction

Types of Upper Urinary Tract Obstruction	Types of Lower Urinary Tract Obstruction
UPJ obstruction	BPH
Renal/ureteral calculi	Urethral stricture
Renal or urothelial cancer	Posterior urethral valves
Ureteral stricture	Prostate cancer
UVJ obstruction	Bladder cancer
Fibroepithelial polyp	Meatal stenosis
Infindibular stenosis	Prolapsing ureterocele
Retroperitoneal fibrosis	Bladder/urethral calculi
Pelvic lipotomasis	Foreign body
Retrocaval ureter	Bladder neck contracture
Retro-ovarian vein syndrome	Pelvic organ prolapse
Lower pole crossing vessel	
Retroperitoneal/pelvic mass	
Ureterocele/ectopic ureter	
Abdominal aorta aneurysm	

UPJ, ureteropelvic junction; BPH, benign prostatic hyperplasia; UVJ, ureterovesical junction.

In female patients, an additional area of narrowing can occur as the distal ureter crosses posterior to the pelvic blood vessels and the broad ligament in the posterior pelvis. Women may also experience urinary tract obstruction when the ureters become externally compressed by pelvic tumors or by locally advanced gynecologic malignancies. In older women, a severe prolapse of the pelvic organs, such as the bladder (cystocele) or uterus (procidentia), can lead to urinary tract obstruction. In younger women, pregnancy can cause urinary tract obstruction secondary to ureteral obstruction from the gravid uterus. Gynecologic malignancies must always be considered when upper tract obstruction is present.

Extrinsic causes of upper urinary tract obstruction are less common but can still cause significant obstruction by applying pressure to the urinary tract or by impairing ureteral peristalsis. A lower pole vessel arising from the aorta, known as a crossing vessel, can cause an obstruction to the UPJ or the proximal ureter, which can lead to significant renal atrophy or failure of that kidney. Abdominal aortic aneurysms and common iliac artery aneurysms have also been implicated in causing ureteral obstruction. Vascular graft placement has been shown to cause hydronephrosis in up to 10% to 20% of patients from a mechanical obstruction of the ureter, which may or may not resolve spontaneously.[3]

A retrocaval ureter caused by the persistence of the posterior subcardinal vein in utero causes obstruction by coursing the ureter behind the inferior vena cava, which in turn causes an obstruction. A majority of these cases happen on the right side with a male predominance. Most patients become symptomatic in the third or fourth decade of life.[3]

Retroperitoneal fibrosis can cause unilateral or bilateral ureteral obstruction by trapping the ureters in the fibrotic tissue. This trapping inhibits ureteral peristalsis, thus impeding the flow of urine. Grossly, retroperitoneal fibrosis can appear as fibrosis, a whitish plaque surrounding the retroperitoneal structures, including the ureters. An underlying malignancy can be the cause in 8% to 10% of such cases.[3]

In children, an obstruction may be more commonly due to a ureteropelvic junction or a ureterovesical junction

obstruction, a ureterocele, an ectopic ureter, or an obstructed megaureter. Prenatal screening with ultrasonography is important and vital for the early detection of an obstruction. In addition, children with new onset incontinence or UTI need a workup because they may also have some type of urinary tract obstruction.

Lower Urinary Tract Obstruction

A lower urinary tract obstruction can occur anywhere from the bladder to the urethral meatus. A good history and physical examination can help delineate an upper from a lower urinary tract obstruction in a majority of patients. In older men, the most common cause of obstruction is benign prostatic hyperplasia (BPH), which causes growth of prostatic tissue into the prostatic urethra. This causes the mechanical obstruction of urine flow from the bladder to the distal urethra. Symptoms of BPH can include the frequency of urination, an urgency of urination, increasing nocturia, slow stream, postvoid dribbling, incontinence, or an inability to void. In younger boys, posterior urethral valves can cause significant obstruction.

Urethral or bladder neck strictures can cause a mechanical obstruction to the flow of urine from the bladder to the meatus, which usually results in severe lower urinary tract symptoms or an inability to void. These strictures can be developmental in nature as well as infectious or iatrogenic. Prior prostate surgery can also lead to bladder neck contractures or the regrowth of prostate tissue, which can lead to obstructive symptoms or an inability to void.

Clinical Syndromes of Urinary Tract Obstruction

The clinical presentation of urinary tract obstruction varies with the location, duration, degree of obstruction, and the patients themselves. A thorough history and physical examination is key in the patient evaluation. An upper urinary tract obstruction (kidney, ureter) can manifest as flank pain, ipsilateral back pain, ipsilateral groin pain, or no pain at all. Nausea and vomiting are also common and usually occur in acute obstruction. Chronic obstruction is usually indolent and may be asymptomatic. When infection is present, the patient may experience fever, chills, and/or dysuria. Hematuria may or may not be present. When a bilateral obstruction or a unilateral obstruction in a solitary kidney is severe and renal failure exists, a uremia can be present in the patient, as well as anuria. Symptoms of uremia can include weakness, peripheral edema, mental status changes, and pallor. If hydronephrosis is severe, the kidney may be palpable on a physical examination, especially in children. In cases that involve an infectious process, costovertebral angle tenderness may indicate pyelonephritis. Pain from an obstruction of a stone in the ureter will manifest as waxing and waning severe pain. During these pain episodes, the patient will often be found rolling around in bed unable to get comfortable. In contrast, a patient with peritonitis would lie very still and not move.

Lower urinary tract obstruction (bladder, urethra) can manifest as voiding dysfunction such as urgency, frequency, nocturia, incontinence, decrease in the force of stream, hesitancy, postvoid dribbling, and a sensation of incomplete emptying. Suprapubic pain or a palpable bladder indicates urinary retention in some cases. An infection may be present, and patients may experience dysuria. Hematuria may be present with or without infection. Gross hematuria may indicate the presence of a tumor; stone; infection; blood clot; bleeding vessel in the kidney, ureter, bladder, prostate, or urethra; or a foreign body present within the lower or upper urinary tract.

A digital rectal examination can reveal prostate enlargement, a normal-sized prostate, or inflammation suggestive of prostatitis. A urethral stricture often requires a cystoscopy for diagnosis. A urethral meatal stenosis is usually apparent on a physical examination. Patients with a urethral stricture may report a history of trauma, instrumentation, radiation to the pelvis, or a sexually transmitted disease. They may also experience a split urinary stream. In women, the presence of a uterine or bladder prolapse can be visualized on a pelvic examination. A urethral diverticulum can also be palpated on a physical examination.

Indications to treat a patient with urinary obstruction include a patient with bilateral complete obstruction; any type of obstruction in a solitary kidney; an obstruction causing fever, infection, or both; or a renal failure needs immediate attention by a trained physician. Patients with pain that is uncontrolled with oral pain medications or persistent nausea and/or vomiting, which causes dehydration, also need immediate medical attention as well as hospital admission.

In addition, patients may also present with sequelae of urinary tract obstruction such as renal cortical atrophy, hydronephrosis, kidney failure, polycythemia, hypertension, bladder or renal calculi, UTI or sepsis, or urinary ascites.

Hydronephrosis, Renal Cortical Atrophy, and Renal Failure

The volume of the unobstructed collecting system of a kidney is between 5 to 10 mL. Once a kidney or ureter becomes obstructed, the proximal collecting system will become dilated. Chronic urinary obstruction can lead to massive dilation. With this dilation, an increase in intraluminal pressure can occur proximal to the obstruction. This pressure and dilation will eventually affect the medulla of the kidney, with increasing pressure in the tubules of the cortex of the kidney causing cortical thinning and atrophy. In children, this can happen at an accelerated rate with minimal dilation or symptoms, so prompt management is required.

Although hydronephrosis is a strong sign of urinary tract obstruction, a renal cortical atrophy of the kidney is what leads to acute and chronic renal failure. Three mechanisms

have been proposed as to why hydronephrosis leads to renal failure. The first is pressure atrophy due to the rise of intraluminal pressure proximal to the obstruction, leading to damage to the cortex of the kidney. The second is an intrarenal reflux, most commonly seen in children with vesicoureteral reflux, which is the reflux of urine into the ureters and kidneys from the bladder during micturition due to insufficient tunnel length of the intravesical portion of the ureters, causing the ureters to be open during a bladder contraction. This reflux can cause damage to both the medulla and cortex of the kidney, especially if the urine is infected.[4,5] The third cause is ischemia due to a lack of renal blood flow. This can be caused by a massive renal pelvis impeding blood flow through the renal hilum. A chronic obstruction also can lead to decreased renal blood flow, which can lead to ischemic atrophy of the kidney.

Urinary Tract Infection Associated with Obstruction

A UTI can be a serious or even a fatal complication of urinary tract obstruction. The stasis of urine behind the obstruction provides a perfect medium for bacteria to proliferate. The symptoms of a UTI depend on the location and severity of the infection. Acute pyelonephritis will usually present with fever and ipsilateral flank or back pain and costovertebral angle tenderness, whereas acute cystitis or urethritis will present with suprapubic tenderness, dysuria, and increased frequency or urgency.

The main goal of treating a UTI with urinary tract obstruction is to relieve the obstruction if possible and place the patient on empiric antibiotics while the culture is pending. Upper urinary tract obstruction often requires ureteral stenting and, less frequently, nephrostomy tube placement. Lower urinary tract obstruction typically requires Foley catheter placement. The urine culture can be negative if the sample is taken distal to the obstruction. If the patient continues to have fevers 48 hours after appropriate antibiotics are started, the patient should undergo repeat imaging.

Urolithiasis

Urinary tract calculi are a common cause of obstruction in the upper urinary tract (Fig. 19.1). Ureteral calculi can obstruct the ureter and may require surgical management if medical expulsive therapy is unsuccessful or not advisable. In the absence of infection, conservative management for a patient with a ureteral stone smaller than 5 mm is appropriate as there is a high likelihood of stone passage.[3] Ureteral stones larger than 5 mm are unlikely to pass spontaneously and may require earlier surgical intervention.

Complicated upper urinary tract calculi are often struvite (magnesium ammonium phosphate–calcium carbonate) and result from the association of urinary infection with urea-splitting bacteria. The current management of these stones is an aggressive surgical approach. The American Urological Association (AUA) guidelines strongly recommend endoscopic approaches for these stones to remove all stone burden within the collecting system.[3] These stones have a natural tendency to reoccur if all stone burden is not removed or if the infection causing the stones is not eradicated.[3]

FIGURE 19.1 An axial computed tomography image of a known cystine stone former showing bilateral lower pole stones and a stone within the patient's left proximal ureter.

Hypertension Associated with Urinary Tract Obstruction

In urinary tract obstruction, hypertension may develop for many reasons, including extracellular fluid (ECF) volume expansion, increased renin secretion, or decreased synthesis of prostaglandins. After the relief of bilateral obstruction, volume overload from fluid resuscitation may result in temporary hypertension.

A unilateral urinary tract obstruction (UUO) has been proven as a cause of temporary hypertension. The relief of temporary hypertension and the return of normal renal vein renin levels has been shown with the removal of upper tract unilateral obstruction compared to the obstructed kidney.[5–7] This sequence resembles the hypertension associated with unilateral renal artery stenosis both in rats and humans. Indeed, ureteral occlusion does cause an acute increase in renin release from the obstructed kidney.[8,9]

PATHOPHYSIOLOGY OF URINARY TRACT OBSTRUCTION

The aforementioned clinical syndromes also influence the pathophysiology of obstructive uropathy. Specifically, the age of the patient and level of obstruction are important, as well as the severity and duration of obstruction and the presence or absence of complications such as infection or sepsis.

The effects of obstruction on renal function may be discussed by considering the functions of the kidney, including renal blood flow (RBF), glomerular filtration rate (GFR), and tubular function. The endocrine–metabolic aspects of renal function must be considered, particularly the renin–angiotensin and prostaglandin systems.

Hydrodynamics in the Urinary Tract

Under normal conditions, the propulsion of urine from the kidney to the bladder under normal conditions is the result of three factors: (1) hydrostatic pressure, (2) ureteral and pelvic peristalsis, and (3) the rate of urine flow.[10,11] The urinary collecting system is lined by a transitional epithelium and surrounded by circular and longitudinal layers of smooth muscle. Action potentials that originate in smooth muscle cells of the minor calyx in the renal pelvis are conducted along the pelvis and down the ureter. The urine enters the pelvis and the proximal ureter in a passive state, but the presence of urine in the ureter causes peristalsis of the ureteral wall. Dilation of the ureter clearly interferes with this process. The nature of normal ureteral peristalsis also prevents retrograde transmission of the pressures generated during coaptation (10 to 25 mm Hg) to the renal pelvis, and renal pelvic pressures seldom rise above 4 mm Hg.[10]

After acute obstruction, smooth muscle fibers increase in tension within the urinary tract in response to the increase in pressure by contracting. With persistent obstruction, tension may decrease as the smooth muscle of the ureteric wall contracts with less force, and dilation of the wall continues. With a superimposed urinary infection, as often occurs in chronic obstruction, the loss of muscle tone is even more dramatic and progressive dilation occurs with no further increase or decrease in wall tension.[12]

Evidence shows that even with a completely obstructed kidney, filtration at the level of the glomeruli does not stop. Urine may escape through the walls of the collecting system, known as forniceal extravasation, and can relieve pressure within the collecting system. In addition to renal tubular reabsorption, urine may be reabsorbed directly across the walls of the renal pelvis through the lymphatics (pyelolymphatic reflux) or the renal venous system (pyelovenous reflux). The lymphatic flow from the kidneys is increased markedly during acute and chronic obstruction. This is most likely due to increased pressure within the venous system of the kidney rather than to urine reabsorbed from the renal pelvis. [13]

Changes in Intrarenal Pressure, Glomerular Filtration, and Renal Hemodynamics

The factors determining the fall in GFR during obstructive uropathy have been clarified by micropuncture studies of glomerular dynamics in experimental animals. Changes in intratubular pressure including stop-flow pressure, which represents glomerular filtration pressure, have provided important insight on the pathophysiology of obstructive nephropathy after unilateral (UUO) and bilateral ureteral obstruction (BUO).

Glomerular filtration may be expressed by the formula: $GFR = K_f(P_{GC} - [P_T + \pi_{GS}])$, where K_f is the glomerular ultrafiltration coefficient, P_{GC} is the glomerular capillary pressure, P_T is the intratubular pressure, and π_{GC} is the mean oncotic pressure along the glomerular capillary. δP is the difference between P_{GC} and P_T and represents the pressure gradient across the glomerular capillary wall. An increase in P_T without a concomitant increase in P_{GC} will result in a decrease in δP, the driving force for filtration.[3] Glomerular filtration also depends on the rate of blood flow entering the glomerular capillary. A decrease in glomerular blood flow during obstructive uropathy will decrease GFR because the rate at which capillary oncotic pressure rises is accelerated when a given volume of filtrate is removed from a smaller volume of blood. Both glomerular blood flow and hydrostatic pressure depend on renal vascular resistance, which is largely divided between two resistance segments—the preglomerular segment (afferent arteriole) and the postglomerular segment (efferent glomerular arteriole). Peritubular capillaries may also provide a postglomerular vascular resistance in urinary tract obstruction.

During Obstruction

After either a unilateral or bilateral ureteral obstruction, renal blood flow increases significantly (15% to 25%) in the first 1 to 2 hours and is accompanied by an increase in P_T. This decrease in renal vascular resistance immediately after a complete ureteral obstruction is probably secondary to the synthesis and release of vasodilator prostaglandin (PG; see the following paragraphs). With persisting unilateral or bilateral ureteral obstruction, renal blood flow progressively decreases to 40% to 50% of normal levels by 24 hours.[14,15] GFR is more markedly reduced than renal blood flow; that is, filtration fraction is low, and GFR is 20% to 30% of normal levels in both UUO and BUO obstruction after 24 hours.[16,17] However, the site of changes in intrarenal vascular resistance and, therefore, the mechanisms responsible for the decrease in GFR differ between UUO and BUO (Table 19.2).

After an acute UUO, there is an immediate increase in intrapelvic and proximal tubular hydrostatic pressure, the severity of which depends on the diuretic state of the animal.[18] Despite this increase in intratubular pressure, the GFR in surface nephrons is about 80% of normal because of an increase in glomerular capillary hydrostatic pressure and glomerular plasma flow secondary to afferent arteriolar dilation and decreased renal vascular resistance.[19] As unilateral obstruction persists, progressive vasoconstriction and a decrease in nephron filtration rate develop within about 4 hours. By 24 hours, surface nephron GFR is 30% of normal because of a decrease in glomerular capillary pressure and plasma flow associated with an increase in renal vascular resistance, presumably at the level of the afferent arteriole.[16] Proximal intratubular pressure is now normal rather than increased as during the first few hours of obstruction.[14,16,20–22]

During acute BUO, proximal tubular hydrostatic pressure increases to a higher level than after unilateral obstruction

19.2 Comparison of Changes in Hemodynamics and Filtration Dynamics in Complete Unilateral and Bilateral Ureteral Obstruction

	Unilateral Ureteral Obstruction			Bilateral Ureteral Obstruction		
	During			During		
	1–2 hr	18–24 hr	After	1–2 hr	18–24 hr	After
RBF	↑	↓	↓	↑	↓	↓
P_T	↑	N	N	↑↑	↑	N
GFR	↓	↓↓	↓↓	↓	↓↓	↓↓
GPF	↑	↓	↓	↑	N	↓
P_{GC}	↑	↓	↓	↑	N	↓

RBF, renal blood flow; P_T, proximal tubular pressure; GFR, glomerular filtration rate; GPF, glomerular plasma flow; P_{GC}, glomerular capillary pressure; ↑, increase; ↓, decrease; N, normal.

and, in sharp contrast to unilateral obstruction, intrarenal pressure remains twice the normal level after 24 hours. Renal blood flow changes are similar to unilateral obstruction.[15,23,24] The surface nephron GFR after 24 hours is reduced to about 30% of normal levels in BUO as in UUO. However, the decrease in GFR in BUO is because of a persistent increase in proximal tubular hydrostatic pressure, whereas glomerular capillary pressure and plasma flow are normal.[17] The predominant site of increased vascular resistance thus appears to be the efferent arteriole during a bilateral obstruction, compared to the afferent arteriole with a unilateral obstruction.

In addition to increasing renal blood flow for several hours and increasing pressures in the ureter and renal tubules, an acute ureteral obstruction has hemodynamic effects.[25] Several effects have been observed and include blunted vasoconstrictor responses and decreased autoregulation of renal blood flow when ureteral pressure exceeds 75 mm Hg. RBF is directly related to arterial pressure, and vasodilator effects may be shifted due to increased levels of renin being released from the obstructed kidney.[26–30]

During a chronic complete ureteral obstruction, renal blood flow progressively decreases. After 1 day of a complete obstruction, there is a 40% to 50% decrease in renal blood flow to the kidneys. Prolonged UUO is associated with a further decrease in blood flow to 30% at 6 days, 20% at 2 weeks, and 12% at 8 weeks.[31] The glomerular filtration rate depends on the fluid status of the patient and may not change during a chronic partial obstruction.

After Relief of Obstruction

At 1 day postrelief of a unilateral obstruction, GFR remains reduced and renal vascular resistance is increased. However, they soon normalize after 1 week.[16,21,22] Following the relief of bilateral obstruction for 24 hours, intratubular pressure decreases from elevated levels to normal, but glomerular capillary pressure and plasma flow also decrease because of afferent arteriolar vasoconstriction, resulting in a persistent decrease in GFR.[17,24,27,32,33] Afferent arteriolar pressures appear to keep renal blood flow and glomerular filtration similar the first day after relief of the obstruction.

GFR recovery is dependent on both the duration and the severity of the obstruction. Studies in dogs have looked at reversible factors in the recovery of GFR.[34,35] The maximum GFR retained after obstruction of 7 days' duration was about two-thirds of the GFR before obstruction. When the duration of obstruction was 1 month, the GFR returned to only 20% of its original function. In general, the maximal degree of recovery was observed within 2 to 4 weeks after release of the obstruction.[34,35]

Nephron function after recovery from an obstruction is not uniform throughout the kidney. There is a decrease in the functioning juxtamedullary nephrons in the superficial cortex of rats after 1 day of UUO.[21] One study showed an 85% recovery of the whole obstructed kidney and 100% function in the contralateral nonobstructed kidney after 2 weeks with a return to normal GFR.[36] The single-nephron GFR of functioning superficial and juxtamedullary nephrons was higher postobstruction than in the contralateral normal kidney.

The findings of function recovery after an obstruction have also been observed in humans, but the number of supporting clinical studies is limited to children with congenital lesions. These studies have shown that the earlier the relief of obstruction, the greater return in GFR during follow-up.[37,38]

Mechanisms of Changes in Glomerular Filtration Rates and Renal Hemodynamics

Changes in renal hemodynamics and GFR in obstructive nephropathy are of interest because of their clinical significance. Nishikawa et al.[39] demonstrated increased PG synthesis in the hydronephrotic isolated perfused kidney, which leads to changes within the kidney on a metabolic and hemodynamic level. Vasodilator and vasoconstrictor PGs have been studied in relation to the functional changes of urinary tract obstruction with respect to renal hemodynamics.

The early hemodynamic consequences of acute ureteral obstruction are blunted or prevented by the inhibition of PG synthesis after indomethacin. This was studied by giving it prior to obstruction, then measuring intraureteral pressure of the affected kidney.[40] The studies also found decreases in glomerular capillary pressures and proximal tubular pressure with its administration.[40–44] The increase in RBF beginning immediately after UUO is prevented by indomethacin or meclofenamate and a similar effect is seen on the vasodilatation that follows BUO.[40–44,46,47] The impairment of autoregulation that is seen in the kidney with ureteral obstruction is prevented by indomethacin, and normal autoregulation of renal blood flow with changes in arterial pressure is restored in the obstructed kidney.[44] A recent study in 2010 showed that Cox-2 inhibition led to decreased intrarenal levels of prostaglandins in bilateral ureteral obstruction with concomitant ureteral relaxation and decreased contractility in rats.[48]

Two vasoconstrictors, TXA_2 and Ang II, play a major role in the decrease in renal plasma flow per nephron and the decline in single-nephron GFR seen following ureteral obstruction.[47] Both TXA_2[49] and Ang II[50] are able to contract mesangial cells in culture and reduce the glomerular capillary area available for filtration, which leads to a decrease in GFR. Rats pretreated with angiotensin-converting enzyme (ACE) inhibitors and thromboxane synthesis inhibitors before ureteral obstruction were observed not to show a decline in renal function.[51]

The Renin–Angiotensin System

Maximal renin secretion into the renal veins has been observed shortly after ureteral obstruction due to afferent arteriole dilatation associated with the aforementioned postobstructive renal hemodynamics.[52,53] This secretion has been shown to be completely halted by the preobstruction administration of cyclooxygenase inhibitors, leading to the conclusion that renal cortical prostaglandins may act as a strong stimulus for renin secretion.[54,55]

Angiotensin II plays a central role in the modulation of hemodynamic changes following a ureteral obstruction. The preobstruction administration of captopril[56,57] and enalapril[57] appear to be highly effective in ameliorating the decline in GFR and renal plasma flow in response to a ureteral obstruction.[56] Rising levels of angiotensin II also can lead to tubulointerstitial fibrosis during an obstruction due to increased levels of tumor necrosis factor alpha (TNF-α) within the first few hours of an obstruction. This cascade of events can lead to tubular cell apoptosis.[3]

Postobstructive Diuresis

During acute partial UUO, there is a significant decrease in sodium, potassium, and solute excretion with a decrease in urine sodium concentration and an increase in urine osmolality.[58] This is due to the increase in both sodium and water reabsorption within the tubules during a partial obstruction,[58] which had first been thought to be due to a decline in GFR seen with obstruction.[49,59] This reverse phenomenon seen with increased blood flow and increased reabsorption of sodium with the juxtaglomerular cortical nephrons is not expected and appears not to be due to renal nerve activity.[60,61]

During chronic partial obstruction, the gradual decrease in GFR is accompanied by an increase in the fractional excretion of filtered sodium, thus indicating decreased tubular reabsorption. A micropuncture of surface nephrons in chronic partial UUO or of a solitary kidney with a partial obstruction in the rat indicates that the increased fractional excretion of sodium is due to decreased reabsorption in the distal tubule or the collecting duct of the nephron.[62]

After the relief of chronic partial UUO in humans, there is no increase in absolute sodium and water excretion from the hydronephrotic kidney, although a decreased concentrating ability and an increased fractional excretion of sodium are observed.[63] Other factors, such as volume expansion or a further reduction in functioning nephron mass with uremia, are necessary to cause an increase in salt and water excretion (postobstructive diuresis) following the relief of an obstruction.

After the relief of a complete obstruction of both kidneys or a solitary kidney, there is a prolonged diuresis due to massive losses of water, sodium, and other solutes. A single study showed urine output can equal one-half of the GFR, indicating a dramatic decrease in the reabsorptive ability of the nephron.[64] If not replaced, such losses can lead to severe hypovolemia and life-threatening electrolyte imbalance due to significant losses in sodium and water from an inability to reabsorb them in the nephron.[65,67–70] However, a brisk diuresis following the relief of a urinary tract obstruction may also be physiologically appropriate or even iatrogenic rather than an indicator of tubular malfunction. The degree of fluid replacement in a given case will depend on the mechanism involved. Salt diuresis due to ECF expansion can lead to hypervolemia and an increase in atrial natriuretic peptide (ANP) levels, stimulating a diuresis after the relief of the obstruction. This can be continued after the relief of an obstruction iatrogenically due to physicians keeping up with urine output during the diuresis with intravenous fluids that maintain a high ECF volume. Another factor could be the amount of retained urea within the bloodstream and nephrons that act as an osmotic diureticlike mannitol,[65,67,71] leading to natriuresis. Recovery of GFR is dependent on the duration of obstruction and will dictate the length of postobstructive diuresis.[72]

Impaired Urinary-Concentrating Ability

A well documented feature of obstructive uropathy is the loss of the ability to concentrate urine. One exception is during an acute partial obstruction due to the increase in renal tubular absorption.[73] A recent relief of an obstruction or chronic obstruction has been well documented to show a decrease in renal concentration ability.[74,75] Patients with a marked impairment may present with nephrogenic diabetes insipidus and may demonstrate polyuria and persistently hypotonic urine.[76–79] Hypernatremia and severe dehydration can develop if fluid intake is not adequate.[80] The distal portions of the nephrons, particularly the juxtamedullary nephrons, are the major sites affected.[81,82] Aquaporins are a family of membrane water channels. Aquaporin-2 (AQP2) is predominantly found in the cytoplasm apical domain of the collecting duct principal cells. Berlyne and colleagues[83,84] report that AQP2 expression is decreased in the setting of bilateral or unilateral obstruction. The reduction in aquaporin expression may explain the postobstructive polyuria and the impairment in urinary-concentrating capacity found in bilateral ureteral obstruction due to a decrease in water reabsorption.

Recovery of Tubular Function after Obstruction

Although the acute effects of relief of a ureteral obstruction are well described, the long-term effects are less known. Studies after the release of a UUO after 24 hours in rats revealed that abnormalities of tubular function persist beyond a time (14 days) when the whole kidney GFR had returned to normal.[36]

DIAGNOSIS OF URINARY TRACT OBSTRUCTION

Symptoms and Signs

The diagnosis of urinary tract obstruction is not always straightforward and is sometimes found incidentally with routine imaging or lab work. A working diagnosis of a urinary tract obstruction should always be included in the differential when presented with a patient with acute or chronic renal failure. Early diagnosis is important to resolve the obstruction with a greater probability of reversing damage.

Symptoms of urinary tract obstruction more than likely result from the origin of the obstruction and the related effects on the urinary tract. A lower tract obstruction usually results in urinary urgency, frequency, hesitancy, slow stream, retention, or dysuria. An upper tract obstruction can result in abdominal or flank pain, nausea, or vomiting, or may be asymptomatic. Both may have gross hematuria as a symptom. A past medical history may suggest another probable etiology, such as a history of stones or malignancy.

Signs of a urinary tract obstruction can also be found on a physical examination. Chronic urinary tract obstruction can lead to severe renal failure that presents as peripheral edema, pulmonary congestion, hypertension, or congestive heart failure. Patients may also present with pallor due to anemia of chronic renal failure. On a physical exam, the kidney may be palpated with severe hydronephrosis from an obstruction or from a large mass on the kidney such as a malignancy. A palpable bladder may result from chronic or acute urinary retention in the bladder from an outlet obstruction. A prostate exam should be performed in all men and a formal pelvic examination should be performed in all women presenting with signs of a urinary tract obstruction.

Urinalysis and Laboratory Findings

A urinalysis should be one of the first tests performed when a urinary tract obstruction is suspected. White blood cells (WBCs) in the urine can help identify infection or inflammation. WBCs may be present in the urine for reasons such as ureteral stent placement; stones in the kidney, ureter, or bladder; a malignancy; or recent instrumentation of the urinary tract. Leukocyte esterase or nitrate-positive urine usually indicates an infection or a chronic colonization of the urinary tract. All urine that is positive for WBCs, leukocyte esterase, or nitrates should be sent for urine culture and antibiotic sensitivity. Red blood cells (RBCs) in the urine can be present in an infection, stones, clots, trauma, nephrologic causes, or a tumor within the urinary tract. A few RBCs in the urine can be present without significant pathology. Significant hematuria in a patient should be evaluated by a urologist with a urine culture, a urine cytology, an upper tract imaging, and a cystoscopy.

A serum blood urea nitrogen (BUN) and a serum creatinine can assess the degree of renal insufficiency associated with the obstruction. A renal insufficiency can result from bilateral renal obstruction, solitary kidney obstruction, or a complete bladder obstruction. It is rare to see renal insufficiency in a unilateral obstruction with a normal contralateral kidney unless the patient is severely dehydrated. There are many electrolyte abnormalities that can be associated with a urinary tract obstruction, as discussed in earlier sections of this chapter. A basic metabolic panel will help identify these abnormalities. Hyperkalemia and acidosis may be present and, if severe, should be corrected as soon as possible.

A complete blood count (CBC) should be drawn during the workup. An elevated count can be seen in the presence of an infection or sepsis. Anemia can be detected in the face of chronic renal insufficiency, malignancy, or in acute processes such as blood loss.

Imaging of the Urinary System

Ultrasound

Ultrasonography of the kidneys and bladder is a useful initial imaging modality. This noninvasive and inexpensive test is especially helpful when an allergy to intravenous contrast or an elevated creatinine is present. In children and in pregnant patients, it is most often the initial imaging test. Ultrasonography is sensitive for the detection of renal

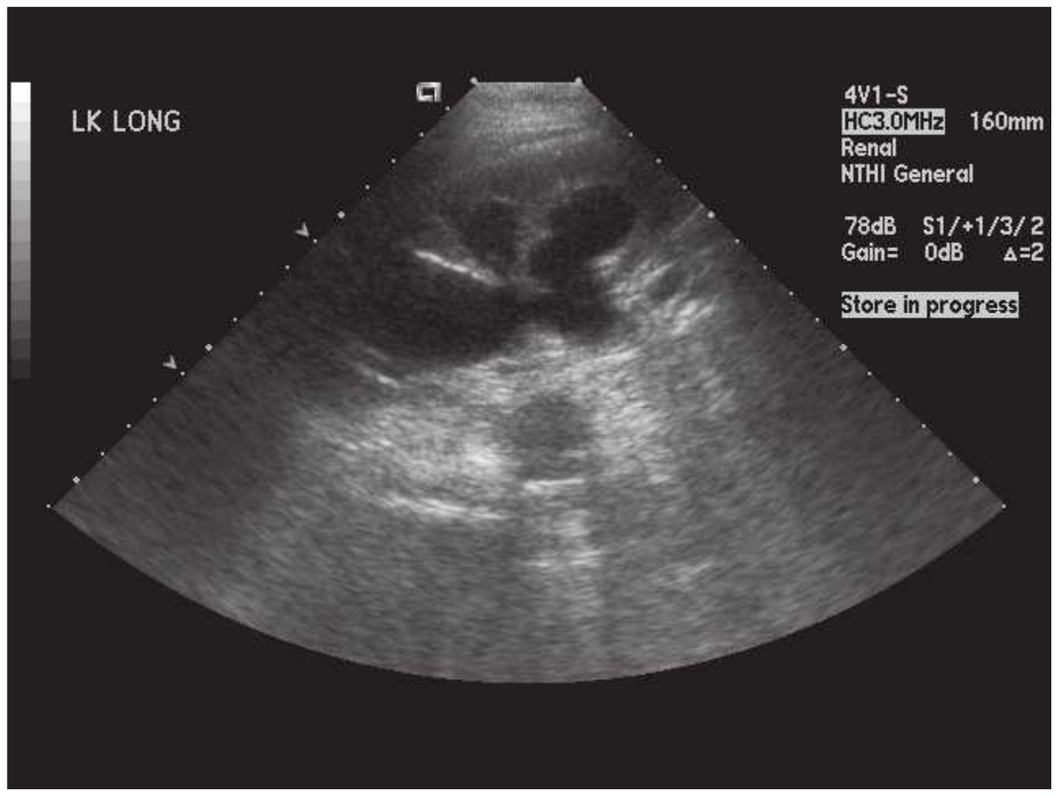

FIGURE 19.2 A renal ultrasound photo showing hydroureteronephrosis of a left kidney due to a bladder outlet obstruction in a patient with known prostate cancer.

masses, hydroureteronephrosis (Fig. 19.2), or a distended bladder (Fig. 19.3). One pitfall of this imaging modality is that the quality and accuracy of the images are dependent on the ultrasonographer. In adults, if the ultrasound findings are abnormal, follow-up imaging is recommended. The combination of renal ultrasonography with flat-plate radiography of the kidneys, ureters, and bladder (KUB) is an inexpensive initial combination.

Intravenous Pyelography

Intravenous pyelography (IVP) involves contrast injection and a series of KUB images over 15 to 30 minutes (Fig. 19.4). It can be performed in patients with a creatinine ≤ 1.5 mg

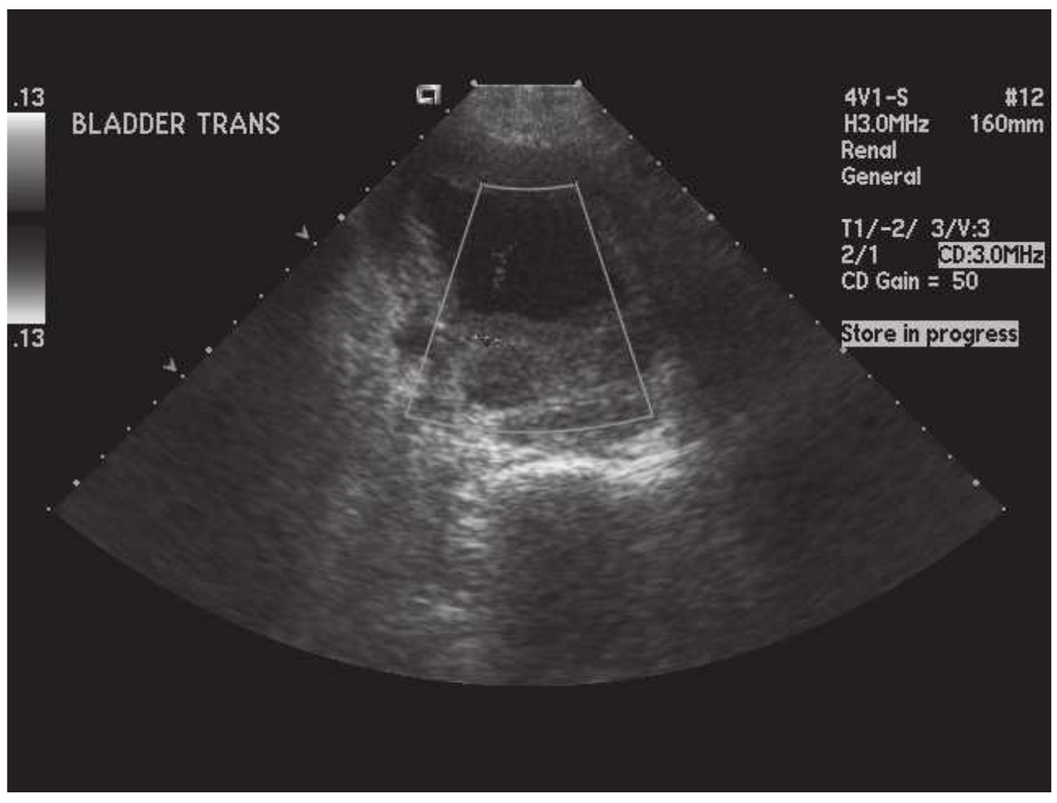

FIGURE 19.3 A fully distended bladder is shown here on ultrasound from a bladder outlet obstruction. Notice the thickened bladder wall circumferentially, which is often seen from a prolonged outlet obstruction from the prostate.

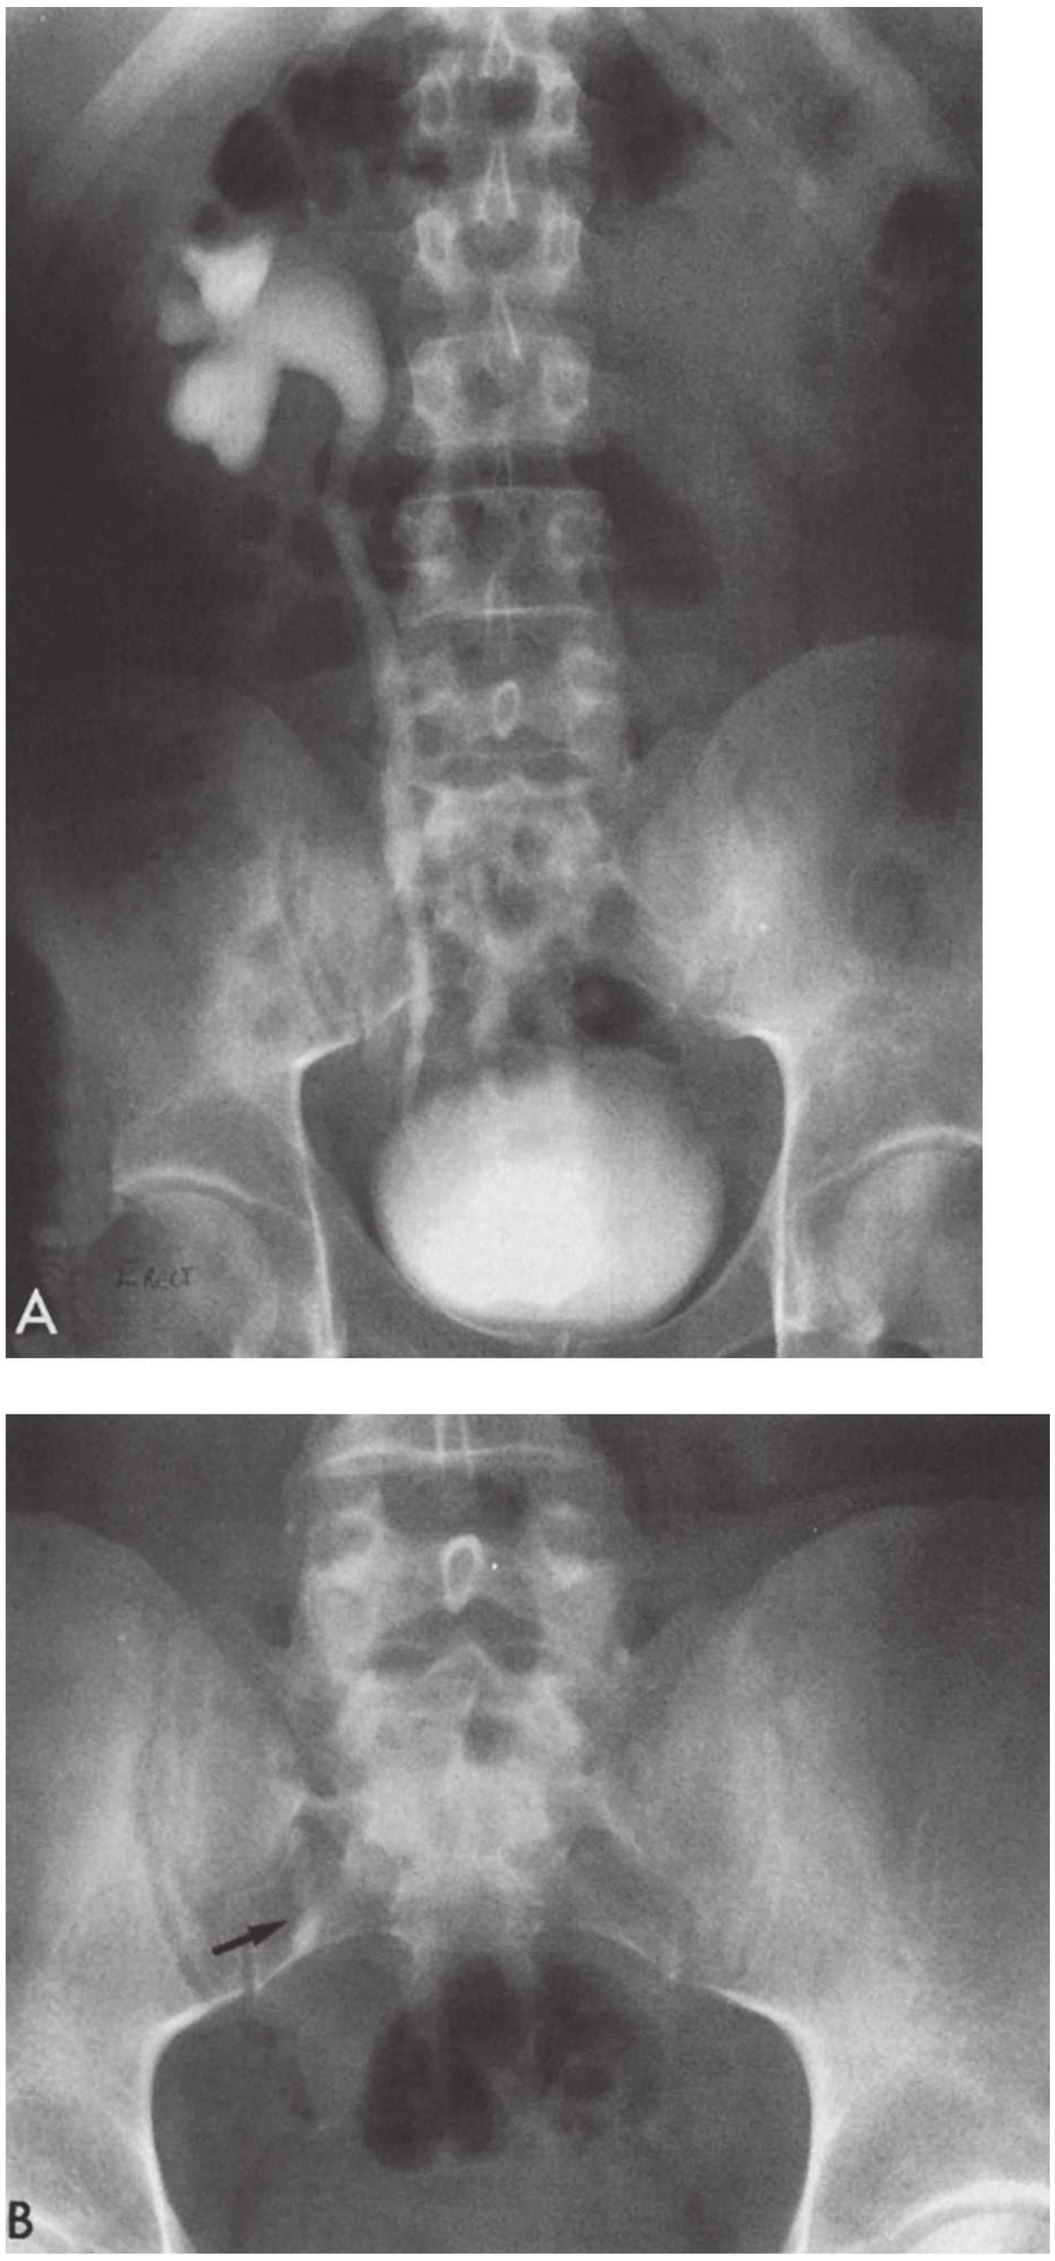

FIGURE 19.4 **A:** An intravenous pyelogram from a patient with right flank pain and hematuria intermittently for several weeks. The radiograph, taken 1 hour after the injection of contrast media, shows a markedly dilated right renal pelvis and a dilated completely filled right ureter. **B:** An examination of the plain radiograph before the dye injection shows several radiopaque stones overlying the sacrum. (From Flamenbaum W, Hamburger RJ. *Nephrology*. Philadelphia: Lippincott; 1982.)

FIGURE 19.5 An axial computed tomography image showing severe hydronephrosis of the patient's right kidney and mild hydronephrosis of the left kidney.

per deciliter for visualization of the upper urinary tracts. It may not be performed in patients with an allergy to IV contrast. This test is unique in that it provides the physician with both anatomic and functional information. Delayed calyceal filling, delayed contrast excretion, prolonged nephrography results, and dilatation of the proximal tract above the obstruction characterize a urinary tract obstruction.

Computerized Tomography Scan

Computerized tomography (CT) imaging is very useful for the identification of urinary tract obstruction, often as a first-line radiographic test (Figs. 19.5 and 19.6). A CT scan will provide information regarding the urinary tract, as well as any possible retroperitoneal or pelvic conditions that can affect the urinary tract via a direct extension or an external compression. A noncontrast CT scan should be obtained first to assess for the presence of calculi within the urinary tract. A contrast-enhanced CT scan is very useful for evaluating renal and ureteral sources of obstruction such as urothelial neoplasms, strictures, and sloughed papilla. Delayed images can be used to monitor the collecting system of the kidney to search for any filling defects and to provide excellent reconstructions of the entire upper urinary tracts. Delayed nephrographic images of the kidney can be seen in pyelonephritis as well as in an obstruction of the kidney. A CT scan can also evaluate for other intra-abdominal processes that can cause similar presenting symptoms (e.g., appendicitis, cholecystitis, diverticulitis, ovarian cysts, abdominal aneurysms, small and large bowel masses with or without obstruction).

FIGURE 19.6 A computed tomography image of a pelvis showing a large bladder stone in the right side of the patient's bladder.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is not used as a first-line modality to evaluate the urinary tract. However, it may be useful in select patients for whom CT imaging is nondiagnostic. An MRI is also useful in delineating specific tissue planes for surgical planning of complex cases as well as in evaluating the presence or the extent of a renal vein or inferior vena cava thrombus associated with a renal cell carcinoma. One drawback to the MRI in imaging the kidney is that it is not very sensitive for urinary stones.

Radionucleotide Studies

A mercaptoacetyltriglycine (MAG)-3 renal scan can be performed to determine the differential function of the kidneys as well as to demonstrate the concentrating ability, excretion, and drainage of the urinary tract (Fig. 19.7). Furosemide can be administered with the renal scan to verify delayed excretion and the presence of obstruction. This imaging is commonly used to evaluate for a UPJ obstruction. An obstructed kidney has a $t_{1/2}$ greater than 20 minutes, normal is less than 10 minutes, and a $t_{1/2}$ between 10–20 minutes is indeterminate.

Retrograde Urethrogram

During a retrograde urethrogram, a catheter tip is placed into the urethral meatus and contrast dye is injected. Fluoroscopic imaging is then performed. This test is mostly performed in the setting of trauma where there is blood at the urethral meatus and a membranous urethral disruption is suspected. It is also helpful in defining the extent of urethral strictures prior to repair.

Retrograde Pyelogram

A retrograde pyelogram, also referred to as a pyeloureterogram, is performed during a cystoscopy in the operating room (Fig. 19.8). A 5- or 6-Fr cone-tip or open-ended ureteral catheter is placed through the cystoscope into the ureteral orifice. Contrast is then flushed through the catheter into the ureter under fluoroscopy. These images will show the anatomic outline of the ureters and the renal pelvis up to the level of obstruction or

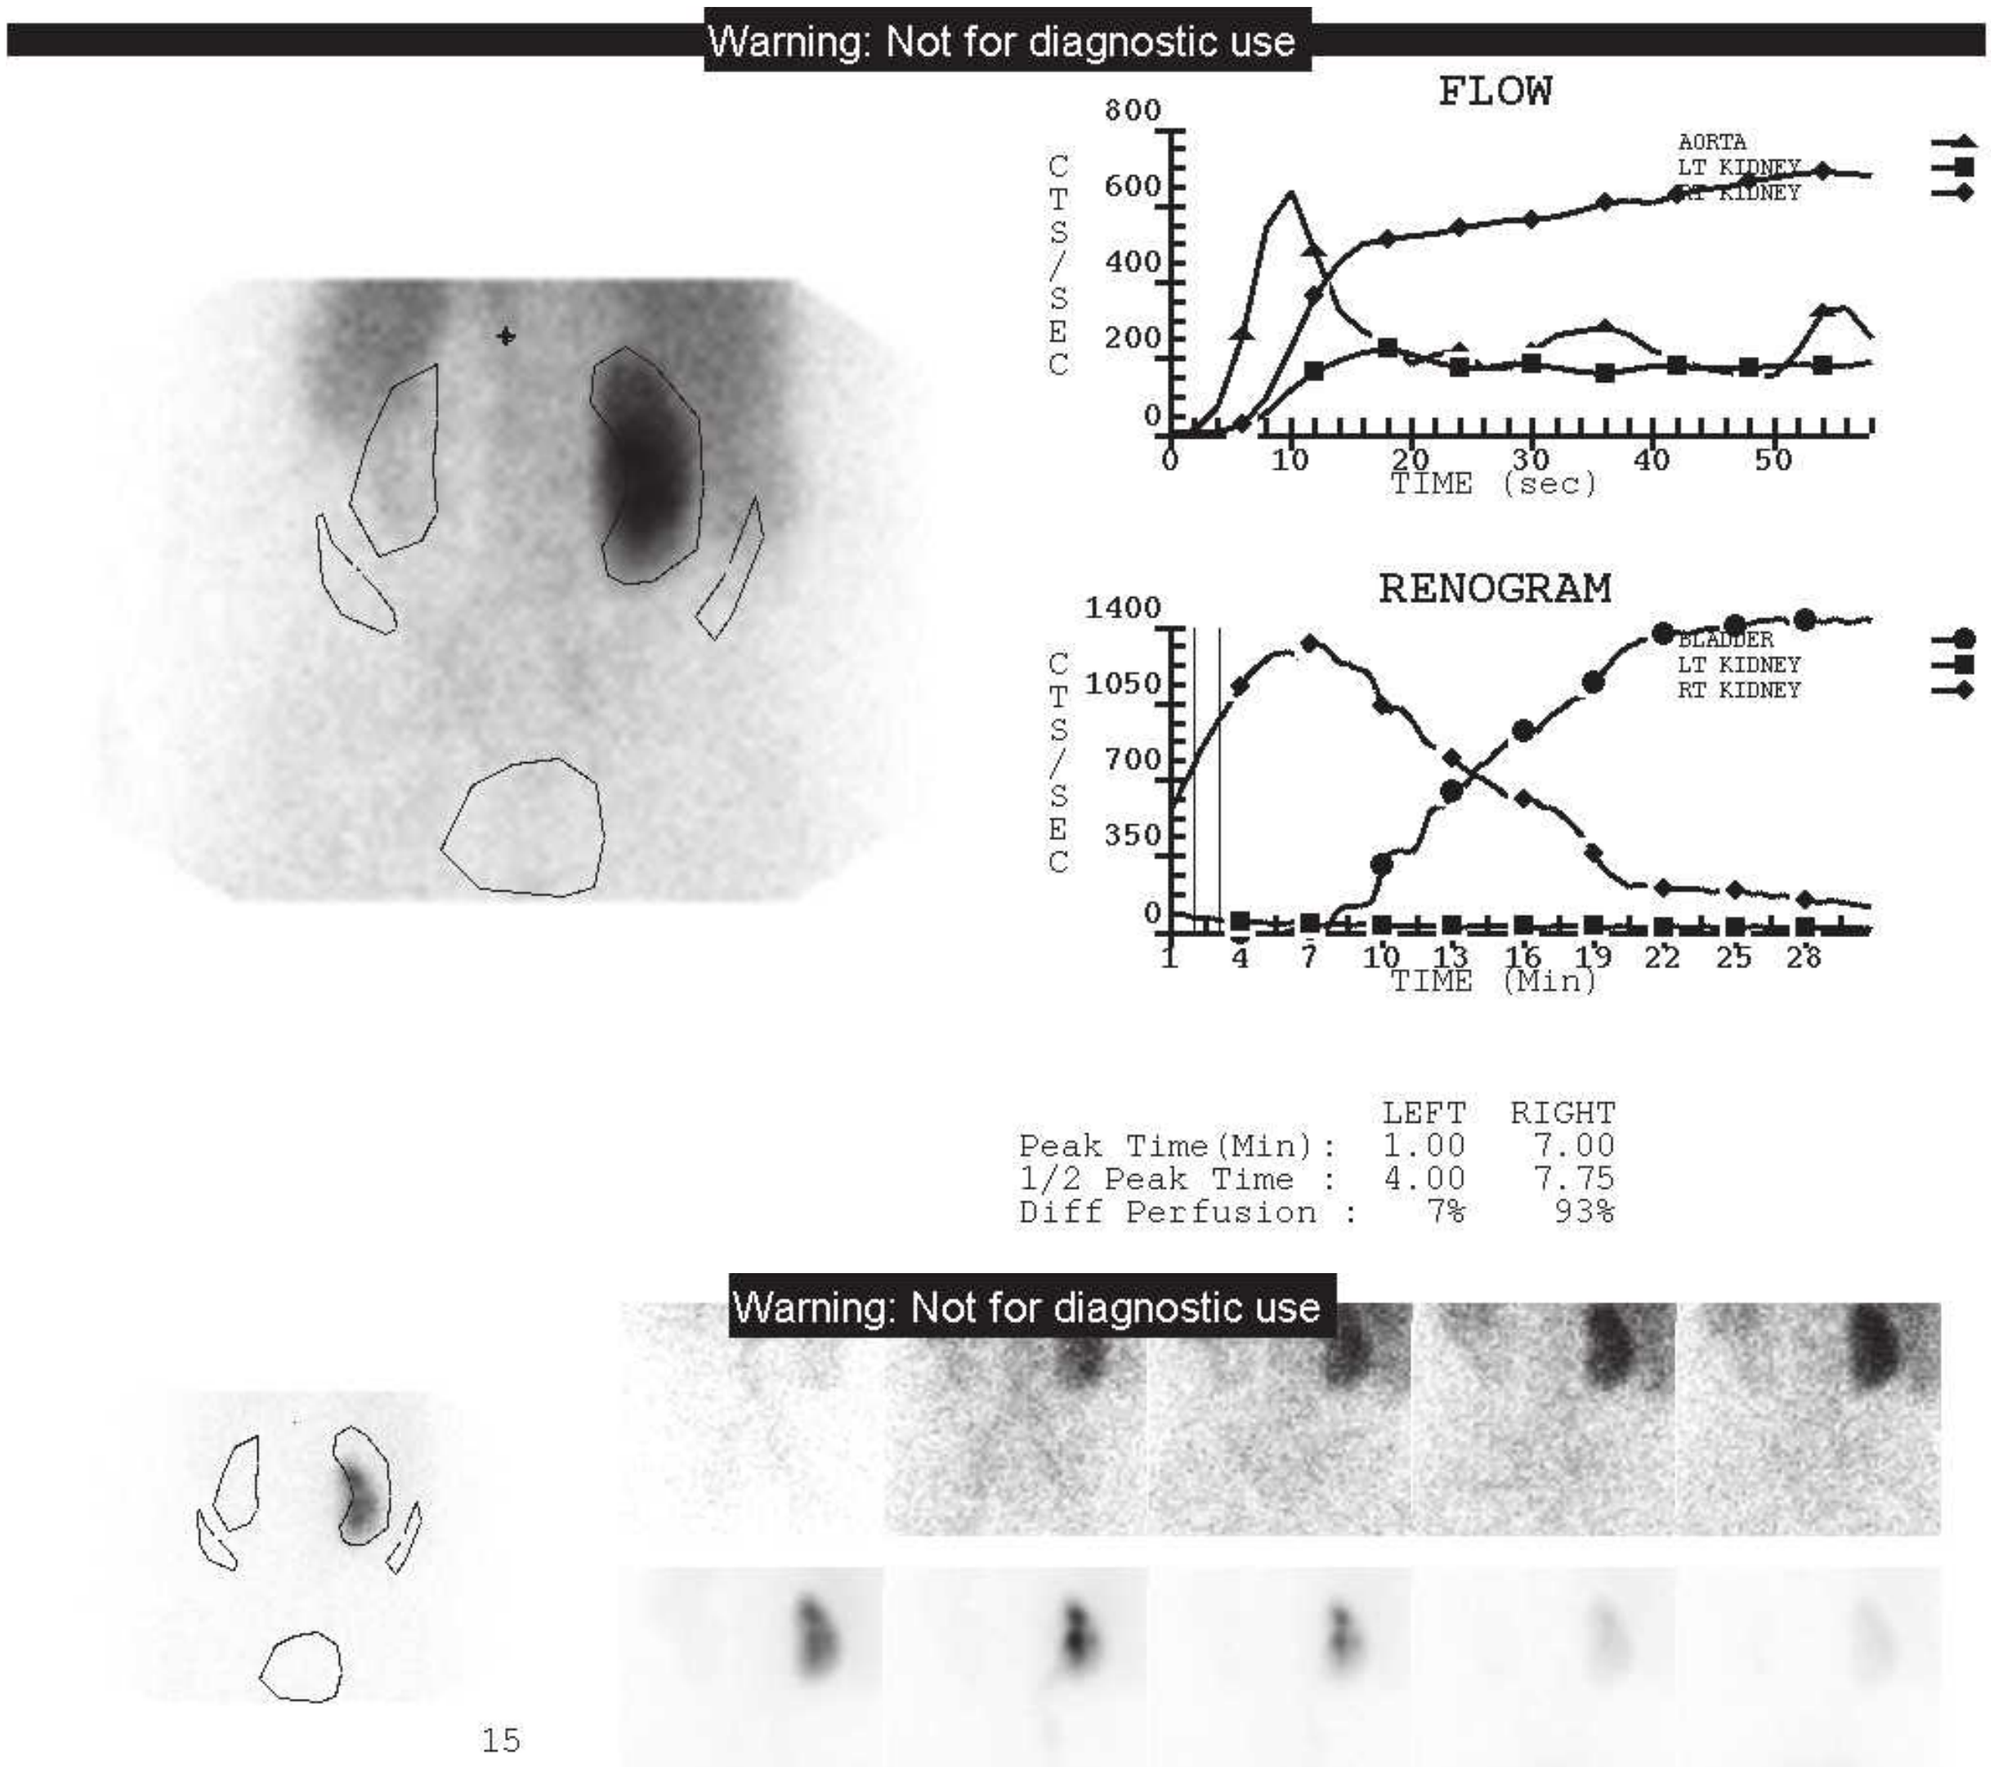

FIGURE 19.7 MAG3 scan images showing the perfusion and drainage studies of the test. This patient was found to have 93% function on the right and 7% function on the left with severe hydronephrosis from obstruction on the left side.

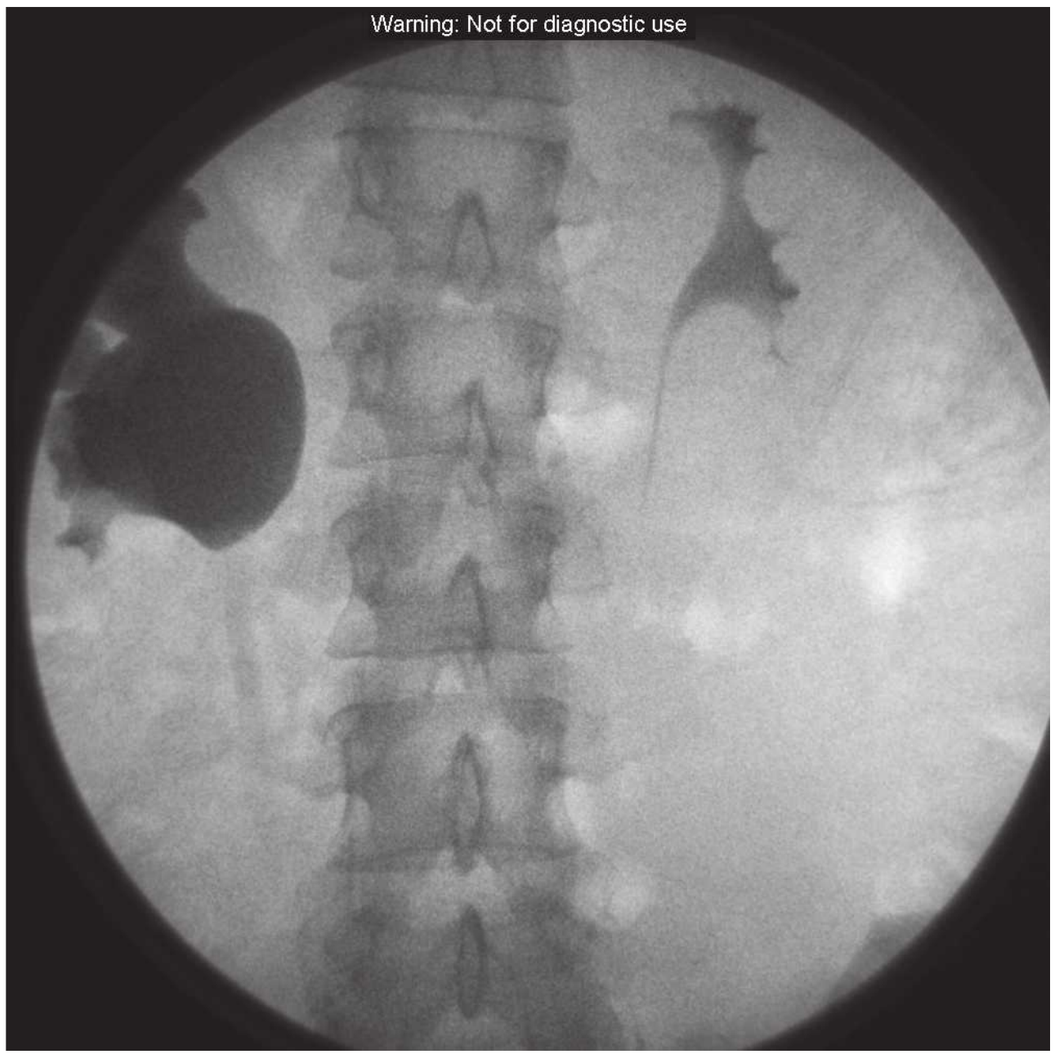

FIGURE 19.8 Bilateral retrograde pyelograms shown here with a normal pyelogram on the right and evidence of a ureteropelvic junction obstruction on the left with a large box-shaped renal pelvis and blunted calyces.

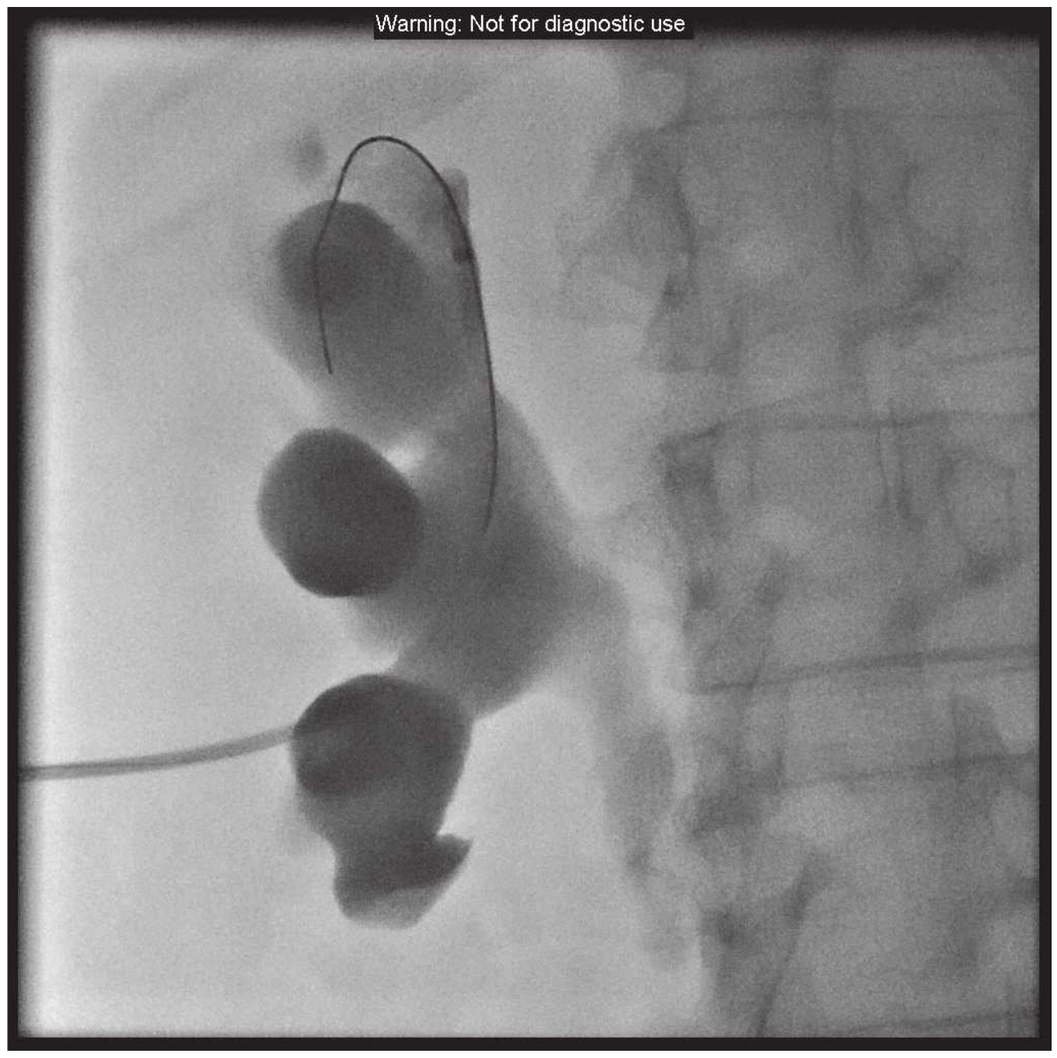

FIGURE 19.9 An antegrade nephrostogram showing the filling of the entire renal pelvis and calyces during percutaneous access of the right kidney.

will show filling defects in the presence of a mass, stone, or clot. Because the contrast load is not significantly absorbed, it may be used in patients with renal insufficiency. It may be also used in patients with an IV contrast allergy.

Nephrostogram

A nephrostogram can be used if the patient has a nephrostomy tube (Fig. 19.9). Contrast dye is flushed through the catheter under fluoroscopy in a similar fashion to the retrograde pyelogram. This imaging is helpful for the evaluation of renal and ureteral pathology when retrograde access is contraindicated or difficult, and it is often combined with interventional intent. This test can also be performed on patients with renal insufficiency or IV dye allergy.

Treatment of Urinary Tract Obstruction

Medical Therapy

The mainstay of treatment for urinary tract obstruction is to eliminate any life-threatening disorder, relieve any complete obstruction of the urinary tract to preserve renal function, and determine the cause of the obstruction (Table 19.3).

Septicemia with pyelonephritis is a possible sequelae of severe partial or complete obstruction of the urinary tract. A fever, an elevated white cell count, hypotension, or severe flank pain may alert the physician to this impending problem. Relief of the obstruction while starting empirical wide-spectrum antibiotics is the best form of treatment for this condition. This should be performed on an emergent basis as these patients may develop urosepsis. Antibiotics can be tailored to blood and urine culture results once they become available. A patient with complete urinary tract obstruction, any type of obstruction in a solitary kidney, obstruction with severe dehydration or uncontrolled pain, or with associated renal failure needs immediate attention.

A partial urinary tract obstruction in the absence of infection or renal failure can be managed on an outpatient

19.3 Indications to Relieve Obstruction

Indications to Relieve Obstruction

Unilateral Obstruction (UUO)	Bilateral Obstruction (BUO)
Pain unrelieved by oral analgesics	Same as UUO
Signs and symptoms of sepsis	Elevated BUN or creatinine
Unable to tolerate food or water by mouth	Uremia
High grade obstruction	Anuria
	Hyperkalemia

BUN, blood urea nitrogen.

basis with analgesics and antibiotics until a complete urologic evaluation can be performed. Antibiotics are often given for prophylaxis and should cover common urologic pathogens. Commonly used antibiotics include trimethoprim-sulfamethoxazole, ciprofloxacin, nitrofurantoin, and cephalosporins. Pain secondary to urinary tract obstruction is often managed with opioid analgesics and nonsteroidal anti-inflammatory medications.

Acute or chronic renal failure with hyperkalemia, acidosis, convulsions, coma, or pericarditis is another life-threatening clinical presentation of obstructive uropathy that may require an immediate treatment by dialysis until definitive measures can be taken to correct the obstruction.

Identifying the cause of the obstruction is important for determining how and when treatment is to be performed. Urologic and nephrology evaluations are important components of the assessment.

Surgical Therapy

The goal of surgical intervention is to completely relieve the urinary tract obstruction. The specific type of surgical intervention depends on the level of obstruction and the underlying pathology.

Lower Urinary Tract Obstruction

Temporary forms of relief.

1. Urethral (Foley) catheter: A urethral catheter (size: 8 to 24 Fr) is a flexible catheter that extends from the bladder to the urethral meatus to allow urine to flow unimpeded from the bladder (Fig. 19.10). With a difficult catheter insertion, a urologist may need to use a coude catheter, cystoscopy, or urethral dilators for placement.
2. Suprapubic catheter: A catheter is placed through the anterior abdominal wall just above the pubic symphysis directly into the bladder. Performance can be at the bedside percutaneously or in the operating room as an open procedure. Ultrasound guidance should be used to locate the bladder if done at the bedside. An open approach in the operating room should be performed if the patient has had prior lower abdominal surgery.

Temporary forms of relief for an upper urinary tract obstruction include the following:

1. Ureteral stent: A ureteral stent is a flexible tube that extends from the renal pelvis down the ureter and into the bladder (Fig. 19.11). The stent curls at both ends

FIGURE 19.11 A fluoroscopic image showing bilateral double J stents in the correct position within both renal pelvises.

in the shape of a "J" to maintain its position. Common sizes range from 4.5 to 8 Fr in diameter. It can be placed during cystoscopy over a guide wire to relieve the obstruction along any point in the ureter. A ureteral stent generally needs to be replaced or removed after 3 to 6 months due to calcification or obstruction.

2. Nephrostomy tube: A nephrostomy tube is a flexible tube that is placed percutaneously through the flank/back directly into the renal pelvis. If a ureteral stent cannot be placed from the bladder, a nephrostomy tube can be placed into the kidney to allow the obstruction to be relieved. A stent may be placed through the nephrostomy tube tract over a guide wire in an antegrade fashion if a stent cannot be placed in a retrograde fashion.

Definitive Therapies

A meatal stenosis can be dilated with urethral sounds. Urethral strictures can be dilated with filiforms and followers, which are a series of dilators (Fig. 19.12). They may also be endoscopically incised at the 12 o'clock position with a cystoscopic knife under anesthesia.

The prostate and bladder neck are very common causes of a lower urinary tract obstruction in men of increasing age. The gold standard of relieving an obstruction secondary to benign prostatic hyperplasia (BPH) has been the transurethral resection of prostate (TURP) (Fig. 19.13). Traditionally, this has been performed with a resectoscope loop. Currently, most TURPs are performed endoscopically using a variety of lasers resulting in less bleeding and greater potential for the procedure being considered as an outpatient procedure. Bladder neck contractures may be seen after a TURP.

Upper Urinary Tract Obstruction

The most common causes of upper urinary tract obstruction are renal and ureteral calculi (Fig. 19.14). Urinary tract

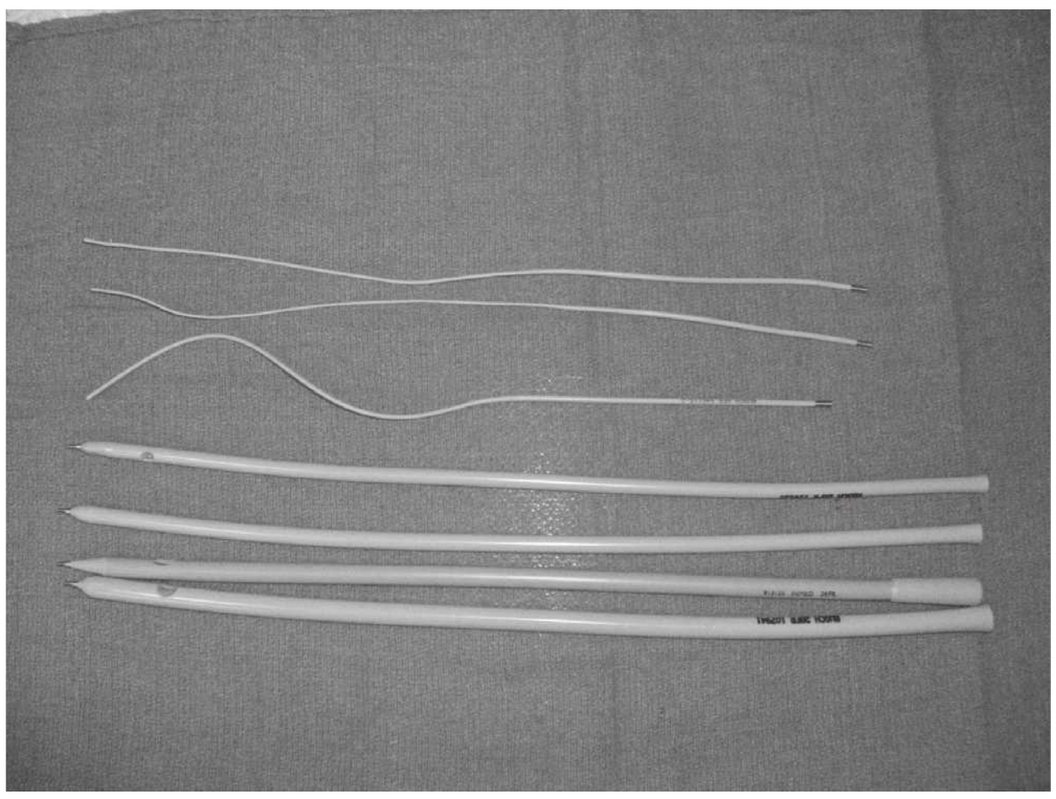

FIGURE 19.12 A picture of various filiforms (*top*) and followers (*bottom*) used for urethral dilatation.

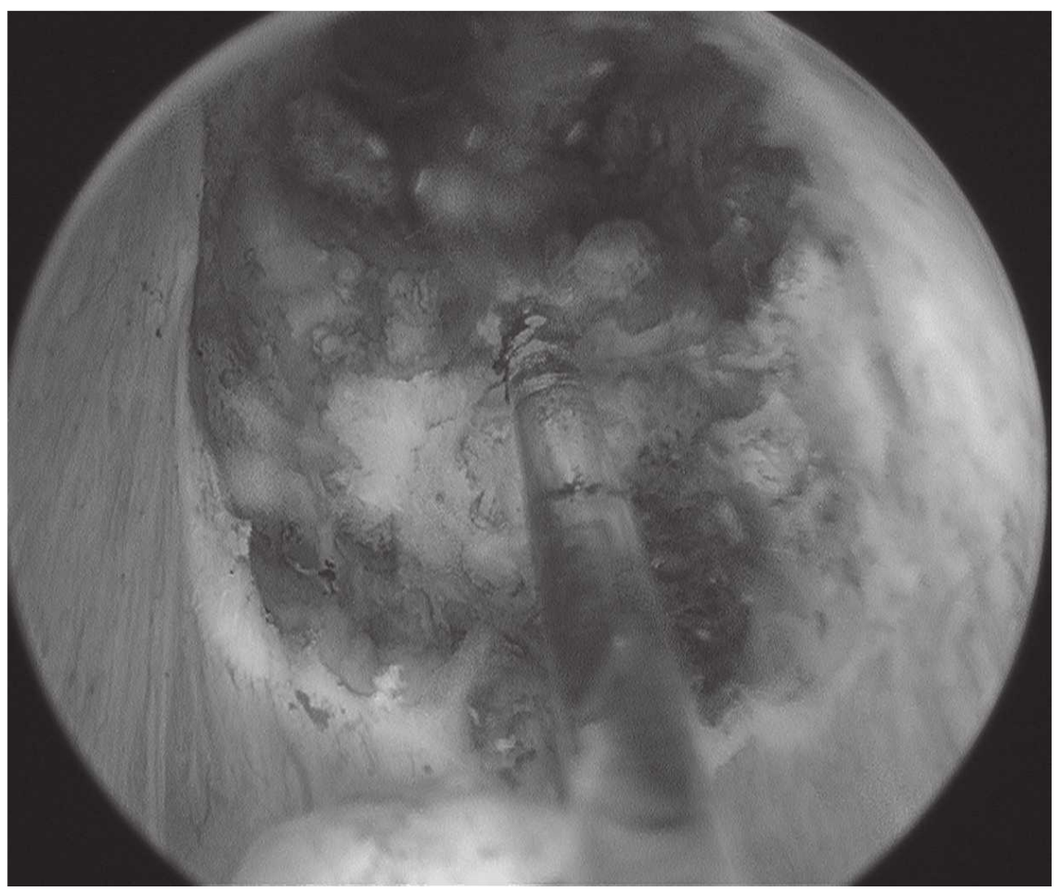

FIGURE 19.13 A single-shot photo of a laser transurethral resection of the prostate. This laser ablates the prostate tissue to widen the urethral channel through the prostate.

calculi can be removed surgically or monitored for spontaneous passage. In one study, ureteral calculi less than 4 mm, 4 to 6 mm, and greater than 6 mm have a chance of passing on their own in 80%, 59%, and 21% of patients, respectively.[85,86] Patients may have 4 weeks to pass a partially

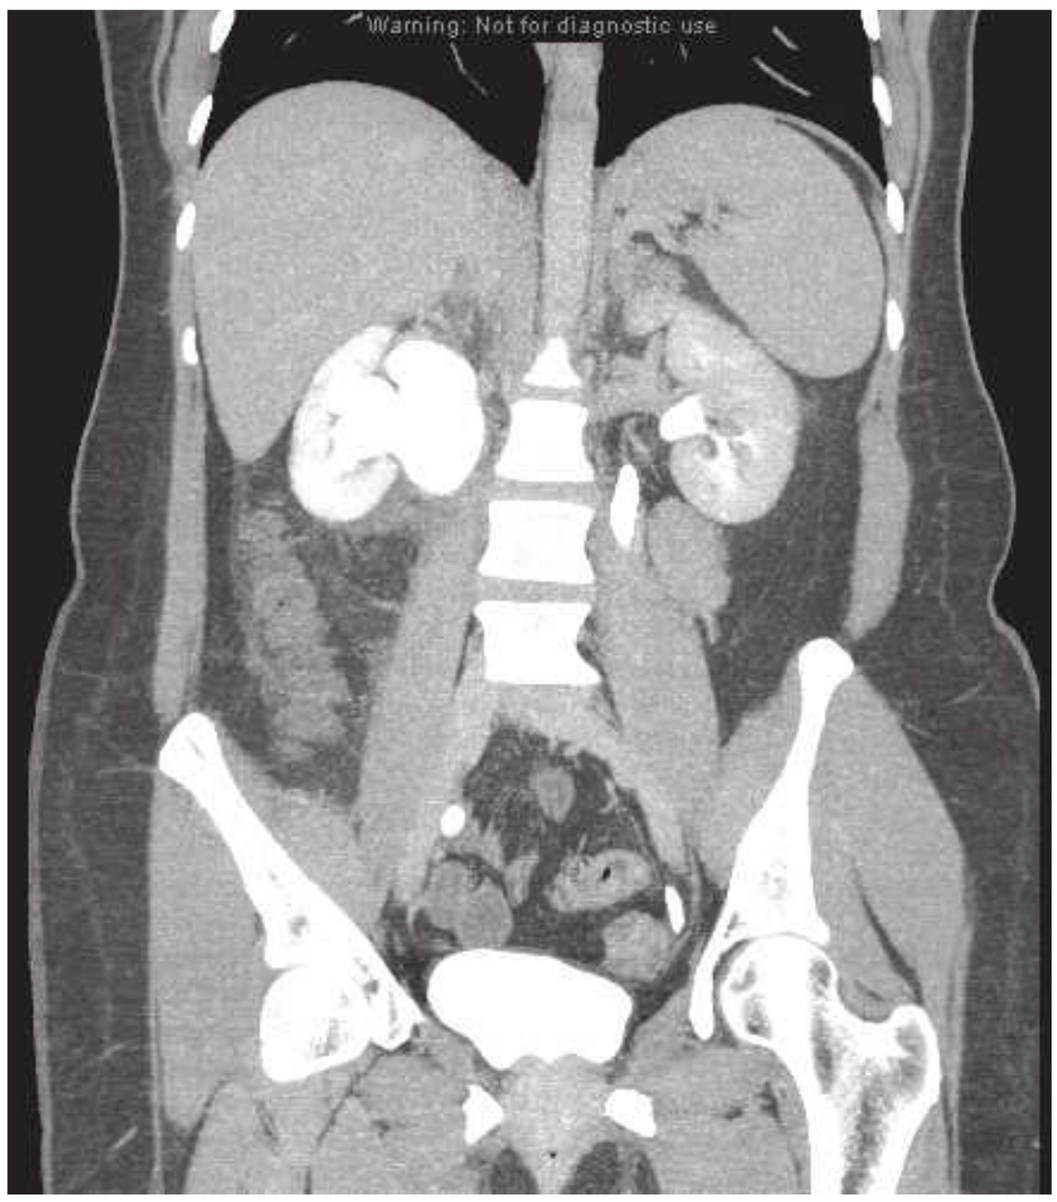

FIGURE 19.14 A coronal computed tomography image of the abdomen showing a ureteropelvic junction obstruction with hydronephrosis of the patient's right kidney on delayed contrast images with a normal left-sided collecting system.

obstructing stone before renal damage starts to occur. If the pain is intractable, then they have failed medical management and need operative intervention. Distal ureteral stones are commonly removed using a ureteroscopy. Proximal and midureteral stones are removed either by a ureteroscopy or an extracorporeal shockwave lithotripsy (ESWL) depending on their size and location. Open surgery for stones is usually reserved for ureteral calculi greater than 2 cm or an anatomic abnormality, which would preclude other options. Renal calculi surgery is dependent on the size of the stone and surgeon preference. Options include flexible ureteroscopy, ESWL, or percutaneous removal through a nephrostomy tract.

Ureteroscopic, laparoscopic, or open surgery may be required depending on the pathology of upper tract obstruction. Ureteropelvic junction obstructions are most commonly treated with a pyeloplasty, using an open or laparoscopic technique to remove the obstructed ureteral segment. A balloon dilation and an incision of the UPJ obstruction are less frequently used alternatives.

Ureteral strictures can be treated using a variety of methods. Small strictures can be dilated endoscopically with a balloon dilator. Larger or treatment-refractory strictures require a resection and reanastomosis to the nondiseased segment. Distal ureteral strictures may be treated with ureteral reimplantation directly into the bladder, a psoas hitch, or Boari flap.

Obstruction due to urothelial neoplasms are treated with either a segmental resection of the mass or a complete removal of the kidney and ureter if the mass is within either entity. Endoscopic management is now being used in superficial lesions of the ureter or kidney if oncologic principles can be maintained to spare as many nephrons as possible (Fig. 19.15).

FIGURE 19.15 An axial computed tomography image showing a filling defect of the patient's right proximal ureter during delayed contrast imaging.

Conclusions

The prognosis of urinary tract obstruction depends on the cause, location, degree, and duration of obstruction as well as the presence of urinary tract infection. The longer the duration of obstruction, the greater the severity of obstruction and the presence of a concomitant infection, which can lead to a poor prognosis. The prognosis is favorable if the renal function is normal, the infection is cleared, and the obstruction is relieved in a timely manner.

VESICOURETERIC REFLUX AND REFLUX NEPHROPATHY

Introduction

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the upper urinary tract. Because VUR can be relatively asymptomatic, diagnosis may be difficult. When symptomatic, it can lead to pyelonephritis, scarring of the kidney, and even end-stage renal failure. The diagnosis and optimal management of VUR is controversial.

History of Vesicoureteral Reflux

In 150 A.D., Galen first described the UVJ as a mediator of unidirectional flow of urine from the kidney to the bladder.[87] da Vinci described the free flow of urine from the bladder to the kidneys most likely after dissecting the body of a patient with VUR.[88] It was not until 1893 that a gynecologist first described the backflow of urine from the bladder after having cut a distal ureter during a hysterectomy.[89] In 1907, Sampson suggested that the backflow of urine may lead to pyelonephritis after studying the UVJ.[90]

In the 1950s, there were two important breakthroughs on the impact of VUR on the upper urinary tracts. In 1952, Hutch[91] reported that VUR may lead to recurrent pyelonephritis in paraplegic patients. In 1959, Hodson[92,93] made the correlation between UTIs, renal scarring, and VUR. In 1979, Ransley and Ridson[94] defined the pathophysiology of VUR by showing the relationship between infection, scarring, and reflux. These discoveries and subsequent studies eventually led to a consensus system for grading reflux in 1985 by Lebowitz and colleagues.[94a]

For the past several decades, the treatment of VUR has evolved and has been widely debated. Newer, less invasive surgical treatments for VUR have broadened the treatment armamentarium and algorithm. However, the debate will continue until a true consensus can be reached.

Demographics

Because VUR can resolve spontaneously or can be asymptomatic, the true prevalence of this disease can be difficult to define. In 2000, a meta-analysis of children undergoing a cystography for various indications identified that those with UTIs had a 30% incidence of VUR, whereas 17% without a history of UTIs had VUR.[95] In contrast, an earlier study found that up to 70% of infants with UTIs may have some

element of reflux.[96] Using prenatal ultrasonography for screening, Gunn et al.[97] estimated that the incidence of VUR was 0.36:100 births in 1995.

VUR is more common in females. In 1992, the number of boys entered into the International Reflux Study in Children was 10% in the United States and 24% in Europe. This finding demonstrated an increased prevalence in the female population.[98] Several confounding factors play into finding the true incidence of VUR between the two groups because not all children are screened. For instance, uncircumcised boys are at a 12-fold increased risk of developing a UTI and are more likely to be screened for VUR.[99] The true incidence and difference between males and females with respect to VUR may never be made unless screening of the general population becomes available.

Because VUR tends to resolve spontaneously, its incidence decreases with age. A study by Baker[100] showed that the incidence of reflux in patients diagnosed with a UTI decreases with age. The incidence of VUR in children <1 year old was 70%, 25% in 4 year olds, 15% in 12 year olds, and 5% in adults who were screened for VUR after being diagnosed with a UTI.

Whether race predisposes patients to VUR is still not known because reflux has been studied primarily in Western countries. A 10-fold decrease in the frequency of reflux in female children of African American descent has been reported, as well as a quicker resolution of their reflux.[101]

Primary Vesicoureteral Reflux

Primary VUR is the regurgitation of urine through a vesicoureteric junction that has been rendered incompetent by a congenital defect of the length, diameter, muscle, or innervation of the submucosal segment of the ureter (Fig. 19.16). The vesicoureteric junction works normally as a flap-valve, which permits the flow of urine from the ureter into the bladder but prevents flow in the opposite direction. The submucosal segment of the ureter holds the key to ureteric continence and is dependent on factors such as the length of the intramural portion of ureter, the nature of the ureteric orifice, and the integrity of the bladder wall musculature.

The most common explanation for the defective valve mechanism of the vesicoureteric junction is the shortness of the submucosal segment secondary to the congenital lateral ectopia of the ureteric orifice.[105] Paquin described the principle that the ureteral tunnel must be five times as long as the ureteral diameter at the UVJ for reflux not to occur. When the bladder fills, a further shortening of the submucosal segment of the ureter may take place, accounting for the observation that reflux may only occur if the bladder is either full or in the act of voiding. The complex anatomy of the vesicoureteric junction and its relationship to the bladder trigone and the urethra is best approached from a developmental point of view.[103] Oswald et al.[104] proposed that a congenital muscular structural insufficiency of the distal ureter is important in the pathogenesis of the vesicoureteral reflux.

FIGURE 19.16 A single-shot fluoroscopic image of a patient's abdomen showing a contrast within the bladder as well as a reflux of contrast up the left collecting system.

The ureter, both extravesically and intravesically, must remain fixed with adequate ureteral tunnel length for the ureter not to reflux. Another important principle is that the intramural ureter must remain compressed during bladder filling so urine will not reflux up during this time. Opening of the UVJ is achieved by contraction of the longitudinal muscle of the ureter within the intramural tunnel. This causes the extravesical and intravesical points to decrease in length while opening the ureter to allow the bolus of urine into the bladder from the ureter. If the tunnel length is not long enough, urine can reflux back into the upper tracts at the end of this process. This can occur even in the presence of a low-pressure urine storage profile in the bladder.

Secondary Vesicoureteral Reflux

Increased bladder pressure, which may overcome the antirefluxing mechanism in a normal UVJ, can lead to VUR. The backflow of urine can lead to the dilation of the upper tracts and potential scarring of the kidney or renal failure. The most common pediatric cause in boys is posterior urethral valves (PUVs). Reflux, oftentimes high grade, can be associated with 70% of these boys due to an obstruction of the urethra. Valve ablation successfully treats the obstruction.[105,106] The most common cause in girls is a prolapsing ureterocele across the bladder neck, causing urinary obstruction.[107]

A neurogenic bladder without an anatomic obstruction is also a very common cause of VUR. In pediatric patients, a host of neurologic diseases that affect the lower and upper motor neurons can have damaging effects on the bladder. A physiologic obstruction can lead to high pressure systems within the bladder that lead to reflux into the upper tracts as a pop-off mechanism. Subsequent dilatation of the upper tracts and, eventually, scarring of the kidney may ensue. During the first years of potty training, dysfunctional voiding can lead to high-pressure bladders.

McGovern et al.[108] observed that myelodysplasia can be associated with high-pressure bladders and reflux. In a study of 42 children with myelodysplasia, 35 had detrusor areflexia. Of the latter, 5 had flat detrusor pressures during bladder filling and the remaining 30 had steeply rising, low-compliance patterns. When the voiding pressure to produce leakage was higher than 40 cm of water, 15 showed reflux.

Urinary Tract Infections and Reflux

Reflux does not cause a UTI. However, if a uropathogen is introduced into the urinary system, reflux can help maintain the pathogen within the system by allowing the bacteria to enter the upper tracts from the bladder, stay within the upper tracts due to dilatation of the upper tracts from reflux, or not be effectively cleared by voiding. Cystitis can cause irritability at the UVJ, resulting in a decreased threshold for reflux. Thus, reflux with a UTI can potentiate pyelonephritis by allowing uropathogen entry into the upper tracts. These pathogens can cause scarring of the renal parenchyma.

Pathophysiology of Reflux

The association with VUR and reflux nephropathy has been studied extensively in porcine models. Some studies have shown that the intrarenal reflux of sterile urine can cause focal scarring. This has yet to be proven in humans.[109] Most pathologic findings in humans have been taken from nephrectomy specimens due to chronic pyelonephritis or hypertension. These specimens have a tendency to show more scarring at the poles of the kidneys, which is most likely due to the fact that compound papillae are found at these poles and are more susceptible to damage from reflux.

Renal scarring or reflux nephropathy depends on a multitude of factors. The grade of reflux has been shown to be directly proportional to the development of scarring. A study of 735 children with primary VUR showed that 43.5% of patients had evidence of renal scarring, especially when high-grade reflux was present.[110] This association was also reported by Smellie[111] using intravenous urography. Renal scarring was detected in 69% of children with moderate to severe reflux and in 24% of those with mild reflux. In a separate study, 41 male patients with primary VUR were screened with a dimercaptosuccinic acid (DMSA) scan to assess for congenital renal scarring. Thirteen patients had low-grade reflux and none of these patients had scarring on DMSA. Of the 28 patients with high-grade reflux, 10 had slight scarring of the kidneys, whereas 8 had severe scarring of the kidneys.[112]

The age of the child at the time of exposure to infected urine is also important. Children less than 4 years old were more susceptible to renal damage, most likely due to an immature system that was unable to fight off the infection.[113] The "big bang" theory observed that most renal scarring took place after the first bout of pyelonephritis and further scarring was unlikely if no further episodes of pyelonephritis occurred.[114]

Ransley and Ridson[115] performed a landmark study in pigs in which they unroofed the intravesical portion of the UVJ, allowing for reflux. When an infection was introduced into the urine, the pigs subsequently developed pyelonephritis and renal scarring. In the absence of infected urine, scarring did not occur. This study influenced the investigation into the principle that sterile urine did not lead to scarring of the kidney, which paved the way for nonsurgical management for VUR.

The long-term effects of VUR can be devastating, leading to chronic renal insufficncy and end-stage renal disease (ESRD). Although older studies identified that 15% to 30% of ESRD in children was due to VUR, newer studies show that only 2.2% of VUR children develop ESRD.[116,117]

Although hypertension is a well-known sequalae of VUR, the pathophysiology is not well described. Derangements in the renin-angiotensin-aldosterone (RAA) system as well as the intrarenal sodium-potassium pump dysfunction have been investigated. A 2004 study[118] showed that 20% of 157 adult patients with hypertension and no other renal parameters on cystography had VUR. It remains unclear whether it is nephropathy due to the scarring or congenital dysplasia associated with the reflux that causes or predisposes the patient to renovascular hypertension.

Associated Anomalies with Vesicoureteral Reflux

Several anatomic anomalies are associated with VUR in the pediatric patient. The presence of VUR should prompt an evaluation for these conditions. UPJ obstruction can be seen in 9% to 18% of children with VUR.[119] The UPJ obstruction may be secondary to the VUR or may represent two separate entities. High-grade reflux can cause kinking of the upper ureter that leads to a secondary or

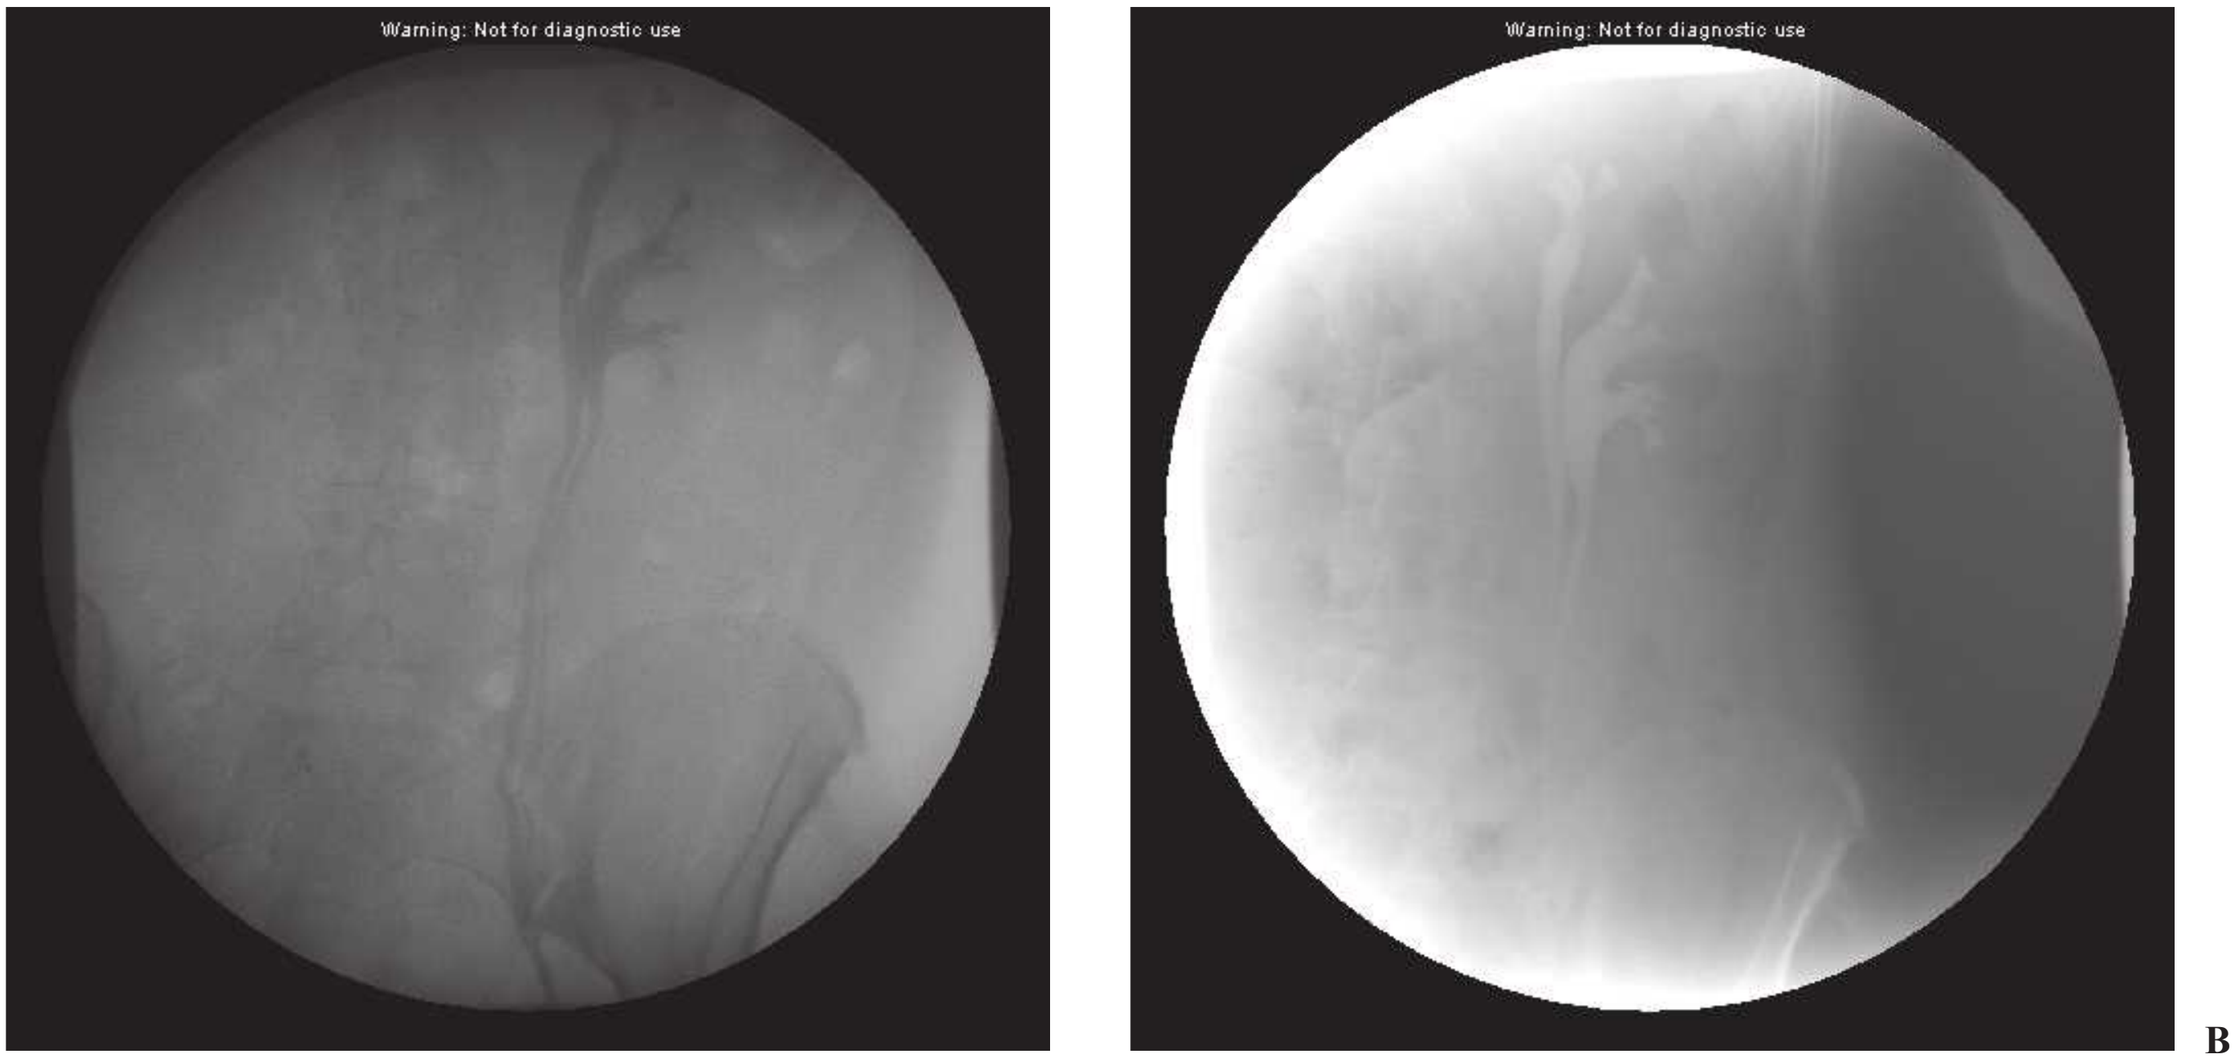

FIGURE 19.17 A fluoroscopic image from a voiding cystourethrogram showing contrast refluxing up into an incomplete duplicated system on the patient's left side.

"incipient" UPJ obstruction. High-grade VUR is five times more likely to be associated with UPJ obstruction than low-grade VUR.[120]

VUR is the most common abnormality associated with ureteral duplication (Fig. 19.17). The embryology of the duplication and the ureteral insertion into the trigone during development explains the association of these conditions. The lower pole ureter inserts into the trigone early in development. As the trigone expands, the ureteral orifice from the lower pole moves cranially and laterally. The resultant decrease in length of the intramural tunnel leads to VUR of the lower pole segment. The upper ureter enters the trigone later in development, is located more caudally and medially, and is more prone to obstruct than reflux. This is known as the Weigert-Meyer law.

Renal anomalies are also very common with VUR. With multicystic dysplastic kidneys, the incidence of VUR on the contralateral side is as high as 25%.[120] Renal agenesis is associated with a higher incidence of contralateral VUR with a prevalence of 28% in one study.[121]

Pregnancy and Vesicoureteral Reflux

Pregnant women are predisposed to bacteriuria because of decreased bladder tone. In a study of 321 patients evaluated with cystography during their third trimester, the incidence of pyelonephritis in pregnant women with VUR was 33% compared to <5% in women without VUR.[122] Women with a history of reflux have an increased risk of infection-related morbidity during pregnancy regardless of prior correction. The consensus is that the reflux should be corrected before pregnancy.[123]

Natural History of Vesicoureteral Reflux

VUR can spontaneously resolve as a result of remodeling of the UVJ with growth. The age of the child and the degree of reflux at the time of diagnosis influence the likelihood of spontaneous resolution. Lower grades of reflux have a higher likelihood of spontaneous resolution. Several studies have shown that low-grade reflux (I and II) will resolve on their own. A study of 500 children with known VUR in Brazil who were observed from birth reported a spontaneous resolution rate of 87.5% for grade I, 77.6% for grade II, 52.8% for grade III, 12.2% for grade IV, and 4% for grade V reflux.[124]

The age at which VUR is diagnosed can also be a factor in the likelihood of spontaneous resolution. For years, many studies had shown that the earlier the reflux is detected, the greater the likelihood of spontaneous resolution. Newer studies have shown that diagnosis at age 5 or at infancy had the same rate (20%) of resolution over a 5-year period regardless of age.[125] The accepted period of observation for resolution of reflux has been 5 years, but the patient's risk of UTI or pyelonephritis is the same throughout the observation period and should be discussed with the patient and his or her family.

Management of Vesicoureteral Reflux

The main goals of management of a patient with VUR are to prevent any or recurrent febrile UTIs, to prevent a loss of renal function or renal scarring, and to minimize the morbidity and mortality of the treatment option. The two primary options in treating VUR are watchful waiting with single

low-dose antibiotic suppression therapy or surgical correction. The traditional approach is medical therapy first, then surgical correction if the reflux does not resolve or if medical management fails. In 2010, based on a meta-analysis of the literature, the AUA published guidelines for the management and screening of primary VUR in children.[123]

The long-debated question is how long to wait to determine if the reflux will resolve. A landmark study by Olbing[126] in 2003 showed that renal scarring does not seem to develop after age 5 in severe reflux patients. It is common practice now to allow the watching of newborns with VUR until age 5 if they have no breakthrough infections.[123] Boys with low-grade reflux are generally not followed after the age of 5 and taken off suppression if they continue with good elimination habits while girls are offered surgical correction due to the dangers with pregnancy in the future. A study in 2000 showed that taking these patients off low-dose antibiotic suppression would lead to only 10% requiring surgical correction in the future for a febrile UTI.[127]

Diagnosis of Vesicoureteral Reflux

The two gold standard tests for diagnosing VUR are the voiding cystourethrogram (VCUG) and radionucleotide cystography (RNC). Both of these methods involve the administration of contrast into the bladder through the urethra with subsequent imaging.

The VCUG is a fluoroscopic study in which images are taken while the bladder fills with contrast through a catheter when the bladder is full, when the patient is voiding, and after the contrast has drained (Figs. 19.18 and 19.19). Anterior, posterior, and oblique images are obtained.

FIGURE 19.18 A voiding cystourethrogram showing a normal bladder without vesicoureteral reflux.

FIGURE 19.19 A voiding cystourethrogram fluoroscopic image showing bilateral vesicoureteral reflux.

Contrast can reflux into the upper tracts during all phases of the VCUG or only during the voiding phase of the test. This test provides functional and anatomic information of the bladder and the urethra. It can also show how the patient voids and if any dysfunction is present.

The RNC uses a radionucleotide tracer, usually technetium-99m (99mTc), in the bladder. Reflux is detected with a scintigraphic gamma camera and provides less radiation exposure (1%) compared to the VCUG.[128] The RNC is a functional test but gives little information on an anatomic level. The test is more sensitive for grades II through V reflux but can miss grade I reflux due to the overlying exposure of radionucleotides in the bladder.

Another option, DMSA (technetium-99m-labeled dimercaptosuccinic acid) renal imaging, can provide information regarding the degree of existing renal cortical abnormalities and can serve as a baseline for future comparison (Fig. 19.20). Children with VUR grades III through V, younger children, those with an abnormal renal ultrasound, and those with recurrent febrile UTIs are most likely to have renal scarring that would show up on a DMSA scan. The scan works by an IV injection of the radionucleotide, which enters the venous system and eventually is filtered by the kidney. The radionucleotides are taken up by functional proximal tubules where they bind for several hours. Images of the kidneys are taken and defects of the cortex can be seen if renal scarring or nonfunctional parenchyma are present. In a study of 79 children, DMSA scanning had a 98% sensitivity and a 92% specificity with regard to renal scar detection in children who were followed for 1 to 4 years.[112]

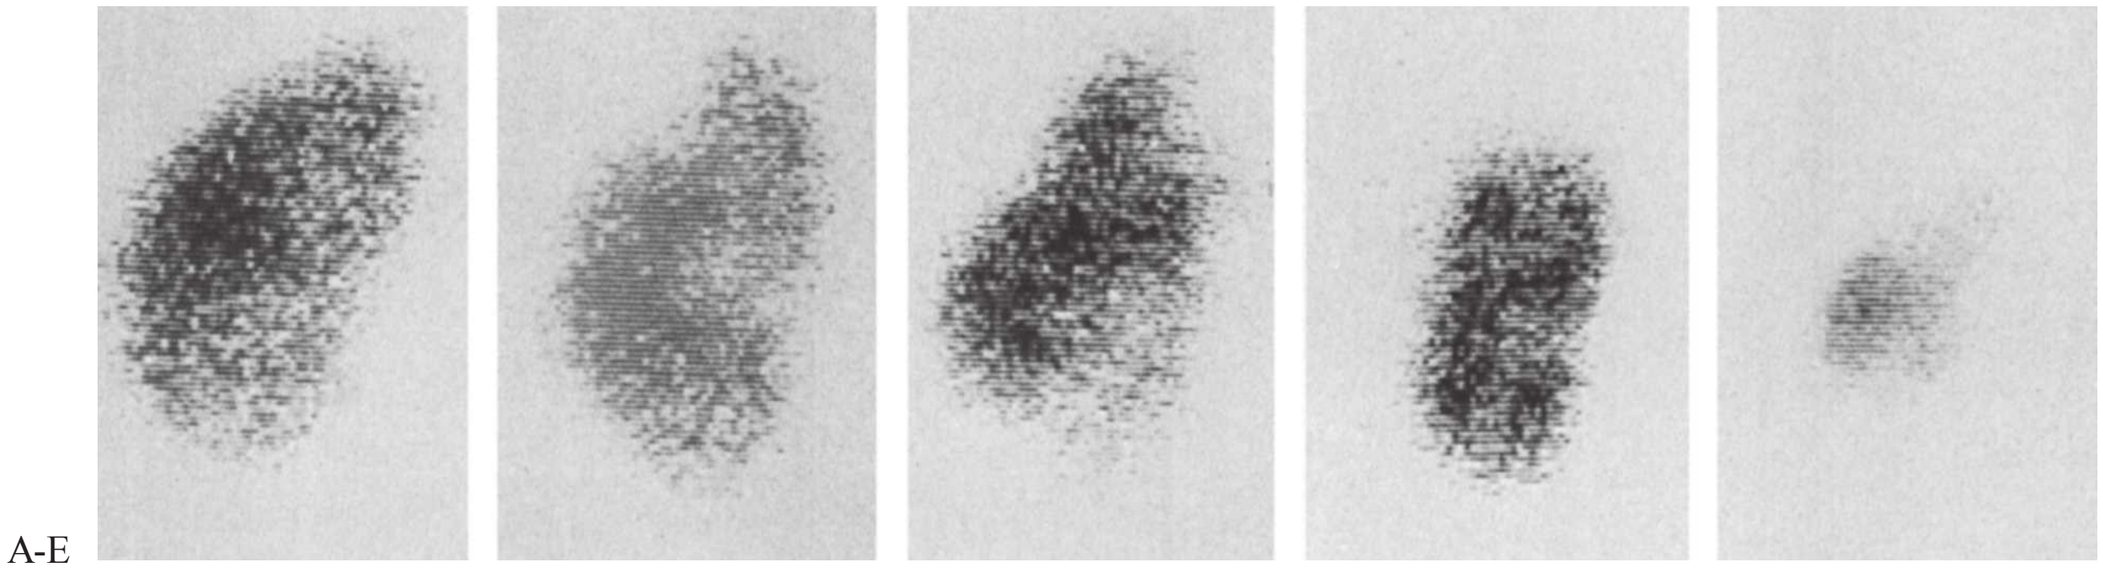

FIGURE 19.20 The classification of kidneys with reflux nephropathy (RN) on 99mTc-DMSA scanning. **A:** Normal. **B:** Type 1 (no more than two scarred areas). **C:** Type 2 (more than two scarred areas, with some areas of normal parenchyma). **D:** Type 3 (generalized damage to whole kidney, similar to obstructive nephropathy [i.e., contraction of entire kidney with or without focal scars]). **E:** Type 4 ("end-stage" kidney with little or no uptake of radionuclide [i.e., less than 10% of overall function].) (Courtesy of Dr. Noemia P. Goldraich, Porto Alegre, Brazil.)

Grading of Vesicoureteral Reflux

The current grading of VUR is based on the 1981 International Reflux Study Committee recommendations for five different grades of reflux (Fig. 19.21). These grades are based on VCUG imaging.[129]

Grade I shows contrast refluxing into a nondilated ureter.

Grade II shows contrast refluxing into the pelvis and calyces without dilatation.

Grade III shows mild or moderate dilatation and/or tortuosity of the ureter and mild or moderate dilatation of the pelvis. There is no or only slight blunting of the fornices.

Grade IV shows moderate dilatation and/or tortuosity of the ureter and moderate dilatation of the pelvis and calyces. There is complete obliteration of the sharp angles of the fornices. However, there is maintenance of papillary impressions in the majority of calyces.

Grade V shows gross dilatation and tortuosity of the ureter, pelvis, and calyces. Papillary impressions are no longer visible in the majority of the calyces.

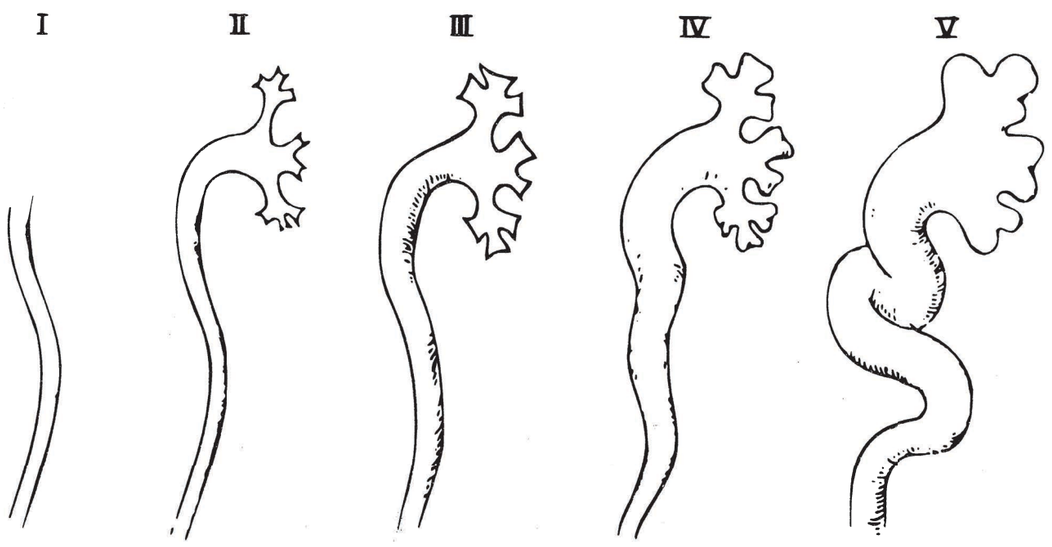

FIGURE 19.21 The classification of grades of vesicoureteral reflux used by the International Reflux Study Committee. (From Report of the International Reflux Study Committee. Medical versus surgical treatment of primary vesicoureteral reflux. *Pediatrics* 1981;67:392, with permission.)

There is no current grading system for reflux done with RNC. Grades II and III are lumped together as low-grade reflux and grades IV and V are combined as high-grade reflux.

Initial Management of Vesicoureteral Reflux

At the initial presentation of a patient with VUR, the first step is to treat any underlying infection if present. After a history and physical, a baseline renal ultrasound should be obtained. If bilateral renal abnormalities are identified, a serum creatinine is indicated. A baseline serum creatinine is obtained to establish an estimate of GFR for future reference. Height, weight, and blood pressure should be documented. An assessment of voiding patterns is recommended to detect the underlying voiding dysfunction. A urinalysis for proteinuria and bacteriuria is also recommended. If the urinalysis indicates an infection, a urine culture and sensitivity is recommended.[123]

Once VUR has been diagnosed, factors including age, race, degree of reflux, and compliance should be considered. Children under 1 year of age should be treated with surgery or antibiotic prophylaxis and should not be observed because of the increased risk of renal scarring in this age group. Treatment of children over the age of 1 year or adults should be based on clinical judgment, taking into account these factors including renal scarring.[123]

Medical Management of Vesicoureteral Reflux

Medical management, or "watchful waiting," has been the standard approach over the past 20 years (Tables 19.4 and 19.5). Sterile urine is maintained with low-dose antibiotic suppression therapy and is usually given at nighttime to achieve peak antibiotic concentrations during the longest period between voids when infection is most likely to develop. Children less than 2 months old are given either trimethoprim or amoxicillin at one-third to one-fourth the normal dose every day. After 2 months of age through adulthood,

the drugs of choice become trimethoprim-sulfamethoxazole or nitrofurantoin.

The basis for medical management is based on several important studies from the 1990s. The hypothesis was that antibiotic prophylaxis could prevent infection and halt renal scarring and deterioration, whereas reflux resolved over time in children.

The International Reflux Study in Children[130] randomized children younger than 9 years old with high-grade reflux to either antibiotic prophylaxis or corrective surgery. Surgery reduced the incidence of pyelonephritis, but the incidence of UTI (38%) and new renal scarring was the same in both groups.

The Birmingham Reflux Study[131] prospectively randomized children to surgery versus medical management over a 5-year period. This study once again showed the incidence of new renal scarring to be similar in both groups, but more scarring was found in children within the first 2 years of observation. There was no significant difference in the incidence of breakthrough UTI between the two groups. However, there were two patients that did progress to ESRD in the observation group and four who developed extensive scarring and hypertension.

Recently, pediatricians question if antibiotic prophylaxis is needed in patients with reflux if good elimination habits are present. Two randomized studies[132,133] from 2008 demonstrated that patients with reflux followed over a period of 1 to 2 years experienced no difference in the incidence of pyelonephritis or renal scarring with respect to antibiotic prophylaxis or observation.

Unfortunately, infections on antibiotic suppression do occur. Breakthrough infections can represent noncompliance or even overdosing of the antibiotic. In this case, a urinalysis and urine culture must be obtained. If the urine culture grows bacteria that are sensitive to the antibiotic, noncompliance is suspected. If the bacteria are resistant to

the medication, too high a dose of the suppressive antibiotic may lead to the killing of normal intestinal flora and the growth of resistant bacteria. Rates of infection can be as high as 12% to 33% on antibiotic suppression in a compliant patient.[134,135]

Surgical Management of Vesicoureteral Reflux

Surgical management has been the definitive treatment for VUR since the 1950s when Hutch[136] first described his technique on nine paraplegic patients. Open ureteral reimplantation into the bladder has been a standard of care. In the early 1980s, endoscopic management for the treatment of VUR emerged and has since become an alternative to open surgery. Surgical therapy is indicated for females with unresolved reflux who may become pregnant, for noncompliant patients, and for failed medical management patients who have had breakthrough infections or who are unable to tolerate the antibiotics.

Surgical techniques all have the same principles, which include mobilizing the distal ureter without compromising its blood supply, creating a submucosal tunnel that provides the 5:1 ratio previously described, gentle handling of the bladder, and adequate muscle backing to the ureter within the submucosal tunnel. Cystoscopy at the time of the procedure can be performed, but is not mandatory.

Open Ureteral Reimplantation

Open ureteral reimplantation can be classified as either intravesical, extravesical, or combined. Using a Pfannenstiel incision, intravesical repairs require opening of the bladder from the dome of the bladder anteriorly to just proximal to the bladder neck. The ureteral orifices are then identified and a 3- or 5-Fr feeding tube is placed into the ureter to aid in dissection. The distal ureter is then dissected away from the bladder to the level of the peritoneum, keeping the blood supply and the ureteral sheath intact. Once an adequate length is obtained, the surgeon's preference determines how the ureter will be reimplanted.

The Politano-Leadbetter technique requires moving the ureter into a new submucosal tunnel with the neo-orifice located in a more medial and inferior position on the trigone (Table 19.6). The Paquin technique is similar to this except the dissection of the distal ureter and placement of the proximal end of the submucosal tunnel is done extravesically. The Glenn-Anderson technique uses the same hiatus as the old orifice but moves the orifice closer toward the bladder neck to increase the length of the submucosal tunnel. The Cohen cross-trigonal technique moves the right orifice to the left side of the bladder under a submucosal tunnel while the left ureteral orifice is moved to the right side of the bladder. This should not be done on patients with a known history of stones or a family history of nephrolithiasis.

The Lich-Gregoir repair is the most common extravesical ureteral reimplant technique used. The ureter is dissected after ligation of the obliterated hypogastric artery off the bladder muscle and trigone. The bladder serosa and muscle are dissected off the bladder mucosa 4 to 5 cm superior and lateral from the ureteral orifice. The ureter is placed between the detrusor flaps, and the flaps are sewn over the distal ureter, thus creating a submucosal tunnel.

An open surgical correction of VUR, regardless of which technique is used, has a very high success rate with an overall cure rate of 98.1%.[123] Postoperative complications include recurrent reflux, contralateral reflux, UTI, and obstruction.

Endoscopic Treatment of Vesicoureteral Reflux

The first case of cystoscopic treatment for VUR was described in 1981 by Matouschek[137] when he injected polytetrafluoroethylene (PTFE) in a subureteric fashion. It did not become a popular mode of treatment until O'Donnell and Puri[138] published their series of 103 ureters injected with Teflon leading to a 75% success rate after one injection. One year later, they treated ureters with grades IV to V reflux with an 84% success rate at a 6-month follow-up.[139] Resolution rates

19.6 Types of Ureteral Reimplants into the Bladder

Author	Technique	Advantages	Disadvantages
Politano–Leadbetter	Intravesical ureteroneocystotomy	Potential for a long submucosal tunnel; anatomic alignment of the ureters for retrograde catheterization	Potential complications as a result of neocystotomy (obstruction, transperitoneal placement, bowel injury)
Glenn–Anderson	Intravesical trigonal advancement	No neocystotomy and anatomic alignment of ureters; simple to perform	Not suitable for dilated ureters as a result of limitation of submucosal tunnel length
Cohen	Intravesical cross-trigonal advancement	No neocystotomy and potential for long tunnel length; simple to perform	Ureters not in anatomic alignment could prevent retrograde catheterization
Gil–Vernet	Intravesical medial advancement	No neocystotomy; simple and rapid procedure because of limited dissection of ureters	Less successful than other intravesical techniques and only suitable if ureters are highly mobile within the bladder
Lich–Gregior and Zaontz and colleagues	Extravesical neocystotomy with or without advancement	Ureters in anatomic alignment; less postoperative bladder symptoms and hematuria	Difficult dissection; potential temporary urinary retention when performed bilaterally

From Austin JC, Cooper CS. Vesicoureteral reflux: surgical approaches. Urol Clin North Am 2004;31:543, with permission.

are lower in children with bowel and bladder dysfunction (50%) compared to those without dysfunction (89%).[123]

Under a general anesthesia, a cystoscope is placed into the bladder and the refluxing ureteral orifice is identified. A cystoscopic needle is placed at the 6 o'clock position and the material is injected into the submucosal space, causing the submucosal tunnel to lengthen and allowing for easier compression of the ureter at rest and during voiding. The injection should be done slowly and the surgeon should see a mound forming at the ureteral orifice and the orifice itself rising into a "volcanolike" orifice. There are several types of injectable material used for this procedure including PTFE, bovine collagen, polymethysiloxane, and Deflux as well as autologous material such as fat, collagen, muscle, and chondrocytes (Table 19.7). The overall success rate of endoscopic treatment for VUR varies from 50% to 92%.[123]

Follow-up for Medical Management

Patients on antibiotic prophylaxis should have an ultrasound at least every 12 months and a VCUG every 12 to 24 months.[123] In patients with grades I to II VUR, follow-up imaging is not considered mandatory, and there is no evidence to support continuous follow-up imaging with a VCUG unless to prove a resolution of the VUR.[123] In the presence of an abnormal ultrasound, a great concern of scarring due to a breakthrough UTI, or a decrease in the patient's overall kidney function, DMSA scanning of a child can be done.[123]

Follow-up for Surgical Therapy

The standard of care after a patient has a corrective surgery for VUR is a renal ultrasound to rule out or diagnose an obstruction of the upper tract. A postoperative VCUG may be done if the patient had an open surgery, but it is recommended when endoscopic correction was performed because the success rate is lower.[123] The rate of obstruction after open or endoscopic surgery is less than 1%. There is no current recommendation on the duration of prophylactic antibiotics after surgery.[123]

Screening of Family Members

VUR can be familial, and the mode of transmission is autosomal dominant. Kaefer[140] reported a 100% prevalence in identical twins. The current recommendation is that a noninvasive test be done on siblings. If scarring is present, then invasive testing may be performed, especially if the sibling is less than 3 years of age.[112]

19.7 Success Rates of Endoscopic Management of Vesicoureteral Reflux

Implant	% Reflux Cured with Implant One Injection[a]	Biodegradable	Comments
Autologous chondrocytes	55	Autologous	Requires two procedures: cartilage harvest and the subsequent subureteric injection
Bovine cross-linked collagen	72	Yes	Skin allergy testing prior to treatment; high relapse rate after 1 year
Dextranomer/hyaluronic acid copolymer	72	Yes	Nonimmunogenic; easy to inject with syringe and needle; only implant FDA approved for the treatment of reflux in children in the United States
Polydimethylsiloxane	82[b]	No	Solid silicone elastomere soft tissue-bulking agent suspended in bioexcretable carrier gel
Polytetrafluoroethylene	73	No	Teflon particles suspended in glycerine; small particle size makes migration a concern; most studied of all implants with largest series

[a]Overall for all refluxgrades.
[b]Grades I–III only.
From Austin JC, Cooper CS. Vesicoureteral reflux: surgical approaches. Urol Clin North Am 2004;31:543, with permission.

Conclusion

Clinical consequences of vesicoureteral reflux can range from asymptomatic to end-stage renal disease. A prompt diagnosis of the condition in a patient with a UTI is mandatory to salvage renal function, especially in children less than 1 year of age. Surgical or medical therapies are accepted management options and should be discussed after the diagnosis. The main goal in the treatment of VUR is to prevent damage to the upper tracts and to preserve renal function.

CHAPTER

20

Nephrolithiasis

Keith A. Hruska • Anne M. Beck

In the United States, the prevalence of kidney stones has risen over the past 30 years.[1] By 70 years of age, 11% of men and 5.6% of women will have a symptomatic stone.[1] Nephrolithiasis is a costly malady to society. Estimates in the 1970s exceeded $5 billion annually in the United States.[2] More current estimates exceed $30 billion. The incidence of nephrolithiasis in the United States is highest in the Southeast,[3,4] with peak incidence occurring in the late summer months. In addition, sedentary, white collar workers are more likely to form stones than are active, blue collar laborers.[5,6] The rising prevalence of renal calculi highlights the importance of environmental factors, such as diet, in their formation. Fructose consumption, which increased since the introduction of high fructose corn syrup, is associated with stone formation.[7] Increased rates of hypertension and obesity are linked to nephrolithiasis.[8] Stones are distinctly less common in African Americans, American Indians, and people of Asian descent. The age and sex distribution of patients referred for evaluation of nephrolithiasis shows a 2:1 ratio of male to female patients and a maximum incidence in the 30- to 50-year-old group (excluding patients with cystinuria and infection stones).

The natural history of stone disease is characterized by recurrence. Although many studies of the natural history and incidence of stones have been biased by referral practices and differences in definition of recurrence, there is clear evidence in the literature of the recurrent nature of stone disease.

A common dilemma faced by the clinician is whether or not to evaluate and treat the first-time stone former. The risk of recurrence after an initial episode has been estimated to be about 50% by 5 years, with almost two thirds of patients having a recurrence by 9 years.[6,9] Even when nephrolithiasis is evaluated and treated appropriately, the incidence of recurrence in first-time stone formers is not significantly different from that in treated patients with a history of multiple stone episodes.[10] In fact, these patients most likely represent recurrent stone formers in the initial stage of their disease. These and other data demonstrating Randall's plaque[11,12] suggest that such patients should be evaluated and treated in the same manner as patients with recurrent nephrolithiasis.

Patients who have undergone shockwave lithotripsy represent another group at risk for stone recurrence. Stone fragmentation often leads to regrowth of stone material, because residual fragments may act as a nidus for ongoing crystal deposition and stone formation. Medical therapy aimed at correcting underlying urinary abnormalities in these patients may prevent or limit stone growth and recurrence.[13]

Despite the almost inevitable risk of nephrolithiasis recurring if it is left untreated, diagnostic evaluation and selective treatment of metabolic abnormalities that decrease the incidence of new stone formation and can induce complete remission are not routinely practiced.[14] Calcium, uric acid, cystine, and struvite stones differ from one another in terms of pathogenesis and treatment. Therefore, each stone type is described separately. The clinical manifestations by which the stones present are not related to the composition of the stone, and this should be kept in mind.

CLINICAL MANIFESTATIONS

The classic presentation of nephrolithiasis is acute renal colic manifesting as colicky flank pain radiating to the groin. As stones descend in the ureter, the pain may localize to the abdominal area overlying the stone and radiate to the gonad. Peritoneal signs are generally absent. Stones at the ureterovesical junction may cause lower quadrant pain that radiates to the urethral tip, urinary urgency, frequency, and dysuria resembling bacterial cystitis. Exam often reveals patients in distress, unable to find a comfortable position, with tenderness in the costovertebral angle or lower quadrant. Gross or microscopic hematuria is present 90% of the time, but the absence of hematuria does not preclude the diagnosis of nephrolithiasis. Owing to the shared splanchnic innervation of the renal capsule and intestines, hydronephrosis and distension of the renal capsule may produce nausea and vomiting. Thus, renal colic may mimic acute abdominal or pelvic conditions.

The best means of confirming the diagnosis of a urinary stone is unenhanced computed tomography (noncontrast helical CT scan) of the abdomen and pelvis. The sensitivity approaches 96% with a specificity of 100%.[15] Positive and

negative predictive values are 100% and 91%, respectively. Negative CT scans often detect other abnormalities including appendicitis, pelvic inflammatory disease, diverticulitis, abdominal aortic aneurysm, and bladder cancer. Plain abdominal radiography assesses whether the stone is radiopaque, which is the case 75% to 90% of the time. Ultrasonography has a high specificity but a much lower sensitivity than CT. Ultrasonography is appropriate as the initial imaging test in pregnancy and in pediatrics and in patients who should avoid radiation. Intravenous pyelography has been replaced by helical CT as the preferred imaging test.[16] Secondary signs of urinary tract obstruction such as ureteral dilatation, hydronephrosis, and perinephric stranding, are variably seen depending on the duration of pain prior to imaging and the sign itself.[17]

Management of acute renal colic involves a decision whether urgent intervention is required or not. The presence of an obstructed infected upper urinary tract, renal deterioration, intractable pain or vomiting, anuria, or obstruction of a solitary or transplanted kidney are all indications for urgent intervention. Intervention is carried out by urology, and is beyond the scope of this chapter. Pain management has traditionally included narcotics, but stimulation of dependency and long-term effects make nonsteroidal anti-inflammatory drugs (NSAIDs) attractive alternatives. When urgent intervention is not selected, the interval between acute colic and elective intervention for failure of stone passage is an important topic. Observation for up to 4 weeks is considered generally reasonable.[18]

CALCIUM STONES

Classification of Calcium Nephrolithiasis by Urinary Chemistries

Biochemical and physical disturbances that contribute to the formation of calcium stones are quite varied, based on two surveys from the mid-1990s.[19,20] Several disturbances have the potential to create the environment conducive to renal stone formation. Several investigators utilize the presence of such disturbances as the basis for diagnostic categorization of nephrolithiasis.[19–21] Earlier studies based on ambulatory evaluations of patients with nephrolithiasis reported 10 metabolic etiologies composing four types of hypercalciuria, hyperuricosuria, hyperoxaluria, renal tubular acidosis (RTA), uric acid stones, and infection stones, and an 11% incidence of finding no metabolic abnormalities.[22] Now more than 15 etiologic categories of nephrolithiasis have been described (Table 20.1). A single diagnosis is found in the minority of patients whereas approximately 60% have more than one diagnosis. The finding of no metabolic abnormality can be reduced to the range of 2% to 4% of patients with care and repeated measures. Hypercalciuric nephrolithiasis accounts for about 60% of the patients. Hyperuricosuria associated with calcium nephrolithiasis can be subdivided into hyperuricosuric calcium nephrolithiasis and patients with gouty diathesis. Hyperoxaluric calcium nephrolithiasis, which occurs in about 8% of patients with recurrent stones, has been subdivided into enteric, primary, and dietary variants. Hypocitraturic calcium nephrolithiasis, which affects about 30% of patients in its idiopathic variant, is also associated with incomplete RTA and the chronic diarrheal syndrome. Hypomagnesiuric calcium nephrolithiasis, infection stones, and cystinuria are uncommon, accounting for 7%, 6%, and 1% of patients, respectively. The acquired problem of low urinary volume, less than 1 L per day according to Levy and colleagues[19] and less than 1.5 L per day according to Seltzer and Hruska,[20] is the single most common abnormality.

The descriptions of clinical subtypes that follow represent the minimal diagnostic criteria used to establish the presence of the entities listed in Table 20.1, according to Hruska and Seltzer.

Absorptive Hypercalciuria Type I

Diagnostic criteria include: calcium nephrolithiasis, normocalcemia, normophosphatemia, hypercalciuria (>200 mg per day) on a calcium-restricted diet, normal fasting urinary calcium (<0.11 mg per dL glomerular filtrate [dL GF]), exaggerated calciuric response to an oral calcium load (>0.20 mg urinary calcium per mg urinary creatinine), and normal to suppressed serum parathyroid hormone (PTH) function.[23–30]

Absorptive Hypercalciuria Type II

Criteria are the same as for type I, except for normal urinary calcium (<200 mg per day) on the restricted diet.[23–29,31]

Absorptive Hypercalciuria Type III (Renal Phosphaturia)

Diagnostic criteria are characterized as similar to type I, except for persistent hypophosphatemia (2.5 mg per dL or less).[32]

Sodium-Linked Phosphate Transporter

Low serum phosphate concentrations due to a decrease in renal phosphate reabsorption occur in some patients with renal calcium stones and/or bone demineralization. Two different heterozygous mutations in the sodium-linked phosphate transport protein encoded by the NPT2a gene have been associated with this disorder.[33] Subsequent studies have shown that although genetic variants of NPT2a are not rare, they do not seem to be associated with clinically significant renal phosphate or calcium handling anomalies in a large cohort of hypercalciuric stone-forming pedigrees.[34]

Renal Hypercalciuria

Diagnostic criteria include: calcium nephrolithiasis, normocalcemia, normophosphatemia, hypercalciuria on the restricted diet, elevated fasting urinary calcium (>0.11 mg per dL GF), and elevated serum parathyroid hormone (PTH).[35]

Primary Hyperparathyroidism (Resorptive Hypercalciuria)

Criteria for diagnosis include: nephrolithiasis, hypercalcemia, hypercalciuria, and high serum PTH with surgical confirmation of abnormal parathyroid tissue.[23–26,28,36,37]

20.1 Urinary Chemistries in Evaluation of Nephrolithiasis[a]

[a]The category definitions in the table refer to Jewish Hospital, Washington University, St. Louis. Criteria for the University of Texas Southwestern data are provided in the text.
RTA, renal tubular acidosis.

Fasting Hypercalciuria and Elevated Fasting Urinary Calcium

Calcium nephrolithiasis and hypercalciuria on a restricted diet can be categorized into a resorptive form because of fasting hypercalciuria. Fasting hypercalciuria is further characterized by normal to suppressed parathyroid function, eliminating renal calciuria, normocalcemia, and normophosphatemia (>2.0 mg per dL).

Hyperuricosuric Calcium Nephrolithiasis

The diagnostic criteria for hyperuricosuric calcium nephrolithiasis (HUCN) include: calcium nephrolithiasis, hyperuricosuria

(>700 mg per day for females; >750 mg per day for males), and frequently a low urinary pH of ≤5.5.[38–40]

Gouty Diathesis

Criteria include uric acid or calcium nephrolithiasis and low urinary pH (<5.5) in the absence of excessive gastrointestinal alkali losses[41–43] or animal protein excess. Hyperuricemia, hypertriglyceridemia, and a history of gouty arthritis may be present.

Hyperoxaluric Calcium Nephrolithiasis

Criteria include calcium nephrolithiasis and hyperoxaluria (>44 mg per day). The three forms of hyperoxaluric calcium nephrolithiasis are:

1. Enteric hyperoxaluria, defined as the presence of ileal disease (Crohn disease, ulcerative colitis, jejunoileal bypass, or intestinal resection), or fat malabsorption with hyperoxaluria on the random and restricted diets.[44–47]
2. Primary hyperoxaluria, consisting of marked hyperoxaluria (>80 mg per day) without evidence of bowel disease, high oxalate diet, low calcium diet, treatment with calcium-binding agents, enhanced oxalate absorption, or high doses of vitamin C.[48]
3. Dietary hyperoxaluria, marked by high oxalate diet, hyperoxaluria on a random diet, and normal urinary oxalate excretion on the restricted diet.[47,49,50]

Enteric hyperoxaluria is typically associated with hypocitraturia due to intestinal loss of HCO_3, low urinary volume, and low normal urinary calcium excretion.

Hypocitraturic Calcium Nephrolithiasis

Diagnostic criteria include calcium nephrolithiasis and hypocitraturia (<320 mg per day),[39] that compose:

1. Distal RTA, which is characterized by systemic metabolic acidosis or defective urinary acidification following an ammonium chloride load and urinary pH above 6.5. The acidosis is a hypokalemic, hyperchloremic nonanion gap metabolic acidosis.[50] In the complete form, metabolic acidosis is present before an ammonium chloride load, whereas in the incomplete form, urinary acidification following an ammonium chloride load is impaired despite normal serum electrolytes before the load.
2. Chronic diarrheal syndrome, which is defined as chronic diarrhea with excessive alkali loss from various gastrointestinal disorders (e.g., gastric resection, ileal disease, Crohn disease, and ulcerative colitis).[51]
3. Idiopathic hypocitraturia of unknown etiology.

Hypomagnesiuric Calcium Nephrolithiasis

Criteria for diagnosis include: nephrolithiasis, hypomagnesuria (<50 mg per day) on the random diet, and absence of a diarrheal disorder.[52]

Infection Stones

Criteria for diagnosis include struvite or carbonate-apatite nephrolithiasis.[53]

Cystinuria

Diagnosis is based on cystine nephrolithiasis and urinary cystine level higher than 200 mg per day.[54]

Low Urine Volume

Diagnosis is based on calcium or uric acid nephrolithiasis and urine volume less than 1 L per day.[55]

No Metabolic Abnormality

This is attributed to calcium nephrolithiasis and a normal biochemical evaluation.[56]

Difficult to Classify

Those that fall into this category are generally nephrolithiasis with recognized stone risk factors.[57] A definitive diagnosis cannot be made due to borderline or inconsistent laboratory values or to the absence of critical data (e.g., stone analysis or roentgenographic visualization).

HYPERCALCIURIC NEPHROLITHIASIS

The majority of patients with calcium nephrolithiasis exhibit hypercalciuria (Table 20.1) and have idiopathic hypercalciuria, which is a term used to describe recurrent nephrolithiasis associated with hypercalciuria, and is probably a distinct entity. However, most of the data suggest that multiple metabolic abnormalities besides excess calcium excretion contribute to nephrolithiasis associated with hypercalciuria. Furthermore, there is a much higher incidence of idiopathic hypercalciuria than nephrolithiasis in the general population.[58] Several estimates place the incidence of idiopathic hypercalciuria at 2% to 4%,[59] whereas the incidence of nephrolithiasis is no more than 0.5% to 1.0%. Between 40% and 50% of calcium stone formers excrete excess calcium in their urine, defined as more than 300 mg per 24 hours (men), 250 mg per 24 hours (women) on ≥1,000 mg calcium intake, or 4 mg per kg body weight per 24 hours (either sex). The term idiopathic hypercalciuria applies if the serum calcium level is normal and sarcoidosis, RTA, hyperthyroidism, malignant tumors, rapidly progressive bone disease, immobilization, Paget disease, Cushing disease (or syndrome), and furosemide administration have been excluded. Virtually all normocalcemic hypercalciuria encountered in patients with nephrolithiasis falls under the umbrella of "idiopathic hypercalciuria."[19]

Among patients with recurrent calcium stones who have served as control subjects in randomized, controlled trials of interventions, new stones formed in 43% to 80% of subjects within 3 years.[14,60–62]

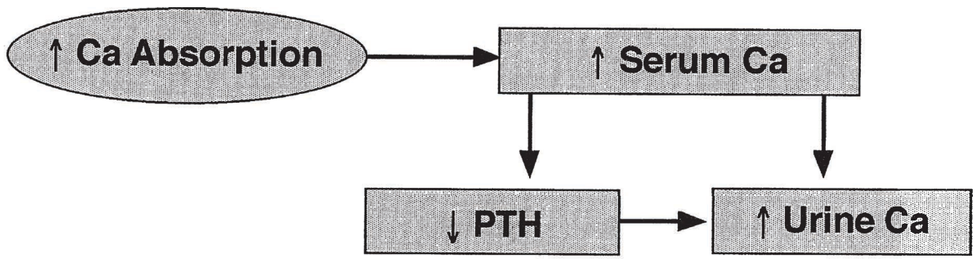

FIGURE 20.1 Pathogenesis of absorptive hypercalciuria. Intestinal hyperabsorption of calcium leads to an increase in serum calcium and a reduction of parathyroid hormone (PTH). The increase in the filtered load of calcium and the reduced calcium reabsorption produced by loss of PTH activity lead to hypercalciuria.

Idiopathic Hypercalciuria

Idiopathic hypercalciuria is an inherited syndrome. Studies of families of patients with hypercalciuric nephrolithiasis reveal a high incidence of hypercalciuria in first-degree relatives.[63] The pattern of inheritance in consecutive generations with high frequency is compatible with an inherited trait with the broad characteristics of autosomal dominant transmission. This pattern of inheritance was demonstrated in large kindred.[64] Hypercalciuria also occurs in children at the same rate as in adults.[65] Spontaneous hypercalciuria similar to that observed in hypercalciuric nephrolithiasis of humans has been demonstrated in the laboratory rat,[66,67] which has become an animal model of the human disorder.

The pathogenesis of idiopathic hypercalciuria involves excessive intestinal calcium absorption and depressed renal tubular calcium reabsorption (Fig. 20.1). The latter is largely due to suppression of PTH[68,69] and can be considered as a major factor in preventing hypercalcemia associated with increased intestinal absorption. When placed on low calcium diets, patients with hypercalciuric nephrolithiasis often demonstrate a negative calcium balance.[70] This could be due to defective renal tubular calcium reabsorption, but renal hypercalciuria should produce secondary hyperparathyroidism, which is rarely observed.[19,20] In addition, considerable evidence indicates that PTH levels are suppressed and that the negative calcium balance stems from excessive skeletal remodeling and bone resorption.[68,69] The question of whether depressed renal tubular calcium reabsorption greater than that expected with PTH suppression contributes to the hypercalciuria of nephrolithiasis remains unanswered. It is supported only by data from a few patients in whom secondary hyperparathyroidism has been documented (see "Renal hypercalciuria" in Table 20.1).

In hypercalciuric calcium oxalate stone formers, the initial site of calcium/phosphate crystal deposition is the basement membrane of the thin limbs of Henle's loop. There is subsequent extension to the vasa section, then the interstitium and, in the most severe cases, to the papillae. Alternatively, in patients with hyperoxaluria secondary to intestinal bypass and idiopathic calcium phosphate stones, the initial crystals were again calcium/phosphate complex, but these arose within the tubule lumens of terminal collecting ducts. Non–stone formers, when subjected to nephrectomy, had neither plaque nor crystals. Thus, there are different sites of crystallization depending on the metabolic abnormalities leading to stone formation.[71,72]

Additionally, in patients with idiopathic hypercalciuria, there was evidence for crystal-induced cell injury in areas of dense crystal deposition, whereas in the bypass patients there was not only cell injury, but also cell death.[11]

The genetically hypercalciuric stone forming rats spontaneously form calcium/phosphate stones unless their diet is augmented with an oxalate precursor.[73]

In the genetic hypercalciuric stone forming rats, calcium oxalate (but not calcium/phosphate) stones induce marked proliferation of the urothelium resulting in sequestration of stones.[67]

Thus, rats and humans appear protected against calcium oxalate stone formation unless a nucleation site, such as the calcium/phosphate crystal, is present.

Absorptive Hypercalciuria

Increased intestinal absorption of calcium is a uniform finding in patients with hypercalciuric nephrolithiasis[20] (Fig. 20.1). At issue is whether increased absorption is the primary defect or caused secondarily in the idiopathic hypercalciuric syndrome (Figs. 20.1 to 20.4). All forms of hypercalciuric nephrolithiasis are associated with increased intestinal calcium absorption. Those associated with intestinal calcium hyperabsorption on a secondary basis—renal hypercalciuria, primary hyperparathyroidism, and renal phosphaturia—are relatively uncommon forms of hypercalciuric nephrolithiasis. Furthermore, fasting hypercalciuria appears to be the expression of increased skeletal remodeling and intestinal calcium hyperabsorption together. All of this indirectly suggests that a specific problem producing intestinal calcium hyperabsorption is a major, if not the basic, underlying defect in idiopathic nephrolithiasis.

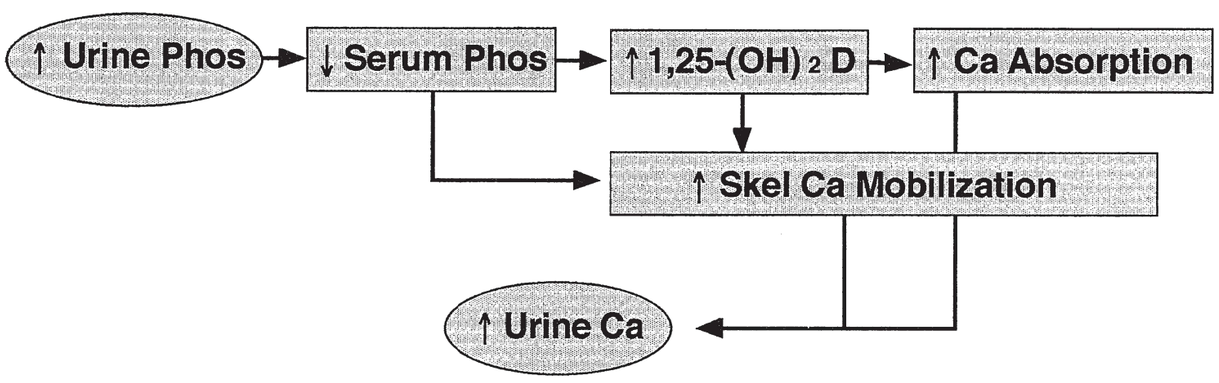

FIGURE 20.2 Renal phosphaturia. Hypophosphatemia leads to increased production of $1,25(OH)_2D_3$, intestinal hyperabsorption of calcium, and increased skeletal calcium mobilization. As a result, hypercalciuria develops.

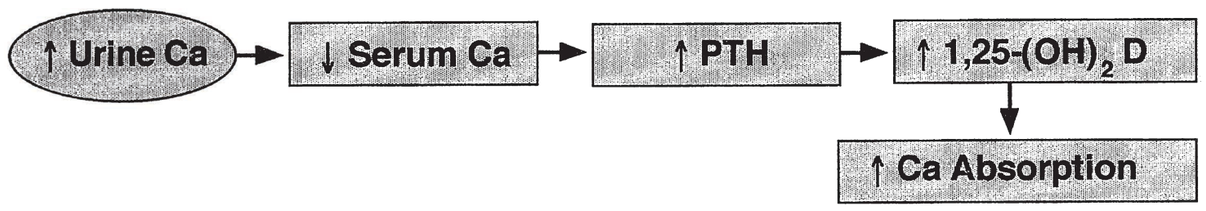

FIGURE 20.3 The pathogenesis of renal hypercalciuria. Defective renal calcium reabsorption leads to hypocalcemia and a stimulation of parathyroid hormone (PTH) secretion. The latter increases the production of $1,25(OH)_2D_3$, stimulating calcium absorption and leading to hypercalciuria. The hypercalciuria in turn compensates for the reduction in serum calcium but compensation never completely restores normal calcium, and elevated PTH values are required in this syndrome.

Intestinal Calcium Absorption

Net calcium absorption is the difference between the mucosal absorptive rate and the secretion of calcium into biliary, duodenal, and pancreatic fluids. Although calcium absorption rates may be measured using oral radiolabeled calcium, only overall balance studies in which fecal losses are measured can quantitate net calcium absorption. The mucosal to serosal absorptive rate is higher in patients with hypercalciuric nephrolithiasis than in healthy individuals[26,36,74–81] (Table 20.2), but overlap is extensive. In six studies, individuals with no signs of hypercalciuric nephrolithiasis absorbed an average of 27% to 52% of an oral dose of radioactive calcium, whereas those with hypercalciuric nephrolithiasis absorbed 22% to 80%. If one chooses only the six studies incorporating normal control subjects, the more efficient calcium absorption by hypercalciuric nephrolithiasis subjects is particularly evident. Increased mucosal-to-blood transport of calcium, but not magnesium, has also been demonstrated directly by in vivo jejunal perfusion in hypercalciuric nephrolithiasis.[29] At normal calcium intakes, <1,500 mg per day, calcium absorption in the duodenum and proximal jejunum is an active process mediated by a mucosal membrane calcium pump (ECaC)[82,83] and efficient cytosolic calcium binding proteins (calbindin),[84] both transcriptionally regulated by calcitriol. At high calcium intakes, passive transport mechanisms in the more distal small bowel and colon may account for most of calcium absorption as the proximal active calcitriol-regulated mechanisms are suppressed.

In normal individuals, urine calcium excretion rises slowly with net absorption[85] (Fig. 20.5), and calcium balance is usually positive when the absorption rate exceeds 200 mg per 24 hours. At all levels of net absorption, urinary calcium excretion was higher in hypercalciuric than in normal subjects, so much so that none of the patient data fell within the 95% confidence band derived from studies of normal individuals (Fig. 20.6). For example, in the range of 200 to 300 mg of net calcium absorption, not one of 38 normal subjects excreted as much as 300 mg of calcium in the urine, whereas 16 hypercalciuric patients did (compare Figs. 20.5 and 20.6). In other words, hypercalciuric nephrolithiasis subjects excreted in the urine an abnormally high percentage of the calcium they absorbed from the intestine. This is compatible with suppression of renal tubular calcium transport rates by low levels of PTH. Net absorption rates exceeded 200 mg per 24 hours in 55 normal subjects (Fig. 20.5). Urine calcium excretion was less than net absorption; that is, calcium balance was positive in 48 subjects. If a generous margin for error (50 mg per 24 hours) is allowed in the balance data, none of the 55 normal individuals were in negative calcium balance. Among 37 hypercalciuric patients with a calcium absorption rate above 200 mg per 24 hours, however, calcium excretion exceeded net absorption in 23 patients by more than 50 mg per 24 hours (Fig. 20.6). In other words, negative calcium balance was frequent in idiopathic hypercalciuria subjects but not in normal individuals. This is compatible with either reduced tubular reabsorption, which should produce elevated levels of PTH, or with excessive bone resorption. The latter appears most likely.

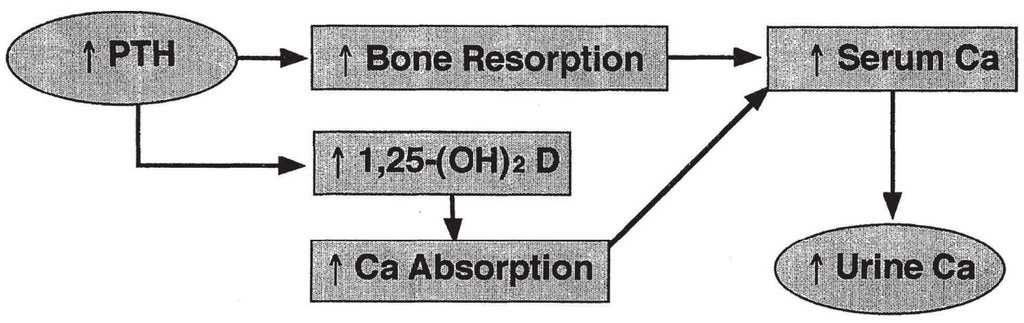

FIGURE 20.4 Pathogenesis of hypercalciuria and primary hyperparathyroidism. Excess secretion of parathyroid hormone (PTH) stimulates bone remodeling and elevations of $1,25(OH)_2D_3$ and calcium absorption. The resultant increase in serum calcium leads to an increase in the filtered load of calcium. The latter overwhelms the stimulation of renal tubular calcium transport by PTH, and hypercalciuria results.

Renal Tubular Calcium Reabsorption

Two systematic studies[86,87] have evaluated overall renal fractional calcium reabsorption (Table 20.3). In both, the filtered load of calcium was calculated from inulin clearance or creatinine clearance and ultrafilterable serum calcium concentration. The fraction of the filtered calcium load excreted was calculated for several clearance periods in normal and hypercalciuric nephrolithiasis subjects. Fractional calcium excretion was clearly high in the hypercalciuric nephrolithiasis subjects. The effects of hydrochlorothiazide and acetazolamide on the renal tubular handling of sodium, magnesium, and calcium suggested to the authors a generalized defect in proximal tubular reabsorption.[86–88] These studies did not examine the role of suppressed or elevated PTH levels in the subjects with hypercalciuric nephrolithiasis. The general finding of a tendency for PTH levels to be

20.2 Intestinal Calcium Absorption in Normal Subjects and Patients with Idiopathic Hypercalciuria

suppressed and the rarity of secondary hyperparathyroidism call for a reexamination of the issue regarding renal tubular calcium fluxes.

A rare syndrome, X-linked hypercalciuric nephrolithiasis (XLHN), or Dent disease, is characterized by recurrent calcium nephrolithiasis and has been found to be due to mutations in a proximal tubular intracellular vesicle chloride transport protein, CLCN5.[89–93] Two other types of hypercalciuric nephrolithiasis, which map to the same defective gene on the X chromosome (Xp11.22) as Dent disease, X-linked recessive nephrolithiasis and recessive hypophosphatemic rickets, are associated with inactivating mutations in CLCN-5.[89]

The CLCN-5 gene is a member of a family of genes that encode voltage-gated chloride channels.[90] CLCN-5 is found in the kidney tubules and in bone cells. All mutations in the CLCN-5 gene found to date have been functional, with loss of function manifested as a lowered conductance of the mutated channel. CLCN-5 is distributed in the human kidney in the proximal tubule, in the thick ascending limb of the loop of Henle, and in the α-type intercalated cells of the collecting duct.[90] These sites are where calcium is resorbed from the filtrate. CLCN-5 knockout animals are hypercalciuric and proteinuric.[91]

CLCN-5 colocalizes with the vacuolar H+-ATPase in proximal tubular cells and a-type intercalated cells. CLCN-5 mutations are associated with modifications in the polarity and expression of H1-ATPase, but not ultrastructural alterations in proximal tubular cells.[93] The variability in diseases

with the CLCN-5 mutations involves impaired solute reabsorption by the proximal tubule and range from kaliuresis, glycosuria, phosphaturia, and/or hypouricemia. Constant findings of Dent disease include hematuria and low molecular weight proteinuria. Dent disease progresses to renal failure due to nephrocalcinosis and tubulointerstitial nephritis.

Thiazide diuretics reduce hypercalciuria in patients with CLCN-5 mutations, but thiazides can make these patients become hypokalemic. The beneficial effect must be weighed against the potential side effect profile.[92] Langman finds little reduction in stone formation even when urinary calcium is lowered to normal in such individuals.[94]

Peacock and Nordin[135]	1.27% (5)	4.25% (9), $P < 0.01$

[a]Number of subjects studied are shown in parentheses next to fractional excretion values.
[b]Urine calcium >300 mg/24 hr (men) or 250 mg/24 hr (women).

Another Voltage-Gated Chloride Channel

Bartter syndrome is a disease arising from one of three possible genes in the thick ascending limb that bear mutations in the Na^+-K^+-2Cl- gene NKCC2, in the K^+ channel ROMK, or in the chloride channel CLCNKB. Each of these mutations produces a phenotype that includes hypercalciuria and kidney stone formation with or without nephrocalcinosis. A missense mutation in the CLCNKB gene leads to disease of intrafamilial heterogeneity of urinary calcium levels. Some family members have Bartter syndrome with frank hypercalciuria, but others have hypocalciuria and a clinical phenotype of Gitelman syndrome.[95]

Hypomagnesemia/Hypercalciuria

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive tubular disorder that is frequently associated with progressive renal failure. The primary defect is related to impaired tubular reabsorption of magnesium and calcium in the thick ascending loop of Henle. Mutations in PCLN-1, which encodes the renal tight junction protein paracillin-1, were identified as the underlying genetic defects. Affected patients usually present in childhood or adolescence with symptomatic hypocalcemia.[96–98] Recurrent nephrolithiasis and nephrocalcinosis are also seen and progression to renal insufficiency and an acidification defect are common. The problem with acidification has been attributed to defective ammonia transfer to the deep nephrons and impaired medullary hydrogen ion secretion due to nephrocalcinosis.[99] Treatment with magnesium salts and thiazides seems to have no effect on the progression of the disease.

A second form of primary hypomagnesemia, Gitelman syndrome, is associated with hypocalciuria. It is due to mutations in the gene encoding the thiazide-sensitive sodium-chloride-cotransporter. Because thiazides are used to treat hypercalciuric nephrolithiasis, it is important to know that they can mimic the syndrome of hypomagnesemia including hypokalemia induced by magnesuria.[100]

Skeletal Remodeling

The high frequency of negative calcium balance in patients with idiopathic hypercalciuria on low calcium diets was the first indication that exaggerated bone resorption characterized the syndrome. Additional evidence for elevated skeletal remodeling in hypercalciuric nephrolithiasis has accrued. Several investigators[69,101] have documented reduced vertebral bone density in hypercalciuric nephrolithiasis by both CT and dual energy X-ray absorptiometry. Patients who exhibit fasting hypercalciuria tend to have a greater reduction in trabecular bone density than do other hypercalciuric patients, but there is significant overlap, and patients with absorptive hypercalciuria and normal fasting calcium excretion exhibit a high prevalence of reduced bone mineral density. Increased rates of skeletal remodeling with resorption favored over formation are supported by the findings of increased osteocalcin secretion and increased urinary hydroxyproline levels in patients with fasting hypercalciuria.[69] The pathogenesis of exaggerated bone remodeling rates may be due to elevations in 1α,25-dihydroxycholecalciferol ($1\alpha,25[OH]_2D_3$) levels, or due to elevations in bone cytokine activity such as prostaglandin activity[102] and interleukin-1 activity.[69] The result of this exaggerated skeletal remodeling is an increase in calcium release to the systemic circulation and suppression of PTH secretion.[103] One possibility is that exaggerated skeletal remodeling is a component of the syndrome of idiopathic hypercalciuria. Activation of skeletal remodeling in the hypercalciuric patient results in increased skeletal remodeling, leading to the loss of a quantum of the skeleton before counterregulatory influences decrease remodeling rates, removing the component of fasting hypercalciuria from the hypercalciuric syndrome. Such a scenario is sufficient to explain the clinical picture, as we currently understand it. Greater clarification of the roles of fasting hypercalciuria, and of bone remodeling, and their pathogenesis is required in patients with hypercalciuric nephrolithiasis. The role of skeletal remodeling in nephrolithiasis was further clarified by the recent discovery of a mutation in the type 2a, sodium-dependent phosphate cotransporter gene found in the proximal tubule and osteoclasts.[33]

Fasting Hypercalciuria

Except for negative calcium balance, either primary intestinal calcium absorption or a primary renal calcium leak could produce the findings summarized in Tables 20.2 and 20.3 and in Figures 20.5 and 20.6. Primary intestinal overabsorption increases postprandial serum calcium levels

above normal and increases the filtered load of calcium (Fig. 20.1). PTH secretion is reduced by the hypercalcemia, and suppression of PTH secretion would reduce calcium reabsorption because PTH stimulates renal tubular calcium reabsorption. In contrast, a renal tubular transport defect (Fig. 20.2) leading to hypercalciuria would produce secondary hyperparathyroidism. PTH, in turn, would stimulate the production of $1\alpha,25(OH)_2D_3$ and produce intestinal calcium hyperabsorption. Hyperabsorption would elevate postprandial serum calcium levels, raising the filtered calcium load and decreasing the magnitude of secondary hyperparathyroidism. The only way of distinguishing one mechanism from the other is by testing specific predictions that differ in the two forms of hypercalciuria. Clinically, PTH levels are the most clear-cut basis of distinction. Fasting hypercalciuria is not a means of detecting a renal calcium leak because it can be and is caused by exaggerated bone remodeling.

Absorptive hypercalciuria is associated with low or normal fasting immunoreactive PTH (iPTH) levels. The absorptive hypercalciuria hypothesis predicts a spectrum of fasting PTH values, but it forbids the combination of elevated fasting urinary calcium-creatinine ratio, and normal-to-suppressed iPTH levels. Normal PTH levels are typically observed in patients with fasting hypercalciuria and hypercalciuric nephrolithiasis. The renal model requires elevated fasting urinary calcium-creatinine ratios and a high serum iPTH level. This is seen uncommonly (Table 20.1).

On the other hand, evidence exists for suppressed PTH levels in patients with hypercalciuric nephrolithiasis who exhibit fasting hypercalciuria[103] (Fig. 20.7). When fasting hypercalciuric subjects are treated with sulindac, an NSAID agent, their urinary calcium excretion is decreased but, more importantly, their PTH levels are increased. This suggests that a bone resorptive process is releasing calcium to the circulation and suppressing PTH. Inhibition of bone resorption by sulindac results in an increase in PTH levels, suggesting that the levels are suppressed in patients with fasting hypercalciuria.[103]

Past studies attempting to detect low or normal PTH levels[26,35,79,104,105] suffer from difficulties with the radioimmunoassay for PTH. More recent double-antibody techniques that enable the measurement of intact hormone and the detection of low circulating PTH levels circumvent these problems and support the finding of low or normal PTH levels in patients with hypercalciuric nephrolithiasis.

Pathogenesis of Absorptive Hypercalciuria

A potential explanation for the pathogenetic process identified in absorptive hypercalciuria is abnormally elevated $1,25(OH)_2D_3$ levels. Patients with idiopathic hypercalciuria tend to exhibit elevations in $1,25(OH)_2D_3$ levels.[32,36,70,79,106] The frequency of high $1,25(OH)_2D_3$ levels in idiopathic hypercalciuria is controversial, but it appears to range from 30% to 40%. Kaplan[36] demonstrates that fractional calcium absorption correlates with the serum concentration of $1,25(OH)_2D_3$. Two thirds of the patients in this study did not have elevated $1,25(OH)_2D_3$ levels.

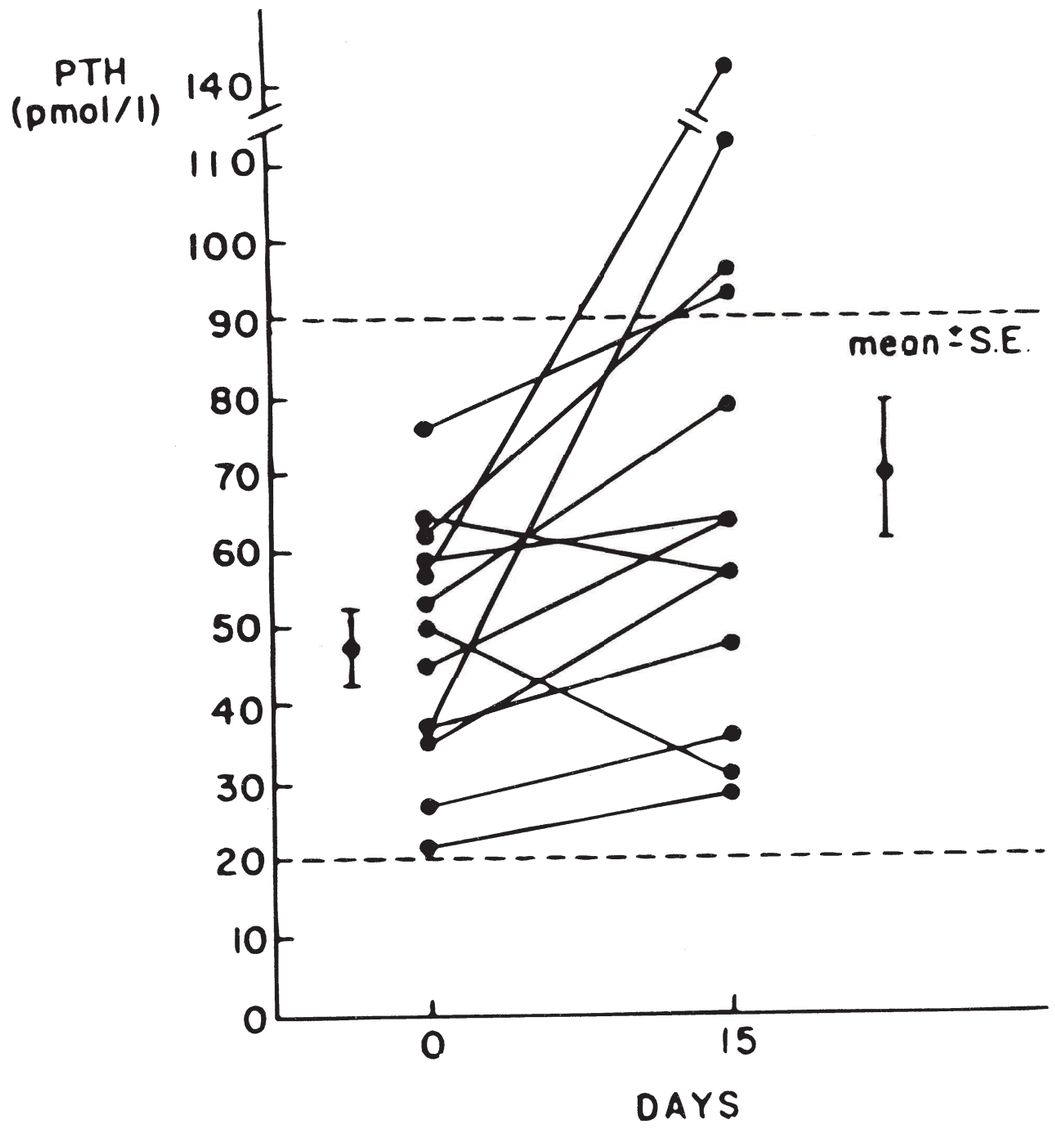

FIGURE 20.7 Changes in serum immunoreactive parathyroid hormone (PTH) in patients with fasting hypercalciuria after 15 days of diclofenac treatment. *Dotted lines* indicate the normal range of PTH. (From Filipponi P, Mannarelli C, Pacifici R, et al. Evidence for a prostaglandin-mediated bone resorption mechanism in subjects with fasting hypercalciuria. *Calcif Tissue Int.* 1988;43:61, with permission.)

On the other hand, evidence exists that shows that increased intestinal absorption of calcium may be primary and independent of vitamin D. Several studies indicated that the hypophosphatemia observed in idiopathic hypercalciuria is not sufficient to stimulate $1,25(OH)_2D_3$ levels.[107,108] Breslau[109] used ketoconazole, an imidazole antimycotic agent[110] capable of reducing serum $1,25(OH)_2D_3$ levels by 40%, in normal subjects and in patients with primary hyperparathyroidism after 1 week of therapy.[111] Ketoconazole was used as a probe to investigate the pathogenetic importance of $1,25(OH)_2D_3$ in patients with absorptive hypercalciuria. Twelve of 19 patients responded to ketoconazole with a reduction in serum $1,25(OH)_2D_3$ levels, intestinal calcium absorption, and 24-hour urinary calcium excretion. In the responding patients, intestinal calcium absorption was directly correlated with serum $1,25(OH)_2D_3$ levels and 24-hour urinary calcium excretion. In seven nonresponders, a reduction in $1,25(OH)_2D_3$ produced no change in intestinal calcium absorption or 24-hour urinary calcium excretion. The authors conclude that absorptive hypercalciuria is a heterogeneous disorder composed of both vitamin D–dependent and vitamin D–independent subsets.[109] The vitamin D–dependent subsets incorporate patients with elevated $1,25(OH)_2D_3$ levels, patients with abnormally responsive vitamin D receptors, and patients with allelic variations

20.4 Types of Renal Stones Formed and Frequency of Occurrence[a]

	CaOx and Cap	CaOx	Cap	Uric acid	Cystine	Struvite	Number of stones

in the vitamin D receptor that have been incriminated in causing osteoporosis.[112] Animal studies in the genetically hypercalciuric rat support the possibility that an abnormal vitamin D receptor could contribute to the pathogenesis of absorptive hypercalciuria.[113]

Pathogenesis

The crystals that form into renal stones consist of calcium salts, uric acid, cystine, or struvite (magnesium ammonium phosphate). Calcium stones are the predominant variety (Table 20.4) and they are composed of calcium oxalate (CaOx), CaOx and calcium phosphate as apatite, or apatite alone.[12,114–119] Two forms of CaOx crystals—monohydrate and dihydrate—differ in their lattice structure and microscopic appearance[120] and this may be relevant to pathophysiology. The calcium phosphate crystals are most commonly apatite or hydroxyapatite. Calcium carbonate is a crystal form usually found mixed in struvite stones or a high pH environment. Occasionally, brushite (calcium hydrogen phosphate), whitlockite (calcium orthophosphate), and octacalcium phosphate are found.[118] Calcium phosphate crystals are as common in stones as are CaOx crystals (Table 20.4), but the amount of CaOx in mixed stones generally exceeds that of calcium phosphate. Additionally, pure CaOx stones are much more frequent than are pure calcium phosphate stones.

Formation of Renal Stones

The formation of renal stones composed of calcium salts is a complex process that remains poorly understood despite considerable efforts over many centuries. The process consists of a calcium salt precipitating from solution (nucleation) forming a crystal. Subsequent crystal growth and aggregation lead to a stone nidus. When the aggregate adheres to the tubulopelvic uroepithelium, continued epitaxial growth of the crystal aggregate eventually leads to a detectable size, making it a renal stone.

Nucleation

Nucleation describes the process that occurs when the activity of calcium salts reaches the level at which the solid phase begins. If one compares urine to an aqueous solution, it quickly becomes apparent that urine is able to hold much higher levels of calcium salt in solution than is water. If one considers an aqueous solution containing crystals of a calcium salt when the crystal neither grows nor shrinks, the solution is in equilibrium. The product of the free ion concentrations (activity product) at this equilibrium determines the equilibrium solubility product (SP) of the salt (Fig. 20.8). Solutions with concentrations of salt less than the equilibrium SP are undersaturated. A higher free ion activity product will cause the solid phase, the crystals, to grow (epitaxy). However, if the crystals are removed from a

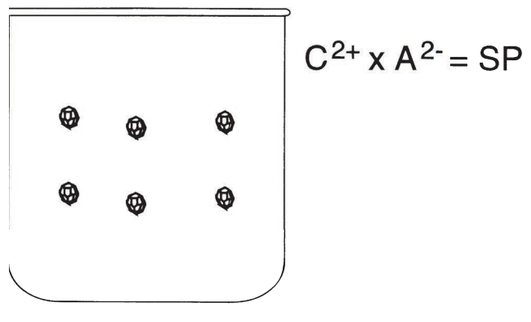

FIGURE 20.8 A solution containing calcium salt (a calcium salt consists of cations, C^{2+}, and anions, A^{2-}) crystals is in equilibrium when the crystals neither grow nor shrink. At this point, the product of the free ion concentration (activity product) is the equilibrium solubility product (SP) of the salt.

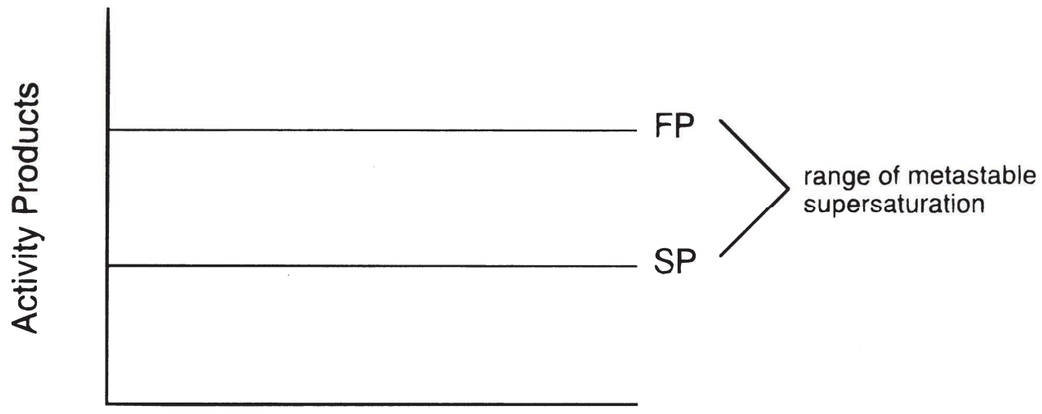

FIGURE 20.9 When calcium salts are added to a solution, precipitation (nucleation) does not occur until free ion activity products well above the solubility product are reached. The activity product at which solid phase begins to form is the formation product.

solution at the level of the equilibrium SP and then the ion activity product is elevated, the activity product that would have caused growth of preformed crystals now results in no appearance of a new solid phase. This solution is called metastably supersaturated (Fig. 20.9). The activity products of calcium salts in urine are almost constantly in the range of metastable supersaturation. In the range of metastable supersaturation, if the activity products are raised sufficiently, new crystals will appear. The activity product at which new crystals form is called the formation product (FP), or the upper limit of metastability (Fig. 20.9). Above the level of the FP, a solution is unstable, creating new crystal nuclei. Urine may be undersaturated, metastably supersaturated, or unstable with respect to CaOx or the stone-forming calcium phosphate crystals (brushite, octacalcium phosphate, hydroxyapatite, and apatite), but most of the time it is metastably supersaturated and, particularly for brushite, close to the FP.

Factors Influencing Urinary Supersaturation

The multiple factors influencing urinary supersaturation in a clinical setting are shown in Table 20.5. The renal excretion of calcium salts that precipitate and take part in stone formation is a primary determinant of urinary supersaturation. Thus, urinary volume, calcium, oxalate, and phosphate ions all participate in the risk of calcium stone formation. In addition, binding of calcium and oxalate to cells, or the solid phase, and urine pH (which influences relative amounts of monohydrogen phosphate and dihydrogen phosphate) drastically alter free ion concentrations and have great importance in regulating saturation—at least equal to the role of the total concentrations of the respective substances. This is the reason why hypercalciuria, oxaluria, unduly alkaline urine, and low urinary volumes are not sufficient to ensure that stones will form in and of themselves. Binding of the components of calcium salts also complicates the measurement of urine saturation, and simple concentration measurements give only small clues to actual free ion activity products.

Alternative substances to calcium salts may be considered as inhibitors of urinary saturation and contribute to the ability of urine to hold salts in solution to a much greater extent than does a simple aqueous solution. The known inhibitors of urinary saturation include the divalent cation magnesium, which forms oxalate, and phosphate salts, which are more soluble compared to those of calcium. In addition, citrate and sulfate are anions with which calcium forms soluble complexes as alternatives to phosphate or oxalate. Urine also contains substances to which calcium binds, thereby reducing the free ion activity. Pyrophosphate, nephrocalcin, and osteopontin are other inorganic and organic crystal inhibitory calcium-binding sites, and are discussed in greater detail later in this chapter. In addition, certain substances to which calcium salts may complex actually promote precipitation. In this category, uric acid and sodium urate are found. These substances are also discussed later in the chapter.

20.5 Factors Affecting Urinary Supersaturation in the Clinic

- Altered epithelial calcium oxalate binding

Measurements of Urinary Supersaturation

Because simple concentration measurements give little clue to the activity of specific ions in urine, several strategies have been designed to estimate urinary supersaturation.[61,121,122] These approaches are computer-based calculations of urinary free ion activity for calcium, oxalate, and phosphate derived from their concentrations and their known tendencies to form soluble complexes with each other and with other ligands such as citrate and sulfate. A calculated free ion activity product such as the CaOx ion product, when divided by the corresponding equilibrium SP, yields an activity product ratio (APR), which estimates the degree of saturation (Fig. 20.10). A ratio above one indicates urinary supersaturation. Ratios below one represent undersaturation. The upper limit of metastable supersaturation can be

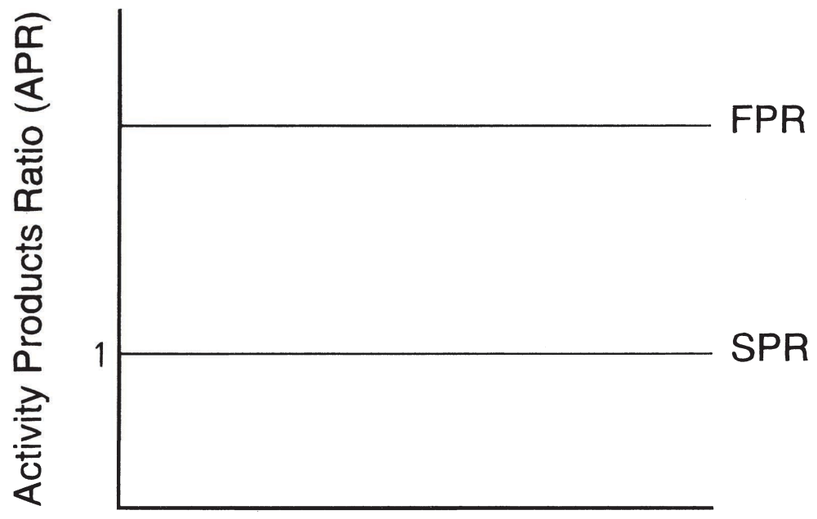

FIGURE 20.10 The calculated activity product of a calcium salt factored by its solubility product (SP) yields a ratio (R) describing undersaturation (<1), saturation (1), metastable supersaturation (>1), and the formation product ratio (FPR) at the point when the solid phase begins to form. The FPR determined for calcium oxalate (CaOx) by Pak and Holt[23] was 11 ± 3.

determined by raising the APRs to the point at which precipitation or solid phase formation begins to appear. The APR at this point is called the formation product ratio (FPR).[61] Pak and Holt[123] modified the approach to measuring urinary supersaturation by adding seed crystals to urine and incubating at 37°C with stirring at constant pH, for 2 days. The ratio of concentration products at the start and end of the incubation must equal the APR, even though the concentration products themselves do not equal the activity products. Pak and Holt[121,123] show that the assumption of stable activity coefficients is valid, so that that the empirical concentration product ratio is a valid estimate of the APR, within limits.

Observations of Urinary Supersaturation

Several investigators[124–128] with varying approaches have accumulated evidence indicating that urine from stone formers is more supersaturated than normal (Table 20.6). Because of differences in methodology, the absolute values of activity products differ among investigators. However, stone formers, whether hypercalciuric or normocalciuric, had higher average values of urine saturation than did those who did not form stones. This held whether saturation was measured with respect to CaOx, brushite, octacalcium phosphate, or hydroxyapatite.

An important observation common to approaches both with and without the use of seed crystals is that activity products of normal urine, on average, are above the equilibrium SP (Fig. 20.9) or oversaturated, except with respect to brushite. In the data from Pak and Holt[123,127] and Weber,[128]

20.6 Urine Calcium Oxalate and Calcium Phosphate Activity Product Ratios in Normal Subjects and in Stone Formers[a]

	Normal subjects	Hypercalciuric stone formers	TCH Normocalciuric TCH stone formers
Calcium oxalate monohydrate			
Robertson[b]	3 ± 1.2 to 10.7 ± 1.3	5.5 ± 1.3 to 18.2 ± 1.3	—
Pak[c]	1.45 ± 0.70	2.8 ± 1.4	2.2 ± 6.1
Weber[d]	1.97 ± 0.90	3.3 ± 2.2	2.2 ± 1.0
Brushite			
Pak[e]	0.35 to 0.26	1.74 ± 0.79	0.9 ± 0.5

this is a visible fact: Added crystals grew in urine from most normal persons. The use of urine measurements to assess supersaturation may be insufficient to reveal the full crystallization potential that exists in the renal tubule. Hautmann and colleagues[129] studied the calcium and oxalate concentrations in tissue from cortex, medulla, and papillae of human kidneys. The CaOx concentration product in the papillae exceeded that of urine and the concentrations in the medulla and cortex. If the high chemical concentration product in the papillae reflects a high free ion product in tubular fluid or interstitium, CaOx crystallization in this region may occur more rapidly than would be predicted from the ion product of the final urine.

Formation Products

The urinary APR at which urine produces new crystals has been measured for CaOx and brushite for those with no signs of stone formation and hypercalciuric, normocalciuric, and hyperparathyroid stone formers. Surprising variability was reported by Pak[127] (Fig. 20.11). However, the APR at the limit of metastability, the FPR, is higher in normal urine than in urine from stone formers. Furthermore, the FPR in urine from patients with hyperparathyroidism may be below the value observed for simple aqueous salt solution. This low of a value of FPR suggests facilitation of crystal formation. This type of data from several investigators yielded several conclusions. The first is that urine is abnormally supersaturated in stone formers. The values of APRs lie close enough to the FPR, at least for CaOx, so that new crystal formation would be expected. Most urine, even from those without stone formations, is metastably supersaturated with respect to CaOx so that growth of crystal nuclei into a significant mass is predictable.

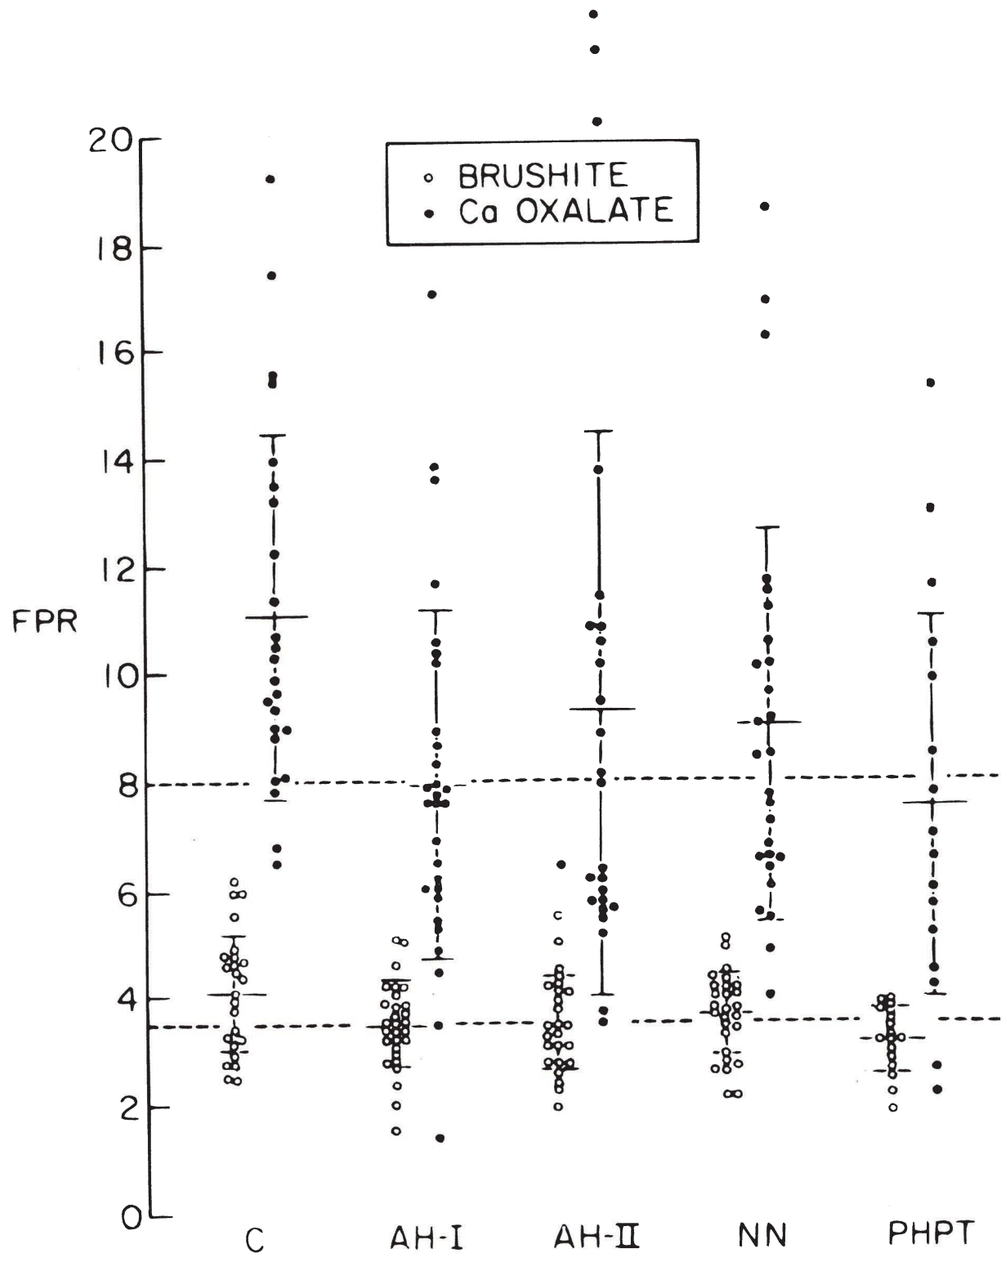

FIGURE 20.11 Formation product ratios (FPRs) for calcium oxalate (CaOx) and brushite of urine from normal subjects and stone formers. Each point shows the value for a single urine sample. For an aqueous solution, the activity product ratios at which spontaneous crystallization of CaOx and brushite occurs, the so-called FPRs, are shown by *dotted lines* at 8 and 3.6, respectively. *C*, control subject; *AH-1* and *AH-2*, severe and mild absorptive hypercalciuria; *NN*, normal calciuric stone formers; *PHPT*, primary hyperparathyroidism. Mean values in standard deviations (SD) are shown by *horizontal lines*. (From Pak CYC, Holt K. Nucleation and growth of brushite and CaOx in urinary stone-formers. *Metabolism*. 1976;25:665, with permission.)

Homogeneous Versus Heterogeneous Nucleation

Nucleation, the initial precipitory event in stone formation, may be homogeneous or heterogeneous. In an unstable solution, crystals form spontaneously by homogeneous nucleation. Much higher levels of supersaturation are required to produce homogeneous nucleation than heterogeneous nucleation.[130] The latter occurs in metastably supersaturated urine as certain macromolecules, or other crystals that can act as nuclei, stimulate precipitation. Because urine contains a number of macromolecular and cellular degradation products, crystallization is most often heterogeneous.[130,131]

The efficiency of heterogeneous nucleation depends on the similarity between the spacing of charged sites on the preformed surface and the spacing in the lattice of the crystal that is to grow on that surface. This matching is referred to as epitaxis, and its extent is usually referred to as a good or poor epitaxial relationship.[132] A number of urine crystals have good epitaxial matching and behave toward one another as heterogeneous nuclei. Monosodium urate and uric acid are excellent heterogeneous nuclei for CaOx,[133,134] so uric acid or urate could, by crystallization, lower the FPR for CaOx. Heterogeneous nucleation is thought to play a role in linking hyperuricosuria to CaOx stones,[38,135–138] a matter discussed later in this chapter. Epitaxial overgrowth of CaOx on a surface of uric acid has been experimentally documented.[139] At a pH above 6.9, brushite may transform to hydroxyapatite, which can serve as a nucleus for CaOx.[140] Based on observations that calcium phosphate is the most common crystal in human urine,[141] is ubiquitous in human urinary stones, and is often seen at the center of mixed CaOx/calcium phosphate urinary stones,[142] nucleation of CaOx crystals is proposed to be induced by calcium phosphate.[11,12] In addition, both apatite and brushite crystals induce crystallization of CaOx in vitro from metastable solutions of CaOx.[143,144] The other possible epitaxial relationships have not yet been linked explicitly to particular varieties of stone disease.[145] However, the low FPRs in primary hyperparathyroidism suggest that heterogeneous nucleation may be occurring.

Crystal Growth

Once present, crystal nuclei grow if suspended in urine with an APR above one (Fig. 20.12). Crystal growth is critical to stone disease, because microscopic nuclei are too small to cause obstruction. Crystals are regular lattices, composed of repeating subunits, and they grow by incorporation of calcium and oxalate, or phosphate, into new subunits on their surfaces. In metastable solutions at 37°C, growth rates of CaOx and the stone-forming calcium phosphate crystals are rapid. Appreciable changes in macroscopic dimensions occur over hours to days. Growth rate increases with the extent of oversaturation and tends to be most rapid in urine having the highest APR.

Factors Influencing Crystal Growth

In urine, the upper limit of metastability is higher and crystal growth rates are lower than in a salt solution with the same APR. The nature of the materials that confer crystal growth rate inhibition on urine is incompletely known. Crystal growth inhibitors for calcium phosphate crystals may not be the same as the substances that affect CaOx crystal growth.

Inorganic pyrophosphate increases the FPs of calcium phosphate and CaOx in salt solutions and, by absorbing their surfaces, retards the growth of hydroxyapatite[138] and CaOx crystals.[140] Urinary pyrophosphate concentrations range from 20 to 40 μM in adults. This concentration is sufficient to inhibit crystal growth.[146] Fleisch and Bisaz[137] suggest that urine raises the FP for calcium phosphate above the level expected from the pyrophosphate it contains. They suggest that other inhibitors accounted for approximately 50% of the total inhibition of calcium phosphate crystal growth. Smith and colleagues[147] have produced similar estimates. Bisaz[148] suggests that pyrophosphate, citrate, and magnesium ions contribute about 77% of the total calcium phosphate crystal inhibition capacity of urine. However, several investigators[140,149] concluded that urine pyrophosphate contributes insignificantly to CaOx crystal growth inhibition.

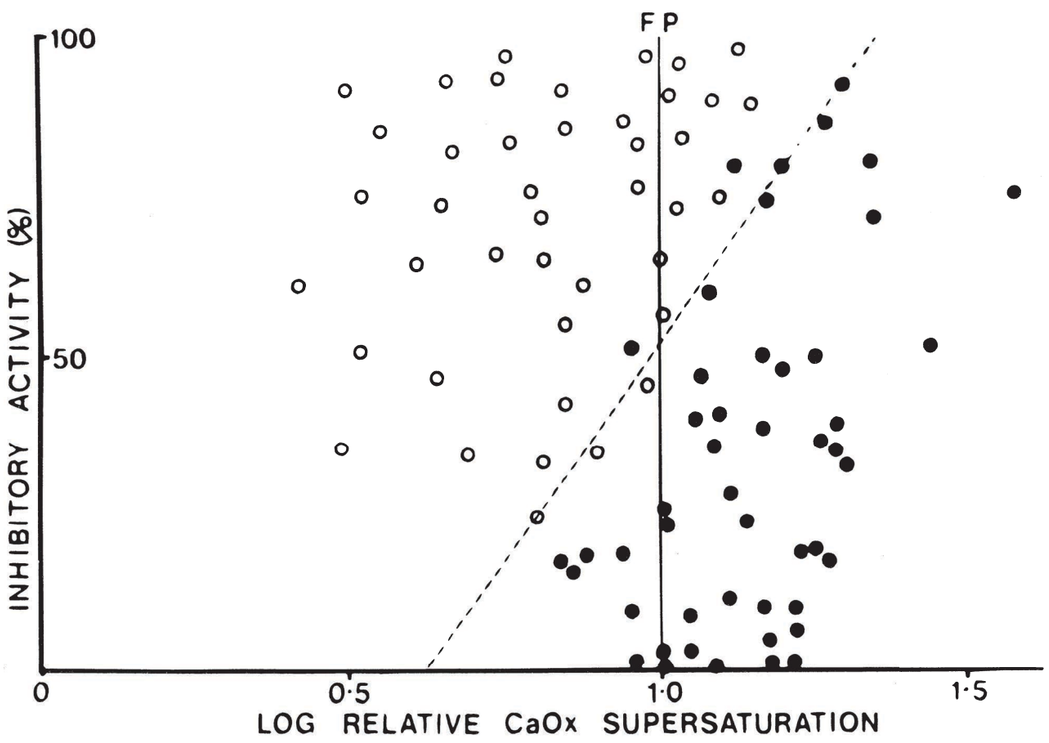

FIGURE 20.12 Saturation-inhibition index of urine from stone formers in normal subjects. The ability of dilute urine to prevent crystal aggregation in an in vitro system (inhibitory activity) is shown as a function of relative supersaturation with respect to calcium oxalate (CaOx) (*x* axis). A value of 1.0 represents the saturation at the level of the formation product (FP); a value of 0.1 would be near the solubility product. Stone formers (*solid circles*) and normal subjects (*open circles*) fall into separate zones; the *dotted line*, obtained by statistical analysis, is the best plane of separation. (From Robertson WG, Peacock M, Marshall RW, et al. Saturation inhibition index as a measure of the risk of calcium oxalate stone formation in the urinary tract. *N Engl J Med*. 1976;294:249, with permission.)

Inhibitors of Calcium Oxalate Crystal Growth

Some progress has been made describing the urinary inhibitors of CaOx crystal growth. The studies of Robertson and associates[150,151] suggesting that a urinary proteoglycan may significantly contribute to CaOx crystal growth inhibition have not been further supported. Strongly acidic peptides such as nephrocalcin and osteopontin have been described as important inhibitors of CaOx crystal growth.[59,146,152–155] Strongly acidic peptides such as poly-L-aspartate and poly-L-glutamic acids inhibit CaOx crystal growth, and urine appears to contain several glycopeptides unusually rich in these two amino acids. Two of the best known of these are nephrocalcin and osteopontin.[155] Treatment of urine with nonselective proteases diminishes the inhibition of CaOx crystal growth,[146] which may be related to urinary glycoproteins. Nephrocalcin contains γ-carboxyglutamic acid (Gla), and is an amphiphilic molecule with a molecular mass of about 15 kd. It tends to self-aggregate into a series of higher molecular mass polymers.[59,152]

Nephrocalcin from stone formers lacks the Gla residues, which is associated with a loss of ability to form stable film at an air-water interface, perhaps reflecting decreased amphiphilicity. The nature of the molecular abnormality leading to decreased inhibition of CaOx crystal growth is unknown. A separate abnormality in nephrocalcin has been identified from the urine of patients with X-linked recessive nephrolithiasis.[156] Nephrocalcin from affected males and carrier females with X-linked recessive nephrolithiasis is poorly phosphorylated, with decreased ability to inhibit crystal growth.

Osteopontin (OPN) is a more recently isolated CaOx crystal growth inhibitor.[153] Expression of OPN under basal conditions is limited to bone matrix, kidney, inner ear, decidual glands, and smooth muscle.[157] OPN is found in breast milk and serum.[158,159] It is expressed in response to various mitogens and growth factors, including phorbol esters and transforming growth factor-beta (TGF-β)[160,161] and is also expressed by cells in response to injury. Kleinman[162] finds that renal tubular OPN expression increases markedly after ischemic injury. However, OPN excretion is not decreased in renal stone formers. It appears that the level of phosphorylation is the critical issue in regard to the function of OPN as a urinary crystal inhibitor.[155] The full OPN protein is not required for functional activity. Small domains of the OPN primary sequence were able to independently inhibit

calcium oxalate monohydrate (COM) crystal growth. The phosphorylated OPN peptides are potent inhibitors of COM crystal growth, but not COM crystal aggregation.[155] The extent of phosphorylation of OPN is responsive to hormonal influences such as those of vitamin D.[163] The role of OPN in the kidney is not fully understood, although it is protective against CaOx monohydrate crystal aggregation and retention in the kidney as demonstrated by studies in OPN null mice, genetic hypercalciuric stone-forming rats, and humans.[67,164]

The role of OPN in biology is complex.[165] It is an osteoclast autocrine regulating motility and bone resorption.[166] OPN is a ligand for the cell surface receptors of $\alpha_v\beta_3$ and CD44, and it stimulates osteoclast signal transduction upon binding.[166,167] In the kidney $\alpha_v\beta_3$ is found largely on the basolateral surface of the distal nephron[168] and CD44 localization is unknown, whereas OPN is secreted mainly by the thick ascending limb into the tubular fluid at the luminal surface of the epithelial cell. OPN is structurally related to proteins found in other mineralized tissues, notably mollusk shells, which have contrasting effects on crystallization depending on whether they are in solution or immobilized on a surface. When in solution, these proteins inhibit calcite, CaOx, and apatite crystal growth.[169] However, if these proteins are immobilized on a support before incubation with a supersaturated solution of the mineral phase, they are able to initiate crystal nucleation in specific orientations.[170] It is believed that OPN serves as a modulator of crystallization and is important for ordered crystal structure of the bone.[171] In its phosphorylated state, it inhibits and thereby regulates apatite formation.[172] OPN is also found in association with the pathologic calcification of stone matrix[173] and atherosclerotic plaques.[160,174] Phosphorylation of OPN renders it inhibitory to vascular calcification[175] and skeletal mineralization.[171]

Tamm-Horsfall protein (THP) is the major urinary glycoprotein of normal urine. THP from stone formers is abnormal, with a higher tendency to aggregate under conditions of increased ionic strength and low pH.[176] Normal THP is an inhibitor of crystal aggregation, but THP from stone formers is less active in preventing aggregation and, under some conditions, THP from stone formers may promote the formation of crystal aggregates, especially in the presence of high concentrations of calcium. The structural abnormalities responsible for impaired inhibitory activity are not completely understood.[177] One study demonstrated that Tamm-Horsfall glycoprotein and citrate concentrations are linearly related to CaOx monohydrate agglomeration inhibition.[178] The effects of the two substances are synergistic. Tamm-Horsfall glycoprotein removal from the urine dramatically reduced CaOx agglomeration.[178]

Hallson and Rose[179] suggested that certain materials in urine, which they refer to as uromucoids, might promote calcium phosphate crystallization and aggregation. The significance of these findings is unclear. Of greater interest, urate anions in urine appear to bind and adsorb inhibitor substances, suggesting that hyperuricosuria could promote CaOx stones by reducing levels of urine crystal growth inhibitors.[150] When incubated in vitro, monosodium urate is able to bind heparin, a potent proteoglycan inhibitor of CaOx crystallization.[180] This demonstrates that at least one specific polyanion inhibitor could be adsorbed by a solid phase of uric acid.

Relationship of Oversaturation and Crystal Growth Inhibition to Clinical Nephrolithiasis

The force that drives calcium salts out of solution, into the solid phase, is oversaturation. Compared to homogeneous nucleation, heterogeneous nucleation facilitates stone formation by decreasing the degree of oversaturation required for nucleation. Inhibitors such as magnesium, pyrophosphate, osteopontin, and nephrocalcin suppress nucleation; increase the supersaturation needed to produce the solid phase; and retard the growth of nuclei already formed. In the most important stone-forming conditions, oversaturation, heterogeneous nucleation, and reduced inhibitors have documented, or at least postulated, roles that vary from one disease to another (Table 20.7). Treatment is often successful in reversing stone formation by eliminating the disturbances that enhance the risk of stones or, in some cases, by introducing secondary biochemical changes that compensate for the underlying defect.

Oversaturation occurs in idiopathic hypercalciuria, primary hyperparathyroidism, and hyperoxaluria because of overexcretion (Table 20.7). Both hypercalciuria and phosphaturia occur in RTA. Oversaturation with respect to calcium phosphate salts, which make up most of the stones in RTA, is also increased by alkaline urine and by low levels of urinary citrate, an important calcium-binding agent.

The finding of urine formation products below those of simple salt solutions provides evidence for heterogeneous nucleation in hyperparathyroidism. The basis for this finding is unknown. Hyperuricosuria is thought to engender urine crystals of uric acid or sodium hydrogen urate, which are efficient heterogeneous nuclei for CaOx.[38,133,134] It is uncertain whether these crystals are in a gel state.[150]

Low levels of urine inhibitors have been demonstrated in some hypercalciuric and normocalciuric stone formers.[125] Robertson[125] reports lower inhibitor levels in hyperuricosuric stone formers. In general, the levels of crystallization inhibitors in the urine of stone formers differ from those in non–stone formers and, consequently, their urine samples can be distinguished from samples of normal people more reliably when inhibitor content is measured than by the use of supersaturation measurements alone (Fig. 20.13). This fact highlights the presence of low inhibitor levels in stone-forming patients and suggests that inhibitors are very important in preventing stones.

More recent measurements of urinary inhibitors of CaOx monohydrate crystal growth show that the lowest inhibitor levels occur in patients with hypercalciuria, but not hyperuricosuria,[180] and that samples from normal subjects can be distinguished from those of stone formers no more

20.7 Pathogenetic Mechanisms in Some Established Forms of Calcium Nephrolithiasis

	Mechanisms		
	Overexcretion	**Heterogeneous nucleation**	**Reduced inhibition of stone formation**
Idiopathic hypercalciuria	+	−	Unknown
Primary hyperparathyroidism	+	+	−
Hyperuricosuria	−	+	−
Renal tubular acidosis	+	Unknown	−
Hyperoxaluria	+	−	−
No detectable metabolic abnormality	−	−	−

reliably by a combination of inhibitor and supersaturation measurements than by measurements of inhibition alone. Nephrocalcin from urine of stone-forming patients[181] or CaOx stones[182] seems abnormal; it lacks Gla and forms weak air-water films. The difference between these results and those of Robertson[125] is probably related to differences in methodology. Hallson and Rose[179] present additional evidence that inhibitors of crystallization are functionally important and differ in stone formers from those in normal subjects.

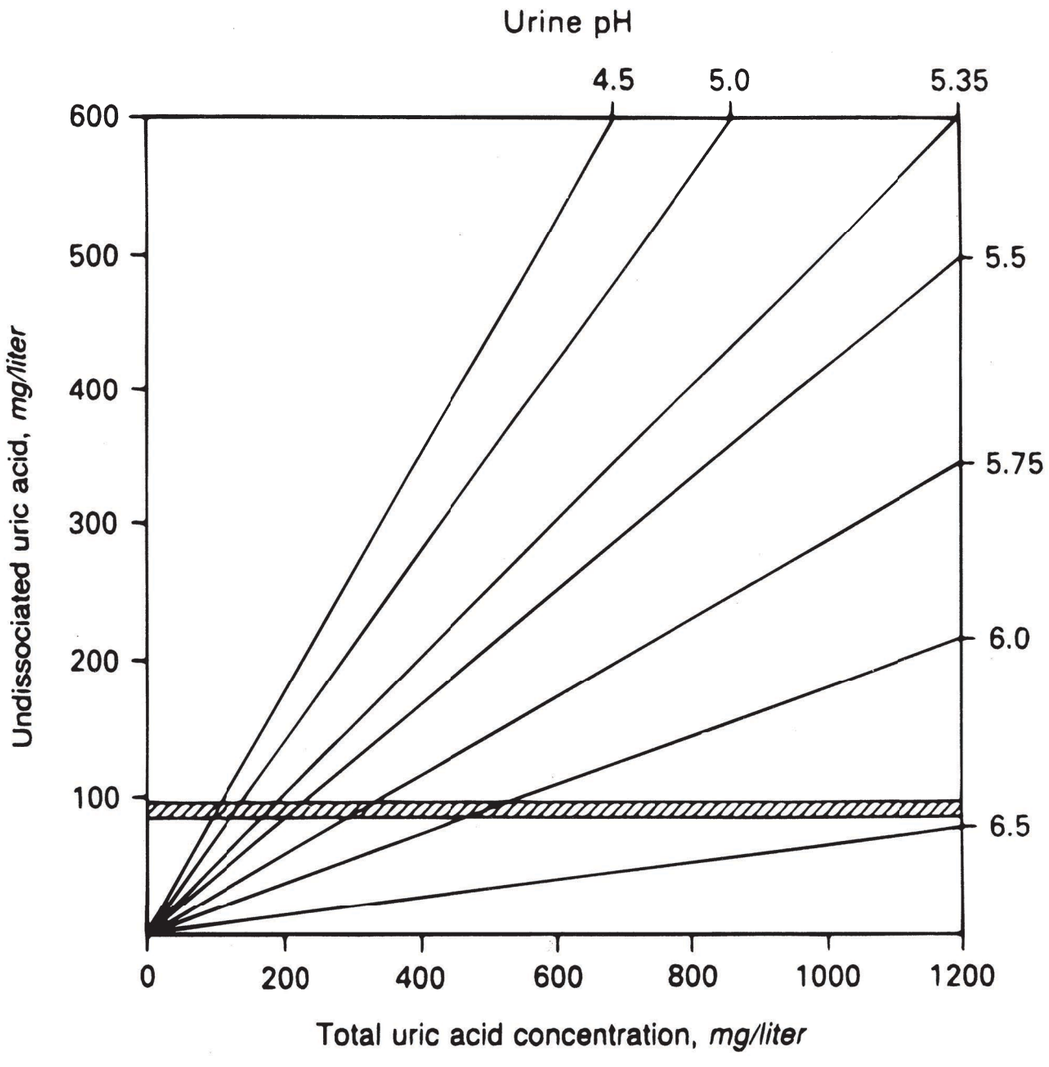

FIGURE 20.13 Nomograms showing undissociated uric acid concentration at values of urine pH and total uric acid concentration. The solubility limit for uric acid is shown by crossed hatched bars (96 ± 2 mg per L). (From Coe FL. Uric acid and calcium oxalate nephrolithiasis. *Kidney Int.* 1983;24:392, with permission.)

Medical Management of Hypercalciuric Nephrolithiasis

The conservative recommendations made for all patients, regardless of the underlying etiology of stone disease, are affected somewhat by the diagnosis of hypercalciuria. Measures undertaken to increase urinary output to more than 2 L per day, to avoid high oxalate and sodium intake, and to restrict animal proteins with extremely high purine levels are generally recommended in any patient with recurrent nephrolithiasis. With these conservative measures alone, a significant number of patients are able to normalize urinary risk factors for stone formation and reduce the incidence of recurrence. After 3 to 4 months of conservative therapy, the patient needs reevaluation. If the patient's metabolic or environmental abnormalities have been corrected, the conservative approach to therapy should be considered and the patient followed every 6 months with repeat 24-hour urine testing. Follow-up is essential, not only to monitor the efficiency of treatment but also to encourage patient compliance. However, if a metabolic defect persists despite conservative treatment, medical therapy may be instituted. For example, if significant sodium-dependent hypercalciuria persists despite dietary recommendations of restricting salt intake, medical therapy with thiazides or citrate may be instituted.

The issue of dietary calcium in patients with hypercalciuric nephrolithiasis has become an important one. It is clear that adequate calcium intake is needed to maintain skeletal homeostasis during adulthood and old age. However,

high calcium intakes are not tolerable in patients with hypercalciuric nephrolithiasis and absorptive hypercalciuria. Nevertheless, a low-calcium diet promotes oxalate absorption by decreasing CaOx salt formation in the intestine. In the absence of calcium, increased free oxalate anion is available for absorption. The impact of low-calcium diets favoring hyperoxaluria has been tested in a large population study from Framingham, Massachusetts.[183] Curhan and coworkers[183] show that dietary calcium intake is inversely associated with the risk of kidney stones in patients who did not have a prior history of kidney stones. Thus, low-calcium diets increased the risk of the development of a kidney stone. It is important to realize that this study specifically excluded most patients with idiopathic hypercalciuria who had already had a renal stone. It is a mistake to recommend high-calcium diets in patients with hypercalciuric nephrolithiasis, especially those who have absorptive hypercalciuria.

Despite improved elucidation of pathophysiology and formulation of diagnostic criteria for nephrolithiasis of different causes, selective medical treatment programs for nephrolithiasis have not been widely implemented. Confusion and controversy regarding the pathogenesis of hypercalciuria, and the absence of an ideal therapeutic approach to absorptive hypercalciuria, have contributed to this situation. Thiazide diuretic therapy remains the mainstay of the medical approach to hypercalciuria. Treatment with a thiazide is ideal, pathophysiologically, for renal hypercalciuria. Thiazides directly stimulate renal tubular calcium transport and suppress the secondary hyperparathyroidism associated with the condition. However, renal hypercalciuria, as previously discussed, is an uncommon form of hypercalciuria associated with nephrolithiasis. Because idiopathic hypercalciuria is largely an intestinal overabsorption problem, an ideal treatment would be one that directly and specifically inhibits calcium absorption. Such a pharmacologic agent is not available.

Sodium Cellulose Phosphate

Sodium cellulose phosphate reduces urinary calcium excretion, especially in patients with intestinal hyperabsorption. However, sodium cellulose phosphate induces a reciprocal increase in oxalate excretion due to the binding of intestinal calcium. The resultant hyperoxaluria offsets the beneficial effects of the hypocalciuria induced. In one study, the oxalate excretion rate rose from 30 to 60 mg per 24 hours[184] and the mean APR for CaOx fell only 20%, from 2.75 to 2.19. Other investigators[185] described the clinical response of recurrent CaOx stone disease to cellulose phosphate. The therapy reduced stone recurrence in patients who received cellulose phosphate to the same degree accomplished by just reducing dietary calcium intake. The latter is known to be ineffective as a single therapeutic approach. Thus, cellulose phosphate is not a treatment for the typical calcium stone former. Although the rationale for its use might seem reasonable, it is flawed by the reciprocal hyperoxaluria. In addition, the high frequency of negative calcium balance in patients with idiopathic hypercalciuria must also be of concern with use of this type of agent.

Thiazides

Thiazides have been extensively used for the treatment of hypercalciuric nephrolithiasis.[186–188] Hydrochlorothiazide is most effective in patients with renal hypercalciuria because, by reducing the high PTH levels, hydrochlorothiazide inhibits its $1\alpha,25(OH)_2D_3$ production and reduces intestinal calcium absorption. Thiazides exert significant hypocalciuric action in patients with intestinal hyperabsorption without reducing intestinal calcium absorption.[30] Nonetheless, thiazides may show long-term effectiveness in absorptive hypercalciuria. Despite the hypocalciuric action of thiazides and the resultant increase in serum calcium, intestinal calcium absorption remains persistently elevated. These studies suggest that retained calcium is added to the skeleton at least during the first few years of therapy. Bone density, determined in the distal third of the radius by photon absorptiometry, increases significantly during thiazide treatment and absorptive hypercalciuria, with an annual increment of 1.34%.[189] With continued therapy, however, the increase in bone density stabilizes and the hypocalciuric effect of thiazide becomes attenuated. These results suggest that thiazide treatment causes low turnover of bone, which interferes with the continued calcium accretion in the skeleton. The resulting hypocalciuric effect of thiazide is blunted by an increase in the serum calcium level and the resultant increase in filtered calcium load.[189]

In addition to the aforementioned studies, several controlled and uncontrolled studies documented the effectiveness of thiazide therapy in hypercalciuric nephrolithiasis.[119] Thiazides directly inhibit the sodium chloride cotransport protein for apical sodium entry in the diluting segment of the cortical thick ascending limb and the early distal nephron. This transport protein is also expressed in the osteoblast, which may further contribute to the positive actions of thiazides in patients with absorptive hypercalciuria leading to increased skeletal calcium accretion. Additional studies will be required to delineate the role of this potential mechanism in the therapeutic benefits resulting from thiazides.

Orthophosphate

Orthophosphate (neutral or alkaline salt of sodium/potassium phosphate given in doses of 0.5 g of phosphorus three to four times per day) reduces $1,25(OH)_2D_3$ synthesis. However, no convincing evidence exists that this treatment restores normal intestinal calcium absorption. Orthophosphate reduces urinary calcium by directly impairing the renal tubular reabsorption of calcium and by binding calcium in the intestinal tract. Urinary phosphorus is markedly increased during therapy—a finding reflecting the absorbability of soluble phosphate. Physicochemically, orthophosphate reduces the urinary saturation of CaOx, but increases that of brushite. Moreover, the urinary inhibitor activity is increased, probably owing to the stimulated renal excretion of pyrophosphate and citrate. The results of studies on the efficacy of orthophosphate are mixed.[189–191] Although reports to the

contrary have appeared, orthophosphate therapy can cause soft tissue calcification and PTH stimulation.[192] Furthermore, orthophosphate therapy is contraindicated in patients with nephrolithiasis complicated by urinary tract infection and in patients with renal insufficiency.

PRIMARY HYPERPARATHYROIDISM

In the past, primary hyperparathyroidism was a major cause of hypercalciuric nephrolithiasis. The advent of routine screening of serum chemistries in hypercalcemic patients led to early detection of primary hyperparathyroidism. Consequently, most patients with primary hyperparathyroidism are detected in an asymptomatic phase before nephrolithiasis becomes a problem. Currently, primary hyperparathyroidism accounts for less than 1% of hypercalciuric nephrolithiasis[19,20,193] (Table 20.1).

The pathogenesis of nephrolithiasis in primary hyperparathyroidism is a direct response to the presence of excessive PTH levels in the circulation. PTH is the primary regulator of renal tubular calcium transport and one of the primary mechanisms regulating bone remodeling. PTH regulates intestinal calcium absorption secondarily through $1,25(OH)_2D_3$. PTH acts on the proximal nephron by decreasing phosphate reabsorption increasing the production of $1,25(OH)_2D_3$ (see Chapter 72). In the thick ascending limb and the distal nephron, PTH directly stimulates tubular calcium reabsorption by regulating both transcriptional and posttranslational modifications of transport proteins both at the entry step in the luminal membrane and the exit step, the calcium ATPase, on the basolateral membrane. Measurement of tubular calcium reabsorption in hypercalcemic patients is technically difficult, but perhaps of a diagnostic value.[194] Enhanced tubule reabsorption of calcium is responsible for normal urinary calcium excretion rates in some hyperparathyroid patients,[195,196] and for the observation that for any given level of serum calcium, urinary calcium excretion is lower in hyperparathyroidism than in other nonparathyroid types of hypercalcemia (i.e., sarcoidosis and multiple myeloma).

Although PTH stimulates tubule calcium reabsorption, urinary calcium excretion is greatly elevated in primary hyperparathyroidism due to the increase in filtered calcium load.[197] The elevation of circulating $1,25(OH)_2D_3$ contributes to the hypercalcemia and. as a result, adds to the hypercalciuria seen in patients with primary hyperparathyroidism.

A major component of hypercalcemia stems from PTH stimulation of bone remodeling. PTH affects both bone formation and bone resorption through its direct actions on marrow cells at varying stages of osteoblast differentiation. Stimulation of osteoprotegerin ligand in the osteoblast and marrow stromal cells stimulates osteoclast differentiation.

Renal stones observed in patients with primary hyperparathyroidism are usually composed of hydroxyapatite and CaOx. Stones often recur and become bilateral if the diagnosis is not made early in the course of the disease. Nephrocalcinosis may be the only renal manifestation of hyperparathyroidism. PTH increases the APRs for CaOx and brushite mainly due to hypercalciuria. Phosphate overexcretion may be observed, but it also may be absent because chronic phosphaturia tends to cause a negative phosphorus balance. The urine pH is not abnormally alkaline in primary hyperparathyroidism and the magnitude of the acidosis is negligible when glomerular function is normal. This suggests that altered acid-base metabolism in hyperparathyroidism does not contribute significantly to stone formation.[120] Pak and Holt[123] demonstrate an unexplained reduction of the FPR for CaOx and brushite in primary hyperparathyroidism (Fig. 20.11). The diagnosis of primary hyperparathyroidism rests with repeated determination of the serum calcium and iPTH levels. The assays for circulating PTH levels using double-antibody techniques enable the detection and measurement of the intact hormone.[198,199] More recently, the "intact" hormone assays have been recognized as also detecting PTH inhibitory peptides lacking the first few amino acids from the NH_2-terminus.[200] Assays that specifically recognize PTH and its first amino acid have been developed and are referred to as "bioactive" PTH assays.[200,201] In the diagnosis of primary hyperparathyroidism, detection of familial hypocalciuric hypercalcemia is critical. This inherited disease is produced by a mutation in the PTH gland calcium sensor such that PTH secretion is not adequately sensitive to the serum calcium levels. Affected patients may exhibit mild hypercalcemia and mild hyperparathyroidism but do not have complications related to the hyperparathyroid state. Thus, detection of patients with the familial disease is crucial so that they are not exposed to surgical therapy for primary hyperparathyroidism. The very low urinary clearance of calcium factored by creatinine excretion is currently the most sensitive means of separating primary hyperparathyroidism from familial hypocalciuric hypercalcemia.[202]

Surgical removal of adenomas or excess parathyroid tissue is indicated in patients with primary hyperparathyroidism who have sustained complications of the disease. Nephrolithiasis is one of the main complications of primary hyperparathyroidism, and any patient who has had a renal stone should undergo surgical correction of the disease state.

HYPERURICOSURIA

Hyperuricosuria can be a significant factor in the formation of calcium stones. Reduction in calcium stone formation in hyperuricosuric patients treated with allopurinol establishes hyperuricosuria as a contributory agent.[135,186,203] Hyperuricosuria is defined as a urinary excretion rate of uric acid that exceeds 700 mg per 24 hours in women or 750 mg per 24 hours in men.

Hyperuricosuria is not the cardinal risk for the development of uric acid stones. Instead, the overriding pathophysiologic process is the unduly acidic urine.[204] Epidemiologic data from converging sources have featured obesity, type II diabetes mellitus, and the metabolic syndrome as strong

associations with low pH.[205–208] With the obesity epidemic in the United States, the incidence of nephrolithiasis has grown in parallel.[209,210] Increased calcium excretion in the obese covaries with intake of animal protein and sodium. No relationship was found between body mass index (BMI) and urinary supersaturation of calcium oxalate. These results suggest that the augmented incidence of nephrolithiasis in the obese is secondary to uric acid stones.[205]

Either of two theories may explain the mechanism by which uric acid promotes calcium stone formation. The prevailing hypothesis states that through epitaxy,[211] the growth of one crystal on the substance of another, uric acid can serve as a seed for precipitation of a calcium salt. Studies have demonstrated that sodium urate accelerates precipitation of CaOx or calcium phosphate in vitro.[133,134] This has been attributed to physiologically relevant urinary concentrations of monosodium urate (0.1 mg per mL).[133] An alternative hypothesis states that urate can complex with and thus neutralizes endogenous urinary acid mucopolysaccharides, which normally retard the crystallization of CaOx.[212]

Urinary uric acid depends on both the renal filtered load of uric acid and its subsequent tubular transport. Hyperuricosuria is usually due to a high filtered load. The source of this uric acid is purines, which come from the dietary intake of purine-rich foods, endogenous synthesis of purines from nonpurine precursors, and salvage of purine bases from tissue catabolism.[213] Coe and colleagues[214] have studied the contribution of dietary purine overconsumption to hyperuricosuria in CaOx stone formers. They find that hyperuricosuric patients consume more purine than control subjects eating isocaloric diets. Overall, a very close correlation exists between urine uric acid and dietary purine intake. Coe and colleagues[214] also find that excessive purine intake does not fully account for the hyperuricosuria, as some patients excrete more urate than normal subjects consuming equivalent amounts of purine. A purine-rich diet is also rich in protein. Gutman[215] hypothesizes that, in some instances, a high-protein diet causes overproduction of uric acid, as the increase in urinary uric acid during a high-protein diet is only partially accounted for by the purine content. It is possible that abnormal tubular handling of urate resulting in hyperuricosuria and normal or low serum urate levels also occurs. Patients with such a defect and stones have been described.[213] Similarly, the Dalmatian dog, which has been well studied, can have hyperuricosuria due to enhanced tubular secretion of urate.[216] Although purine load is the most common mechanism for hyperuricosuria, other factors are contributory.

The treatment of hyperuricosuric calcium stone formers focuses on decreasing the hyperuricosuria. All of these patients should be administered a low-purine diet, which will decrease urinary uric acid excretion,[39,214,217] although in some patients the effectiveness in stone prevention is unproven. A low-purine diet involves avoiding meat, fish, and poultry. Hyperuricosuric calcium stone formers may also be treated with allopurinol, which blocks xanthine oxidase, the last enzymatic step in the purine degradative pathway before uric acid is produced. Very good evidence shows that allopurinol decreases stone formation in this group of patients,[135,186] including the results of a prospective controlled study by Ettinger and colleagues.[203] The usual starting dose of allopurinol is 300 mg per day. A follow-up measurement of 24-hour urinary uric acid excretion after institution of allopurinol will determine the adequacy of the dose. Potassium citrate may be an alternative to allopurinol in patients with mild hyperuricosuria (600 to 1,000 mg per day) in whom hypocitraturia is present, as citrate will inhibit CaOx precipitation.[218]

Uric acid transporters are localized to both the apical and basolateral membranes of the PCT epithelial cells and are coupled to sodium and organic ion transport. The inhibition of the apical membrane URAT1 transporter by probenecid, NSAIDs, salicylates, and losartan can worsen hyperuricosuria.[219]

RENAL TUBULAR ACIDOSIS

RTA is a known risk factor for both nephrocalcinosis and calcium stones. The patients may have severe disease, as in one study by Caruana and Buckalew[220] in which the patients had a mean of 51 ± 14 stone episodes. Only the hypokalemic form of distal RTA (type I RTA) is associated with kidney stones, but the cause of the RTA may be idiopathic or secondary to systemic diseases.[220] Most patients present with nephrolithiasis, a normal serum bicarbonate level but abnormal urinary acidification in response to an ammonium chloride challenge. These patients are believed to have incomplete RTA.[221] The complete form of RTA is often accompanied by nephrocalcinosis. An early description by Albright[222] was of a 13-year-old girl severely affected by RTA with renal calculi, but also with rickets combined with dwarfism. The calculi may be CaOx, calcium phosphate, or a mixture of both, but the presence of calcium phosphate makes RTA a likely etiology.[220,223,224] When both nephrocalcinosis and RTA appear in concert, it may be difficult to define the primary event because nephrocalcinosis can both cause RTA or occur as a result of it. For example, when medullary sponge kidney is associated with kidney stones, nephrocalcinosis, and RTA, it is unclear which is the primary problem.[225]

RTA results in hypercalciuria and hypocitraturia, both of which predispose to nephrolithiasis. Induction of metabolic acidosis with ammonium chloride results in hypercalciuria,[226] which is associated with a net systemic positive acid balance with a stable serum bicarbonate level, suggesting that the acid load is buffered. Because gastrointestinal absorption of calcium does not increase with metabolic acidosis, bone is the likely source of both the urinary calcium and the buffering capacity. This is most likely the link between distal RTA and rickets.[222] Furthermore, as expected, alkali therapy corrects the acidosis and the osteomalacia.[227] Citrate excretion, a known inhibitor of calcium precipitation, is low in patients with RTA due to increased reabsorption.[220]

Simpson[228] demonstrated in vitro inhibition of citrate oxidation by renal cortical slices incubated in medium with a high pH. Furthermore, hypokalemia, a frequent accompaniment of distal RTA, also results in hypocitraturia due to increased reabsorption.

Distal RTA often presents as a familial disease. Primary distal RTA is inherited as either an autosomal dominant or autosomal recessive trait (OMIM179800, 276300, and 602722). Autosomal recessive distal RTA often presents in infancy, whereas autosomal dominant distal RTA may not present until adolescence or young adulthood.[229] Patients with autosomal dominant and recessive distal RTA have been shown to harbor mutations in the gene encoding the chloride-bicarbonate exchanger AE1 (SLC4A1).[229–235] Mutations in ATP6N1B, encoding a kidney vacuolar proton pump protein 116kD subunit, cause recessive distal RTA with preserved hearing.[229,236] On the other hand, mutations in the gene encoding B1 subunit of the proton pump (ATP6V1B1) and (ATP6V0A4) cause renal tubular acidosis with sensory neurodeafness.[229,237,238] Mutations in the genes encoding carbonic anhydrase (CA) II,[239–241] kidney anion exchanger 1 (K AE1),[231,234–236,242] and subunits of the H+-ATPase[229,238,243] have also been identified in patients with distal RTA.[229] In the familial forms of RTA, renal deposition of calcium salts (nephrocalcinosis) and renal stone formation commonly occur. Replacement of alkali corrects the systemic metabolic defects and improves the nephrocalcinosis and nephrolithiasis. Such treatment does not affect the hearing loss of the patients with recessive distal RTA.

Pseudohypoaldosteronism type II is a genetic disorder that produces a clinical phenotype that includes hypertension, hyperkalemia, and metabolic acidosis. It has been linked to mutations in the gene encoding WNK-1 or -4 and is localized to the distal nephron.[244] A recent study demonstrated that in an affected family with a mutation in the WNK4 gene, there was marked hypercalciuria and osteopenia. Thiazide diuretics completely reversed both the urine and bone abnormalities.[244] Distal RTA is possible only if fasting urine pH is above 5.3. If so, an ammonium chloride challenge is necessary to prove the diagnosis. A urine pH above 5.3 after ammonium chloride–induced (100 mg per kg) acidification indicates the presence of RTA.

The treatment of RTA-associated nephrolithiasis consists of alkali therapy. Coe and Parks[245] and Wilansky and Schneiderman[246] document dramatic decreases in stone disease when patients with RTA are treated with alkali. This treatment may also result in an associated decrease in nephrocalcinosis. The dose of alkali is 1 mEq per kg (approximately 80 mEq per day) in four divided doses orally, but the dose should be adjusted to normalize 24-hour urinary citrate excretion. The alkali is usually given in the form of citrate, which both normalizes urinary citrate[247] and decreases urinary calcium.[227,246,247] Potassium citrate is preferable over sodium citrate, because potassium citrate causes a greater decrease in calcium excretion.[247] By replacing buffer capacity with oral alkali, potassium citrate causes calcium excretion to fall as less bone buffers are mobilized. It is likely that sodium citrate does not decrease hypercalciuria as much as the potassium salt, because the extra sodium may have a calciuric effect. Potassium citrate is contraindicated in severe renal insufficiency, and care should be taken to avoid hyperkalemia in the presence of mild or moderate renal insufficiency.

HYPEROXALURIA

Excessive urinary oxalate excretion (>40 to 45 mg per day) contributes to stone formation by increasing the saturation of urine with respect to CaOx. Signifying the importance of hyperoxaluria, increased urinary concentration of oxalate has a greater impact than does urinary calcium on the saturation of CaOx.[248] Hyperoxaluria is a relatively frequent finding in patients with kidney stones and was detected in 34% of 587 consecutive patients evaluated for recurrent nephrolithiasis at the Jewish Hospital of St. Louis Kidney Stone Center from 1987 to 1993. In 8% of these patients, hyperoxaluria was the only identifiable defect (Table 20.1).[249]

Oxalate is an end product of metabolism excreted primarily by the kidneys. Under normal conditions, oxalate is poorly absorbed from the gastrointestinal tract and only about 10% of urinary oxalate can be accounted for by dietary intake.[250] Urinary oxalate excretion varies among patients and is determined by intrinsic oxalate production and metabolism and gastrointestinal oxalate absorption.

Oxalate Production and Metabolism

Oxalate production occurs through a number of metabolic pathways, some of which remain incompletely characterized (Fig. 20.14). The oxidative metabolism of glyoxylate is a major contributor to oxalate production; in addition, ascorbic acid and tryptophan are converted directly to oxalate. Pyridoxine (vitamin B_6) is required as a cofactor for the transamination of glyoxylate to glycine. Moreover, deficiency of vitamin B_6

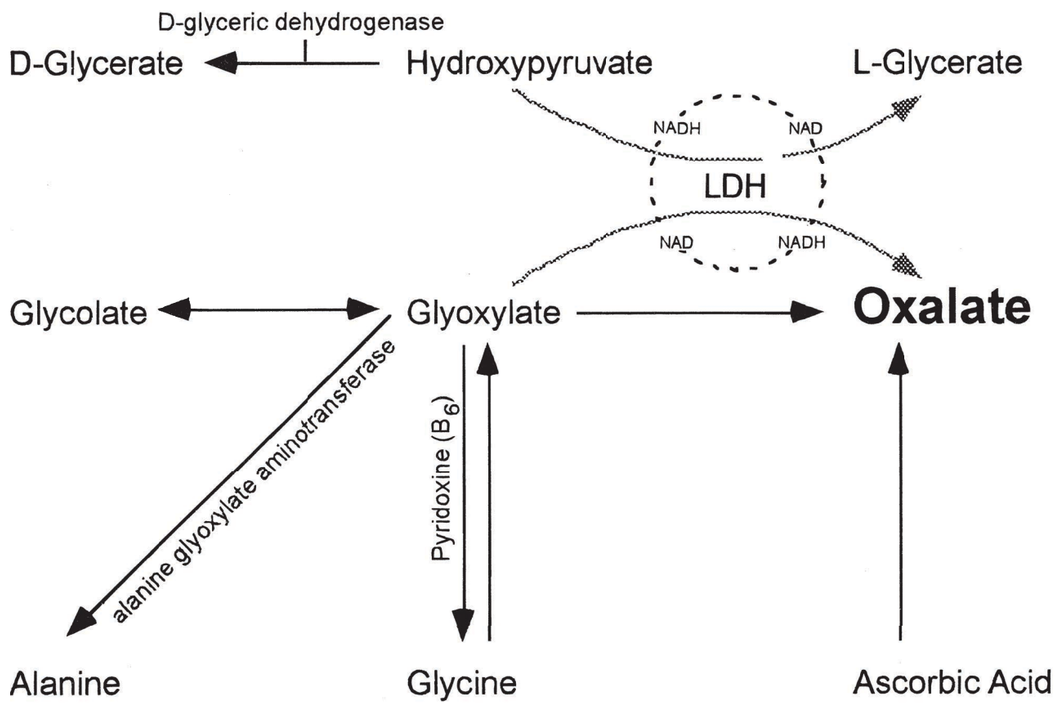

FIGURE 20.14 Metabolic pathways of oxalate production. Oxidative metabolism of glyoxylate is the major endogenous source of oxalate. Ascorbic acid (vitamin C) is also directly converted to oxalate.

may result in accumulation of glyoxylate, increased production of oxalate, and hyperoxaluria.[251] Disordered red cell oxalate exchange and defective oxalate transport may occur as an inherited trait and has been proposed to be a factor in hyperoxaluria within certain families.[252]

Increased availability of substrate for oxalate production can occur clinically in patients taking large doses of ascorbic acid (vitamin C) and in those who ingest ethylene glycol. Metabolism of ethylene glycol results in increased production of glycolate, increased glyoxylate, oxalate formation, and hyperoxaluria. Ascorbic acid, when taken in large doses (4 to 8 g per day), may lead to marked increases in urinary oxalate[253]; however, in some patients, hyperoxaluria may develop with doses as small as 500 mg per day.

Primary hyperoxaluria (PHO) is a rare metabolic disorder with autosomal recessive inheritance. PHO is induced by one of two enzymatic defects, both of which result in markedly enhanced conversion of glyoxylate to poorly soluble oxalate which is then excreted in the urine. Glyoxylate is normally metabolized in three ways. Glyoxylate is converted to glycine by the hepatic peroxisomal enzyme alanine:glyoxylate aminotransferase (AGT). AGT is abnormal in type I PHO.[254] Pyridoxine (vitamin B_6) is a coenzyme of AGT. Glyoxylate is converted to glycolate by the cytosolic enzyme glyoxylate reductase/D-glycerate dehydrogenase (GRHPR). GRHPR is deficient in type II PHO.[255] Patients with this disorder excrete increased amounts of L-glyceric acid as well as oxalate. Glyoxylate is also converted to oxalate by lactate dehydrogenase.

A small number of patients fit the diagnostic criteria for having primary hyperoxaluria (PH), but when studied in vitro, they demonstrate full function of the two now enzymatic defects. This group constitutes about 7% of the 95 patients reported in the Mayo Clinics International Registry and such patients are classified as type III.[256–259]

Type I PHO is much more common than type II. The defect in AGT, which normally converts glyoxylate to glycine, results in an increase in the glyoxylate pool available for conversion to oxalate. The AGT gene maps to chromosome 2q36–37 and encodes for a 43 kDa protein. A number of different mutations have been identified in the coding region of the AGT gene in type I PHO. These defects lead to absent AGT protein, and/or absent AGT catalytic activity.[254] The GRHPR gene has been mapped to chromosome 9 and contains nine exons, spanning 9 kilobases.[260]

In most patients with type I PHO, glycolate excretion is increased. Practically all patients with type II disease have increased excretion of L-glyceric acid. In general, hyperoxaluria plus increased urinary excretion of glycolate or L-glyceric acid is strongly suggestive, but not absolutely diagnostic, of either type I or II PHO. In addition, hyperoxaluria alone, without increased glycolate or L-glyceric acid excretion, does not exclude the diagnosis of PHO.[48]

The presence of AGT deficiency can be confirmed by liver biopsy. Evaluation of the hepatic tissue includes quantification of enzymatic activity, an immunoblot to analyze the protein, and an immunoelectronic examination to demonstrate the virtual absence of AGT in the peroxisomes. AGT activity is less than 2% of normal in one-third of cases and ranges from 2% to 48% of normal in the remaining patients.[255] The relative ease in modern laboratory medicine with performing sequence analysis, and the delineation of the molecular basis of many of the mutations behind PHO type I and PHO type II, has led to the proposal of molecular diagnostic algorithms that may obviate the need for invasive biopsy procedures.[261,262]

Phenotypically, type I PHO is heterogeneous, ranging from severe infantile oxalosis and death to milder forms with renal stone disease in later life. Type II PHO has a less severe clinical course, but there may be a decline in renal function associated with the presence of nephrocalcinosis. Children with nephrolithiasis secondary to hyperoxaluria should have urinary glycerate measured to exclude type II PHO.[10]

Gastrointestinal Oxalate Absorption

Increased absorption of oxalate occurs with excess dietary oxalate intake, diminished binding of oxalate by dietary calcium and magnesium, or enhanced permeability of the colon to oxalate. Foods with relatively high oxalate content include spinach, beets, rhubarb, asparagus, cranberries, wheat germ, colas, teas, chocolates, nuts, beans, and various green leafy vegetables. Once ingested, oxalate forms insoluble salts with available calcium (and magnesium) in the intestinal lumen and is poorly absorbed; any free unbound oxalate is available for absorption distally in the colon.

Disorders characterized by absent or dysfunctional small bowel, as well as any causes of fat or bile acid malabsorption, can lead to hyperoxaluria.[263] Fat malabsorption allows luminal calcium and magnesium to saponify, leaving inadequate free calcium (and magnesium) to bind oxalate. Bile acid malabsorption causes increased permeability of the colon to oxalate.[264] Thus patients with inflammatory bowel disease, those who have had ileal bypass surgery or resection, and those with disorders associated with malabsorption develop hyperoxaluria due to an increase in unbound oxalate and enhanced colonic absorption.

Patients following a low-calcium diet and those taking sodium cellulose phosphate for the treatment of absorptive hypercalciuria may also manifest hyperoxaluria as a result of such therapy. Diminished oral calcium intake (with a low-calcium diet) and binding of calcium and magnesium in the gut by sodium cellulose phosphate allow increased amounts of unbound oxalate to be presented distally in the colon where it is readily absorbed.[265,266]

Therapy

Treatment of primary hyperoxaluria is difficult. Reducing sodium intake to 2 to 3 gm per day and limiting or avoiding high-oxalate foods is recommended. Supplemental citrate, magnesium, and phosphorus may help decrease urinary oxalate crystallization. Calcium intake should not be restricted

because this can increase intestinal calcium absorption. Approximately 10% to 40% of patients respond to pyridoxine supplementation, but vitamin C and D supplements should be avoided. Dialysis does not remove oxalate adequately. Hepatic transplantation remains the only therapy capable of correcting the underlying abnormalities in these patients.[267]

Treatment of patients with enteric hyperoxaluria should include a low-fat diet with restriction of oxalate-rich foods, appropriate therapy of any underlying gastrointestinal disorders, and avoidance of a low calcium intake. Some patients may benefit from the addition of oral calcium and magnesium supplements taken with meals, which act to bind dietary oxalate in the intestinal lumen, making it unavailable for absorption. Cholestyramine may also be of some benefit in those patients with significant fat and bile acid malabsorption as it acts as a nonabsorbable resin to bind fats and bile acids. Pyridoxine supplements may be effective in patients with moderate to severe hyperoxaluria.[268]

Patients with chronic diarrhea frequently have hypomagnesemia, hypokalemia, metabolic acidosis, hypocitraturia, and low urinary volumes. For these reasons, they also are prone to the development of uric acid stones. Therapy involves increased fluid intake, correction of hypokalemia and hypomagnesemia, and oral citrate supplements. Attention must also be paid to treatment of the underlying intestinal disorder and diarrhea.

Uric Acid Stones

Uric acid stones are radiolucent stones responsible for approximately 5% of kidney stones in the United States. Other populations may have a higher relative incidence of uric acid stones as a cause of urolithiasis. Due to the difficulty in visualizing these stones on an abdominal radiograph, an intravenous pyelogram is often necessary to make the diagnosis. Stones containing some calcium may be visualized on the radiograph, which may have important therapeutic implications.

Pathogenesis

Uric acid is the normal breakdown product of purine metabolism and is a natural urinary constituent. Precipitation of uric acid to form a stone can be demonstrated best by the relationships demonstrated in Figure 20.8.[42] The solubility limit of undissociated uric acid is 96 ± 2 mg per L at 37°C. In a given sample of urine, undissociated uric acid is dependent on the total uric acid concentration and urinary pH. The clinical laboratory routinely measures total uric acid excretion, but the undissociated uric acid can be inferred from both the total uric acid concentration and the urinary pH.

The total urinary uric acid concentration is a function of both uric acid excretion and urinary volume. Hyperuricosuria is defined as a urinary excretion rate of uric acid that exceeds 700 mg per 24 hours in women or 750 mg per 24 hours in men. When patients with gout were assessed for risk factors for stone disease, it was found that the incidence of stones increases with increasing degrees of hyperuricosuria.[269] A urinary excretion rate of uric acid of more than 1 g per 24 hours is associated with a 50% incidence of stones.[269] Urinary uric acid excretion depends on both the renal filtered load of uric acid and its subsequent tubular transport. Hyperuricosuria is usually due to a high filtered load. As stated earlier, the source of this uric acid is mostly purines,[213] usually from meat, fish, and poultry. A purine-rich diet is also rich in protein and, as Gutman[215] hypothesizes, in some instances a high-protein diet also causes overproduction of uric acid as the increase in urinary uric acid during a high-protein diet is only partially accounted for by the purine content. The overriding risk for uric acid nephrolithiasis is acidic urine.[270] Low urine pH leads to stone precipitation with relatively modest amounts of uric acid excretion whereas urine pH above 6.0 requires large amounts of urinary uric acid for lithogenesis. In two large cohorts of uric acid stone formers, there was a strong negative correlation between BMI and urine pH.[208] Each component of the metabolic syndrome appears to confer a risk for more acidic urine.[206] The dysfunction is impaired ammoniagenesis and, therefore, insufficient buffering of urinary protons. Low ammonium production leaves free protons to be buffered by titratable acids (i.e., phosphates and sulfates) thereby lowering urine pH. Reabsorption of filtered citrate is stimulated in the proximal tubule in states of acidosis/acid loads and hypocitraturia results.

The link between metabolic syndrome and impaired ammoniagenesis is thought to be mediated by insulin resistance.[207,271,272] Impaired ammoniagenesis is not the only pathogenic feature of patients with abnormally low urine pH. Increased net acid excretion and titratable acidity has been observed in uric acid stone formers even on fixed diets.[272–274] The biochemical origin of these findings is unclear, but may be related to post-prandial alkaline tide.[275,276]

Diseases Associated with Uric Acid Lithiasis

Among patients with uric acid lithiasis, a family history of gout or kidney stones often exists, predominantly in men. Most cases of uric acid lithiasis are idiopathic, but some disease associations should be considered when treating a patient with uric acid stones.

Primary Gout

Twenty-two percent of patients with primary gout have uric acid stones.[269] Eighty-three percent of these stones are pure uric acid, whereas 4% are mixed stones and the rest are calcium stones. Often, the uric acid stone disease antedates the diagnosis of gout. Conversely, the stones may only appear after administration of uricosuric drugs for gout. As discussed previously, uricosuric agents may treat the gout but cause uric acid stones.

Secondary Gout

Underlying diseases that cause gout confer a higher risk for kidney stones than does primary gout (42% versus 22%).

These diseases are associated with excess generation of uric acid due to nucleotide turnover (e.g., myeloproliferative disease, polycythemia due to congenital heart disease, and chronic granulocytic leukemia).

Chronic Diarrhea

Because intestinal fluid losses may result in urinary concentration of excreted urate, chronic diarrhea can result in uric acid stones. Likewise, fecal bicarbonate loss causes renal regeneration of bicarbonate with subsequent urinary acidification and more undissociated urate.

Familial Disease

Hereditary disorders associated with overproduction of uric acid include inborn errors of metabolism such as Lesch-Nyhan syndrome and type I glycogen storage disease. Lesch-Nyhan is caused by hypoxanthine-guanine phosphoribosyl transferase (HGPRT) deficiency and Kelley-Seegmiller syndrome is a partial enzymatic defect.[277] Type I glycogen storage disease is secondary to glucose-6-phosphatase deficiency. A single gene that is located distally on the long-arm of the X chromosomes codes for HGPRT. Purification of mutant HGPRT genes in patients with partial or complete deficiency of HGPRT has led to the identification of single amino acid substitutions in five known variants of HGPRT.[278] The lack of feedback control by the purine salvage pathway leads to massive overproduction of uric acid and may lead to repeated episodes of urolithiasis and renal failure. Several families with inherited predispositions to uric acid stones have been described,[279] although the underlying cause is unknown. A candidate gene for uric acid nephrolithiasis has been identified on 10g21-g22 from a local Sardinian population with known susceptibility to uric acid kidney stone disease.[280]

Treatment

The fact that urinary uric acid concentration and urine pH can influence urate precipitation underlies the following treatment modalities.

Existing stones can be dissolved with alkali (to keep the urine pH at 6.5 or above) and a large amount of fluids to keep the urine output at more than 2 L per day. Allopurinol should also be given to reduce hyperuricosuria. Uric acid stones that contain calcium may be refractory to dissolution. Furthermore, the presence of obstruction or refractory pain may necessitate more rapid therapies such as lithotripsy or invasive urologic techniques.

Stone prevention necessitates dietary counseling and alkali therapy. Dietary modification entails keeping urine output at more than 2 L per day and reducing dietary purine intake (i.e., meat, fish, and poultry). Furthermore, patients should also reduce their protein intake to decrease both urine uric acid and the acid load. Likewise, alcohol intake should be limited because it may increase uric acid production. Alkali treatment should be given, aiming for a urine pH of 6.5. Approximately 1 mEq per kg of potassium citrate given in three divided doses is effective.[215] Sodium bicarbonate may be a less desirable form of alkali because the sodium load may aggravate hypercalciuria, which may aggravate nephrolithiasis.

Allopurinol can decrease urinary uric acid excretion by blocking the conversion of xanthine to uric acid by xanthine oxidase. Allopurinol serves as a second-line agent used when patients either refuse treatment or diet and when alkali therapy fails. Furthermore, it may be of benefit when uric acid loads are large, such as prior to chemotherapy for large volume rapidly growing tumors, or if the urinary uric acid excretion rate is more than 1 g per 24 hours. In the treatment of hyperuricosuria due to chemotherapy, a brisk diuresis should still be maintained because xanthine, the precursor of urate, may accumulate and cause acute renal failure, as can other products of tumor lysis.

The potential role of Oxalobacter formigenes in the treatment of primary hyperoxaluria has shed some light on the role of the intestine in maintaining oxalate balance. The use of the intestine to alter oxalate balance when kidney excretion alone is inadequate is among the therapeutic options on the horizon for the treatment of primary hyperoxaluria. Studies in rats have shown that intestinal colonization with O. formigenes can induce colonic secretion of oxalate, in part by producing a favorable concentration gradient through oxalate degradation.[281] Hoppe et al.[282] reported efficacy of oral O. formigenes administration in humans with primary hyperoxaluria. The majority of subjects with normal kidney function showed a 22% to 92% reduction in urinary oxalate. Two of three dialysis patients had a significant reduction in plasma oxalate levels as well, and with improvement in clinical symptoms.[283]

STRUVITE STONES

Struvite stones are composed of magnesium ammonium phosphate with variable amounts of carbonate apatite. This compound forms only in the presence of chronic urinary tract infection with bacteria capable of producing urease. The action of bacterial urease on urine urea yields ammonia and carbon dioxide. These are further hydrolyzed to ammonium and carbonate, resulting in a urine pH above 7.2—ideal conditions for struvite formation. Most species of Proteus and Providencia produce urease. Klebsiella, Pseudomonas, Serratia, Haemophilus, Staphylococcus, and Corynebacterium species are all capable of urease production. Escherichia coli does not possess urease activity.

Struvite now accounts for less than 10% of all stones and occurs most often in women and patients with spinal cord injury, neurogenic bladder, urinary diversion, or chronic indwelling bladder catheters due to their increased frequency of chronic urinary tract infection. Clinical findings may include evidence of urinary tract infection, hematuria, flank pain, or obstructive uropathy. Rarely, infection stones may cause xanthogranulomatous pyelonephritis. Struvite, when calcified, presents radiographically with a

characteristic multilobulated shape and laminated appearance and may extend to involve all calyces forming so-called staghorn calculi.

Because struvite formation occurs in the region surrounding bacterial colonies, all struvite stone material is infected. In addition, antimicrobial agents are unable to adequately penetrate struvite and achieve bactericidal levels. Therefore, the only curative treatment is eradication of infection with antimicrobials and removal of all stone material. Combined percutaneous nephrostolithotomy and extracorporeal shock wave lithotripsy is recommended as the first line treatment choice.[284] In those patients who are not candidates for surgery, a conservative approach may be indicated. Chronic antibiotic therapy may limit stone growth and result in partial dissolution[285] in nonsurgical patients. Another potentially useful agent is acetohydroxamic acid (AHA), which is a potent inhibitor of bacterial urease and can limit stone growth.[286] Despite the potential usefulness of AHA, it has been associated with frequent side effects, including potentially carcinogenic effects,[287] particularly in patients with renal insufficiency. For these reasons, use of AHA should be limited to patients with normal renal function who are unable to undergo surgical intervention.

CYSTINE STONES

Cystinuria is an inherited abnormality in amino acid transport affecting the gastrointestinal and proximal renal tubular epithelia. As a result of abnormal renal tubular transport of cystine and the other dibasic amino acids (ornithine, lysine, and arginine), abnormally large amounts of the amino acids are excreted in the urine. Cystinuria accounts for 1% of renal calculi in adults, but up to 10% in children.[288] Even with medical management, long-term outcome is poor due to insufficient efficacy and low patient compliance. The solubility of cystine in urine is approximately 300 mg per L. When overexcretion leads to higher concentrations than the solubility limit, cystine stones tend to form. Biochemically, it has been known for decades that different phenotypes in cystinuric populations exist. The disease has been differentiated by amino acid excretion in obligate heterozygotes as type I (normal urinary amino acids), type II (high excretion of dibasic amino acids), or type III (modest elevation in dibasic amino acids). Given the identification of only two affected genes, a new classification scheme is now utilized.[289] Mutations in SLC3A1 and SLC7A9 are responsible for all three phenotypic subtypes of cystinuria. To date, all mutations of SLC3A1 produce the type I phenotype whereas mutations in SLC7A9 can cause all phenotypic subtypes.

In the new classification, cystinuria is defined as type A if mutations are found in both SLC3A1 alleles, type B if mutations are found in both SLC7A9 alleles, and putative type AB if one mutation is found in each gene.[289] Heterozygous type AB individuals have been identified,[290] but cystinuric patients from families of such individuals have two mutated alleles in the same gene in addition to a mutated allele in the other gene. Because type AB double heterozygous individuals do not produce stones, and two mutations in the same gene were found in patients from these families, digenic inheritance of cystinuria was ruled out.[291]

The amino acid transport system b(o)+AT is the main effector of cystine reabsorption in the kidney. This system was identified by expression cloning of renal cDNA (related to bo,+ amino acid transporter [rBAT]) that induces the $b^{o,+}$ system in Xenopus oocytes. In oocytes, the rBAT ($b^{o,+}$-like) system acts as a tertiary active transport mechanism. A cloned "light" subunit ($b^{o,+}$AT) coexpresses system $b^{o,+}$ activity in heterologous expression systems. Both proteins are expressed in brush-border membranes of proximal straight tubule and small intestinal mucosa. Whereas all renal $b^{o,+}$AT is disulfide bound with rBAT, there is an excess of rBAT covalently bound to an unidentified "light" subunit (X) in renal brush-border membranes. The rBAT/$b^{o,+}$AT heterodimer shows a gradient of expression along the proximal tubule: higher in the convoluted tubule and lower in the straight tubule. In contrast, the rBAT/X heterodimer has the opposite gradient of expression along the proximal tubule.

More than 50 unique SLC3A1 /2p16.3-p21 mutations have been identified in cystinuria patients. Missense mutations show loss of transport function in oocytes, apparently due to trafficking defects during transfer from endoplasmic reticulum to plasma membrane. Null SLC3A1 mutations are fully recessive in cystinuria heterozygotes. Mutational analysis and linkage studies have demonstrated genetic heterogeneity in cystinuria. The SLC3A1 gene is only associated with type I (fully recessive) cystinuria. A second locus, accounting for types II and III cystinuria (incomplete recessive forms), has been identified by linkage analysis at chromosome 19q13.1–13.2. The gene for the non-type I cystinuria (SLC7A9) codes for the "light" subunit ($b^{o,+}$AT) of rBAT, where 37 unique cystinuria-specific mutations have been identified. This strongly supports the notion that rBAT/$b^{o,1}$AT heterodimer (system $b^{o,+}$) is the main apical reabsorption system for cystine.

In non-type I cystinuria, the urinary hyperexcretion of cystine and dibasic amino acids among heterozygous carriers of SLC7A9 mutations correlates well with the severity of defective amino acid transport in vitro. In some cases, mild SLC7A9 mutations account for heterozygous type I cystinuria. Patients with the mixed form of cystinuria (type I/III) excrete slightly lower levels of cystine and appear to have a lower risk of nephrolithiasis in the first decade. An SLC3A1 mutation is rarely identified on the fully recessive allele in these patients.[292]

While the molecular physiology of the renal cystine transport mechanism is being worked out, additional clarification is needed. In particular, we need to understand the physiologic role of the SLC3A1 gene, why mutations in the "heavy" subunit (rBAT) of system $b^{o,+}$ produce a silent phenotype in carriers whereas mutations in the "light" subunit ($b^{o,+}$AT) produce a dominant negative effect, and which genes modulate urolithiasis in patients with cystinuria.

Additionally, three similar, but distinct, syndromes are associated with cystinuria. The 21p21 deletion syndrome, hypotonia-cystinuria syndrome (HCS), and atypical HCS are associated with deletions of/and genes contiguous to SLC3A1.[293–298]

Pathobiology

Although a kidney biopsy is not usually performed, examination of renal tissue obtained during stone removal procedures reveals associated parenchymal abnormalities that may partly explain the loss of kidney function associated with this disorder.[299]

The ducts of Bellini are plugged with cystine crystals, and apatite crystals can be seen in the inner medullary collecting ducts and in the thin loops of Henle. Focal areas of dilatation with varying degrees of surrounding interstitial fibrosis are present. These findings are in contrast to the histopathology of routine calcium oxalate formers (interstitial deposits of apatite without intratubular crystals). The crystallization of cystine in terminal ducts of Bellini may cause local obstruction and tissue injury contribution to loss of kidney function.

Pathogenesis

Cystine overexcretion raises urinary cystine concentration above the limits of solubility for this relatively insoluble amino acid. Characteristic hexagonal crystals are identified in cystinuric patients particularly in the first voided morning urine, which is concentrated and usually acidic.

All patients with an episode of nephrolithiasis before the age of 30 or a strong family history of recurrent nephrolithiasis should be screened for cystinuria. A rapid qualitative screening test with sodium cyanide-nitroprusside is used for diagnosis when the pathognomonic crystals are not visualized.

Normal adults excrete less than 30 mg of cystine in 24 hours (19 mg per g of creatinine),[300] whereas homozygous cystine stone formers usually excrete more than 350 mg of cystine per day (250 mg per g of creatinine).

Heterozygotes and patients with the Fanconi syndrome generally excrete less than 250 mg per day and usually do not form stones. Given that proximal tubular transport requires maturation, it is frequently difficult to diagnosis cystinuria prior to the age of 1 year.[301]

Treatment

Therapy is designed to reduce the excretion and increase the solubility of cystine. Methionine is the precursor of cystine and dietary restriction of methionine reduces urinary excretion of cystine.[302] However, methionine is an essential amino acid and dietary restriction is, therefore, not a practical mode of treatment. Lowering urinary cystine concentration by increasing urinary volume reduces the likelihood of precipitation and thus provides the basis for clinical treatment. An intake of more than 4 L per day may be required.

The pH of urine alters the level of cystine saturation, but until urinary pH is 7.0 or greater, the effect of pH on solubility is minimal.[303] Dent et al. showed that the solubility of cystine in urine is approximately 250 mg per L up to a pH level of 7.0, but increases to 500 mg per L or more with a pH level of 7.5 or greater. This degree of urinary alkalinization may require up to 3 to 4 mEq/kg/day of potassium citrate or potassium bicarbonate taken in three to four divided doses.[21]

If urinary alkalinization and high fluid intake are ineffective, then a cystine binding drug is added to the regimen.[304] D-penicillamine (DP) and α-mercapto-proprionyl-glycine (MPG) are equally effective in clearing the disulfide bond of cystine into cysteine, which is 50 times more soluble.[305,306] Side effects occur in 20% to 50% of patients and limit treatment success. Typical side effects for both drugs include rash, arthralgia, leukopenia, thrombocytopenia, myositis, and proteinuria (due to membranous nephropathy).

Captopril, a first generation ACE inhibitor, contains free sulfhydryl groups. Captopril cysteine disulfides are 200 times more soluble than cystine alone. Although captopril can reduce cystine excretion by more than 50%, hypotension often limits tolerance.

Medical therapy is beneficial with adequate patient adherence, but there is a high rate of continued stone formation and most patients require multiple urologic interventions. Cystine stone formers have significantly higher procedure rates than other stone formers.[307] Patients may form stones of mixed composition mandating a broader investigation during follow-up.[308]

The response to therapy is monitored both biochemically and radiologically. The preferred imaging test is spine CT. Urinary cystine concentration is measured serially to estimate whether the amount excreted can be held in solution at the urine volume and pH achieved by the patient. The measurement of urinary cystine is imprecise in the presence of thiol drugs. Solid phase assays overcome this barrier and should be used to monitor patients' response to interventions.[309,310]

CHAPTER 21

Host–Pathogen Interactions and Host Defense Mechanisms

Keira Melican • Ferdinand X. Choong • Agneta Richter-Dahlfors

Urinary tract infections (UTIs) represent the most common urologic disease in the United States based on the Centers for Disease Control's (CDC) statistics of visits to office-based physicians and hospital outpatient clinics. Women account for a majority of cases. The 2005/2006 Ambulatory Medical Care Utilization Estimates attributed an annual figure of approximately 8.1 million of all diagnosed patients with UTIs as the main ailment.[1a] Although no clear cost estimate is available currently, total expenditures in the year of 2000 alone was estimated to amount to US$3.5 billion.[2a]

The human urinary tract is a normally sterile environment that presents invading bacteria with numerous challenges of a dynamic nature. These challenges include the mechanical stress of urine flow, various physical barriers such as the mucosal epithelium, and the attack of invading immune cells that form part of the host's immune response. The dynamic nature of these challenges means that invading pathogens must rapidly adapt to their changing niche in order to enable colonization. Infections of the urinary tract occur when pathogens, often originating from fecal flora, enter the urethra. Although continuous cycles of urine production, storage, and voiding relentlessly expel invading organisms, pathogens are able to migrate to the bladder, where they may cause symptomatic cystitis or asymptomatic bacteriuria (ABU).[1] Pyelonephritis manifest when pathogens ascend further up to the kidney, colonizing the tubules of the nephrons.

Asymptomatic bacteriuria is defined as the presence of bacteria in the urinary tract, which do not cause any obvious clinical symptoms in the patient. ABU has been described as similar to a commensal state[2] where patients may carry up to 10^5 CFU per milliliter of urine without symptoms. ABU strains are genetically similar to those that cause symptomatic infections, but they notably tend to lack adhesion organelles.

Cystitis, or a lower UTI, occurs when the pathogens that have entered the urinary bladder attach themselves to cells of the bladder epithelial lining, where they start multiplying. A lower UTI often presents with clinical symptoms such as pain and urgency of urination. The urine of cystitis patients often appears cloudy due to the presence of bacteria, white blood cells (WBCs), and sloughed epithelial cells.[3] A urine examination and culture are essential for a diagnosis, and the infection is usually treated with antibiotics.

Further migration of bacteria up the ureters leads to an infection of the kidneys.[4] A bacterial infection of the kidney is medically termed pyelonephritis, indicating that the infection has reached the renal pelvis—the so-called pyelum—of the kidney (nephros). Upper UTI infections are more difficult to diagnose than cystitis. They show similar symptoms to a lower UTI but are often accompanied by a sudden increase in temperature and unilateral or bilateral flank pain.[5] Pyelonephritis is commonly defined as a tubulointerstitial disorder based on the pathologic picture observed in renal biopsies. This indicates that the tubules and interstitial tissue are most commonly involved.[6] In light of the greater level of inflammation, as compared to cystitis, pyelonephritis is considered a serious infection.[7] Gross pathology includes abscess formation in the renal parenchyma and edema, often leading to irreversible scar formation. Renal scar formation with fibrosis can contribute toward the development of renal insufficiency.[7]

The normal kidney is considered relatively resistant to infection but abnormalities in the structure and function of the urinary tract can increase susceptibility.[8] Risk factors in children include voiding dysfunction and vesicoureteral reflux, whereas in adults, genetic susceptibilities and behavioral risk factors are most relevant.[9]

An essential step in bacterial colonization and the initiation of a UTI is the bacterial binding to the urinary epithelium. However, the epithelia that line the urinary tract are far from uniform. The bladder is lined by a transitional stratified epithelium consisting of multiple layers, topped with facet or umbrella cells, and covered with apical plaques of hexagonal uroplakin.[10] The bladder epithelium, together with the transitional epithelium, covers the ureters and the renal pelvis and is also known as uroepithelium. The Bowman capsule (the epithelial structure that surrounds the glomerular capillary tufts) is lined with thin squamous epithelial cells. The tubular systems of the nephron all consist of a

single layer of epithelium, which expresses a unique structure and function depending on the tubule segment.[11,12,13,14] The proximal tubule consists of cuboidal/columnar epithelia covered with microvilli (~150 per square micrometer of cell surface), which function to increase the surface area for tubule reabsorption.[12] Distal tubule cells lack microvilli and constitute a tight epithelium, displaying low endocytic capacity and low permeability to water.[13,14] This suggests that bacteria do not only meet very different epithelial linings on their way up the urinary tract, but also that they do so while being exposed to a continuously altered composition of filtrate/urine.

Uropathogenic Escherichia coli (UPEC) are implicated as the causative agent in up to 80% of community-acquired UTIs, making it the leading urinary pathogen.[7] However, other gram-negative bacterial species are also associated with UTIs, including Klebsiella, Enterobacter, Pseudomonas, and Proteus mirabilis.[7] The latter accounts for more than 40% of UTIs in infant boys. Gram-positive bacteria implicated in UTIs include Staphylococcus strains, epidermidis, and aureus, as well as Enterococcus faecalis.[7] Using culture-based methods, a Canadian study of bacterial isolates in ambulatory patients with community-acquired UTIs revealed that 74.2% contained Escherichia coli, 6.2% contained Klebsiella pneumoniae, 5.3% contained Enterococcus, 2.8% contained Streptococcus agalactiae, 2% contained Proteus mirabilis, 1.4% contained Staphylococcus saprophyticus, 0.9% contained Viridans streptococci, 0.9% contained Klebsiella oxytoca, and 0.8% contained Pseudomonas aeruginosa.[15] Although the proportion of isolates vary depending on the region, the disease state, and the patient type, UPEC unanimously remains the major causative microbe for UTIs and, as such, has been used as the primary pathogen in a number of molecular studies of the UTI process. This chapter will accordingly focus on current knowledge gained from UPEC-induced UTIs.

VIRULENCE OF UROPATHOGENIC ESCHERICHIA COLI

Bacteria entering the urinary tract must rapidly adapt to their new environmental niche. To enable this adaptation, UPEC strains express specific genes that encode a class of proteins termed virulence factors. This name originates from the finding that these factors assist in the initiation and progression of the infection. UPEC strains have a larger genome and therefore contain more genes than their nonvirulent ABU or commensal E. coli counterparts. For example, the clinical isolate CFT073 has 590,209 more base pairs in its genome than the K-12 MG1655 strain.[16] Based on recent genetic approaches, it was proposed that UPEC, ABU, and commensal strains may have evolved from the same virulent ancestral parent, with the ABU and commensal strains having lost virulence factors.[17,18] Due to the relatively minor genetic variations between the UPEC, ABU, and a commensal gut E. coli, genetic mutations and differences in expression of certain genes may actually differentiate virulence potential rather than genomic content itself.[17]

The extra genes that confer virulence are commonly located in specific regions of the chromosome, termed pathogenicity-associated islands (PAIs).[19,20] This unique subset of genomic islands has been acquired by horizontal gene transfer.[21] PAIs were originally identified by Hacker and colleagues[22] when they analyzed segments of chromosomal regions that encode multiple, distinct virulence-associated phenotypes in UPEC strain 536.[23] Further characterization has demonstrated that PAIs are present in a wide range of bacterial pathogens, that PAI segments range from 10 to 200 kb in size, and that they are rich in virulence and antibiotic resistance gene insertion sequences or other mobile genetic elements. PAIs are easily identifiable by their unique G+C content,[24] and their location near or within tRNA genes. One bacterium may possess multiple PAIs,[25,26] as exemplified by UPEC strain 536, which contains six well-characterized PAIs.[27–29]

The chromosomes of E. coli appear highly diverse aside from a core genome that is highly homogeneous in G+C content.[24] A large proportion of this diversity arises from a variable pool of mobile genetic elements, conjugative plasmids, bacteriophages, transposons, insertion elements, as well as by the recombination of foreign DNA into host DNA.[24] This has been highlighted in comparative studies of the nonpathogenic E. coli K-12 lab strain MG1655,[28] the enterohemorrhagic O157:H7 strain EDL933,[30] and the UPEC strain CFT073.[16] They were shown to differ significantly in genome size, sharing only 39.2% of proteins in common.[16] The flexibility of bacterial genomes arising from mobile genetic elements may facilitate the timely emergence of new clones,[31,32] which provides new virulence and antibiotic resistance profiles.

However the genetics may look or may have evolved, it remains that pathogenic UPEC strains express proteins that are considered essential for virulence. These virulence factors characterize disease isolates.[33] Although the early definitions of virulence factors came from the basic epidemiology practice of comparing properties of fecal strains from healthy controls with urinary isolates from patients,[34] Falkow[35] introduced a new view in 1988, which he named the molecular Koch's postulates for pathogenesis. These postulates include[36]:

- The phenotype or property under investigation should be associated with the pathogenic members of a genus or pathogenic strains of a species.
- Specific inactivation of the gene(s) associated with the suspected virulence trait should lead to a measurable loss in pathogenicity or virulence, or the gene(s) associated with the supposed virulence trait should be isolated by molecular methods. Specific inactivation or deletion of the gene(s) should lead to loss of function in the clone.

- Reversion or allelic replacement of the mutated gene should lead to restoration of pathogenicity, or the replacement of the modified gene(s) for its allelic counterpart in the strain of origin should lead to a loss of function and a loss of pathogenicity or virulence. Restoration of pathogenicity should accompany the reintroduction of the wild-type gene(s).

Fifteen years later, Falkow[36] reviewed these postulates in light of the new advances in technology available to infection biologists. Here he described how the postulates should be considered as a "working hypothesis for the study of the genetic and molecular basis of pathogenicity" and not a ridged determination of virulence factors. Some virulence factors may play different roles in different model systems and, as technology advances, the definitions of what a virulence factor is may need to evolve. Some of these factors may also be considered as "fitness factors" (i.e., factors that enhance the growth and colonization of the bacteria but may not be absolutely essential for infection). Siderophores, which allow bacteria to sequester iron, have been annotated as fitness factors because their expression is advantageous but not essential to virulence.[37,38] Conversely, the acquisition of certain traits such as antibiotic resistance, which would appear advantageous for virulence, can have a negative effect on bacterial fitness.[39,40]

UROPATHOGENIC ESCHERICHIA COLI ADHESION

The traditionally annotated UPEC virulence factors include adhesion factors, exotoxins, lipopolysaccharides, capsules, proteases, and iron acquisition systems.[41,42] Research on these factors has been carried out in vitro and forms the foundation for their current definition. Thus, the expression of certain adhesion factors is still defined by their in vitro agglutination abilities.[34,42] In UPEC, the best described virulence factors are involved in bacterial adhesion to the uroepithelium, and these proteinaceous structures are referred to as fimbriae or pili.[20] These organelles allow UPEC to bind to the epithelium and help bacteria to withstand the stress of filtrate and urine flow. UPEC express numerous different fimbriae including P, type 1, F1C, S, and Afa/Dr adhesins.[42] The great redundancy in fimbriae expression is further illustrated by the fact that one bacterium contains the genes for many different fimbriae.[43] The current understanding of the roles of the various fimbriae in UTIs is described in detail in the following paragraphs.

Bacteria have many tools aiding their rapid adaptation to changing microenvironments. They contain genes for numerous different fimbriae and it has been shown there is a redundancy between these fimbriae.[43] Phase variation means the bacteria can vary their fimbriae expression, thereby altering their nature of adhesion depending on the microenvironment. This common feature not only allows for rapid adaptation but also, at the same time, allows for the development of a heterogeneous bacterial population.[44] A genetic switch, the so-called *fim* switch, controls the phase variation of type 1 fimbriae expression. This invertible element contains the main promoter for the fimbrial structural subunits.[44] Negative cross-talk between type 1 and P fimbriae has been demonstrated, with PapB being shown to repress the FimB-promoted off-to-on inversion of the *fim* switch.[45] This means that UPEC express either Type 1 or P fimbriae but it is unlikely that they express both simultaneously. A cross-talk between P fimbriae expression and motility has also been reported, showing that the expression of P fimbriae also regulates the synthesis of flagellum, a protein-based extrusion that mediates bacterial mobility. The PapX protein, encoded at the end of the pheV associated pap gene cluster in UPEC strain CFT073, represses motility by binding to the *flh*D promoter, thereby repressing transcription of $FlhD_2C_2$, the master regulator of flagella.[46] These regulatory mechanisms highlight one mechanism by which bacteria can fine-tune their expression to adapt to the challenging microenvironments they encounter upon infection.

Type 1 Fimbriae

Type 1 fimbriae are attachment organelles produced by the vast majority of E. coli strains, both commensal and pathogenic. Initially visualized in 1950,[47] type 1 fimbriae are mannose sensitive adhesion organelles, which means their ability to agglutinate erythrocytes is inhibited by mannose.[48,49] This feature, found in the mid 1950s, is still used today to define type 1 fimbrial expression.

The type 1 fimbriae are made up of 500 to 3,000 repeating subunits of the FimA protein, which is formed into a 7-nm thick right-handed helical rod. At the outermost end of the rod is located a 3-nm thick distal tip that contains several copies of the adapter proteins FimG and FimF as well as the tip adhesin FimH.[50–52] Assembly of the rod-like type 1 fimbriae occurs via the chaperone-usher pathway, which represents a common assembly pathway for fimbriae in gram-negative bacteria.[52] The chaperone and usher proteins required for the formation of type 1 fimbriae are all encoded in the *fim* operon.[51] FimC is the periplasmic chaperone, which delivers bound subunits to the outer membrane usher protein FimD. From here, the subunits are incorporated into the growing fimbriae.[51]

The ability of the tip adhesion FimH to bind mannose-containing glycoproteins means that type 1 fimbriated bacteria can adhere to a wide range of human target cells.[53,54] The crystal structure for FimH was recently resolved.[55,56] Whereas intestinal E. coli express certain variants of the FimH adhesion,[57,58] UPEC express a FimH that has an increased affinity for terminal monomannose (M1) residues[59] and displays a 20-fold higher ability to bind uroepithelium.[57,58,60] The traditional view of type 1–mediated binding is that the mannose moiety is present on cells or structures associated with the mucosal lining, or alternatively, that mannose is bound to abiotic surfaces. Whereas the first situation refers

to bacterial colonization on the mucosal lining, the latter is implicated in bacterial biofilm formation in vitro.[61] Recently, a novel alternative was presented, demonstrating the importance of type 1 fimbriae in mediating interbacterial contact and biofilm formation in vivo, thus providing a means for bacteria to withstand the shear stress from the renal filtrate (see the following text for further details).[62]

In UPEC strains, the role of type 1 fimbriae in cystitis has been extensively described. The uroplakins on the surface of bladder epithelium contain monomannose moieties to which FimH binds.[42,55] Therefore, uroplakins serve as anchoring sites allowing UPEC to gain a foothold in the bladder.[63] Although the kidney lacks mannose moieties, a new hypothesis was recently proposed in which the FimH tip adhesions of type 1 fimbriae facilitate interbacterial binding and, in synergy with P fimbriae, thus enable tubule colonization.[62] This broadens the role for type 1 fimbriae to infectious niches other than those with surface-bound mannose moieties.

The urinary tract represents a compartment continuously exposed to some degree of mechanical flow, primarily in the form of urine. Bacteria entering into this compartment will thus be exposed to shear stress generated by the flow of urine over the epithelial surface. Over recent years, it has become increasingly appreciated that the stress may affect bacterial adhesion. The UPEC FimH protein has been shown to display enhanced binding to mannosylated surfaces in vitro in the presence of shear stress.[64,65] This interaction is reported to operate via a force-enhanced allosteric catch-bond mechanism, functioning via a finger-traplike β sheet twisting mechanism.[64]

In the initial report of FimH shear-dependent binding, it was shown that at a shear of 0.02 dynes per cubic centimeter, the binding strength of FimH was weak, whereas as the shear increased to 0.8 dynes per centimeter, this binding became stronger.[65] The same laboratory also showed that UPEC positively select for a FimH variant that maintains an attachment following a drop in shear, as compared to fecal or vaginal E. coli isolates.[66] This variation in the signal peptide of FimH, which results in expression of less, though longer, fimbriae, may be very relevant under the fluctuating conditions facing UPEC in vivo. The fact that certain bacterial adhesion events are enhanced by tensile force, as opposed to bacteria being washed away, is particularly relevant in an environment such as the urinary tract where bacteria must bind in the face of fluctuating filtrate flow. Thus far, FimH is the best described bacterial adhesin in terms of shear-enhanced adhesion, whereas binding of PapG, the tip adhesion of P fimbriae, has been shown to be shear-independent, being able to mediate binding even under relatively low shear.[67]

Although the shear-mediated adhesion may assist type 1 adhesion to the bladder epithelium via mannose binding, it may also function during UPEC colonization of the renal tubule, albeit via a different mechanism. Within the nephron, FimH may mediate interbacterial binding and help prevent bacterial washout by renal filtrate.[62] Interestingly, FimH is present in all virotypes of E. coli,[60] and a role for FimH in interbacterial binding may explain a general function for these fimbriae in diverse perfused environmental niches.

Type 1 fimbriae have been found to fulfill molecular Koch's postulates. Microarray studies of an in vivo mouse model show high levels of type 1 expression.[68] A mutant unable to make FimH is severely deficient in colonization of the urinary tract in a mouse UTI model, and complementation of the mutant has been shown to restore virulence.[69]

P Fimbriae

P fimbriae were one of the first virulence factors associated with UPEC. In 1976, it was demonstrated that E. coli from patients with acute pyelonephritis adhered in greater numbers to uroepithelial cells in vitro than strains causing asymptomatic bacteriuria.[70] Their adherence was not inhibited by the prototypic type 1 inhibitor mannose, and further investigation led to the identification of P fimbriae. They were designated P because of their ability to agglutinate red blood cells (RBCs) of the P blood group when analyzed in vitro.[34,71] P fimbriae are encoded by the pap (pyelonephritis-associated pilus) operon, which consists of 11 genes located on chromosomal pathogenicity islands. Unlike the *fim* operon, the pap operon is selectively distributed in E. coli.[24,72] The morphology of this fimbriae is extremely similar to type 1 fimbriae.[73] P fimbriae are hetero-polymers consisting of a helical rod of PapA subunits with a tip consisting of the minor pilins PapE and PapF. The tip adhesion PapG mediates attachment to Galα1-4Galβ containing glycolipids, which are often found on the renal epithelium.[73,74] PapG is known to have at least three allele variants: class I, class II, and class III. Class II is primarily linked to human pyelonephritis and class III is linked to cystitis.[71,75,76] Some strains, such as the prototypical UPEC strain CFT073, carries two pap gene clusters, both of which encode for the PapGII allele.[16,71]

Although P fimbriae have long been considered an important virulence factor in UTIs, they do not fulfill the molecular Koch's postulates. P fimbriae are expressed by a majority, but not all, clinical isolates.[34,77] Approximately 80% of UPEC strains express P fimbriae,[78] and a strong relationship exists between the severity of infection and the prevalence of P fimbriae. Indeed, clinical isolates lacking PapG adhesin were observed to cause comparatively less kidney damage than the PapG positive counterpart. Interestingly, despite the known role of P fimbriae in the adhesion colonization capability of strains in both the kidneys and bladder, it was found to be independent of PapG mediated adhesion.[79–82]

Expression of P fimbriae is controlled by phase variation, and varies depending on environmental conditions. The reversible epigenetic switch that controls the initiation of pap operon transcription allows bacteria to fine-tune their P fimbriae expression to suit their changing environment in vivo.[44,83,84]

Recently, P fimbria were shown to facilitate the early stage of UPEC colonization of renal tubules.[62] Using high-resolution live animal imaging, it was shown that strains

expressing P fimbriae were able to bind and initiate colonization in the face of sheer stress from renal filtrate flow. It was also demonstrated that the P fimbriae act in synergy with type 1 fimbriae in a heterogeneous bacterial community to facilitate renal tubule colonization. P fimbriae were shown to mediate bacterial binding to the epithelium, whereas the type 1 fimbriae mediated interbacterial binding as the colony expanded into the tubule and away from the epithelium.[62] It is interesting to note that unlike type 1 fimbriae, only E. coli and not other gram-negative rods carry the genes for P fimbriae.[85]

Dr Adhesin

Aside from type 1 and P fimbriae, several other adhesins are implicated in mediating urinary tract infections, though their roles are not as established. The Dr adhesins family embraces fimbrial and afimbrial structures, which are found on the extracellular surface of E. coli, and have in common that they bind to Dr blood group antigens.[86] The Dr blood group antigen is a component of the decay-accelerating factor (DAF), a membrane protein that prevents host lysis by complement.[87,88] This binding leads to the internalization of Dr^+ E. coli into nonfusogenic intracellular vacuoles where bacteria are shielded from the host immune system.[89] Dr adhesin mediated binding of E. coli to the bladder epithelium has also been correlated with recurrent UTIs in young adults and with pyelonephritis in pregnant women.[90] Among the Dr adhesin family, only Dr fimbria possess the ability to bind both type IV collagen of basement membranes and DAF.[91] The latter is mediated via the subunit DraE.[92] When investigating the significance of DraE-type IV collagen binding, it was shown that disruption of this capability resulted in the inability of E. coli to cause a persistent kidney infection.[93]

F1C Fimbriae and the S Fimbria Family

Although the role of type F1C fimbriae for UTIs has not been fully determined, epidemiologic data suggest this fimbriae to be more prevalent in pyelonephritis and cystitis strains than among fecal strains of E. coli.[94] Data suggest these fimbriae are expressed in vivo and provide bacteria the capacity to adhere to human distal tubular and collecting tubular epithelium, as well as the vascular endothelium on kidney tissue sections.[95,96] The two minor glycosphingolipids, galactosylceramide and globotriaosylceramide, have been identified as target tissue receptors for F1C fimbriae in rats, canines, and humans. Galactosylceramide is found throughout the urinary tract, with the exception of the urethra, whereas globotriaosylceramide is unique to the kidney.[95] The binding of F1C-fimbriated bacteria to renal epithelial cells in vitro was shown to induce similar levels of interleukin (IL)-8 production as compared to those levels produced by the adhesion of type 1- and P-fimbriated bacteria, thus supporting a role for F1C in pyelonephritis.[95]

The S fimbriae bind terminal NeuAcα2, 3-galactose sequences present on glycoproteins. Although shown to bind several host cell types, the occurrence of S fimbriae expressing E. coli strains in UTIs is infrequent.[97,98] The role of S fimbriae in UPEC pathogenesis may thus be minor.

BACTERIAL TOXINS AND VIRULENCE FACTORS

α-Hemolysin

The 107 kDa lipoprotein α-hemolysin (Hly) is considered an important UPEC virulence factor, yet no more than 50% of pyelonephritogenic E. coli organisms express this toxin. The Hly operon is commonly located adjacent to genes encoding P fimbriae,[99,100] which may account for the two- to threefold higher probability of UPEC having hly genes over fecal strains.[101] Hly exerts concentration-dependent, biphasic activities on target cells. The traditional view focuses on Hlys cytotoxic effect. Hly is lytic for numerous cell types, including erythrocytes, polymorphonuclear leukocytes, monocytes, mast cells, basophils, and lymphocytes.[102,103] More recently, the sublytic concentration of Hly was shown to elicit Ca^{2+} signaling in primary proximal tubule cells.[104] Via frequency-modulated activation of the transcription factor nuclear factor-kappa B (NF-κB), Hly activated proinflammatory signaling in epithelial cells. When analyzing a role for Hly in vivo, intravital imaging of the infection process within a nephron of a rat was applied. This showed that the same end result was achieved whether or not UPEC expressed Hly. However, the kinetics of the tissue response was severely influenced.[105]

Cytotoxic Necrotizing Factor

CNF1 is a toxin contributing to UPECs invasion of the epithelium.[106,107] The toxin induces the formation of stress fibers via the deamination-dependent activation of small, actin-regulatory GTPase proteins of the Rho family.[108,109] The gene encoding CNF1 is positioned adjacent to hemolysin,[110,111] and coregulation of their expression is mediated by RfaH.[112,113] Although the role of CNF1 in vivo remains unclear, in vitro studies do suggest a role for the toxin in urinary tract disease.[114,115]

Secreted Autotransporter Toxin

Among the array of toxins studied in UTI models, the 107-kDa Sat protein is more frequently secreted from pyelonephritogenic E. coli strains than fecal isolates, suggesting a possible role of the toxin in pathogenesis.[116] Sat has serine protease activity and shows cytopathic effects (cytoplasmic vacuolization) on human bladder and kidney cell lines, and in the mouse kidney.[117] However, Sat is not required for kidney colonization.[117] Originally isolated from the prototypic UPEC strain CFT073, Sat was found to share homology with various virulence-related proteins from a range of E. coli pathotypes.[118] Among these, Sat possess a high similarity to Pet and EspC, two SPATE (serine protease autotransporters of Enterobacteriaceae) proteins.[118]

Siderophores

Mammals possess efficient systems such as the proteins transferrin and lactoferrin to efficiently scavenge free iron within the host. During an infection, the deprivation of free iron is used as a host defense mechanism as upregulation of iron acquisition and storage mechanisms are up-regulated. Low iron availability limits bacterial viability. To counteract this, bacteria produce low-molecular-weight chelators called siderophores (Greek sideros, iron; and phoros, bearing). Siderophores are secreted into the extracellular environment where they bind ferric iron (Fe^{3+}) and internalize it via receptor-mediated mechanisms. UPEC strains produce four distinct siderophore systems: enterobactin, salmochelin, yersiniabactin, and aerobactin. Among these, enterobactin is conserved in all isolates.[119,120] UPEC also expresses siderophore-associated receptors such as ireA[121] and iroN,[122] and other iron acquisition systems.[16,20] Strains with impaired iron acquisition capability were shown to have decreased fitness and virulence in mouse models.[123]

The precise contribution of each iron uptake mechanism to bacterial virulence is presently unclear. However, a study of coincident urinary and rectal strains from patients with recurrent UTIs suggested UPEC infections are facilitated by yersiniabactin and salmochelin.[119] Some UPEC strains express siderophore receptors but not siderophore. These strains are hypothesized to take advantage of neighboring siderophore-expressing bacteria in a polymicrobial setting by competitively scavenging excreted iron-bound siderophores.[20,124,125]

Lipopolysaccharide

The serotyping of E. coli strains is based on three determinants: the somatic antigen O, the capsular antigen K, and the flagella antigen H.[126] This system, developed by Kauffmann in 1940, has identified more than 50,000 different E. coli serotypes of various combinations of the 173 O, 80 K, and 56 H types, in addition to all nontypable strains. The association of O-antigen serogroups with UTIs is complex. Although studies have observed the presence of certain serogroups (O1, O2, O4, O6–8, O18, O25, and O75) to be more frequent in E. coli isolates in symptomatic UTIs,[127] the pattern of other potential virulence factors confound O-antigen-based epidemiology data.[128,129] Furthermore, the horizontal mobility of antigen determinant clusters obscures the phylogenetic relation of E. coli strains.[130] Employing isogenic mutants of O antigen synthesis, a possible link between UTI pathogenesis and the ability of a strain to synthesize an O antigen was observed.[131] However, there is yet to be clear experimental evidence closely correlating a particular O antigen type with a pathogenic tendency.

ORGANS OF THE URINARY TRACT

Host responses are initiated the very moment a bacterium starts interacting with the host tissue. In response to the accompanying microenvironmental changes, bacteria rapidly adapt their gene expression and alter their physiology to cope with the situation. The net effect of these opposing forces determines the duration of the infection and the end result: bacterial clearance, containment or commensalism, or the death of the host. Depending on the physiology and function of the organ, the nature of such challenges varies.

Urine

Urine is a highly variable and dynamic environment that both prevents and promotes infection. High osmolality, high urea concentrations, and low oxygen tension exhibit bacteriostatic and bactericidal effects.[129–134] On the other hand, thin films of urine retained at the bladder mucosa act as a reservoir of bacteria, allowing repopulation following each voiding event.[131,133–136]

The Bladder

The cascade of events that occur when urinary pathogens and, particularly, UPEC come into contact with the bladder epithelium has been well studied. Type 1 fimbriae bind to mannose residues on the surface of uroepithelia via the FimH adhesion. Once adhered, UPEC can withstand the forces of bladder emptying. However, FimH is believed to act not only as an adhesion, but also as an invasin that promotes bacterial entry into mast cells, macrophages, and the bladder epithelium.[137,138] Lipid raft domains on the host cells have been reported to facilitate type 1 fimbriated bacterial invasion with cholesterol, and caveolin-1 has been shown to cluster around the bacteria upon binding.[50,136,139] Localized rearrangement of host actin cytoskeleton is required for FimH-mediated epithelial invasion and is mediated via phosphoinositide-3-kinase signaling.[140] However, the internalization of bacteria into the bladder epithelium does not appear to be the end of the story; far from it. There are two alternative reported pathways for bacteria once they enter the bladder epithelium.[141] Upon internalization, bacteria multiply within intracellular bacterial communities (IBCs) present in membrane-bound vacuoles.[141,142] Within the IBC, bacteria change from a bacillary shape to a smaller, more coccoid shape[139] that forms pods within the facet cells. At this stage some bacteria on the periphery of the pod regain a bacillary shape and become motile, thus leading to bacterial spread.[143] There have been suggestions that the behavior of bacteria within these pods seems to be "biofilmlike."[139] Some bacteria within IBCs form long (<70 μm) filaments, which move extracellularly and induce reinfection via reseptation, thus leading to further rounds of IBC formation.[144]

Upon infection of the bladder epithelium, one host response includes an exfoliation of the infected cells.[143,145] Exfoliation results in a loss of surface epithelial cells from the underlying transitional layer. Although this functions well to clear many epithelial cells infected with IBCs, the bacteria have an alternative mechanism by which they can establish quiescent intracellular reservoirs (QIRs).[144] In QIRs, bacteria remain within the membrane-bound compartments with no extensive multiplication. When these transitional cells

develop into new facet cells, the QIRs remain intact and are proposed to be a possible source of recurrent UTIs.

The Kidney

Acute pyelonephritis is considered the most serious form of UTI and can lead to renal scarring, kidney damage, kidney failure, hypertension, and sepsis.[71] The study of infection in the kidney has slightly lagged behind the bladder when it comes to high-resolution molecular studies of host–pathogen interaction. Whereas Type 1 fimbriae play a major role in bladder infection, a limited role is implied in the kidney because renal epithelia lack uroplakin. Instead, P fimbriae have been considered a key player in the development of pyelonephritis due to its overrepresentation in pyelonephritogenic isolates.[146] However, experimental data have not yet proven P fimbriae to be essential for disease. Only subtle roles for P fimbriae–mediated adherence have been described in uroepithelial cell culture models,[146,147] and its role in ascending infection models has yielded inconsistent and conflicting results.[81,82,148] Early studies showed that lab strains of E. coli overexpressing P fimbriae persisted longer in mouse kidneys than strains lacking the pap operon.[149] However, bacterial numbers in the tissue never reached the same level as that of clinical strains, and it was accordingly suggested that P fimbriae are not the defining factor in virulence. Years later, when it was possible to genetically introduce a precise deletion of defined pap genes in UPEC isolates, it was demonstrated that a lack of P fimbriae did not significantly affect kidney colonization or pathophysiology 1 week after infection.[82]

Pyelonephritis does show a greater level of inflammation than cystitis, indicating the presence of a sensitive immune response system that detects colonizing bacteria.[150] Toll-like receptor family (TLR) and, particularly, TLR4 play a significant role in UTIs. An experimental ascending UTI model, using mice lacking TLR4 expression, failed to clear the invading pathogens and expressed less proinflammatory mediators.[151] The same group also reported that TLR4 expression on renal medullary collecting duct cells facilitated the translocation of bacteria across this epithelial barrier.[152]

Recently, live animal imaging applied to renal UPEC infection allowed for a high-resolution study of a live infection in real time.[62,153] In this rat model, GFP^+-expressing UPEC bacteria were slowly infused directly into the lumen of a superficial renal tubule to allow for spatial and temporal control of the infection. Fluorescence-based multiphoton microscopy showed that very few bacteria initially adhered to the tubule epithelium in the face of the flowing glomerular filtrate. These few bacteria rapidly adapted to the environment and began colonizing the tubule.[153] In this dynamic study of infection, new roles for the P and type 1 fimbriae in kidney infections were established, functions that had been undetectable in previously used infection models.[146,154] Bacterial P fimbriae expression demonstrated a fitness advantage in withstanding tubular filtrate flow and in mediating early phase adhesion to the epithelium, whereas type 1 was shown to mediate interbacterial binding and biofilm formation in the center of the tubule lumen, away from the epithelium. Synergy between the two fimbriae aids in the efficient colonization of the renal tubule. This work highlighted the narrow nature of the spatial resolution of an infectious niche with the center and periphery of a single tubule lumen exerting different pressures for adaptation.[154]

As an infection progresses, major alterations of the infected organ's physiology occur. One of the first significant findings relates to the rapidity of kidney responses to a local infection, with a majority of events occurring within the first 22 hours (Fig. 21.1A–D). Early tissue changes included vascular coagulation, epithelial breakdown, vascular leakage, immune cell recruitment, and general tissue destruction.[153,154] Coagulation in local peritubular capillaries (Fig. 21.2), and the subsequent vascular shut down, occurred within 5 to 6 hours of the infection, and accompanied a dramatic loss of local tissue oxygen.[155] Subsequent signs of ischemic injury were seen. This response was found to protect the host from urosepsis by keeping the infection site confined. Although extravasation of neutrophils inevitably causes tissue damage, the ischemic response efficiently hindered bacteria from gaining access to the bloodstream, thus giving time for neutrophils to clear the infection (Fig. 21.1E,F). Furthermore, bacterial colonization was shown to affect renal filtration, leading to obstruction.[3] Renal ischemia and obstruction are both well-studied physiologic injuries and both cause inflammation and tissue destruction in their own right.[156,157] Both are multifactorial and can vary in severity. Severe ischemia or obstruction can lead to end-stage renal failure, as can pyelonephritis. Thus, this study revealed that the pathophysiology of pyelonephritis is in fact a combination of infection and physiologic injuries such as ischemia and obstruction.

HOST RESPONSES TO INFECTION

The mammalian urinary tract is protected by numerous defense mechanisms, which together strive to maintain a sterile environment.[3,158] The physical defense of the epithelial barrier is complemented by mechanical defenses, including the sheer stress of urine flow, and chemical defenses, such as the expression of proinflammatory cytokines and antimicrobial peptides.[159,160] The colonization of the urinary tract can either lead to symptomatic disease, such as cystitis and pyelonephritis, or can develop into asymptomatic bacteriuria.[18,160] How the infectious process is developed is defined by the intimate interplay between features specific for the pathogen (i.e., virulence factors) and those defined by the host. One major host defense is the immune response, which usually is divided into the innate and the adaptive immune responses.[160,161] Innate responses are those mechanisms that recognize and respond immediately to the bacterial threat. Innate responses are nonspecific, whereas the adaptive immune response contains a memory that can build a specific immunity to a pathogen. The adaptive response can take days to weeks to develop to its full capacity.[162]

Real-time studies of the progression of bacterial infections and immediate tissue responses in live animals. *Cell Microbiol* 2007;9(2):413–424, with permission.) (See Color Plate.)

Shear Stress as a Natural Defense

One of the first defense mechanisms in the urinary tract is the shear stress caused by the flow of urine. In the bladder, this stress varies dramatically as the bladder fills and then empties upon voiding. In the kidney, this stress may be considered less extreme but it too fluctuates as the body regulates kidney function. Bacterial attachment to the epithelial lining of the urinary tract is considered extremely important to withstand this stress and the relationship between shear stress. Bacterial attachment was discussed in earlier sections of this chapter.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria (ABU), or infection with strains that do not cause clinical symptoms, has also been proposed as a mechanism to protect the urinary tract from more severe infections. Although ABU has been suggested to resemble commensalism due to the apparent lack of host immune response, it differs from the complex commensal flora of the intestine because it is normally a monoculture of only one bacterial strain.[162] The ABU strain E. coli 83972, isolated from a patient with long-term ABU, has been used extensively as a prophylaxis treatment to protect patients from symptomatic UTIs by outcompeting pathogens.

The Immune Response

Epithelia are equipped to rapidly recognize the presence of microbes. Toll-like receptors (TLRs) are closely related to the Drosophila toll protein,[161,162] which is known for its primary role in the innate immune system. Among a family of 10 characterized human TLRs and 12 mouse TLRs, TLR4, TLR5, and TLR11 have been linked to the urinary tract. When TLR recognizes specific bacterial molecules, so-called microbe-associated molecular patterns, activation of TLR signaling via coreceptor engagement leads to the onset of proinflammatory responses.[162] Uroepithelial cells expressing TLR4 are actually as sensitive to LPS, the endotoxin of gram-negative pathogens, as macrophages.[163–167] Though the ligand for TLR11 remains unknown, this receptor is important in a mouse model of UTIs,[168] and so is TLR5, which recognizes bacterial flagellin.[169]

The renal expression of TLR4 has been a matter of some debate, with reports showing that renal cells do[167] or do not[165] express TLR4. This discrepancy may be explained by experimental design, which includes infected as well as noninfected conditions. In uninfected animals, TLR4 is predominantly located at the apical surface of the distal tubule.[170] However, under septicemia, all kidney segments show TLR4 expression,

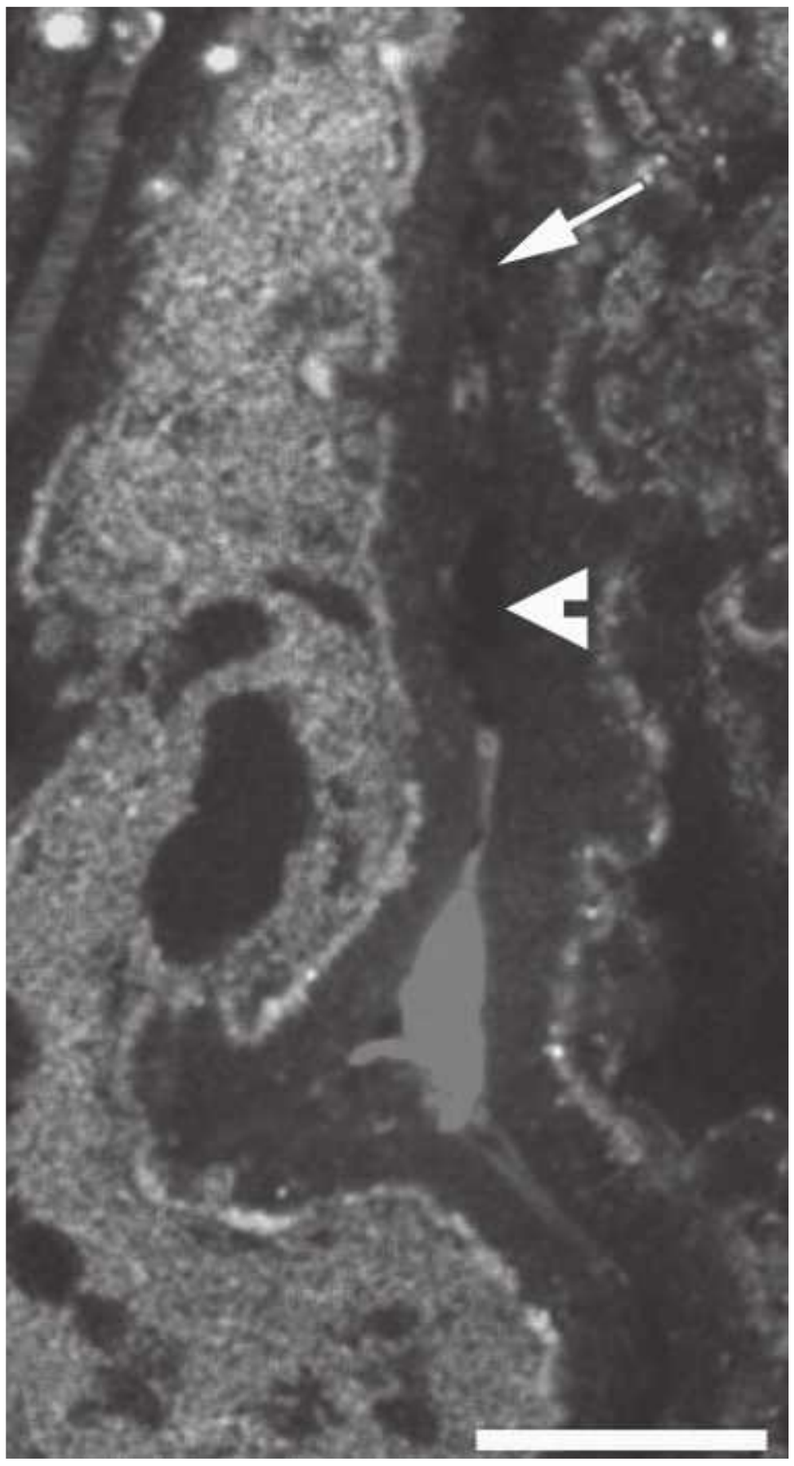

FIGURE 21.2 Blood clotting in mucosal infections. The live multiphoton image shows black silhouettes *(arrow)*, indicative of platelets, within the blood vessels *(red)* surrounding an LT004-infected *(green)* proximal tubule *(blue)* 2.5 hours postinfection. Black masses adhering to the wall of the vessel *(arrowhead)* suggest platelet aggregates. The intense *red* seen in the area represents stagnant flow, indicating a lack of red blood cell movement. Scale bar = 30 μm. (Reprinted from Melican K, et al. Bacterial infection-mediated mucosal signalling induces local renal ischaemia as a defence against sepsis. *Cell Microbiol* 2008;10(10):1987–1998, with permission.) (See Color Plate.)

suggesting TLR4 is upregulated during inflammation. The TLR4 expression pattern is thought to affect an individual's susceptibility to UTIs.[171] Children prone to ABU have reduced TLR4 expression on neutrophils[171,172] and those carrying the TLR4 A(896)G allele are prone to develop recurrent UTIs.[173]

In response to TLR4 signaling, cytokines are produced that orchestrate the immune response. Polymorphonuclear neutrophils (PMNs) and other inflammatory cells extravasate into the tissue as they follow this chemotactic gradient to the infection site. IL-8 is the main human chemokine (MIP-2 in mice) involved in the promotion of transepithelial PMN migration, which involves the IL-8 receptor CXCR1.[174] Studies have identified disease-associated polymorphisms and mutations in the CXCR1 gene of patients prone to pyelonephritis,[175] thus highlighting the importance of this receptor for a proper immune response. Neutrophils are commonly regarded as the primary cell type involved in the eradication of bacteria. Recent studies based on real-time intravital imaging of pyelonephritis in rat kidneys revealed that PMNs started to appear at the infection site as early as 3 to 4 hours postinfection, and by 8 hours, they constituted approximately 20% to 40% of nucleated cells present in the vasculature.[105] Not until hours later were neutrophils the predominant cell type at the infection foci. Although there is little doubt that PMNs are actively engaged in the clearance of bacteria in pyelonephritis, it appears that other cell types of hitherto unknown origin may also be involved in the early inflammatory process. PMNs are expected to kill bacteria via phagocytosis, and their ingestion of pathogens can occur with or without prior opsonization. The latter event is mediated by the main opsonins IgA and IgG, and by antimicrobial peptides.

Neutrophil recruitment is associated with severe tissue damage. The liberation of neutrophil granules containing antimicrobial peptides, proteins, and proteolytic enzymes can lead to the dissolution of extracellular matrix, can harm cell structures or cell function, and can induce acute and potentially irreparable damage.[174] PMN isolates from experimental acute pyelonephritis were observed to kill syngeneic renal epithelial cells in a culture within 24 to 48 hours.[176] In contrast, the suppression of acute suppuration in in vivo models reduced tubular epithelial cell damage and renal scarring despite the greater bacterial burden.[177,178] Furthermore, in IL-8 receptor knockout mice, impaired PMN translocation and unproductive accumulation in the subepithelial space resulted in kidney scarring and abscesses.[179] A picture has started to emerge that tissue damage results from the coherent action of bacteria, the inflammatory response, and physiologic injuries such as ischemia and obstruction.[62]

The antibody response in UTIs occurs both locally and systemically. Elevated levels of IgA, IgG, and occasionally, IgM have been observed in both the urine and the blood of UTI patients.[180,181] Systemic antibody titers vary distinctly between kidney and bladder infections,[182,183] with cystitis patients often showing titers as low as control groups.[180,184] Similarly, bacteria coated with antibodies are less frequently observed in patients with cystitis rather than with pyelonephritis.[182,183] Antibodies in urine play an important role in host protection. They may act as opsonins in opsonophagocytosis for PMNs recruited to the site, or they may target bacterial adhesins and, therefore, are likely to interfere with bacterial attachment to uroepithelial cells.[185] Another possibility is that antibodies trigger the agglutination of bacteria, thereby promoting bacterial clearance by voiding. They may also act to neutralize the detrimental effects of virulence factors.[186–188]

In cystitis and pyelonephritis, cell-mediated immunity is activated a day or more following the acute phase, as observed by an increased number of T cells in the infected organ

of the human. Earlier studies showing a close association between CD4 and plasma cells seemed to demonstrate the involvement of CD4 cells in host responses during repeated infections.[189,190] Experimental evidence now suggests that cell-mediated (T and B cells) immune responses appear to have a larger role in the kidney's response to chronic and repeat infections, rather than against acute infections. This is in contrast to bladder infections where the cell-mediated immune response is implicated in the acute phase. To illustrate this, T-cell depletion or deficiency does not have a significant effect on the outcome of kidneys under experimental bacterial infection.[191,192] γδ T lymphocytes are abundant in the mucosa, where they are known to modulate inflammation in response to various insults.[193] The central importance of γδ T lymphocytes in the clearance of bacteria from the bladder was recently demonstrated because these cells acted as the major source of IL-17A, which is a key mediator for the innate immune response to UTIs.[194]

Antimicrobial Proteins and Peptides

Host defenses against bacteria have been hypothesized to be dependent on epithelial-derived antimicrobial proteins that hinder survival of uropathogenic bacteria. The Tamm-Horsfall protein (THP) is the most abundant protein in human urine. THP is an evolutionarily conserved glycoprotein produced exclusively by epithelial cells of the ascending Henle loop.[195,196] Rich in mannose and sialic acid sequences, THP was shown to bind directly to type 1 fimbriated E. coli, and was therefore initially postulated to alleviate bacterial burden by sequestering bacteria within the urine for voiding.[197,198] This hypothesis was later discarded when the role of THP as a potent activator of innate and adaptive immune responses was revealed.[199,200] Examples include (1) the cell-specific stimulation of granulocyte toward IL-8 production,[199,201] (2) the upregulation of costimulatory molecules and MHC expression on dendritic cells (DCs), (3) cytokine production, and (4) DC maturation via TLR-4 signaling. So potent is the effect of THP that overstimulation of the immune system can lead to interstitial nephritis.[199,200]

Other important antimicrobial peptides in UTIs are the β-defensins and α-defensins, which are secreted from the local renal epithelium and the infiltrating neutrophils, respectively[200,201] Defensins possess a two-pronged effect, showing direct antimicrobial activity on invading bacteria and indirectly via the enhancement of the innate and acquired immune response. In the latter, defensin-induced secondary signaling arising from target cells and tissues have been implicated in acute inflammation regulation, immune cell recruitment, angiogenesis, and wound healing.[200] Examples include mast cell degranulation, the promotion of neutrophil chemotaxis, and naive T-cell and immature dendritic recruitment.[200]

Cathelicidins, such as LL-37, are antimicrobial peptides with direct bactericidal action. LL-37 is produced by neutrophils, myeloid bone marrow cells, epithelial cells of the skin, the gastrointestinal tract, the epididymis, and the lungs.[157,202] In the urinary tract, the peptide is produced from uroepithelial and tubular renal cells with a subsequent release into the lumen.[203] Given the presence of high cathelicidin-related antimicrobial peptides in the early stages of an infection well before leukocyte infiltration, a two-stage process was proposed in which the main source of the peptide shifts from the epithelium to leukocytes as the infection progresses.[203,204] Interestingly, cathelicidins exhibit a greater effect on pathogenic bacteria that cause UTIs as compared to urogenital commensal bacteria.[205] UPEC strains associated with severe UTIs also tend to have higher resistance to the peptide.[206]

Lactoferrin and lipocalin restrict the bacterial availability of essential iron. Lactoferrin is present in the luminal surface of distal collecting tubules where it exhibits its bactericidal activity indirectly by the chelation of iron, and directly by disrupting membrane integrity.[203] Lipocalin, on the other hand, limits iron availability by targeting bacterially expressed siderophores.[207,208]

Genetic Variability in Hosts

Genetic profiles have been observed that influence UTI susceptibility in patients. The genetic variation falls broadly into two groups: (1) factors involving bacterial colonization and (2) components of the host response. Variation in glycolipid receptor expression, which varies with the P blood group, has been shown to be associated with susceptibility to UTIs. Patients prone to UTIs tend to be of the blood group P1 and possess a high density of cell surface receptors for P fimbriae.[209] At present, there is insufficient statistical evidence to substantiate the inverse hypothesis (i.e., that individuals lacking receptors would be resistant to P-fimbriated E. coli).[210] However, treatment with N-butyl-deoxynojirimycin to mimic the previous receptor deficient state showed a protective effect on mice against colonization and inflammation.[211]

Two host factors, TLR4 and CXCR1 (the CXC chemokine receptor for IL-8), have been in focus when linking genetic variation to UTI susceptibility. A deficiency in mouse TLR4 signaling results in an asymptomatic carrier state that can persist for large proportions of the subject's lifespan before the onset of mortality.[33,212] This sequence of events closely resembles untreated ABU patients. CXCR1 is the receptor for the cytokine IL-8, which induces migration and the activation of neutrophils. CXCR1 has been suggested to function in protecting the host against severe infection.[137,213] Subjects with a deficient CXCR1 expression present with symptoms typical of acute pyelonephritis and renal scarring, as both the host's innate defenses and neutrophil migration are disrupted.[143] Children with lower CXCR1 expression and protein levels arising from a single nucleotide polymorphism are prone to pyelonephritis.[140,213] Furthermore, mice unable to express this IL-8 receptor have a higher titer of bacteria, a more rapid progression to bacteriuria, and renal scarring during an infection.

Intracellular Bacterial Reservoirs for Persistent Colonization

Recurrent infections are generally associated with repeated infections by the same bacterial strain. To persistently colonize the host UPEC have been proposed to enter into cells, thus generating a refuge by protecting bacteria from host defense systems. However, the significance of such intracellular reservoirs (IR) in UPEC persistence is not ubiquitous across the urinary tract.

Within the bladder, IRs appear to confer great advantage to UPEC survival. IRs are established when UPEC interacts with integral membrane proteins via FimH-mediated binding to uroplakin, which in turn triggers host cell signaling cascades that results in bacterial internalization.[131,190] The luminal surface of the mammalian bladder is lined by thick cell layers of pseudostratified transitional epithelia. Several studies have observed an intracellular transition of bacteria 12 hours postinfection,[139,141,154,214] after which IRs are established as bacteria rapidly multiply. Once an IR has become established in one cell, neighboring cells are invaded as UPEC progenies exit the host cell and invade other surrounding cells.[215,216] Although an exfoliation of superficial facet cells occurs, it does not appear to significantly deter UPEC persistence. While substantial IRs are removed with sloughed cells, the inadvertent exposure of the underlying cell layer allows UPEC to establish new IRs.

In the kidney the situation is different. Here, sloughing of the proximal tubule epithelium arising from ensued ischemia appears to negate the survival advantage of bacterial internalization.[217] During early periods of infection, ischemia-induced actin rearrangement and the associated relocalization of membrane-bound intergrins breaks the epithelial barrier function,[154,214] and detachment of epithelial cells from the tubular basement membrane occurs.[218] Loss of the epithelial barrier, however, did not compromise the host. The naked tubular basement membrane hinders the immediate bacterial dissemination into the interstitium.[139,154] while giving time for host responses to occur, such as the cessation of blood flow and PMN recruitment. Moreover, loss of the tubular integrity does not appear to solely benefit the invading pathogen because paracellular movement of UPEC enhances the neutrophil's accessibility to the tubular lumen.

The formation of IRs within the bladder is a highly effective strategy for UPEC persistence in which IRs or bacteria have been observed months after the initial infection, albeit with antibiotic treatment.[215–217] Yet, because of distinct histologic differences of the kidney from the bladder, IR establishment does not provide UPEC the same survival advantage within the kidney.[102,107,154,219]

Acute Kidney Damage

Infection and subsequent injury to the kidney causes extensive damage, which may affect kidney function and which may lead to kidney failure. Over the years, a number of proposed mechanisms for this injury have been suggested. A direct damaging effect of infecting bacteria is possible for those UPEC strains that express tissue-damaging toxins.[176,178,220,221] The strong inflammatory response to pyelonephritis has also implicated a role for collateral damage. Suppression of the immune response in experimental models has shown reduced kidney scarring despite a high bacterial load.[222,223] It has also been shown that neutrophils isolated from acute pyelonephritis can kill syngeneic kidney cells in vitro,[154] and neutrophil-mediated oxidative injury of kidney cells has been confirmed in vivo.[154]

Though physiologic alterations that accompany ischemia–reperfusion injury previously have been implicated in renal scarring,[224] recent data show renal infections do in fact cause ischemia.[154] Ischemia is a restriction in blood supply to a tissue or an organ that is closely associated with tissue oxygen delivery and tension (pO_2). Each kidney nephron has an intertwined peritubular vasculature. During the first hours (4 to 5 hours) of a UPEC infection in the proximal convoluted tubule, epithelia-endothelia signaling initiates the clotting cascade in peritubular capillaries (Fig. 21.2). This clotting leads to localized ischemia that manifests prior to the major infiltration of immune cells. Tissue pO_2 drops significantly, reaching 0 mm Hg within 3 to 4 hours.[154] This infection-mediated ischemia was demonstrated to act as an innate defense mechanism, preventing the systemic dissemination of the pathogen because anticoagulant therapy to prevent this response led to fatal sepsis within a few hours.[154] Although a massive engagement of neutrophils cleared the bacteria (Fig. 21.1E,F), no indications of reperfusion or repair were seen within the first 24 hours. Renal scarring thus appeared to be the end result of infection.

Another physiologic injury that is known to cause tissue damage in its own right is kidney obstruction. Real-time monitoring of renal filtrate flow in a live animal model of pyelonephritis showed how bacterial colonization of the renal tubules affects the flow of filtrate, with complete stoppage occurring within 8 hours. Kidney ischemia and obstruction are both well-studied physiologic injuries and both can cause inflammation and tissue destruction in their own right.[154,155,216,225–232] Both are multifactorial and can vary in severity. Severe ischemia or obstruction can lead to end-stage kidney failure, as can pyelonephritis. Thus, the emerging view is that the pathophysiology of pyelonephritis is in fact a combination of infection and physiologic injuries.[154]

Treatment

A UTI is most commonly treated by antibiotics. Wagenlehner et al.[233] present a comprehensive statistic of clinically prescribed antibiotics and their respective efficacies. The group describes UTIs as broadly divided into uncomplicated and complicated cases, against which treatment is tailored.[233,234]

The following paragraph is adapted from Wagenlehner et al.[233]

> Uncomplicated UTI denotes UTI without relevant structural and functional abnormalities arising from the urinary tract (uropathies), without relevant kidney diseases (nephropathies) and without relevant comorbidities. Conversely, complicated UTI is a complex condition of the following conditions: (1) Anatomical, structural or functional alterations of the urinary tract. (2) Impaired renal function by parenchymal and renal nephropathies. (3) Accompanying diseases or conditions that impair the patients' immune status.

In the treatment of uncomplicated UTIs, the choice of prescription is made based on five considerations[233]: (1) the individual risk to antibiotic treatment; (2) the bactericidal spectrum of the antibiotic and the known susceptibility of the bacterium to the antibiotic; (3) the clinical data of the effectiveness of the antibiotic; (4) the effect of the antibiotic on commensal microbial flora; and (5) side effects.

Complex UTIs require a two-pronged treatment strategy directed at the treatment of complicating factors and the invading pathogen.[234] In complex UTIs, pathogens can be a heterogeneous population of gram-positive and gram-negative strains with a wide range of antibiotic susceptibility and resistance.[233] Very often, the devised treatment must account for the possibility of the resistance development and cross-resistance among antibiotics of the same family.[233]

In general, the treatments of uncomplicated and complicated UTIs share two fundamental aims, namely, to use rapid acting therapy with high efficacy for recurrent infections within a patient, and to prevent the generation of pathogens resistant to the treatment.[233] When treatment is delayed or ineffective, uncomplicated UTIs can progress to sepsis and severe sepsis, requiring specific sepsis therapy. At this point, treatment of urosepsis becomes a combination of (1) eradicating the pathogen, (2) resolving the cause of the infection and the complications (e.g., obstruction), (3) providing life-supportive care, and (4) providing appropriate antimicrobial therapy.[233]

Aside from clinical treatments, folk remedies are commonly used in the treatment of UTIs. Although there are a variety in existence, cranberry juice is by far one of the most common. Cranberry juice and tablets have been used extensively as a remedy for infections of the urinary tract. Originally thought to be due to the bactericidal acidification of the urine by hippuric acid, recent studies have dispelled this mechanism of action. Cranberries contain proanthocyanidins, which inhibit P fimbriae–mediated bacterial adherence,[235,236] and fructose, which inhibits type 1–mediated adherence.[237] Despite the apparent positive effect of cranberries, no definitive findings have been determined in clinical trials.

CONCLUSION

Data presented in this chapter reveal that our current knowledge of UPEC and host–pathogen interactions in UTIs primarily originate from molecularly well-defined in vitro systems. The simplicity of such systems zooms in on specific reactions, controlling for and filtering out the myriad of relevant but confounding interactions that occur simultaneously in the host during an infection. Applying this wealth of information as a foundation and coupled with advanced imaging platforms for real-time studies in the live animal, researchers can now advance from "cellular microbiology" to "tissue microbiology," in their attempt to generate an integrated view on host–pathogen interactions. Such coherent models will help to not only identify both the cross-talk between host and pathogen, but also the dynamic changes occurring in the immediate environment in response to an infection. Murine intravital models of pyelonephritis have shown these changes include tissue oxygen tension and the cessation of blood flow to the infected site. These are but a few of the many factors that need to be tracked during an infection. Across the globe, interdisciplinary research coupling all fields of science is blooming and working to create new technologies. And as our understanding of host–pathogen interactions advances, so will clinical diagnostics, treatment, and patient care.

CHAPTER

22 Cystitis and Urethritis

Annelie Brauner • Milan Chromek

Bacteriuria, which is bacteria in the urine, is often (but not necessarily) a sign of infection. Therefore, it is important to put the results from bacterial urine culture into the context of the patient, including clinical symptoms, results of other laboratory tests, as well as methodology used.

Urine samples can be obtained in different ways. In adults, the most common sampling is clean-catch voided urine. In infants up to 1 year of age, however, suprapubic bladder aspiration is recommended, whereas for toddlers it is more common to collect with a urine collecting bag. From patients with an indwelling urinary catheter the urine sample has to be obtained through the catheter. These differences in modes of collection of urine samples inevitably result in differences in the type and number of bacteria isolated.

DEFINITIONS

Urinary tract infections (UTIs) in general can be symptomatic or asymptomatic. Symptomatic UTI can be divided into infections restricted to the lower urinary tract (bladder and urethra) to the upper urinary tract (kidney) or infections with systemic involvement, which is urosepticemia. The focus of this chapter is on infections of the lower urinary tract.

Symptomatic Urinary Tract Infection

Acute Cystitis and Urethritis

Cystitis is defined as an inflammation of the urinary bladder. Urethritis is an inflammation of the urethra. Both are most commonly caused by a bacterial infection; in which case, they are also referred to as lower UTIs.

Classic symptoms of lower UTIs are dysuria, urinary frequency, and suprapubic pain sometimes in combination with hematuria, but normally without fever. The extent of symptoms varies between different patients and can be very mild to severe. Other diseases can mimic lower urinary tract bacterial infections like vaginitis, interstitial cystitis, and pelvic inflammatory disease.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria (ABU) refers to bacteriuria in patients with no clinical UTI symptoms. For women $\geq 10^5$ colony forming units (CFU) per mL in two consecutive clean-catch urine samples is required for the diagnosis of asymptomatic bacteriuria, whereas for men only one clean-catch urine sample with $\geq 10^5$ CFU per mL is required—or a single catheterized urine specimen with one single bacterial strain of $\geq 10^2$ CFU per mL in women or men.[1]

CLASSIFICATION

Acute cystitis and urethritis can be classified as uncomplicated verus complicated UTI, nosocomial versus community-acquired UTI, and sporadic versus recurrent UTI.

Uncomplicated UTI occurs in persons with normal urinary tract, whereas complicated UTI occurs in individuals with functional or structural changes, implying deteriorated voiding predisposing for bacteriuria.

Nosocomial UTI are infections that occur 48 hours or more after admission to the hospital or as a result of health care, whereas community-acquired UTI are UTIs not included in the previous group.

Sporadic UTI include a single UTI treated with antibiotics during 6 months or maximum two UTIs needing antibiotics during 1 year, whereas recurrent UTI comprise at least two antibiotic treated UTIs during 6 months or three or more antibiotic treated UTI during 1 year.

Recurrent UTI can be further divided into relapse or reinfection. Relapse infection includes a recurrent infection with the same bacteria as the previous UTI, whereas a reinfection is caused by different bacteria than in the previous infection. Superinfection is a new infection during antibiotic treatment and where the new bacterial strain is resistant to the used antibiotic.

ETIOLOGY

By far the most common bacterial uropathogen is Escherichia coli, causing more than 80% of UTIs among female ambulatory patients. In men and hospitalized patients, E. coli is

still the most commonly isolated bacteria, but with a lower frequency. Other common uropathogenic bacteria include Klebsiella pneumoniae, Proteus mirabilis, enterococci, Streptococcus agalactiae, and Staphylococcus saprophyticus.[2,3] S. saprophyticus is the only urinary pathogen with a seasonal variation, being most common during the late summer and early autumn months.[4]

In patients with long-term indwelling catheters, bacteriuria is almost inevitably found after about 14 days. Initially, a single species of bacteria is found but later a polymicrobial flora is common, with a wide variety of infecting microorganisms found. In patients with long-term catheters Proteus mirabilis, Providencia stuartii, Morganella morganii, Klebsiella pneumoniae, E. coli, and Pseudomonas aeruginosa are most commonly isolated. In patients with short-term catheters, staphylococci are also common. Although staphylococci seldom cause symptomatic UTIs, they contribute to bacterial biofilm formation.[5,6]

Unusual causes of urethritis and cystitis include urethritis caused by Neisseria gonorrhoeae and Chlamydia trachomatis. They have a distinct pathogenesis and symptoms that can be similar to acute cystitis. They are usually described among sexually transmitted diseases. Adenoviruses (mainly type 11) cause epidemic hemorrhagic cystitis in children, especially in boys, but may cause endemic cystitis as well.[7] Other infectious causes, which are much less common, include Herpes simplex virus; atypical bacteria, like Mycoplasma genitalium and Ureaplasma urealyticum; Mycobacteria; fungi and parasites; Trichomonas spp.; and Schistosoma haematobium. There are also noninfectious forms of cystitis and urethritis—for example, traumatic cystitis, interstitial cystitis, eosinophilic cystitis, and hemorrhagic cystitis—which are described elsewhere.

EPIDEMIOLOGY

UTIs are among the most common bacterial infections.[3,8] Prevalence is different depending on the age and gender of the patient. The overall risk in childhood before puberty is 3% to 5% in girls and 1% to 2% in boys.[9,10] In the neonatal period, the incidence of bacteriuria is about 1%, and this is also the only period when UTI is more prevalent in males than females.[11] After 1 year of age the incidence of UTIs reaches 2% in boys and 8% in girls.[12] During the reproductive period, the gender difference becomes even more pronounced and UTIs are some 50-fold more common in women as compared to men. Approximately 20% of women between 24 and 64 years old have at least one episode of dysuria each year, most of these being caused by bacterial infections.[13] Almost half of all women will experience at least one episode of UTI during their lifetime[8] and about 25% of these have recurrent infections. In the United States alone, UTIs account for approximately 11 million office visits and 1.7 million emergency room visits each year, resulting in almost half a million hospitalizations at a cost of $3.5 billion.[8,14,15] This figure probably underestimates the true incidence because many lower tract UTIs resolve without medical attention.

ROUTE OF INFECTION

UTIs are most commonly ascending infections caused by bacteria mainly from the intestinal tract or vagina. Hematogenous spread of infections to the urinary tract is rare and restricted to a few pathogens, such as S. aureus and Mycobacterium tuberculosis, which cause primary infections elsewhere in the body. Lymphatic spread from sites of infection elsewhere, bacterial spread through a fistula from the bowel, and retrograde infection from the prostate or kidney are very unusual but may also occur.

The perineum is a couple of square centimeters area of skin between the anal and urogenital regions. This is also a place that is highly colonized by bacteria from the gastrointestinal tract and vagina, and from where the bacteria may reach the urinary tract.[16] In the majority of cases, the bacteria are cleared off from the bladder. Sometimes, they persist and colonize the urinary tract causing asymptomatic bacteriuria or even symptomatic UTI.[16] The short female urethra is an insufficient anatomic barrier to the entry of bacteria, which may be massaged easily into the bladder. This may explain the association of UTIs and bacteriuria with sexual activity.[17] Bacteria may also be introduced into the bladder during catheterization of the urethra. Single catheterization of the bladder in ambulatory patients results in a 1% incidence of subsequent UTI.[18] Finally, voiding dysfunction in children is also clearly associated with recurrent UTI[19] and complex treatment of the dysfunction resulted in a substantial decrease of the frequency of UTI attacks.[20] All these observations suggest that ascendance of bacteria from perineum to the urethra and urinary bladder is the most common route of UTI.

PATHOGENESIS

Bacterial Factors in the Pathogenesis of Urinary Tract Infection

How do harmless commensal bacteria from the perineum become urinary pathogens? It is believed that some bacterial clones from the gut can acquire specific virulence characteristics, which increase their ability to adapt to new niches. These virulence and fitness properties are frequently encoded in specific genetic elements called pathogenicity islands. Virulence factors are here defined as proteins or macromolecular structures that contribute to causing disease, whereas fitness factors offer a competitive advantage during infection, but are not required for virulence. A combination of virulence and fitness factors form a specific type that could be called uropathogenic bacterium. However, despite many common features, there is no single profile that would cause UTI.[21,22] Uropathogenic bacteria use a multistep scheme of pathogenesis that consists of adhesion, colonization, invasion, survival, and host damage.[23] Bacterial factors can accordingly be described as adhesion and colonization factors, survival and immune escape factors, and toxins (for details, see Chapter 21).

Host Factors in the Pathogenesis of Urinary Tract Infection

The urinary tract is located in a fragile region in close proximity to the outside environment. Around 2 L of urine a day, produced by the kidneys, are emptied close to the rectum, the area highly colonized by bacteria. Still, the urinary tract is very resistant against infection. It was observed by urologists more than 100 years ago that, despite extensive instrumentation (e.g., frequent catheterization), and even without aseptic precautions, some individuals never or very seldom developed UTI.[24,25] This observation has later been confirmed experimentally, showing that bacteria introduced to the urinary bladders of healthy volunteers were rapidly eliminated.[26] In accordance, only very high concentrations of bacteria, or a combination of bacteria and an irritant substance such as paraffin or turpentine, were needed to establish UTI in experimental animals.[27,28]

In order to successfully colonize the urinary tract and cause infection, bacteria must overpower the specific anatomic organization of the urinary tract as well as chemical defense components of urine and the urinary tract mucosa. Moreover, recognition of uropathogens by human urinary epithelium leads to a strong inflammatory response.

Anatomic Properties of the Urinary Tract

The draining system of the urinary tract is covered with urothelium, a firm carpet of epithelial cells. Urothelium is transitional epithelium consisting of three to seven layers of cells: the basal layer of stem cells, one or more intermediate layer(s), and the superficial layer, usually referred to as umbrella or facet cells. Normal human bladder urothelium is arranged in an increasing complexity from base to surface. Urothelial cells of all layers are connected by interdigitations of cytoplasmic processes and by desmosomes. Adjacent surface cells, in addition, are linked by tight junctions. This organization enables the urothelium to withstand frequent changes in bladder volume with changes in pressure on the bladder wall.[29]

The urothelium is exposed to large changes in hydrostatic pressure with the surface superficial cells and is in contact with urine varying in pH, osmolality, and containing a number of cytotoxic substances. Therefore, cell membranes of umbrella cells need a unique lipid and protein composition that contributes to the low permeability of the membrane and that controls the passage of water, ions, solutes, and large macromolecules across the mucosal surface of the cell into the underlying tissue. The apical surface of umbrella cells is folded and contains specialized uroplakin membrane domains, which undergo active reorganization.[30,31] During the initial phase of bladder filling, the apical membrane unfolds. In the latter phase of filling, the cytoplasmic vesicles are inserted to the apical membrane to accommodate the increasing bladder volume. Emptying of the bladder is then accompanied by endocytosis of the cytoplasmic vesicles and folding of the apical membrane.[32,33] In addition to the highly specialized urothelium, a mucous layer on the surface of the urinary bladder has been described.[34,35] This layer seems to be very thin, and substantially differs from the mucus in the gastrointestinal tract. It consists mainly of glycosaminoglycans and is most likely membrane-bound rather than secreted.[36]

Urine flow, regular bladder emptying, and the valve mechanisms of the urinary tract have traditionally been considered the most important protective mechanisms maintaining this area free of microbes. Accordingly, studies in patients with anomalies of the urinary tract indicate their importance in the protection against bacteria.[37] Functional abnormalities of the lower urinary tract directly influence the entry of uropathogens into the urinary tract and may lead to recurrent UTIs, mainly in children.[19,20] For premenopausal women a new sexual partner, increased frequency of intercourse, and use of spermicides are recognized as risk factors.[38] In postmenopausal women the loss of estrogen results in change of the vaginal flora, with decreased growth of lactobacilli, as well as thinning of the vaginal epithelium and decreased amounts of glycogen which contribute to the risk of recurrent UTIs.

Mucosal Antimicrobial Mechanisms

Although regular urine flow and valve mechanisms of the urinary tract protect the urinary tract against the excessive growth of bacteria, they are not enough to completely eliminate pathogens. This has been demonstrated using an in vitro model of the urinary bladder[26] as well as mathematical simulation.[39] In accordance, the mucosa of the urinary bladder has been shown to possess antimicrobial properties in vitro.[40] Only a combination of mechanical and chemical antimicrobial factors may explain the high efficiency of the urinary tract in eliminating bacteria. Although chemical antimicrobial mechanisms of the urinary tract mucosa have so far not been systematically analyzed, a number of molecules inhibiting the growth of bacteria in the urinary tract or killing bacteria have been identified: Tamm-Horsfall protein, secretory IgA, antimicrobial proteins, and peptides, namely lactoferrin, β-defensin 1 and 2, and cathelicidin.

Recognition of the Presence of Bacteria

The first cell layer in contact with invading bacteria is the urothelium. The presence of uropathogenic bacterium induces a robust immune response already after a short contact with urothelial cells. After sensing the presence of uropathogenic bacteria, epithelial cells react in different ways. They produce substances toxic to bacteria, like nitric oxide, cathelicidin, and β-defensin-2.[41–43] Exfoliation of superficial umbrella cells is also an important protective mechanism, which helps clearing bacteria from the bladder.[44] Despite the effective first line of epithelial defence, uropathogens may sometimes persist or even multiply and invade the host. Therefore, the epithelium possesses efficient tools in order to engage the help of professional

immune system cells. Epithelial cells in the urinary tract and kidney, in response to pathogens, produce a number of chemokines and proinflammatory cytokines.[45] Chemokines attract professional immune system cells, and cytokines activate them. Out of a number of chemokines, interleukin 8 seems to be of crucial importance because of its chemoattraction of neutrophils.[46,47] Cytokine-mediated upregulation of adhesion molecules and cytokine receptors facilitates the process of migration of immune cells. Amongst them, the CXCR1 receptor on renal epithelial cells has been shown to facilitate transepithelial migration of neutrophil granulocytes and bacterial clearance during UTI.[48] Neutrophils accumulate in the inflamed tissue and kill bacteria by different mechanisms: either phagocytosis or the release of the toxic content of their granules.[49] The influx of neutrophils is followed by an influx of other professional immune cells, namely monocytes/macrophages and lymphocytes, which are predominantly important in later stages of infection.

SYMPTOMS

The symptoms of a UTI substantially differ depending on age and type of infection. The symptoms in infants and young children are very nonspecific and UTIs are usually diagnosed first in the stage of upper urinary tract involvement, or septicemia. The signs may involve tachypnea, dyspnea, as well as icterus in neonates and poor feeding, fever, and vomiting in infancy. Therefore, UTIs must always be excluded in unwell children or children with unexplained fever. After infancy, the classic symptoms of lower UTIs—dysuria, urgency, and frequency—are more usual. Adults with urethritis and cystitis typically have frequent and urgent voiding of small volumes of urine and dysuria and nocturia is common. Sensation of lower abdominal discomfort also is a frequent symptom. The urine may be turbid or even bloody in one third of cases.[50] Some infections may progress after 1 or 2 days to develop a clinical picture of upper UTI, including flank or abdominal pain, fever, and vomiting, but acute cystitis very seldom progresses to cause septicemia. On the contrary, the infection may resolve spontaneously even without antimicrobial therapy. Still it cannot be justified to withhold antimicrobial therapy.[51,52]

Studies localizing bacteria by laboratory or imaging techniques have demonstrated a poor correlation between clinical manifestations and localization results. Moreover, UTIs often are asymptomatic in the elderly[53]; and other diseases may also manifest by frequency, urgency, nocturia, and incontinence in this age group. Likewise, patients with neurogenic bladders, a long-term indwelling catheter, or intermittent catheterization usually have unspecific or no symptoms referable to the bladder when a UTI develops.[5] Therefore, there should be a low threshold for microbiologic examination of the urine in these patient groups.

DIAGNOSIS

Examination of urine specimens for bacteriuria and leukocyturia are the primary laboratory investigations in suspected UTI.

Diagnostic Pitfalls

Diagnosis of cystitis and urethritis, as well as other types of UTIs, relies on the detection of bacteria and leucocytes in urine. There are two major pitfalls in the bacteriuria assessment: contamination of urine and confusion with asymptomatic bacteriuria. These problems are more obvious in certain groups of patients—namely children, the elderly, and patients with indwelling catheters—because of nonspecificity of symptoms and difficulty of collection of clean urine samples.

Studies comparing clean-voided urine samples with samples obtained by suprapubic bladder puncture showed contamination rate of 25%.[54] In infants where alternative urine sampling, mainly urine bags and catheterization, are common, the situation is even more difficult. Contamination rates reach 63% in bag specimens and 9% in catheter specimens.[55] Clean-catch sampling of infants is time- and skill-demanding and prepuce flushing in boys may lead to paraphimosis. Therefore, bladder puncture is often the recommended method to collect urine samples in infants younger than 1 year of age when the correct diagnosis is essential. In older children and adults, urine samples should if possible be cultured from clean-catch, midstream urine to avoid contamination.

Another problem is confusion of a true UTI with asymptomatic bacteriuria. Asymptomatic bacteriuria is a common condition[16,56] and, in the majority of cases, no treatment is recommended because antibiotic treatment may increase the risk for development of symptomatic infection.[57] However, in an infant presenting with high fever and bacteriuria, the differential diagnosis between pyelonephritis and asymptomatic bacteriuria with another systemic infection (e.g., adenovirus infection) is very difficult.

Similarly, in the elderly, diseases that are not related to the urinary tract may also manifest by frequency, urgency, nocturia, and incontinence,[53] therefore making the differential diagnosis between lower UTI and asymptomatic bacteriuria troublesome.

The present cut-off levels of significant bacteriuria were defined in a series of classic studies in the 1950s by Ed Kass.[58,59] As in many biologic systems, the numbers of bacteria in urine of patients with UTIs are a continuum and any cut-off is accompanied with a given sensitivity and specificity. The number of bacteria in urine may be influenced by incubation time in the urinary bladder as well as the doubling time of the bacteria. Therefore, a small bladder (e.g., low age), low incubation time (e.g., frequency), and slowly growing bacteria may negatively influence the bacterial numbers in urine specimens. Kass suggested that a threshold of $\geq 10^5$ bacteria per mL of urine reliably distinguished contaminated specimens from true bacteriuria in asymptomatic women, and accurately diagnosed women with acute pyelonephritis. Many clinicians subsequently adopted this single criterion to diagnose cystitis, although Kass had not, in fact, studied women

with lower tract symptoms.[50] Later, it has become apparent that cystitis with significant bacteriuria and cystitis with lower bacterial counts have a similar pathogenesis and may represent different stages of the same disease.[60,61] Approximately 40% of women who experience symptoms of cystitis have midstream urine cultures containing less than 10^5 bacteria per mL.[50,62] Similarly, a pediatric study of 366 infants found that 20% of children with proven symptomatic UTI had less than 10^5 bacteria per mL urine from both suprapubic aspiration and bag specimen.[63] Handling of the urine sample may also significantly influence the result of urine cultures. Only a few hours of room temperature incubation can result in significant multiplication of bacteria and false-positive results.

Nowadays, bacterial counts of 10^4 or sometimes even 10^3 CFU per mL, depending of the infecting microorganism, are regarded as significant in patients with clinical UTI symptoms. Therefore, the number of bacteria in urine must be interpreted in a complex view together with other laboratory tests and in the whole clinical context.

Another laboratory sign of UTI is leukocyturia or pyuria.[64] The finding of pyuria is unfortunately not specific for urethritis and cystitis. Both systemic inflammation and asymptomatic bacteriuria may be accompanied by the presence of leukocytes in urine. Despite its limitations, pyuria together with other tests serves as one of the indications of infection of the urinary tract.[65]

Urine Culture

Conventional microbiologic quantification of bacteriuria is performed by inoculating a predefined urine volume, mostly 1 or 10 μl, onto appropriate agar plates, incubating at 37°C overnight, then identifying the bacterial species and estimating the number of bacterial colonies.[66] Susceptibility testing can be performed either directly from the urine or by subculturing from bacterial colonies. Bacterial species and recommendation of appropriate antibiotic usage can therefore be presented within 24 hours. Matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) is a novel technique for rapid identification of bacterial pathogens, possibly also directly from infected urine. Although it gives high accuracy, conventional culture is still needed for bacterial susceptibility testing.[66a]

Another way of monitoring bacterial growth, especially in the outpatient clinical settings, is the dip slide test. The dip slide consists of a plastic paddle with culture agar on each side that is immersed in urine and then incubated at 37°C overnight. The method allows semiquantitative measurements; however, the accuracy is limited, mainly because of the relatively high inoculums and the small agar surfaces. There are several drawbacks with the method, one being the absence of antibiotic susceptibility testing. Another limitation is the risk of over-interpretation of mixed bacterial cultures, especially gram-negative bacteria and, conversely, the risk of not being able to see and evaluate weak bacterial growth like that often seen for group B streptococci.[67,68]

Microscopic Examination of Urine

Urine can be examined microscopically for the presence of bacteria and leukocytes. Microscopic examination is simple and faster than urine culture. The Gram staining is useful both for analysis of bacterial type, gram-negatives or -positives, morphology, rod or cocci, as well as for quantitative analysis. The presence of one or more bacteria per oil immersion field in uncentrifuged urine correlates with $\geq 10^5$ bacteria per mL on culture with a sensitivity and specificity over 90%.[69] However, this method does not detect low count infections, nor does it give possibility for species identification or antibiotic resistance.

More than 95% of patients with symptomatic UTIs have significant leukocyturia.[70] However, pyuria is also found in several other diseases not related to UTI. Because examination of centrifuged urine sediment is not reproducible, quantitative analysis of a fresh, uncentrifuged specimen of urine is recommended.[64] The most common method is counting under the microscope using a hemocytometer chamber. A count of 10 or more leukocytes per mL is considered abnormal. Most women with symptomatic lower UTI have more than 60 leukocytes per mL.[71] As mentioned before, leukocyturia must be carefully evaluated together with other symptoms and signs because it lacks specificity for symptomatic UTIs. In addition, the accuracy of microscopic evaluation of the urine for leukocytes is no better than that of rapid esterase test on a dipstick. Moreover, laboratory facilities are needed, and results are delayed. Therefore, the role of microscopy for white cells for the diagnosis of UTI was recently questioned.[72]

Rapid Diagnostic Tests

Several methods are being used for the rapid detection of bacteriuria and leukocyturia. Such methods may be very useful in a clinical setting when a fast diagnosis is essential. Optimally, rapid tests have low cost, high sensitivity, and high specificity. Therefore, they are useful as screening methods for groups at risk, such as pregnant women. Moreover, in the laboratory these tests may also help select which specimens require further microbiologic investigation. Two biochemical tests have been devised: the nitrite and leukocyte esterase tests.

The nitrite test is based on the bacteria's ability to reduce nitrate to nitrite. It is rapid to perform and evaluate and easy to interpret.[72,73] A test strip is immersed in urine and a color change is observed within 2 minutes, if positive. The test has high specificity, but low sensitivity, which implies that positive results indicate prevalence of bacteria, whereas negative results do not rule out bacteriuria because high bacterial concentrations are needed. Likewise, some common uropathogenic bacteria will not be positive in the test. S. saprophyticus and enterococci do not reduce nitrate to nitrite and Pseudomonas reduce nitrite further to ammonia and nitrogen—therefore, none of these bacteria will be positive. False-positive results can be obtained after having

eaten phenazopyridine, whereas high levels of vitamin C can give false-negative test results. The Leukocyte esterase test is a simple and rapid test for leukocytes.[74] It has high specificity and sensitivity and gives similar results as microscopy of urine sediment. When granulocytes are available, the test strip rapidly turns purple with intensity corresponding to the leukocyte concentration. It is important to remember that negative results in either or both tests do not exclude bacteriuria and that especially a positive leukocyte esterase test can be due to reasons other than bacterial infection.

TREATMENT

Many countries have guidelines for the treatment of cystitis and asymptomatic bacteriuria. These guidelines take into consideration the local bacterial susceptibility pattern in the respective countries and may therefore vary between different areas.

Asymptomatic Bacteriuria in Adults

Only few patient groups run an increased risk for adverse outcomes due to asymptomatic bacteriuria, mainly pregnant women and patients undergoing urologic intervention. Pregnant women have an increased risk of developing acute pyelonephritis in the early phase of pregnancy and are also likely to experience premature delivery.[75,76] Therefore, screening during the early stage is recommended and pregnant women should be treated with antibiotics if urine culture shows significant bacterial growth.[1]

In the majority of patients who undergo urologic interventions, bacteriemia occurs, with clinical evidence of septicemia in up to 10%.[77] Therefore, in patients with urologic intervention, where mucosal bleeding is expected, antibiotic treatment should be initiated prior to such intervention.[1] Although an increased risk of symptomatic UTIs may be observed in remaining cases, screening for or treatment of asymptomatic bacteriuria is not indicated.

Cystitis in Adult Women

Uncomplicated acute sporadic cystitis in previously healthy nonpregnant women should be treated with antibiotics if the patients present themselves with typical symptoms. Recommendations differ regarding the need of verification with rapid tests or urine culture. Most countries have reached consensus that nonpregnant women with uncomplicated sporadic cystitis presenting with typical symptoms can be treated without previous urine culture or dipstick. The treatment strategy is to cover the infecting microorganism but not disturb the normal bacterial flora in the gut. The antibiotic concentrations in the urine should be high with a narrow antibacterial spectrum. If left untreated about 30% have no symptoms after about 1 week. There are currently new guidelines from the Infectious Disease Society of America (IDSA) and European Society for Microbiology and Infectious Diseases (ESCMID),[78] which will be referred to in the text. Variations may of course exist in other countries.

For women with symptoms of acute uncomplicated cystitis and absence of flank pain, fever, or other suspicions of acute pyelonephritis, and where the patient is able to take oral medication, recommended treatment is with one of the following antimicrobial agents: nitrofurantoin, trimethoprim-sulfamethoxazole, fosfomycin, or pivmecillinam. Pivmecillinam is only available in some European countries and not licensed/available in North America.[78] Trimethoprim-sulfamethoxazole is the only of these drugs that can be used if early acute pyelonephritis is suspected. The duration of treatment depends on the choice of therapy; for nitrofurantoin and pivmecillinam 5 days is proposed whereas only 3 days for trimethoprim-sulfamethoxazole. For fosfomycin a single dose is sufficient; however, lower efficacy than some other recommended agents has been observed.[78] Both nitrofurantoin and pivmecillinam are rapidly eliminated through the urine and therapeutic concentrations are only found in the urine up to 1 day after therapy is ended. Trimethoprim on the other hand can be detected in the urine up to 2 or 3 days after the medication is stopped. Patients who are treated with nitrofurantoian should be advised not to take alkalizing agents, such as potassium citrate, because the effect of higher pH correlates to higher minimal inhibitory concentration (MIC).[79] Moreover, women with renal impairment should not be treated with nitrofurantoin because effective concentration of antibiotics in the urine is not possible to reach and toxic concentrations of antibiotics can occur in the plasma.

Quinolones should be avoided for empirical treatment of cystitis and instead used for acute pyelonephritis. Moreover, the high prevalence of resistance against fluoroquinolones has been reported in some areas. Ampicillin and amoxicillin alone should be avoided because they require close follow-up and have lower efficacy than other available agents. When the resistance prevalence to trimethoprim exceeds 20%, or if used for UTI within the previous 3 months, alternative therapy should be considered.[78]

Recurrent Cystitis in Women

The main risk factors for recurrent cystitis differ between premenopausal and postmenopausal women. In premenopausal women an association with sexual intercourse, the use of spermicides, and age of first UTI has been demonstrated. In postmenopausal women vaginal prolapse, cystocele, postvoid residue, changes in vaginal flora, and urinary incontinence are the main risk factors.[80,81]

Nitrofurantoin, trimethoprim-sulfamethoxazole (avoid if resistance prevalence >20%, or if used for UTI during the last 3 months), and pivmecillinam (if in a country where it is available) can be used for treatment.[78] However, it is important to establish a correct diagnosis and, therefore, urine culture with susceptibility testing should be performed and antibiotic treatment adjusted according to the susceptibility results. Patients with hematuria or persistent bacterial growth in spite of appropriate antibiotic treatment should undergo cystoscopy and imaging of the upper urinary tract.

Prevention of Recurrent Cystitis in Adult Women

Recurrent UTI is a significant problem for the individual patient and a need for prophylaxis is often called upon. A Cochrane Review demonstrated that the use of antibiotics is beneficial to reduce the number of clinical as well as microbiologic recurrent UTIs in pre- and postmenopausal women.[82] There are several possibilities for prophylaxis. Most commonly, antibiotics can be continued daily for between 4 and 12 months. However, prophylaxis should not be initiated until 1 to 2 weeks after treatment, when urine culture is negative, ensuring bacterial eradication. Low doses of nitrofurantoin, cephalexin, trimethoprim, and trimethoprim-sulfamethoxazole have been recommended.[83] Women who experience recurrent UTIs, in association with sexual activity, can be offered postcoital prophylaxis. A major advantage with single dose therapy is that it produces fewer side effects because the women only take one third of the antibiotic otherwise used, and the outcome is still similar to daily prophylaxis.[83,84] Postmenopausal women could also benefit from vaginal estrogen, because it has been demonstrated to reduce the number of UTIs.[85,86] Cranberries might reduce the incidence of UTIs in women with recurrent infections,[87] but there is no evidence on concentrations that must be used. In studies performed the withdrawal rate has been high, suggesting that cranberry products are not acceptable over long periods. Adverse events like gastrointestinal intolerance, weight gain, and drug–cranberry interactions have been reported.[88]

Acute Cystitis in Men

Bacteriuria in men is rare and, when it occurs, it is mostly associated with predisposing factors like prostate hyperplasia, prostate cancer, or urethral stricture. At least 50% of men with recurrent UTIs and more than 90% of those with febrile UTIs have prostate involvement,[89,90] which may lead to complications like chronic bacterial prostatitis or prostate abscesses. Therefore, it is important to examine the prostate to rule out prostatitis or other concurrent pathologic changes of the prostate. Ciprofloxacin or trimethoprim-sulfamethoxazole are generally recommended as first choice. For infections caused by enterococcus, with a natural resistance to trimethoprim, amoxicillin is recommended. Due to the frequent prostate engagement treatment duration should be 2 weeks.[91]

Asymptomatic Bacteriuria in Children

Children with asymptomatic bacteriuria do not present with symptoms but bacteriuria is detected by screening. There is relatively good evidence of long-term outcomes and influence of treatment from randomized controlled trials.[92–94] The conclusion from these trials was that treatment of asymptomatic bacteriuria does not influence the emergence of symptomatic UTIs, clearance of vesicoureteric reflux, kidney growth, or the progression of kidney scars. Therefore, in contrast with previous recommendations,[50] the screening for and the treatment of asymptomatic bacteriuria in children is not currently recommended.

Cystitis and Urethritis in Children

The aim of the treatment is to effectively eradicate the infection, relieve symptoms, and minimize the development of complications after a UTI. Currently, there is consensus that symptomatic cystitis/urethritis in children should be treated with antibiotics. There are many studies addressing questions regarding type and duration of antibiotic treatment.[95–97] In summary, there is no difference in outcomes between short duration (2–4 days) and longer duration (7–14 days) of treatment, so short-duration antibiotic treatment should be used for children with lower UTIs. The evidence does not provide guidance as to which antibiotic is most useful but a choice from trimethoprim, nitrofurantoin, a first-generation cephalosporin, or amoxicillin would be supported by current clinical practice. It is recommended to follow local bacterial susceptibility patterns and recommendations in the respective countries and regions.

It is also important to emphasize that infants and children with high risk of serious illness should be referred immediately to a pediatric nephrologist. This also applies for all infants younger than 3 months with a possible UTI, who are initially treated as upper UTI with parenteral antibiotics. Urine analysis including urine culture is essential in the diagnostic algorithm in both of the above-mentioned groups. For children 3 years and older, with typical lower UTIs and positive nitrite and leukocyte esterase tests, urine culture is not necessary. Oral 3- to 5-day courses of antibiotic treatment are recommended for children 3 months and older with uncomplicated lower UTI.[98] The parents or caregivers should also be advised to bring the child for reassessment if he/she is still unwell after 24 to 48 hours. If an alternative diagnosis is not made, a urine sample should be sent for culture and antibiotic sensitivity test if that has not already been carried out. If an infant or child is receiving prophylactic antibiotic medication and develops symptomatic UTI, treatment should be with a different antibiotic. The urine culture and the antibiotic resistance pattern are then especially important.

IMAGING AND FOLLOW-UP

In contrast to upper UTIs, investigations after a single cystitis/urethritis are only recommended in infants younger than 6 months of age when distinction between lower and upper UTI may be difficult. Ultrasound examination of the kidneys and urinary tract within 6 weeks is the recommended method. Further investigation (99m-technetium dimercaptosuccinic acid [DMSA] scintigraphy, micturating cystourethrography [MCUG]) is only required in cases of abnormal ultrasound finding. In infants 6 months and older, and in children, no investigations and no follow-up are required.[98,99]

In children with recurrent lower UTIs, defined as three or more episodes of cystitis/urethritis, or one episode of pyelonephritis and one or more episodes of cystitis/urethritis, much more extensive investigation should be done in order to identify and treat the underlying risk factors. For infants younger than 6 months, ultrasound during the acute infection, DMSA scintigraphy 4 to 6 months following the acute infection, and eventually MCUG are recommended. In infants and children older than 6 months with recurrent UTIs, an ultrasound within 6 weeks and DMSA 4 to 6 months following acute infection are recommended as the initial investigation.[98] Further investigation is indicated in the case of abnormal ultrasound. A careful patient history, with focus on volume and frequency of micturition and toilet habits, is highly recommended because it may reveal functional abnormalities of the urinary tract and may lead to further examinations, uroflowmetry, or more detailed urodynamic investigation.

PREVENTION OF RECURRENCE IN CHILDREN

Recurrent UTIs are associated with considerable suffering and substantially influence quality of life. Therefore, all opportunities to prevent recurrences should be explored. All underlying anatomic and functional anomalies of the urinary tract should be treated. Moreover, clinical studies have identified the following risk factors for recurrent infections in children: age under 6 months at the first infection, family history of UTI, high-grade vesicoureteric reflux, infrequent voiding, poor fluid intake, and functional stool retention, but evidence is limited.[19,100,101] Although no prospective randomized studies have, to our knowledge, been carried out to investigate strategies to influence the risk factors in order to prevent recurrent UTIs, consensus recommendations were made.[98] According to them, children who have had a UTI should be examined with focus on dysfunctional elimination syndromes and constipation. Children should be encouraged to drink an adequate amount, and they should have ready access to clean toilets when required and should not be expected to delay voiding.

Antibiotic Prophylaxis

In many national guidelines it is currently recommended to use a low-dose antibiotic treatment after a UTI until imaging of the urinary tract has been completed. Moreover, long-term low-dose antibiotic treatment has been used as a prophylaxis of recurrent UTIs regardless of the presence of the anatomic or functional abnormality in the urinary tract. Putting together infections of the upper and lower urinary tract, prophylactic antibiotic treatment reduced bacteriuria based on a meta-analysis of eight studies including 1,103 patients.[98] There is, however, no evidence of a reduction in the incidence of symptomatic UTI based on meta-analysis of five studies including 539 patients.[98] Therefore, antibiotic prophylaxis should not be routinely recommended in infants and children following a first-time lower UTI. However, antibiotic prophylaxis may be considered in infants and children with recurrent UTIs.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

At the time of catheter insertion, microorganisms belonging to the patient´s flora can gain access to the urinary bladder. Chronic catheterization leads almost inevitably to bacteriuria. The preferred mechanism of bladder entry is extraluminal. It is speculated that bacteria migrate within the mucopurulent space between the urethra and the catheter. However, organisms can also enter the bladder intraluminally, where the bacteria migrate into the bladder as a result of manipulation of the catheter system.[102–104] Bacteria adhere to the indwelling catheter and form biofilm. Catheter-associated UTI in patients with urethral, indwelling suprapubic, or intermittent catheterization is defined by the presence of symptoms or signs compatible with UTI combined with $\geq 10^3$ cfu/mL of ≥ 1 single bacterial species in a single catheter urine specimen or in a midstream voided urine sample from a patient where the urethral catheter, suprapubic, or condom catheter has been removed. Importantly, no other source of infection should be identified.[5] Due to the variety of infecting microorganisms, with various antibiotic sensitivity patterns, liberal attitude to urine culture including susceptibility testing is advocated. To prevent catheter-associated UTIs, guidelines from many countries recommend antimicrobial coated or impregnated urinary catheters. The most common antimicrobial compounds are silver and nitrofurazone. In a recent Cochrane Review from 2008 it was concluded that silver alloy catheters significantly decreased the incidence of asymptomatic bacteriuria during the first week of catheterization, and with less effect thereafter.[102] A similar effect was observed for nitrofurazone impregnated catheters, but only during the first week of catheterization.[102] However, the effect on bacterial adhesion and persistence has recently been questioned.[103]

When a symptomatic infection occurs, a change of catheter combined with urine culture and antibiotic therapy is appropriate. But as long as the person is asymptomatic, urine culture is not needed and routine treatment is not recommended.

CHAPTER

23 Infections of the Upper Urinary Tract

Lindsay E. Nicollé

In the normal urinary tract, ascending upper tract infections are prevented or delayed by the dynamics of urine flow and the interference of the vesicoureteral junction. The microbial etiology of urinary tract infections (UTIs) is similar throughout the urinary system, but the infection site determines the clinical features, the response to therapy, complications, and the ultimate prognosis; therefore, it is appropriate to identify upper tract infections in this chapter as a unique and significant illness. Parasitic, fungal, and mycobacterial infections of the upper tract are discussed in other chapters. Viruses are commonly excreted in the urine, but with the exception of the syndrome of hemorrhagic fever with renal insufficiency, and parvovirus B19 and other infections in renal transplant patients, the role in renal disease is ill defined; therefore, this chapter focuses primarily on bacterial infections. An infection of the upper urinary tract is not readily diagnosed in the absence of the classic clinical features of acute pyelonephritis. As a result, much of the information available is derived from studies in which the diagnosis of renal infection was imprecise. Complicated urinary infections are reviewed in Chapter 25. Uncomplicated upper tract infections in adults is the principal focus of this review, with a discussion of renal infection in patients with complicated urinary infections where relevant.

DEFINITIONS

Acute Pyelonephritis

Acute pyelonephritis is a clinical syndrome of flank pain, renal tenderness, fever, and chills, and is accompanied by bacteriuria. It may be associated with bacteremia and can progress to the systemic inflammatory response syndrome, septic shock, and, rarely, death. Acute nonobstructive pyelonephritis, also called acute uncomplicated pyelonephritis, occurs in women with a normal genitourinary tract.[1] Pyelonephritis may also occur as one clinical presentation of a complicated urinary infection in persons with structural or functional abnormalities of the genitourinary tract.

Chronic Pyelonephritis

Chronic pyelonephritis is a radiologic diagnosis characterized by renal scarring and destructive changes in the calyceal system, presumed to be caused by bacterial infection, vesicoureteral reflux, or both. Although the classic histologic features of chronic pyelonephritis have included interstitial inflammation and fibrosis, this description lacks specificity for bacterial infection and is now recognized as common to a variety of pathologic processes.

Bacteriuria

Bacteriuria is the presence of bacteria in the urine. Kass[2] introduced the term significant bacteriuria to differentiate contaminated from infected urine using quantitative urinary bacterial counts. Significant bacteriuria is the presence of at least 10^5 colony-forming units (CFU) per milliliter or at least 10^8 CFU per liter (International System of Units). Patients with symptomatic upper tract urinary infections occasionally demonstrate lower bacterial counts in their urine.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is bacteriuria without accompanying signs or symptoms attributed to urinary infections.[3] Pyuria or a serologic response to the infecting organism often accompanies asymptomatic bacteriuria, suggesting the patient is infected and not simply colonized. In females, two voided urine samples with at least 10^5 CFU per milliliter of the same organism are required to diagnose asymptomatic bacteriuria. In men, only one urine culture is necessary. Any quantitative count of a single specimen obtained by catheterization or suprapubic aspiration in men or women is also sufficient.

Recurrent Urinary Infection

Persons who experience one episode of a UTI have a greatly increased risk for a subsequent infection. A recurrent urinary infection is considered a reinfection when a new bacterial strain is isolated in the subsequent infection and is considered a relapse if the strain isolated posttherapy is similar to the

pretherapy isolate. When a relapse occurs, the infecting strain is presumed to have persisted within the genitourinary tract.

Pyuria

Pyuria is the presence of more than 5 polymorphonuclear leukocytes per high-power field (HPF) on a microscopic examination of spun urine sediment, or the presence of more than 10 polymorphonuclear leukocytes per microliter of unspun urine.[4]

HISTORICAL PERSPECTIVES

The initial description of pyelonephritis is attributed to a 9th century Arabic physician. By the mid-19th century, the associations of pyelonephritis with pregnancy and chronic pyelonephritis with a history of recurrent urinary infection were described. In 1881, Roberts[5] noted bacteria in the urine of patients with urinary symptoms, and in 1894, Escherich[6] identified "Bacillus coli" in the urine of children with urinary infections. During the preantibiotic era, recurrent urinary infection was identified as a cause of progressive renal impairment, bilateral contracted kidneys and death from uremia in girls,[7] of long-term complications of hypertension and atrophic pyelonephritis in women,[8] and of hypertension and progression to end-stage renal disease following acute pyelonephritis of pregnancy.[9] Kass,[2] in 1956, revolutionized the study of urinary infection by introducing the quantitative assessment of bacteriuria, and also identified the importance of asymptomatic bacteriuria during pregnancy. The introduction of effective antimicrobial therapy in the middle of the last century has subsequently profoundly altered the impact and adverse outcomes associated with renal infection.

PATHOGENESIS

Bacteriology

Escherichia coli is responsible for 80% or more of 16 cases of acute nonobstructive pyelonephritis (Table 23.1). Strains isolated from renal infection belong to a restricted number of O:K:H serotypes characterized by an array of virulence factors that include toxins, such as hemolysin; iron binding proteins, such as aerobactin; and specific adhesin proteins that bind to receptors on uroepithelial cells.[17,18] These and other virulence genes are often clustered within the genome in pathogenicity islands.[17] Over 95% of strains of E. coli isolated from patients with acute nonobstructive pyelonephritis contain genes for the pap G class II allele of the P fimbria adhesin.[17] The P fimbriae family is one of the mannose resistant adhesins, with a binding specificity for the gal (α1–4) gal-β disaccharide galabiose, which mediates adherence to uroepithelial cells. Specific clonal groups of E. coli, some of which are multidrug resistant, have caused global

outbreaks of uncomplicated urinary infection, including pyelonephritis.[19] For instance, Prats and colleagues[20] described a uropathogenic clone (E. coli 015:K52:H1) isolated during a 1-year period in Barcelona, Spain, which was overrepresented in patients with acute pyelonephritis.

Other gram-negative rods, including Klebsiella spp., Proteus mirabilis, and Enterobacter species, are isolated in a few patients with community-acquired renal infections but are much more common in patients with complicated infections. P. mirabilis accounts for more than 40% of infections in infant boys.[21] P. mirabilis is particularly significant as a renal pathogen because of its propensity to promote struvite calculi.[18] Coagulase-negative staphylococci and Enterococcus faecalis each cause 2% to 3% of invasive renal infections. The latter is a more important pathogen in elderly men. Group B streptococci are isolated in less than 1% of urinary infections, but appear to have a propensity for patients with diabetes and pregnant women.[22] Group A streptococci, Streptococcus pneumoniae, and Neisseria spp. are rare upper tract pathogens. Some patients with Staphylococcus aureus bacteremia from other sites will have S. aureus bacteriuria, with or without associated renal infection.[23] Although Staphylococcus saprophyticus is an important cause of acute cystitis in women, its role in invasive upper tract infections is uncertain. Both Mycoplasma hominis and Ureaplasma urealyticum have infrequently been isolated as the sole pathogen in patients with classic acute pyelonephritis; increases in specific antibody titers to these agents support a role for infection.[24]

Some relatively uncommon organisms isolated include Leptospira spp., Brucella spp., and Salmonella spp. A leptospiral infection usually involves the kidneys and has pathologic changes of interstitial inflammation, hemorrhage, and tubuloepithelial damage.[25] The pathogenesis of these lesions is attributed to leptospiral proteins together with hypotension, hypovolemia, and hyperbilirubinemia. Although renal insufficiency is common, localized renal symptoms are unusual; plasma creatinine and blood urea nitrogen (BUN) usually normalize in the second week of illness. A culture of urine on special leptospiral media is usually positive during the acute illness; a polymerase chain reaction or serology are also useful diagnostic tests, if available. Brucella spp. infection may, rarely, be associated with bacterial pyelonephritis and may also present as glomerulonephritis or interstitial nephritis.[26] Salmonella spp. are also a rare cause of pyelonephritis, although renal dysfunction is reported to occur in up to 36% of infected adults, usually due to dehydration and rhabdomyolysis.[27,28]

The microbiology of pyelonephritis in patients with a complicated urinary infection, including catheter-associated hospital-acquired urinary infection, is substantially different. E. coli, usually arising from the patient's own gastrointestinal tract, remains the most common urinary pathogen, but many other species are frequently isolated, and bacteria are likely to be of increased resistance. The spectrum of infecting organisms in a patient will be influenced by exposures to the health care environment as well as current or recent antimicrobial exposure. E. coli isolated from pyelonephritis in patients with complicated urinary infection have a much lower prevalence of potential virulence factors, including the P fimbria, consistent with host rather than organism factors being the principal determinants of infection.[29–31] More resistant gram-negative rods, including Pseudomonas aeruginosa and Serratia marcescens, account for 10% to 15% of hospital-acquired invasive upper tract infections in some reports, and may occur in outbreaks.[32] Corynebacterium group D2 has been identified as a unique etiologic agent of nosocomial urinary infection, particularly in catheterized patients.[33] These organisms are urease producers and may be isolated from persistent infections including bladder and renal calculi, pyelonephritis, and bacteremia. They are slow growing and sometimes missed if routine cultures are discarded after 24 hours.

Organisms that are unable to use urine as a nutrient source only rarely cause pyelonephritis. These include most species of obligate anaerobes, for which the relatively high oxygen tension in normal urine also likely inhibits growth. In a prospective study of 5,781 urine specimens, Segura et al.[34] identified only 10 patients with positive urine Gram stains and negative aerobic cultures from which anaerobic bacteria were isolated—an overall prevalence of 1.2% of bacteriuric specimens. All but 1 of these 10 patients had complicated urologic problems. Uropathogens surviving in the kidney without cell walls, also called L forms or protoplasts, have been suggested to contribute to relapsing pyelonephritis by enabling organisms to persist and cause chronic disease in the hypertonic environment of the renal medulla.[35] However, studies have not yet confirmed a role for these bacterial forms in urinary infections.

Host Factors and Host Response

Host factors contributing to pyelonephritis and the host immune and inflammatory response are described in detail in Chapter 21. Behavioral factors associated with acute nonobstructive pyelonephritis in premenopausal women are similar to those for acute uncomplicated cystitis—most importantly sexual intercourse and spermicide use for birth control.[12] There is also a genetic predisposition, as evidenced by a twofold to sixfold increased prevalence of urinary infections in the mothers and female siblings of girls and women with recurrent urinary infections.[36] Women who are nonsecretors of the blood group substance have an increased risk of recurrent acute uncomplicated urinary infections,[37] and selected blood group antigens are associated with an increased frequency of urinary infections in girls without vesicoureteral reflux.[21] Epithelial cell receptors necessary for E. coli binding are glycolipids of the globoseries, the antigens of the P blood group system. Recent studies exploring polymorphisms of effector molecules of the innate immune response have described other potential genetic determinants. In children without vesicoureteral reflux, pyelonephritis is reported to be associated with polymorphisms and mutations of the CXCR1 receptors for interleukin (IL)-8 and GCP-2 in some,[38,39] but not all studies.[40] A single nucleotide polymorphism for IL-8 was associated with severity of pyelonephritis among

children.[40] Genetic variation in the Toll-like receptor (TLR) promoter TLR-4 may also influence susceptibility to pyelonephritis in children,[41] whereas a TLR-1 receptor polymorphism has been reported to be associated with protection from pyelonephritis in women.[42]

Individuals with structural or functional abnormalities of the urinary tract have a greatly increased risk of pyelonephritis, apparently independent of behavioral or genetic factors (Table 23.2). Obstruction at the level of the kidney or ureter may directly inhibit urine flow from the upper tract, allowing bacteria to establish infection behind the obstruction. In addition, voiding abnormalities, such as neurogenic bladders, are frequently associated with reflux, which promotes upper tract infections.

Acute pyelonephritis is characterized by an intense local and systemic inflammatory and immune response.[17] Following the stimulation of epithelial receptors within the urinary tract by bacteria or bacterial products, there is activation of the innate immune response through TLRs. The Pap G adhesin appears to be important in stimulating the epithelial cytokine response.[43] Pyuria occurs early, and urinary and serum cytokines and chemokines including IL-6, IL-8, and others are elevated.[42–45] Alterations in the expression of antimicrobial peptides may be another element of the innate response, but there is a limited evaluation to date of the role of these molecules within the urinary tract.[46] The intensity of the inflammatory response correlates with the severity of symptoms. Pyelonephritis is associated with a greater inflammatory response than a lower tract infection, and urinary cytokines have increased levels in symptomatic compared with asymptomatic UTIs. This inflammatory response resolves promptly with the institution of effective antimicrobial therapy.[47] Renal infection is also associated with both a local and a systemic humoral immune response. An immunoglobulin (Ig)M antibody predominates with the initial infection but subsequent infections are dominated by an IgG response.[17,18] The primary antibody response develops about 7 to 10 days following the initial infection. Local urine antibody includes both an IgA and an IgG response to the infecting bacteria. Whether this humoral immune response has any protective role for subsequent infection remains controversial.

23.2 Abnormalities Associated with Complicated Renal Infections

Associated Systemic Diseases
Renal transplantation
Chronic renal failure
Diabetes mellitus with complications
Neutropenia
Immunosuppression
Underlying Structural Abnormalities
Congenital abnormalities (obstruction and/or stasis)
Acquired obstruction (pelvicalyceal, ureteral, urethral)
Neurogenic bladder
Catheter associated (indwelling or intermittent)
Cystocele
Bladder diverticulae
Renal cyst
Renal calculus
Atrophic or malfunctioning kidney
Less Susceptible Pathogens
Pseudomonas aeruginosa
Proteus mirabilis
Candida albicans

PATHOLOGY

Acute Pyelonephritis

A renal biopsy is contraindicated for patients with acute pyelonephritis. When pathology specimens are available, the histologic hallmarks of acute pyelonephritis include abscess formation and edema in the renal parenchyma with an accumulation of polymorphonuclear leukocytes in and around the tubules. Bacteria are often demonstrable in the foci of acute renal suppuration. In general, glomeruli are spared, although small abscesses may surround them. Areas of infection are characteristically wedge-shaped with the apex in the medulla resembling an infarct. Although tissue destruction is greater in the cortex than in the medulla, the relative smaller size of the medulla means the inflammatory response appears to have a greater effect on medullary anatomy and function. The distribution of wedge-shaped areas of suppuration is characteristically focal, usually corresponding to renal lobes, and sharply demarcated from areas of uninvolved renal parenchyma. In adults, the kidney is unlikely to be uniformly affected unless concomitant obstruction is present.

Chronic Pyelonephritis

Chronic pyelonephritis is a focal parenchymal disease with associated changes of the renal collecting system owing to inflammation and deformation. Fibrosis with atrophy of overlying renal tissue leads to surface depression or scars. Neighboring unaffected renal tissue often undergoes hypertrophy and may appear to be a mass lesion. A sharply defined border between normal and diseased tissue is characteristic of chronic pyelonephritis. The capsule is adherent and the cortical surface is irregular. Calyceal clubbing results from a papillary retraction into the scar. Dilatation, muscular hypertrophy, and fibrotic inflammation causing a thickening of the calyceal system all occur to a variable extent. The two kidneys are usually markedly asymmetrically involved, whereas other diseases that cause interstitial inflammation usually affect both kidneys equally.

The histology of chronic pyelonephritis is the pathology of interstitial or tubulointerstitial nephritis and is characterized by a pleomorphic infiltrate of lymphocytes, plasma cells, and macrophages in the interstitium of the kidney. Polymorphonuclear leukocytes and eosinophils may also be present. The vessels in zones of the normal kidney may be normal or may demonstrate hyaline intimal changes. Histologic features of acute and chronic pyelonephritis can overlap. The relative degrees of edema and fibrosis rather than the interstitial cellular response are the most useful criteria to delineate these entities. Previously, many end-stage kidneys were referred to pathologically by the term chronic pyelonephritis. This is now recognized as being a common end stage for many renal diseases, and is seldom attributable to infection.

PREVALENCE AND INCIDENCE

Symptomatic Pyelonephritis

Bacteriuria occurs in 0.7% of full-term infants, and clinically evident urinary infections occur in 0.3%.[21] Males predominate in the first 3 months of life, and account for almost 80% of neonatal urinary infections. Most of these infections appear to involve the upper tracts. In a retrospective review of 11,655 children born at a Stockholm hospital between January 1, 1979 and June 30, 1982, the annual incidence of pyelonephritis during the first 2 years of life was 34 per 10,000.[48] Acute pyelonephritis occurred after a mean of 5.6 months following discharge, with a range of 1 week to 17 months; only one infant had an underlying malformation of the urinary tract. A more recent report from a Seattle group health cooperative reported hospitalization rates for pyelonephritis were 17/10,000 for girls and 6/10,000 for boys age 0 to 4 years.[49] It is estimated 1% to 3% of all girls 1 to 5 years of age experience an episode of pyelonephritis.[21]

About 250,000 episodes of acute pyelonephritis with over 160,000 hospitalizations occur each year in adult women in the United States.[50] The highest rates of acute nonobstructive pyelonephritis are in young women, many of whom also experience acute uncomplicated cystitis (Table 23.3). Ikaheimo and associates[51] reported an incidence of 2.7 episodes of pyelonephritis per 100 patient years during a 1-year follow-up of women in a family practice in Finland who originally presented with an episode of acute cystitis. The ratio of episodes of cystitis to pyelonephritis was 29:1. Stamm and associates[52] followed 51 American women with recurrent uncomplicated urinary infections for a median of 9 years. The mean infection rate was 2.6 per patient year with the ratio of cystitis to pyelonephritis episodes of 18:1 for women not receiving prophylactic antimicrobials.

Hospitalization for treatment of acute pyelonephritis reported from a Canadian province was 11/10,000 women.[54] Pyelonephritis accounted for 0.4% of all hospital admissions.

23.3 Reported Frequency of Pyelonephritis in Selected Populations

Study Design (with Reference)	Population	Incidence
Retrospective,[48] Sweden	Children <2 years	34/10,000 population
Prospective, 12 months, Finland[51]	179 women initially presenting to GP with acute cystitis	2.7/100 patient years
Retrospective,[52] United States 1969–1985	51 women with recurrent cystitis	0.1 ± 0.3/patient year
Prospective,[53] Canada	Diabetic women with bacteriuria	7.2/100 patient years
Administrative data,[54] Canada, hospitalized	Women—all Women >60 years Men	10.9/10,000 population 14.0/10,000 population 3.3/10,000 population
Administrative data,[50] United States, hospitalized	Women <60 years Women >60 years Men <60 years Men >60 years	7.8–15.0/10,000 population 13.5–23.3/10,000 population 1.1–2.4/10,000 population 6.3–12.9/10,000 population
Administrative data, United States[49]	Hospitalized women men Outpatient women men	12–13/10,000 population 2–3/10,000 population 3–4/10,000 population 1–2/10,000 population

The frequency of hospitalization underestimates the incidence of pyelonephritis because many patients with pyelonephritis, especially healthy young women, are not admitted for treatment. Peak pyelonephritis hospitalization rates occurred in women 20 to 29 years old, and men and women older than 50 years. From 0.3% to 0.7% of all pregnancies required hospitalization for pyelonephritis. Women with diabetes were six to 24 times more likely to be admitted with pyelonephritis than nondiabetic women, stratified by age. An American study reported a similar hospitalization rate of 11.7/10,000 for women,[50] but hospitalization rates were not increased in patients with diabetes. The highest rates were observed in younger women aged 20 to 39 years, with 15 hospitalizations/10,000, and women over 80 years, with 23.3/10,000. For women enrolled in a group health cooperative in Seattle, estimated annual rates of outpatient and inpatient pyelonephritis were 12 to 13/10,000 and 3 to 4/10,000, and the highest incidence of 18 to 20/10,000 occurred in young women.[49]

Pyelonephritis in men usually occurs in the context of complicated urinary infections, but acute nonobstructive pyelonephritis may rarely occur. Krieger and colleagues[55] reported an incidence of uncomplicated symptomatic urinary infection of 4.9/10,000 men per year in a 6-year study of male university students, but most of these were likely lower tract infections. Rates of hospitalization for acute pyelonephritis in men, most with complicated urinary infections, were reported to be 3.3/10,000 per year in Canada,[54] and 2.4/10,000[50] and 1 to 2/10,000[49] in the United States. In selected populations with complicated urinary infections, Waites and associates[56] reported 1.8 episodes per person year of urinary infections presenting with fever and chills, presumably upper tract infections, in 64 spinal cord–injured patients managed with intermittent catheterization or condom drainage. A prospective study of residents in long-term care facilities reported 1.1 episodes of febrile urinary infection per 10,000 resident days.[57] The rate was 0.8/10,000 resident days for individuals without chronic indwelling catheters, and 4.6/10,000 for those with chronic indwelling catheters.

Asymptomatic Upper Tract Infections

Asymptomatic bacteriuria is common in many populations,[3] and frequently involves the upper urinary tract (Table 23.4). Presumably, factors such as the duration of bacteriuria, infecting organisms, associated medical illnesses, the presence of

23.4 Localization of Infection in Bacteriuric Populations

Reference	Method	Population Investigated	Symptoms	Site of Infection		
				Renal	Bladder	Equivocal
58	Ureteral catheterization	95 Women 26 Males	Variable	67	54	—
59	Bladder washout	125 Women	52 Asymptomatic 30 Upper 43 Lower	63	52	10
60	Bladder washout	133 Women	90 Asymptomatic 15 Upper 28 Lower	56	54	23
61	Bladder washout	50 Women	25 Upper 25 Lower	21	22	7
62	Bladder washout	105 Women	60 Asymptomatic 24 Lower 20 Upper	65	39	—
63	Bladder washout	50 Women Mean 80 yr	Asymptomatic	17	14	19
64	Bladder washout	51 Women Mean 80.5 yr	Asymptomatic	34	17	—

vesicoureteral reflux, and urinary obstructions influence the likelihood of a UTI in patients with asymptomatic bacteriuria. At least 50% of institutionalized elderly women with bacteriuria have upper tract localization.[63,64] Bacteriuria in these populations often persists and remains asymptomatic for months to years. Bacteriuria is likely attributable to the same biologic variables as recurrent uncomplicated or complicated symptomatic infection, but bacterial isolates causing bacteriuria are rarely a direct cause of subsequent symptomatic infection in the absence of uroepithelial trauma or obstruction.

NATURAL HISTORY AND CONSEQUENCES

Infection during Infancy and Childhood

The short-term morbidity of acute pyelonephritis in children may include hospitalization, severe sepsis and septic shock, metastatic infection, and, rarely, acute renal failure. Following the introduction of antimicrobial therapy, the outcome for adequately diagnosed and treated children is excellent. However, there remain concerns about the potential for long-term renal damage following acute pyelonephritis in childhood.

Renal scarring is observed in 10% to 30% of children following acute pyelonephritis.[21] Established risk factors for the development of renal parenchymal scarring include vesicoureteric reflux, recurrent infection, delayed treatment, and a young age at the time of initial infection.[65] Parvex et al.[66] observed 88 scars in 50 children at 6 months after acute pyelonephritis; 3 years later, 27% were unchanged, 63% were partially resolved, and 9% were completely disappeared. The number of scars was the most important variable associated with decreased renal growth. Increased serum and urine markers of the inflammatory response at presentation with acute pyelonephritis, including IL-8,[67] IL-6,[68] procalcitonin,[69] and C-reactive protein,[69] are associated with subsequent increased occurrence of renal scarring, regardless of vesicoureteral reflux. Recent studies have suggested that cytokine gene polymorphisms may partly explain the differential inflammatory response.[65,70,71] Studies do not support a role for bacterial virulence factors as predictors of subsequent scarring.[72]

The relative importance of vesicoureteral reflux and pyelonephritis in the development of renal scars and impaired renal function in childhood remains controversial. It is now accepted that congenital vesicoureteral reflux, primarily occurring in males and associated with higher levels of reflux and renal dysplasia, is most likely to progress to renal failure, regardless of infection.[73] Postnatal renal damage may also occur with vesicoureteral reflux associated with an infection, or with acute inflammation from an infection of the renal parenchyma without reflux. Scarring after pyelonephritis in infancy is associated with renal growth arrest in the involved kidney and may be associated with progressive kidney damage.[67,73] The risk of renal failure is significantly greater with high-grade reflux (grade IV through V) and with multifocal or global scarring. A careful follow-up with an immediate diagnosis and the adequate treatment of all recurrent episodes of infection, particularly during infancy and early childhood, are considered necessary to prevent progressive renal impairment.[73]

Asymptomatic bacteriuria occurring in girls 5 years or older with normal kidneys on a study entry is benign.[74] It is not associated with renal scar development regardless of antimicrobial treatment. Thus, programs to screen for bacteriuria in school-age girls and to treat infections, if found, are not worthwhile.

Adult-Onset Infection

Short-Term Morbidity

Potential negative short-term outcomes of acute pyelonephritis are lost days of work, hospitalization, septic shock, requirements for urologic intervention, and sequelae of metastatic infection. For patients with complicated urinary infections, additional morbidity may be attributable to the underlying abnormality, which promotes infection. Women with diabetes have been reported to have more prolonged fever and a higher rate of mortality.[75] Acute renal failure occurring with acute nonobstructive pyelonephritis caused by E. coli is rare, but well described.[76,77] This is usually reversible, may be more common in diabetic patients, and, for some of the reported cases, concomitant nonsteroidal antiinflammatory drugs likely contributed to renal failure.

Mortality

A comprehensive population-based study of the incidence and prevalence of bacteremic acute pyelonephritis from 1977 to 1981 in an urban population of 400,000 reported 22% of community-acquired bacteremias were attributed to invasive urinary infections, with an annual incidence of 15.7 per 100,000.[78] The attributable mortality for bacteremic urinary infections was 4.8%, but all 15 deaths occurred in patients with a significant underlying illness. During the same period, these investigators observed 1,520 episodes of hospital-acquired bacteremia, of which 221 (14.5%) originated from the urinary tract (71% in catheterized patients), thus yielding a rate of 7.3 per 10,000 hospitalized persons.[79] The mortality rate attributed directly to infections in these patients with bacteremic nosocomial pyelonephritis, virtually all with complicated urinary infection, was 12.7%. This mortality rate is one-third that of gram-negative bacteremia originating from other sites. A review of 542 episodes of bacteremic gram-negative urinary infection in Olmsted County, Minnesota, from 1998 to 2007 included 57% that were community acquired, 36% that were health care associated, and 7% that were nosocomial.[80] All cause mortality was 4.9% at 28 days and 15.6% at 1 year. The only independent predictor of increased mortality was increasing age, whereas a lower mortality was associated with community-acquired infections and an isolation of E. coli. In critical care units,

14.6% of patients admitted with septic shock had a urinary source.[81] The 28-day mortality when the urinary tract was the origin of the septic shock was only 18%, compared with 36% for all other sites. Berger et al.[82] described a case series of 65 patients admitted from 1994 to 2007 at one Australian center who required emergency nephrectomies due to severe urosepsis; the mortality in these individuals was 20%. Thus, mortality attributable to pyelonephritis occurs, but virtually only in patients with complicated infections.

Metastatic Infections

Genitourinary sepsis accompanied by bacteremia may be complicated by metastatic infections at other sites. Siroky and colleagues[83] identified 175 patients in whom metastatic infections developed from a primary source in the genitourinary tract. Most patients (86%) were men and the mean age was 57 years. A primary prostatic focus was considered the site for dissemination in many of the men, but in 46 patients the upper urinary tract was the likely source of the bacteremia. One hundred six patients (59%) had infections of the skeletal system; 51 patients (28%) had endocarditis; and 13% involved miscellaneous sites, including the eye and the central nervous system. Almost 70% of the skeletal infections were caused by gram-negative rods, with the vertebral column the most common metastatic site, identified in 83 patients (78%) with skeletal infections. In patients with endocarditis, gram-positive organisms were responsible for two-thirds of the infections, and these patients usually had preexisting heart disease. About one-third of these patients had undergone a manipulation of the upper urinary tract prior to the development of metastatic infections. Underlying host factors that would impair resistance to infections were unusual. In a Danish review of cases of vertebral osteomyelitis from 1978 to 1982, the urinary tract was the most common identified source, with the mean latent period separating an episode of acute urinary infection from the onset of symptoms of vertebral osteomyelitis being 54 days.[84]

Renal Impairment

Adult onset pyelonephritis rarely contributes to chronic renal failure. Abnormalities previously attributed to pyelonephritis in autopsy studies are now recognized as being an end stage of other processes such as vascular disease, papillary necrosis, or medullary cysts, with little contribution from infections. In one autopsy study of patients with renal failure, 13% of subjects were considered to have pyelonephritis, but all had vesicoureteral reflux, analgesic abuse, nephrolithiasis, or obstruction as underlying contributory factors for pyelonephritis.[85]

The Bristol Pyelonephritis Registry followed 375 women for 1 to 13 years after a clinical diagnosis of recurrent pyelonephritis. Only one patient had a radiographic progression of renal scars.[86] Other long-term studies that have reported patients with progression to renal failure also invariably identify alternate diagnoses to explain renal functional deterioration in affected patients. Parker and Kunin[87] retrospectively reviewed 74 cases among 163 women hospitalized for acute pyelonephritis 10 to 20 years previously, in the early antimicrobial era. Continuing clinical illness following the index hospitalization had occurred in more than 40% of patients; 28% had had an operative urologic procedure, and 23% had renal stones. Seventeen percent were bacteriuric at the follow-up examination. One patient died of complications of pyelonephritis, one required a transplantation for end-stage renal disease, and two others had significant renal impairment. Seven patients had undergone unilateral nephrectomy for pyelonephritis. Gower[88] followed 62 adult women with treated infections and a radiologic diagnosis of chronic pyelonephritis for a mean follow-up of almost 5 years. Serial studies demonstrated radiographic progression in 11 women, but persisting infection and analgesic ingestion contributed to progressive radiologic damage in all these cases. Two of the 36 patients with bilateral pyelonephritis had renal failure or died during the follow-up. Alwall[89] described a selected series of 29 women with an initial normal-appearing intravenous pyelogram (IVP) who developed contracted kidneys from 1 to 15 years following acute pyelonephritis. Several went on to end-stage renal disease, but for all these cases, analgesic abuse was a concomitant factor that likely accounted for disease progression.

Raz and colleagues[90] described long-term outcomes for women admitted with acute pyelonephritis to a hospital in Israel between 1982 and 1992. Only 31% of the patients were available for a 10-year follow-up, likely a group representing those with more serious or persistent disease. With technetium ^{99}Tcm–labeled dimercaptosuccinic acid (^{99}Tcm-DMSA) scanning, 46% of these women had evidence of renal scarring. Pregnancy and hypoalbuminemia at hospitalization for pyelonephritis were independent risk factors correlated with the finding of renal scars at a 10-year follow-up. Although four women with scars had a glomerular filtration rate (GFR) of less than 75 mL per minute, none had developed renal impairment. Despite the high proportion of this selected group of women who had renal scarring, there were no clinically relevant adverse outcomes.

These long-term prospective studies support the observation that recurrent UTIs in adult women usually have a benign natural history. Adults with recurrent UTIs and no other complicating illness seldom experience clinically significant renal damage directly attributable to an infection. Persons with infection and renal impairment invariably have significant underlying urologic abnormalities or associated renal diseases.

Hypertension

The long-term follow-up of cohorts that have enrolled large numbers of women have consistently reported no significant differences in blood pressure between patients with bacteriuria and those without bacteriuria.[3] Patients entered into the Bristol Pyelonephritis Registry and followed for up to 13 years developed hypertension at the same rate as the

general population.[86] Raz et al.[90] reported a similar frequency of hypertension in women with and without renal scarring 10 to 20 years after hospitalization for acute pyelonephritis. Thus, evidence does not suggest acute or recurrent pyelonephritis contributes directly to development of hypertension.

Pregnant Women

Acute pyelonephritis occurs in 1% to 2% of all obstetric patients in the absence of screening and treatment programs for bacteriuria.[91] It is the most common medical complication requiring hospitalization during pregnancy. Women with asymptomatic bacteriuria early in pregnancy have a 20- to 30-fold increased risk of acute pyelonephritis in later trimesters.[92] This is attributed to ureteral dilation and urinary stasis resulting from progesterone-induced smooth muscle relaxation, together with mechanical compression by the enlarging uterus. Acute pyelonephritis in pregnancy occurs primarily in the second and third trimesters. Case series have reported 52% of episodes occurring in the second trimester, 46% in the third, and 2% in the first,[93] and 11% occurring in the first trimester and the remainder in the second or third trimester.[94]

Acute pyelonephritis, as with any febrile bacterial illness in late pregnancy, is associated with an increased risk for premature labor, presumably due to systemic inflammation.[95] The attributable risk of acute pyelonephritis for maternal toxemia, prematurity, and perinatal mortality remains controversial.[91] Sever and associates,[96] in data collected from more than 55,000 pregnant women, reported a higher incidence of low-birth–weight infants and stillbirths in the 3.5% of women with documented UTIs. Naeye[97] reported a combined perinatal mortality rate of 42 per 10,000 births in bacteriuric women as opposed to 21 per 10,000 births in nonbacteriuric women. McGrady and colleagues,[98] using birth certificate data from Washington State, showed that the fetal mortality rate was 2.4 times higher for UTI-associated pregnancies. Romero and colleagues,[95] in a meta-analysis, documented an increased occurrence of low-birth–weight and preterm delivery with asymptomatic bacteriuria. Smaill (in a Cochrane review)[99] also showed that antibiotic treatment significantly reduced the risk of low birth weight. Thus, asymptomatic bacteriuria is associated with prematurity and low birth weight, but it is not clear whether acute pyelonephritis is also a risk, or whether any presentation of urinary infection is causative for these outcomes.

Pregnant patients have a reduced GFR following acute pyelonephritis, which reverts to normal within 8 weeks of effective treatment.[100] Long-term follow-up studies of women known to have previously experienced bacteriuria during pregnancy report a benign course for the majority of patients.[101,102] In a follow-up period of 10 to 14 years, almost 40% of 134 women with bacteriuria during pregnancy also had bacteriuria on follow-up cultures. Although pyelography showed renal scarring in 28% of these patients, creatinine clearance was normal for both the bacteriuric and the nonbacteriuric women.[102] Raz et al.[90] reported that pregnancy at hospitalization for acute pyelonephritis was an independent risk factor for the presence of renal scars 10 to 20 years later. Subtle differences in renal function were found in long-term follow-ups between women with and without urinary infection during pregnancy, but these were not clinically significant.

Neurogenic Bladder

Following a traumatic spinal cord injury, patients managed with permanent indwelling catheters have substantial subsequent morbidity and mortality attributable to renal infections. The mortality rate from renal failure was 20% within 3 decades from injury in survivors of World War II spinal injuries. This was a consequence of obstruction, nephrolithiasis, suppurative renal disease, and progressive nonobstructive chronic pyelonephritis.[103] More than one-half of the deaths during the 2nd decade after spinal cord injury were caused by renal failure.[104] The introduction and widespread practice of voiding management to maintain a low-pressure system within the genitourinary tract, including the use of intermittent catheterization, have dramatically altered the occurrence of and mortality from complications of urinary infections in this population. Spinal cord injured patients, however, remain at an increased risk of urosepsis and other complications of infection including urethritis, periurethral abscesses, bladder and renal calculi, vesicoureteral reflux, and renal or perinephric abscesses.

LABORATORY DIAGNOSIS

Urine Culture

Quantitative counts of bacteria isolated from urine collected before the initiation of antimicrobial therapy in patients with acute nonobstructive pyelonephritis exceed 10^5 CFU per milliliter for 95% of patients.[2,105–107] In patients with renal infections, ureteral urine bacterial counts vary between 10^1 and 10^6 CFU per milliliter.[58] The maximum stationary phase growth is reached in the bladder after a period without emptying; thus, whenever possible, urine cultures should be obtained following an overnight "incubation" of urine within the urinary bladder. A number of variables, including diuresis, frequency of voiding, partially effective antibacterial chemotherapy, infection owing to fastidious organisms, obstruction, and extraluminal infection, may reduce bacterial counts to lower levels.

The diagnosis of asymptomatic bacteriuria in women is made with 95% assurance if two consecutive urine cultures are positive for the same organism in counts equal to or greater than 10^5 CFU per milliliter.[2,3] In men, a single positive urine culture establishes the diagnosis of bacteriuria.[3] Urine cultures with more than one organism isolated may be difficult to interpret. Such "mixed cultures" usually reflect contamination or, when urinary devices are in place, biofilm colonization. A true multiple organism infection of the urinary tract is uncommon in patients with acute uncomplicated pyelonephritis, but frequent for some patients with complicated urinary infection, particularly in

patients with foreign bodies or renal stones. Occasionally, different organisms may be present in each kidney. Differential growth rates in the bladder or suppression of one organism by the other may result in a report of a single organism isolated in voided urine despite different infecting organisms in ureteral urine cultures, or even the bloodstream.

Pyuria

Demonstrating the presence of pyuria is the most readily available means of establishing the evidence of a host response, presumably differentiating colonization from infection. Renal infection is usually characterized by a higher urinary leukocyte count than bladder infection.[64,108] However, the sensitivity, specificity, and predictive value of pyuria as a diagnostic test for acute pyelonephritis have not been determined. Leukocytes disintegrate at alkaline pH, potentially leading to false-negative findings for pyuria in patients with infections with urease-producing organisms. In addition, neutropenic patients with symptomatic urinary infections may fail to demonstrate pyuria.

Pyuria is usually identified by the presence of leukocyte esterase on a dipstick screening of urine. The more traditional measurement of pyuria by counting the number of cells in centrifuged urine per high power field is imprecise, with many sources of error.[4] Leukocyte excretion rates are more reproducible, but are not applicable to routine patient care. Excretion rates do correlate well with absolute leukocyte counts of random, unspun urine counted in a hemocytometer; counts in excess of 10/mm^3 represent an abnormal host response.[4]

Other Urinalysis Characteristics

Leukocyte casts indicate intrarenal inflammation. They are present in about two-thirds of patients with invasive renal infection but are nonspecific, also being present in many interstitial and glomerular renal diseases. Microscopic hematuria is common in patients with renal infection but has no documented clinical significance. It usually resolves with adequate treatment. Red blood cell casts are unusual. Persistent hematuria after antimicrobial treatment may require a urologic investigation to exclude other causes. Quantitative proteinuria with a urinary protein excretion rate exceeding 100 mg per 24 hours is unusual in either acute or chronic renal infection unless a second renal disease associated with proteinuria is present.

Bacteremia

Between 15% and 30% of hospitalized patients with acute pyelonephritis have a positive blood culture at presentation and, presumably, are at greater risk of metastatic infection to other sites.[10,11,109] Elderly women, patients with diabetes, and individuals with obstruction are more likely to be bacteremic.[75,110]

The routine collection of blood cultures from all patients presenting to the emergency department with acute pyelonephritis is not clinically useful. McMurray et al.[111] reported that 56 (18%) of 307 patients hospitalized with acute pyelonephritis from 1990 to 1992 had positive blood cultures; 32% of positive blood cultures were coagulase negative staphylococci and were presumed to be contaminants. Only one blood culture grew a pathogenic organism that was not also isolated from urine culture, and clinical management was not altered for any patient by positive blood cultures. Velasco et al.[15] obtained routine blood cultures from outpatients presenting with a diagnosis of acute pyelonephritis at a Spanish hospital. Positive blood cultures were found in 147 (25%) of 583 patients, with only coagulase negative staphylococci isolated in 17 (12%) of these. E. coli grew from 91% of positive blood cultures, and 23% of women with E. coli pyelonephritis had positive blood cultures. The blood culture was consistent with the urine culture result in 98% of cases. Wing et al.[16] pooled data from three randomized controlled trials in pregnant women with acute pyelonephritis, from whom routine blood cultures were obtained at study entry. Among 391 women, 94 (24%) had positive blood cultures and 5 (5.3%) grew only S. epidermidis. Smith et al.,[112] however, retrospectively reviewed results from nonpregnant women admitted with acute pyelonephritis through the emergency department of an urban county teaching hospital where blood cultures were obtained selectively rather than routinely. Bacteremia occurred in 36% of 64 women, and was more frequent in black women, women with genitourinary abnormalities, with higher pulse rates on admission, higher levels of pyuria, and more prolonged fever. Blood cultures were positive in 2 patients with negative urine cultures. van Nieuwkoop and colleagues[113] reported that 23% of patients presenting to emergency departments in the Netherlands with both uncomplicated and complicated febrile UTIs had bacteremia; 95% had concordant blood and urine cultures. Factors independently associated with positive blood cultures but negative urine cultures included the presence of a urinary catheter, any malignancy, and already receiving antimicrobial treatment for urinary infection when the urine culture was obtained.

These studies suggest routine blood cultures obtained from clinically stable women presenting with mild or moderately severe symptoms of acute pyelonephritis are not useful and should not be requested. However, patients who are more severely ill, in whom the diagnosis is uncertain, or when an underlying abnormality is present or suspected, should have blood cultures obtained prior to the institution of antimicrobial therapy. This is particularly the case for pregnant women, where failure to initiate appropriate antimicrobial therapy may have adverse fetal outcomes.

C-reactive Protein and Procalcitonin

C-reactive protein and procalcitonin are elevated in children and adults with acute pyelonephritis.[114,115] These are, however, nonspecific markers for inflammation with limited diagnostic use for differentiating pyelonephritis from other febrile illnesses. Procalcitonin has been suggested to be useful

to identify upper tract involvement in children who present to the emergency department with urinary infections.[114] C-reactive protein and procalcitonin have also been evaluated as prognostic markers. Pratt et al.[115] showed that elevated procalcitonin (using a level of 1 ng per milliliter) correlated with the development of renal scars in children, and was more specific for predicting subsequent scarring than C-reactive protein or leukocyte counts. In adults, a higher C-reactive protein level at admission correlated with prolonged hospitalization, whereas an elevated C-reactive protein at discharge predicted recurrence.[116] Other studies in adults reported that the procalcitonin level at admission in patients with urosepsis predicted bacteremia and bacterial load,[117] but did not predict adverse outcomes at 28 days.[118] The clinical use of these or other inflammatory markers for either the diagnosis or prognosis of acute pyelonephritis remains uncertain, and routine testing is currently not recommended.

INFECTION LOCALIZATION

The clinical presentation of acute pyelonephritis is often straightforward, and a diagnosis of renal infection can be made on the basis of clinical signs and symptoms. However, patients with asymptomatic bacteriuria or only lower tract symptoms may also have a renal infection. Table 23.4 summarizes selected studies performed to localize infections in adults with variable symptom presentations.[58–62] In these studies, as many as one-half of women with asymptomatic infections and a substantial minority of women with only bladder symptoms have a renal infection. However, no epidemiologic studies and few therapeutic studies of bacteriuria and its complications have attempted to prospectively localize renal bacteriuria so the clinical implications, if any, of upper tract localization are not clear. Currently, the localization of the site of infection has a clinical use only for the infrequent patient with relapsing infection where localizing the site of infection may influence clinical management. A large number and variety of different approaches for infection localization have been described (Table 23.5), but most of these methods are now of only historical interest.

Cystoscopy with ureteral catheterization is a direct approach to localization and continues to be the only definitive method for confirming renal localization. It also permits the localization of infection to one kidney and can identify different infecting organisms in each collecting system.[119] In practice, however, this procedure has limited usefulness. Careful urologic manipulation with meticulous attention to avoid contamination is required. A cystoscopy and ureteral catheter insertion are performed in an infected urinary tract because antibacterial therapy is withheld until the urine collections are complete. Infected bladder urine must be removed by repeated washing with sterile irrigating fluid before ureteral catheters are introduced through the bladder.[58] Otherwise, positive ureteral urine cultures may result from the carriage of infected bladder urine into the ureters during catheterization.

23.5 Methods Proposed to Identify Urinary Infection Localized to the Kidney

- Ureteral catheterization with differential urine cultures
- Intravenous pyelography/CT scanning
- Nuclear medicine imaging: ^{67}Ga citrate scanning/^{99}Tcm-DMSA scanning
- Bladder washout
- Renal biopsy with culture
- Fluorescent examination of renal tissue for bacterial antigen
- Serum antibodies to lipopolysaccharide antigen
- Urinary enzymes, cytokines
- C-reactive protein
- Serum procalcitonin
- Tamm-Horsfall protein antibodies
- Maximal renal concentrating ability
- Antibody-coated bacteria (ACB)
- Relapse following short course antimicrobial therapy

CT, computed tomography; Tcm-DMSA, technetium-dimercaptosuccinic acid.

The histopathologic examination of renal tissue obtained by a biopsy or at necropsy is another direct approach to the diagnosis of a renal infection. However, a kidney biopsy is contraindicated in the presence of an acute infection. In addition, pyelonephritis is a focal disease, and a random biopsy may not provide either a pathologic or bacteriologic diagnosis.[120] Percutaneous renal biopsies are seldom used to diagnose chronic pyelonephritis, and bacteriologic studies of renal tissue are rarely helpful. The nonspecificity of the histologic findings and their focal nature further limit the diagnostic use of biopsies because concomitant diseases may distort the gross and histologic features and may therefore make it impossible to attribute changes specifically to bacterial inflammation.

Imaging of the kidneys with ^{67}Ga citrate has been proposed to identify a renal infection. Hurwitz and associates[61] compared imaging with ^{67}Ga citrate to cultures obtained by ureteral catheterization or bladder washout in 47 patients and found a false-positive rate of 15% and a false-negative rate of 13% for the imaging procedure. Radioisotopic localization, particularly with ^{99}Tcm-DMSA, may be a more sensitive procedure for diagnosing a renal infection and assessing renal scarring.[121–123] These tests are often positive in patients with invasive upper tract infections, but are less reliable in those with asymptomatic infection.

The measurement of C-reactive protein has been used as a test to localize renal infections in symptomatic children,[124] but the specific level to differentiate upper from lower tract infections has varied among different studies and is not standardized.[125,126] Serum procalcitonin has also been studied to

diagnose pyelonephritis and UTIs in febrile infants and children. When compared to a DMSA scan, procalcitonin levels >0.5 to 0.6 pg per milliliter[127] had an average sensitivity of 85% and specificity of 76%. Urinary IL-6 is increased in children with acute pyelonephritis, with >15 pg per milliliter reported to have a specificity of 94% and a positive predictive value of 87.5%[128] for upper tract infections. None of these parameters, however, have yet been shown to be of use for routine clinical application.

Measurements of urinary enzymes, including urinary dehydrogenase, leucine aminopeptidase, α-glucuronidase, catalase, lactic dehydrogenase, lysozyme, and urinary α1 microglobulin, have all been reported to be useful for localization in at least one study, but not confirmed in subsequent studies to have adequate sensitivity or specificity to be a reliable diagnostic test. Other localizing methods used in previous studies have included the Fairley bladder washout technique,[60] a measurement of serum or urine antibodies to the infecting bacteria, and the fluorescent antibody-coated bacteria test.[129] None of these has proved to be of sufficient ease of use or reliability for clinical applications. Maximal urinary concentrating ability is reduced in many patients with renal bacteriuria. Fluid deprivation for 24 hours with the administration of antidiuretic hormone achieves maximum urinary concentration of more than 800 mOsm per kilogram of water in more than 80% of patients with bladder bacteriuria, but at least 70% of patients with renal infections are unable to concentrate urine to this level following maximal stimulation.[130] Urinary concentration, however, is altered in a number of pathologic states, and the test is not sufficiently sensitive or specific to be of value for an individual patient.

In practice, clinical presentations are used to assess the site of infection. Smeets and Gower[131] screened 43 symptomatic women with the bladder washout technique. Among these women, only fever higher than 38°C correlated with renal involvement. Two-thirds of the patients with upper tract infections were febrile at the time of localization compared to one-third of patients with lower tract infections. These studies and others suggest that no clinical criteria are uniformly reliable to localize the site of the infection.[132]

A short course of effective antimicrobial therapy will cure most uncomplicated bladder infections in women. It has been proposed that differential outcomes with short-course therapy may localize the site of the infection. Comparisons of single-dose therapy outcomes with other localization methods have documented an association between renal infections and failures of single-dose therapy.[133–135] However, single-dose therapy will fail in 10% to 20% of individuals with lower tract infections, and a small proportion of individuals with covert upper tract infections will be cured by short course therapy. For women with a normal genitourinary tract and repeated relapses following nitrofurantoin therapy, however, a renal localization of infections may be presumed because this agent is effective for sterilizing bladder urine, but it will not eradicate renal infection.

DIAGNOSTIC IMAGING

Acute Pyelonephritis

A plain abdominal film of the kidneys provides limited information in patients with presumed acute pyelonephritis. Renal calculi may be visualized, one or both kidneys may be enlarged, or gross changes such as hydronephrosis or renal atrophy may be apparent from the renal outline. Occasionally, perinephric gas or other changes in the retroperitoneal space provide diagnostic clues.[136] Other findings recognized on abdominal films may lead to diagnoses other than acute pyelonephritis, such as a perforated viscus.

Renal ultrasonography and computerized tomographic (CT) scanning have largely replaced IVP for the initial screening for genitourinary obstruction in patients with acute pyelonephritis.[137,138] In addition to identifying anatomic abnormalities and focal complications such as intrarenal or perinephric abscess, ultrasonography usually shows swollen kidneys, although this may only be appreciated by repeat scanning following antimicrobial therapy. The degree of renal enlargement on ultrasonography has been correlated with prolonged pretherapy symptoms, higher leukocyte counts, and prolonged hospitalizations.[137] However, ultrasonography is less sensitive or specific than CT or magnetic resonance imaging (MRI).[138]

An unenhanced CT scan is usually sufficient and will detect most calculi, gas forming infections, hemorrhage, parenchymal calcifications, obstruction, and inflammatory masses. A contrast-enhanced CT scan may be indicated in acute pyelonephritis if the differential diagnosis includes other intra-abdominal or retroperitoneal pathology, or if there is a delayed response to therapy and the ultrasound is normal or equivocal. With an unenhanced CT scan, global swelling of the infected kidney is present.[138] With contrast-enhanced CT scans, either an enlarged kidney with a uniformly homogeneous nephrogram, a striated parenchymal nephrogram, or wedge-shaped segmental defects are seen.[138] The striated pattern is caused by the localization of inflammatory cells and fluid within the collecting ducts. The wedge-shaped low-attenuation areas include renal parenchyma with impaired function caused by vascular spasm, tubular obstruction, or interstitial edema. Renal enlargement, delayed visualization, and a poor definition of calyceal architecture in the involved kidney are also common findings. Renal parenchymal volume increases by 25% to 50% during an episode of acute pyelonephritis and can take 4 to 6 weeks to regress.[139] For atrophic or chronic pyelonephritis, the involved kidney is irregular in outline and below average size unless hypertrophy has occurred owing to compensatory enlargement. A contrast-enhanced study is necessary to fully define changes in renal excretion that occur as a result of inflammation. A helical (or spiral) CT

scan can provide information addressing specific phases of contrast media excretion.[140,141]

An MRI is also used for the imaging of acute pyelonephritis.[141] Features are consistent with those observed with CT scans, including renal enlargement, perinephric stranding, focal decreased enhancement, and abscess cavities. Typically, an infected area has a low signal intensity on T1-weighted images and increased signal intensity on T2-weighted images with a loss of normal corticomedullary differentiation. The use of gadolinium is essential to correctly identify areas of renal involvement. An MRI may also differentiate acute infections from chronic scars. An MRI may be preferred for some patients because it does not require radiation or iodinated contrast material. A limitation of MRI, however, is poor discrimination for the interpretation of gas-forming collections or calculi.

In children, ^{99}Tcm-DMSA scintigraphy is more sensitive then ultrasound for detecting acute pyelonephritis, cortical lesions, and renal scarring.[140,143] Sattari et al.,[144] however, found contrast-enhanced CT scanning more accurate for identifying acute pyelonephritis than DMSA scintigraphy in adult populations. Small lesions and those localized to the inner layer of the renal cortex were present on the CT scan but were not appreciated with the lower resolution of scintigraphic images. Scintigraphy has also been evaluated in children as a predictor of outcomes at a longer term follow-up. Wallin et al.[145] reported that scintigraphy defects present at the time of an acute infection persist at 6 months in 34% of kidneys, and Agras et al.[146] reported that 38.2% of initial cortical lesions persisted at 6 months, and 17.6% at 12 months. Hitzel et al.[147] evaluated the quantitative analysis of DMSA scintigraphy to predict long-term renal scarring following acute pyelonephritis in children and reported the intensity of abnormality with DMSA scintigraphy at the time that an acute presentation was predictive of subsequent scarring.

The term nephronia refers to a renal mass confined to a single lobe, representing localized inflammation but without suppuration. It is thought to be an intermediate phase in the progression from inflammation to abscess.[148] Gallium scanning demonstrates an increased uptake in the area of the mass, which is usually accompanied by generalized increased activity elsewhere in the same or opposite kidney. Ultrasonography shows a sonolucent ovoid mass that disrupts the normal corticomedullary definition and produces low-level echoes. These findings permit differentiation of nephronia from renal abscess or tumor. In adults, this finding may occur more commonly in diabetics. In children, the presence of acute lobar nephronia was reported to be associated with an increased incidence of renal scarring.[149] Identification of this abnormality on imaging studies, however, does not alter therapeutic approaches.[138]

Radiologic changes induced by acute inflammation are usually reversible with antimicrobial treatment.[61,137,149,150] However, a progressive reduction in renal size or the development of a scar may follow an episode of acute pyelonephritis.[149,150] Scars may involve an entire pole of the kidney or, in patients with atrophic pyelonephritis, the entire kidney. The upper pole is the most common site for scars. In serial studies, the initial abnormality was the loss of the renal cortex, with the renal parenchyma becoming thinned. Calyceal clubbing then developed as the renal papilla is retracted into the scar. The cup of the calyx is no longer a "cup," because the papilla does not project into it. In adults with acute pyelonephritis on a CT scan or an MRI at presentation, a focal lesion with peripheral ring enhancement and without central contrast uptake correlated with subsequent scar development.[150] In men and women with acute nonobstructive pyelonephritis and hypodense images on a CT scan at presentation, abnormalities persisted at the follow-up CT scan in 10 of 44 people.[151] In another study, persistent abnormalities were reported at follow-up in 29% of 55 adult women hospitalized with acute pyelonephritis.[150] Early scar formation was present in two patients, whereas two patients with atrophy had renal biopsies that showed chronic interstitial nephritis.

Indications for Radiologic Investigation

Imaging studies of the genitourinary tract for patients presenting with acute pyelonephritis should be selective.[140] Indications for imaging in individuals with suspected acute pyelonephritis include: (1) to assist with the diagnosis of acute pyelonephritis; (2) to assess whether there are underlying abnormalities present that may require intervention; (3) to assess the severity of infection, including identifying abscesses or emphysematous infections; or (4) in follow-up, to determine the extent of persistent damage such as renal scarring. Patients with atypical presentations, with severe sepsis or septic shock in whom obstruction must be excluded, or with a delayed response to therapy should have prompt imaging studies. Radiologic investigations should also be considered in patients who relapse shortly after discontinuing an adequate course of antimicrobial therapy.

Among 170 patients (163 women, 7 men) with acute pyelonephritis for whom an intravenous pyelogram was routinely obtained, 85 had normal pyelograms and 75 had structural or functional abnormalities that were attributable to the acute infection or represented a risk for relapse, but only 10 (5.9%) had specific disorders identified that resulted in a change of management.[152] In an Australian report, only 1 of 74 patients with acute pyelonephritis who had imaging with an ultrasound or a CT scan at admission had an abnormality identified that required an immediate intervention.[153] van Nieuwkoop et al.[154] prospectively identified patients presenting with febrile urinary infection to eight emergency departments in the Netherlands. There were 346 episodes, 140 (41%) in men, and 138 of these episodes (40%) were considered complicated. For all cases, 245 had an ultrasound or a CT scan; 6% of these showed urologic disorders requiring urgent intervention (pyonephrosis), 32 (13%) had nonurgent urologic disorders (nonobstructive renal stones, urologic malignancy, ureteropelvic junction stenosis, enterovesicle fistula), 175 (71%) had clinically irrelevant or normal results, and 24 (10%) had incidental nonurologic

disorders. They reported that a history of urolithiasis, urine pH ≥7.0, and renal insufficiency were the only variables predicting an abnormality on imaging.

Although contrast-enhanced CT scanning is the preferred imaging test for upper tract infection in adults, renal ultrasonography is rapid and noninvasive and may be more accessible. The intravascular injection of radiologic contrast media has risks of hypersensitivity or contrast media–induced renal failure. The concomitant presence of diabetes mellitus, particularly with renal impairment, is a relative contraindication. In children, the initial screening with ultrasonography or DMSA scintigraphy detects scarring and other renal abnormalities.[121,123] Investigations should be performed in any male infant or boy with a proven bacterial urinary infection, and in girls with a recurrent or complicated infection.[155] A voiding cystourethrogram is added for young children or if there is evidence of upper tract disease.

Unless specific new indications emerge in a given patient, serial periodic imaging studies are redundant in adults with recurring infection. Even among patients with a prior radiologic evidence of chronic pyelonephritis, the development of new findings is unusual.[88] Upper tract pathology rarely develops after the age of 1 year in adequately treated children, and repeated examinations are seldom indicated.[156]

CLINICAL PRESENTATION

Infants and Children

In the neonatal period, UTIs usually present as sepsis. The clinical picture, however, can vary from life-threatening septic shock in association with pyelonephritis to asymptomatic bacteriuria.[21] Nonspecific symptoms potentially associated with urinary infections in infants include fever; inadequate weight gain; gastrointestinal symptoms such as anorexia, emesis, diarrhea, and paralytic ileus; meningitis; seizures; lethargy; irritability; hypotonicity; respiratory irregularity; pallor; cyanosis; abdominal distention; gray skin color; and jaundice. Studies have identified jaundice as the hallmark of ongoing infection in the neonate. The frequent occurrence of generalized sepsis, premonitory symptoms prior to the onset of bacteriuria, and necropsy findings demonstrating cortical infection in the presence of a normal renal pelvis support a hematogenous route of renal infection in neonates. The predominance of males is unexplained. The intestinal tract is the presumptive source.

In older children, the clinical features of urinary infection more closely approximate those in adults.[21] As girls mature, abdominal tenderness, vaginal discharge, vomiting, and anorexia become less common features and fever and flank pain predominate. Asymptomatic UTIs in childhood occur almost exclusively in females.

Adults

The classic clinical presentation of acute upper UTIs in adults include fever, often over 38.5°C, chills, unilateral or bilateral pain in the lumbar flank region, and variable systemic symptoms, including malaise, anorexia, nausea, emesis, diarrhea, myalgia, and headache. The illness may progress rapidly, and many patients seek care within 24 hours of the onset of symptoms. Between 15% and 30% of patients experience concomitant symptoms consistent with a lower UTI, including dysuria, frequency, urgency, and suprapubic discomfort. Renal pain may radiate to the epigastrium or the lower abdominal quadrants. Severe flank pain with radiation to the groin is unusual and suggests a ureteral obstruction. Gastrointestinal symptoms, primarily nausea, vomiting, and diarrhea, occur frequently and predominate in about 10% of patients. Although patients presenting with acute pyelonephritis may be severely ill, the spectrum of disease also includes individuals with low-grade or no fever or only mild flank discomfort. Flank pain or discomfort on palpation or fist percussion is usually present. The physical findings are variable, however, ranging from mild discomfort to severe pain or systemic symptoms including septic shock.

Other diseases, both above and below the diaphragm, can mimic the pain of acute pyelonephritis. The differential diagnosis includes acute bacterial pneumonia, appendicitis, cholecystitis, a perforated viscus, diverticulitis, splenic infarction, acute pancreatitis, and aortic dissection. Acute pelvic inflammatory disease may be misdiagnosed as acute pyelonephritis and should be excluded by a pelvic examination in women at risk of sexually transmitted infections. Varicella-zoster virus reactivation (shingles) in an appropriate dermatome can also mimic renal pain. Renal infarction, acute renal vein thrombosis, obstructive uropathy, and acute glomerulonephritis may each have a clinical presentation that can be confused with acute pyelonephritis.

Pinson and colleagues[105] assessed the use of fever in differentiating acute pyelonephritis from other potential diagnoses. In a retrospective chart review, 93% of women who presented to the emergency department with pyuria and other findings consistent with acute pyelonephritis including leukocytosis, costovertebral angle tenderness, and two or more of abdominal pain or tenderness, back pain, and history of nausea and vomiting, were ultimately diagnosed with acute pyelonephritis when fever was also present. When fever was not present, 35% of hospitalized women with this constellation of symptoms ultimately had an alternate diagnosis. All nonhospitalized patients with fever were ultimately diagnosed with pyelonephritis, but 13% without fever had an alternate diagnosis. They concluded that when patients present with findings compatible with acute pyelonephritis but without fever there should be a high index of suspicion for an alternate diagnosis.

The presenting clinical features of pregnant women are similar to those in nonpregnant women. Septic shock may occur, and acute respiratory distress syndrome is reported in 1% to 8% of these women.[92] Patients with diabetes mellitus may present with deteriorating glycemic control. Renal infections in patients with diabetes mellitus and hyperglycemia may, rarely, present as emphysematous pyelonephritis

owing to carbon dioxide production from fermentation of glucose by gram-negative rods.[136,157] Acute pyelonephritis in patients with diabetes may also be accompanied by papillary necrosis. Fragments of the renal papillae can block the ureter, producing colic and hydronephrosis, often accompanied by gross hematuria. In elderly patients, symptoms of a urinary infection may be more difficult to ascertain and chronic symptoms of dysuria, frequency, urgency, and incontinence often occur unrelated to infection. Flank tenderness is less common in elderly patients, and acute confusion, sometimes with other neurologic symptoms or signs, is more common relative to younger age groups. Despite this, classic features of upper tract infections do occur in most elderly patients with acute pyelonephritis.

The clinical manifestations of chronic pyelonephritis are usually nonspecific. Some patients have recurrent acute symptomatic exacerbations of renal infection. Others have no clear-cut symptoms of infection despite persistent bacteriuria. Sometimes, patients may complain of vague flank discomfort, abdominal pain, or intermittent low-grade pyrexia. The improvement of symptoms after a trial of antimicrobial therapy may clarify an association between mild symptoms and a persistent renal infection.

TREATMENT OF UPPER TRACT INFECTIONS

Therapeutic Principles

The following should be considered whenever an upper urinary infection is diagnosed and treated:

1. A laboratory confirmation of infection is essential. The clinical findings of an invasive upper tract infection can be mimicked by many illnesses and, for patients with pyelonephritis, the antimicrobial susceptibility of infecting organisms must be determined to facilitate optimal therapy.
2. Bacteriuria by itself is a nonspecific finding. Patients with asymptomatic bacteriuria, particularly elderly patients and patients with indwelling catheters, frequently have bacteriuria but without renal infection being present or as a cause for acute clinical deterioration.[3]
3. The initial antimicrobial selection is based on known or presumed organism susceptibility and patient tolerance. The clinical evidence base to support any specific regimen is limited. Many clinical studies enroll patients presenting with both acute nonobstructive pyelonephritis and complicated urinary infection, and the relevance of reported outcomes to acute pyelonephritis alone is difficult to assess.
4. An antimicrobial that provides adequate blood and tissue levels as well as a high urinary level is preferred for the treatment of invasive renal infection. Agents that provide high sustained medullary antimicrobial levels are more effective for upper tract infections.[158]
5. Suppurative and obstructive complications frequently complicate acute pyelonephritis, occurring in 5% to 15% of cases. Patients who present with life-threatening infection, who do not respond within 72 hours of antimicrobial therapy, who deteriorate after therapy is started, or who rapidly recur after therapy is discontinued must be investigated urgently to exclude an obstruction or abscesses that require surgical intervention.
6. If the urine culture subsequently reports growth of an organism resistant to the empiric antimicrobial therapy, the antimicrobial should be changed to a susceptible agent even if there has been a clinical response. Despite apparent improvement, these patients will usually rapidly relapse following the discontinuation of antimicrobial therapy.[13,159]
7. Clinical improvement may not equate with the permanent eradication of bacteriuria. A urinary infection is usually a recurrent disease and patients should be aware of this possibility. However, follow-up urine cultures are not necessary to document a bacteriologic cure unless symptoms recur or if the patient is pregnant.

Acute Pyelonephritis

A suspected clinical diagnosis of acute pyelonephritis requires an urgent assessment and the prompt institution of therapy. Appropriate diagnostic tests, including a urine culture prior to antimicrobial therapy, complete blood count (CBC) and creatinine for all cases, and blood cultures for subjects with more severe presentations, should be obtained. In addition to the prompt institution of empiric antimicrobial therapy and appropriate supportive measures, initial therapeutic decisions include whether hospitalization is required and whether early diagnostic imaging studies are indicated to exclude an obstruction or other complicating factors (Fig. 23.1).

Hospitalization

Only 10% to 30% of nonpregnant women with acute uncomplicated pyelonephritis will require hospitalization[160]; a higher proportion of individuals with a complicated urinary infection presenting as pyelonephritis require hospitalization. Patients with severe clinical presentations, including severe costovertebral angle pain, rigors, high fever (>38.5°C), severe nausea or vomiting, and hemodynamic instability should be hospitalized for the initial investigation and parenteral antibacterial treatment. Intravenous fluids, analgesics and antiemetics, and bed rest are usually prescribed during the initial 24 to 48 hours. Hypotension and diminished urine output should be identified early and managed appropriately. Patients with severe sepsis or septic shock should be cared for in a critical care unit. Women who are pregnant or for whom there is diagnostic uncertainty require a more careful follow-up, and hospital admission is recommended in these cases. Where it is unclear whether hospitalization is necessary, an initial dose of parenteral therapy with observation for 12 to 24 hours is an alternate approach. If the

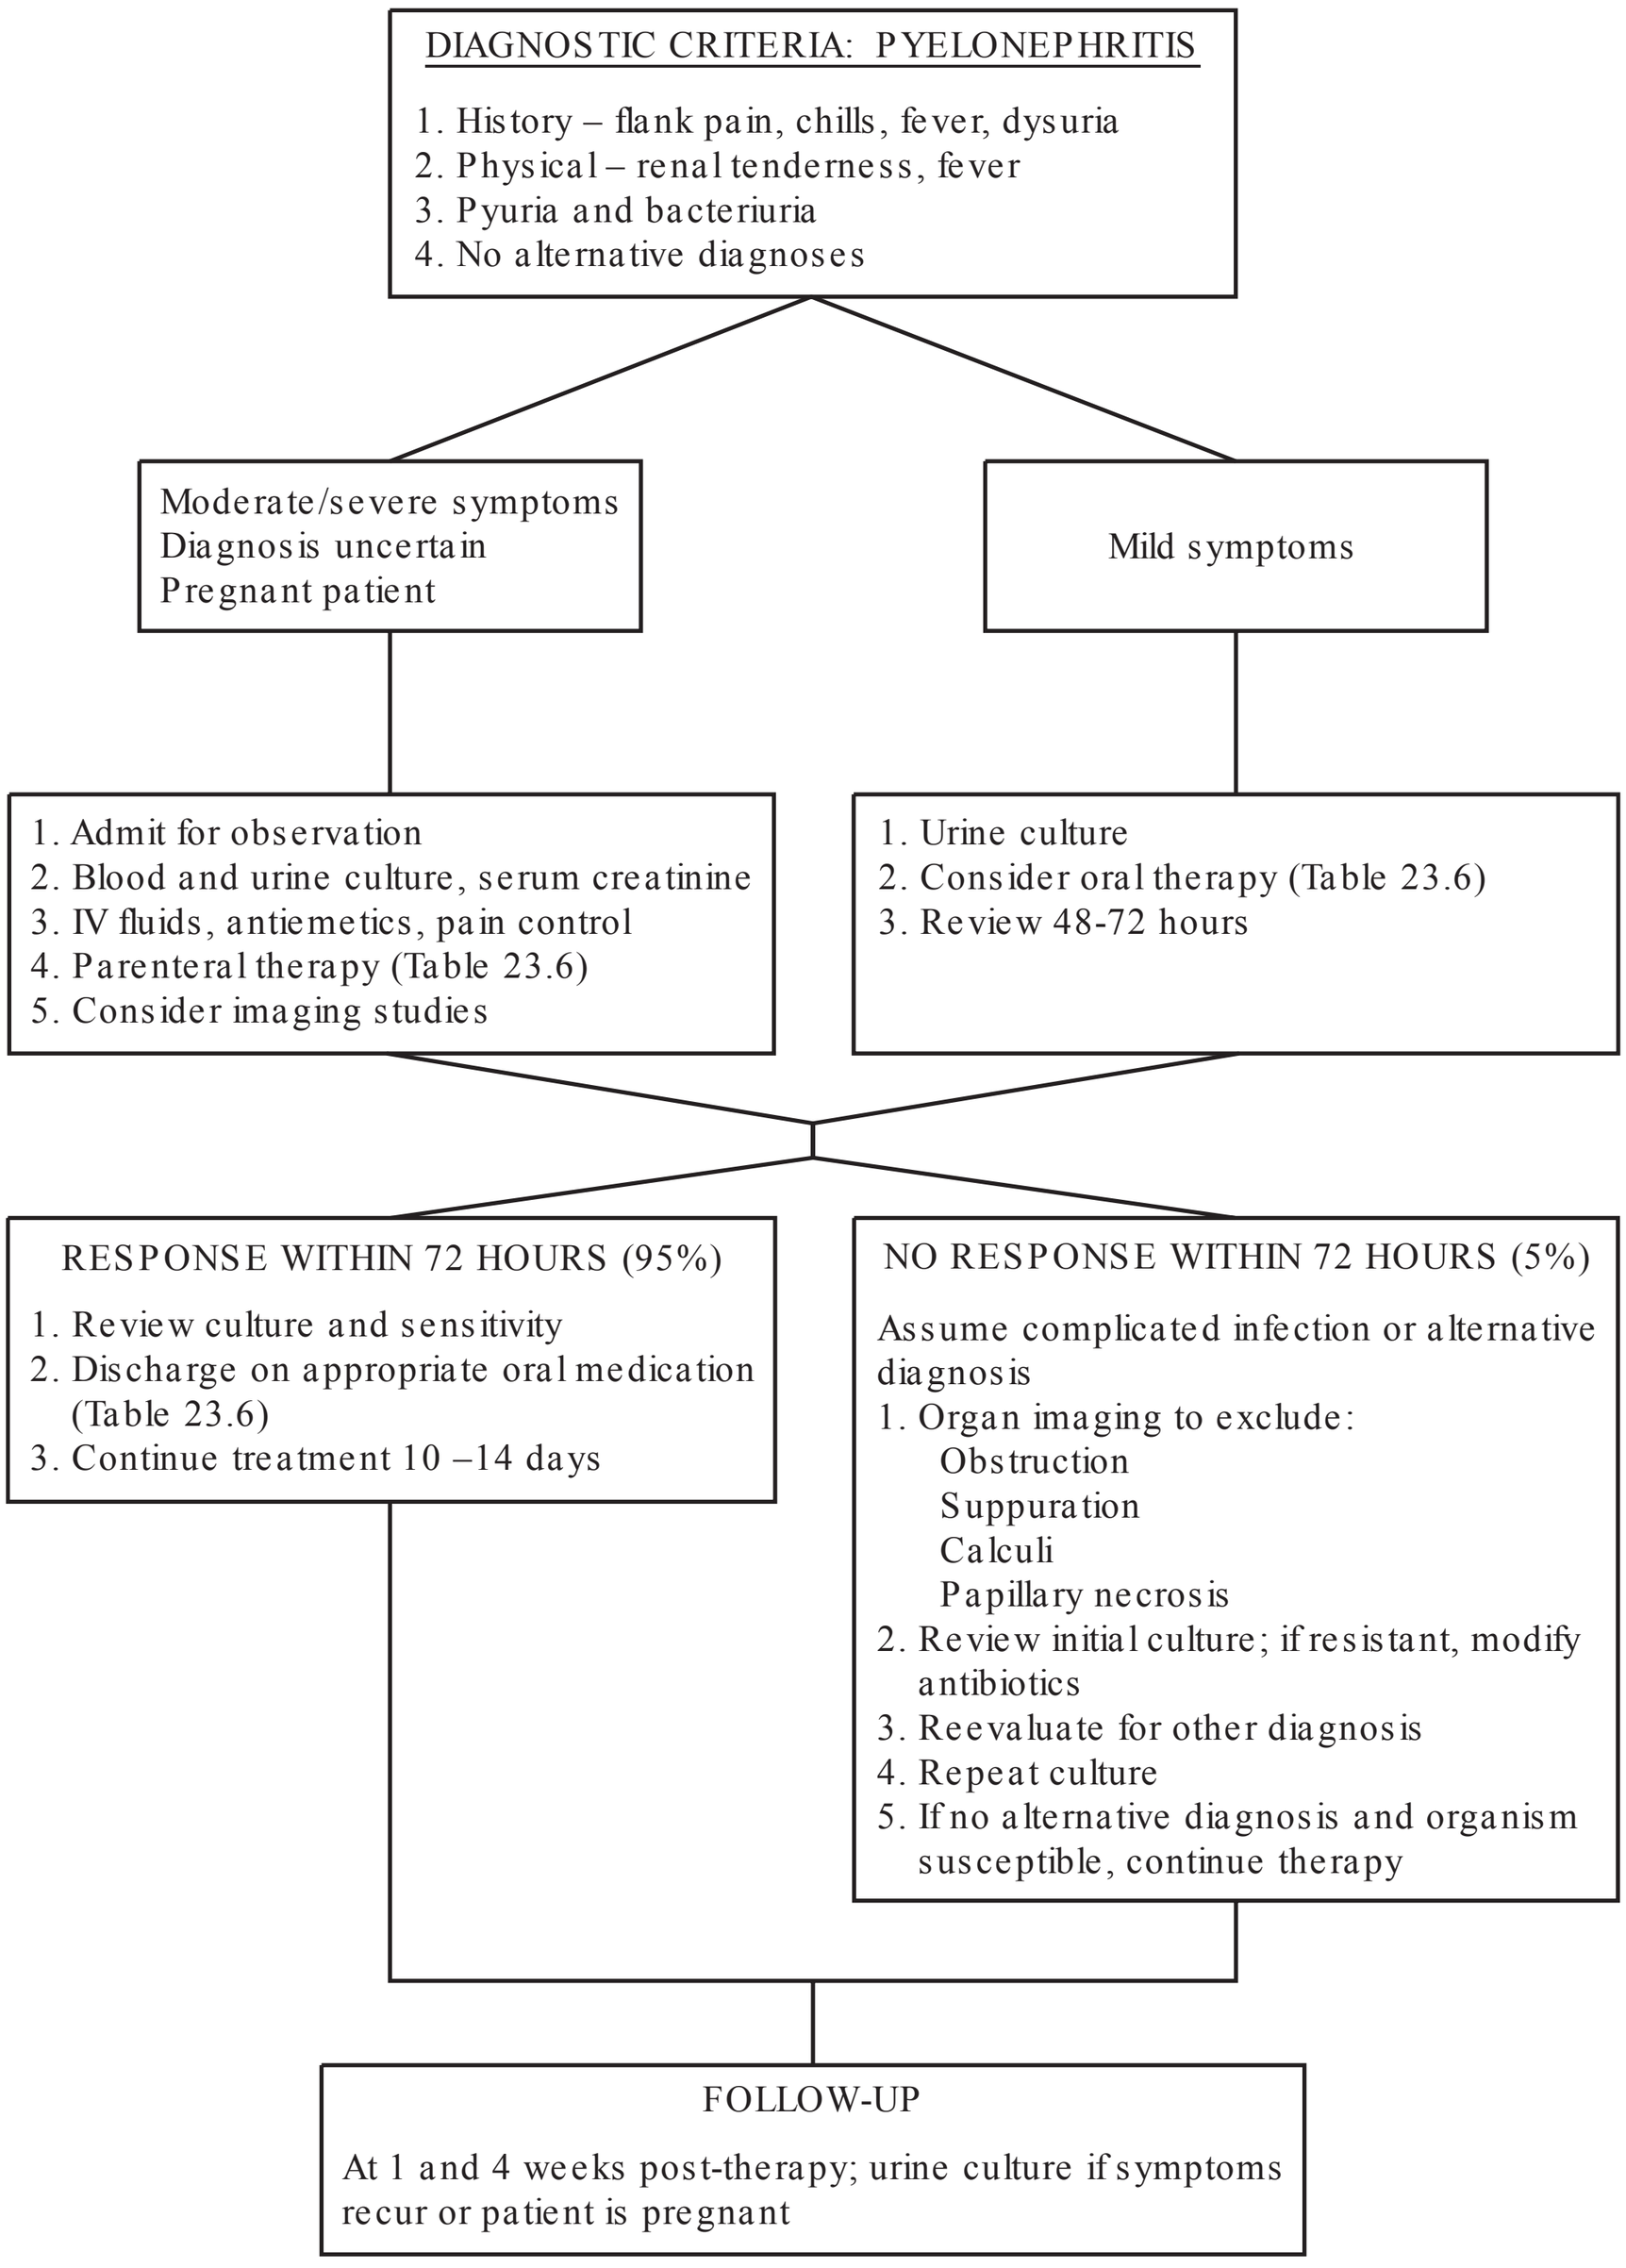

FIGURE 23.1 The management of pyelonephritis.

patient is stable without nausea or vomiting after the initial parenteral therapy and management of systemic symptoms, a discharge home to complete oral therapy is appropriate.

Patients with acute pyelonephritis may be only mildly or moderately symptomatic with low-grade fever, mild flank pain, and few constitutional symptoms. These patients may be managed as outpatients with an oral antimicrobial regimen (Fig. 23.1).[160,161] Specific criteria to identify patients for whom outpatient therapy is appropriate include those who are hemodynamically stable, those who are able to tolerate oral medications, those who are anticipated to be compliant, and those with absent or low-grade fever (38°C or less).

Several studies report similar outcomes for parenteral and oral therapy, with unsatisfactory outcomes in 10% of either group.[10,160,161] Pinson and associates[11] reviewed management and outcomes of 111 febrile women presenting to an emergency room with acute pyelonephritis. Eighty three (75%) were not hospitalized. Women hospitalized for management were older, more frequently had diabetes or known genitourinary abnormalities, and were more ill, as evidenced by vomiting and a higher temperature. Management of nonhospitalized patients usually included a single parenteral antimicrobial dose followed by oral therapy.[11] Nine (12%) of 75 outpatients returned in the follow-up with continuing symptoms of acute pyelonephritis, usually within 24 hours, and 7 of these subsequently required admission but were ultimately cured. The authors concluded that most febrile women with acute pyelonephritis could be treated as outpatients, but an early follow-up after initiation of therapy was recommended. Elkharrat et al.[161] used an algorithmic approach for women presenting to the outpatient department with acute pyelonephritis. All patients received a single intravenous dose of a fluoroquinolone after cultures were obtained, and had an ultrasound examination of the abdomen and pelvis. Patients with normal ultrasonography could be discharged. Of 68 patients, 10 were discharged directly from the emergency ward, 48 after a 12 to 24 hour stay in the observation unit, and 10 were hospitalized. Favorable outcomes occurred in all but one woman.

Parenteral Antimicrobial Therapy

Initial empiric parenteral therapy is indicated for patients with severe symptoms or who cannot tolerate oral therapy. The goal is to step down to oral therapy as soon as the patient is clinically stable and urine culture results are available, usually 48 to 72 hours after the initiation of therapy. A full course of parenteral therapy is necessary only for patients who continue to be unable to tolerate oral therapy or who are infected with a resistant organism for which no oral therapy is available.[162] The Infectious Diseases Society of America (IDSA) guidelines provide evidence-based recommendations for empiric antimicrobial therapy.[163] An aminoglycoside with or without ampicillin, parenteral fluoroquinolone, or extended spectrum cephalosporin or penicillin are recommended as first-line parenteral antimicrobial options. Any empiric regimen for initial treatment of patients with acute pyelonephritis should include in its antibacterial spectrum at least 95% of the potential organisms in the population treated. The selection of a "standard" antimicrobial regimen for empiric therapy requires knowledge of antimicrobial susceptibilities in the community or the individual facility.

A standard approach for initial therapy, pending culture and susceptibility results, is an aminoglycoside, such as gentamicin or tobramycin, in a dose of 3 to 5 mg per kilogram every 24 hours, combined with ampicillin 1 g every 4 hours (Table 23.6). The ampicillin therapy provides coverage for E. faecalis, an uncommon pathogen in younger populations. For the penicillin-allergic patient, an aminoglycoside alone may be adequate empiric parenteral therapy. Aminoglycoside-related nephrotoxicity and ototoxicity are unusual if high sustained trough levels are avoided and the duration of therapy is 4 days or less. Aminoglycoside levels should be monitored if the patient has

23.6 Selected Therapeutic Regimens Appropriate for the Treatment of Pyelonephritis in Patients with Normal Renal Function

Parenteral Therapy
Recommended
Ampicillin,[a] 1 g q4–6h plus aminoglycoside (gentamicin, tobramycin, or netilmicin at 3–5 mg/kg q24h, or amikacin 15 mg/kg q24h)
Ceftriaxone, 1–2 g q24h
Ciprofloxacin, 400 mg q12h
Levofloxacin, 500–750 mg OD
Alternatives
Cefotaxime, 1 g q8h
Ceftazidime, 1 g q8–12h
Ceftizoxime, 1 g q8–12h
Aztreonam, 1 g q8h
Piperacillin-tazobactam, 3.375 g q8h
Ticarcillin-clavulanate, 3 g/100 mg q4h
Ampicillin-sulbactam, 2 g/0.5–1.0 g q6h
Piperacillin, 2 g q6h plus aminoglycoside
Ofloxacin, 200–400 mg q12h
Meropenem, 500 mg–1g q8h
Ertapenem, 1g OD
Oral Therapy
Recommended
Norfloxacin, 400 mg b.i.d.
Ciprofloxacin, 500 mg b.i.d.
Levofloxacin, 500 mg or 750 mg OD
Alternatives
Amoxicillin, 500 mg t.i.d.[a]
Amoxicillin-clavulanate, 500 t.i.d. or 875 mg b.i.d.
Cefuroxime axetil, 500 mg b.i.d.
Cefixime, 500 mg OD
Cephalexin,[b] 500 mg q.i.d.
Ofloxacin, 400 mg b.i.d.
Trimethoprim-sulfamethoxazole,[b] 160/800 mg b.i.d.
Trimethoprim,[b] 100 mg b.i.d.

[a] For Enterococcus spp. or Streptococcus spp.
[b] If the organism is known to be susceptible.
q, every; h, hour; b.i.d., twice a day; t.i.d., three times a day; OD, once daily; q.i.d., four times a day.

renal impairment or will be continued on therapy longer than 5 days. Trough levels should not exceed 2 μg per milliliter for gentamicin and tobramycin or 5 μg per milliliter for amikacin. If a high prevalence of resistance to gentamicin or tobramycin is present, amikacin may be the aminoglycoside of choice for empiric treatment, especially for nosocomial pyelonephritis where more resistant isolates may be anticipated.

Parenteral fluoroquinolones such as ciprofloxacin, ofloxacin, and levofloxacin are also useful agents for the treatment of acute pyelonephritis.[163] The extended spectrum cephalosporins, including ceftriaxone, cefotaxime, ceftizoxime, and ceftazidime, have each been studied as single-agent alternatives to the combination of ampicillin and an aminoglycoside, with cure rates for acute pyelonephritis of about 90% in patients with normal renal function and a normal urinary tract.[163–165] The addition of an aminoglycoside to extended spectrum therapy with cefotaxime did not improve outcomes in women with acute pyelonephritis.[166] Cefazolin should not be used alone for the empiric treatment of invasive renal infection owing to the relatively high prevalence of resistance to first-line cephalosporins among community-acquired and nosocomial pathogens.[163]

Extended spectrum penicillin derivatives have been prospectively compared to the aminoglycoside with ampicillin regimen (Table 23.4).[163–165] In clinical studies reported to date, all regimens appear equivalent. Piperacillin is preferred over the third-generation cephalosporins if Pseudomonas aeruginosa and Enterococcus faecalis are probable etiologic agents. Piperacillin should generally be used in combination with an aminoglycoside but piperacillin/tazobactam may be used alone. Aztreonam is a monobactam β-lactam antibiotic, with an antibacterial spectrum limited to aerobic gram-negative rods, including P. aeruginosa.[167] It has been used successfully to treat patients with acute pyelonephritis. The β-lactam inhibitors in combination with a β-lactam antibiotic are also effective and equivalent to other regimens, and may be drugs of choice for hospital-acquired infections where resistant organisms are a concern. Piperacillin-tazobactam, ampicillin-clavulanic acid, and ticarcillin-clavulanic acid are all effective regimens. The prevalence of infections with an extended spectrum β-lactamase producing E. coli is increasing globally. These strains, if suspected, require empiric treatment with a carbapenem: meropenem, ertapenem, or dorapenem.[168,169] Vancomycin may be required to treat enterococci or staphylococci resistant to the β-lactam antibiotics. Newer parenteral antimicrobial agents are more expensive than the standard therapy of ampicillin plus aminoglycoside and, for susceptible organisms, have not been shown to have improved outcomes. Potential therapeutic advantages must be weighed against the increased expense.

Oral Antimicrobial Therapy

The IDSA guidelines recommend a fluoroquinolone for the initial oral empiric treatment of pyelonephritis.[163] Ciprofloxacin, norfloxacin, ofloxacin, and levofloxacin are all efficacious for the treatment of acute pyelonephritis; fluoroquinolones with limited renal excretion, such as moxifloxacin, should be avoided. Clinical trials document the effectiveness of ciprofloxacin 500 mg twice daily or 1,000 mg extended release daily[13] or levofloxacin 500 to 750 mg daily for acute, uncomplicated pyelonephritis.[170]

A randomized clinical trial compared oral trimethoprim/sulfamethoxazole (TMP/SMX) for 14 days or oral ciprofloxacin for 7 days in 378 women with acute pyelonephritis.[13] For either regimen, an initial parenteral dose of ceftriaxone or ciprofloxacin, respectively, could be given. Therapy was not modified once antimicrobial susceptibilities were obtained (i.e., therapy with TMP/SMX was continued even if the infecting isolate was found to be resistant). The regimens were equally effective when the infecting organism was susceptible to the antimicrobial given. However, TMP/SMX therapy was not effective when given by itself to patients with TMP/SMX-resistant organisms so a higher rate of resistance of E. coli to trimethoprim/sulfamethoxazole resulted in the ciprofloxacin arm being superior overall, with a 96% cure rate at 4 to 11 days and 85% at 22 to 44 days posttherapy. Thus, TMP/SMX is effective therapy but, given the relatively high prevalence of resistance of community-acquired E. coli, this agent is recommended only when the infecting organism is known to be susceptible.

Stamm and colleagues[14] compared 2- and 6-week oral regimens of TMP/SMX or ampicillin for the outpatient management of women with pyelonephritis. They found TMP/SMX to be superior to ampicillin for both treatment durations; the 6-week regimen did not improve cure rates. For TMP/SMX, 83% to 90% of women remained cured at 6 weeks following the discontinuation of antibiotics. Amoxicillin by itself should not be used for nonenterococcal or nonstreptococcal infection because of high community rates of resistance to gram-negative organisms and a tendency to promote colonization with resistant organisms that may cause subsequent infections.[163] However, amoxicillin in combination with the β-lactamase inhibitor clavulanic acid can be prescribed as an oral regimen for selected resistant organisms.

Cronberg et al.[171] enrolled 171 patients, about 60% of whom were women with acute pyelonephritis, into a comparative study of initial cefuroxime for 2 to 3 days followed by ceftibuten 200 mg twice a day (b.i.d.) or norfloxacin 400 mg b.i.d. to complete 10 days once the fever had subsided and the culture results were available. The norfloxacin treatment arm was superior for the eradication of bacteriuria. Sanchez et al.[172] enrolled 105 women into a study comparing ceftriaxone 1 g daily for 10 days or a single initial dose of ceftriaxone followed by oral cefixime for 9 days. The cure rate was 91% for both groups.

Pregnant Women

It is recommended that pregnant women with acute pyelonephritis should be admitted to the hospital, at least for the first several days, to ensure an adequate response to antimicrobial therapy and pending culture results confirming the

infecting organism and susceptibilities.[92] Parenteral outpatient therapy with close monitoring is an option for selected patients in the first and early second trimester.[92] Recommended empiric parenteral regimens are ceftriaxone or an aminoglycoside with or without ampicillin. A prospective, randomized trial of intravenous ampicillin and gentamicin, intravenous cefazolin, or intramuscular ceftriaxone found all three to be equally effective for the parenteral treatment of acute pyelonephritis in pregnancy.[173] Gentamicin has been widely used in pregnant women with no evidence for congenital complications.[92] Extended spectrum penicillins may also be used. Ampicillin or cefazolin, by themselves, are not currently recommended because of the high prevalence of antimicrobial resistance in community isolates. Fluoroquinolones are avoided in pregnancy because of adverse fetal effects, and TMP/SMX should be avoided in the first trimester.

Children

Approaches to the antimicrobial management of acute pyelonephritis in children have recently been critically reviewed in a Cochrane collaboration report.[174] This concluded that initial oral compared with parenteral antimicrobial therapy had similar short-term outcomes of the duration of fever and long-term outcomes of persistent kidney damage at 6 or 12 months. In addition, there was no difference in persistent kidney damage when intravenous was followed by oral therapy or only intravenous therapy was given, each for 7 to 14 days. There was also no difference in outcomes with once or thrice daily aminoglycoside dosing. Thus, the selection of parenteral or oral therapy, or whether to initiate a short initial course of intravenous therapy and complete with oral therapy or treat with oral therapy alone, should be based on clinical evaluation. Infants aged 1 month or less require hospitalization for treatment and investigation because of the very high prevalence of concomitant bacteremia and urologic abnormalities.

For parenteral therapy, aminoglycosides or a third-generation cephalosporin are preferred, with TMP/SMX or amoxicillin/clavulanic acid as first-line agents for oral therapy.[175] Fluoroquinolones are avoided because of potential adverse effects on cartilage. Outpatient parenteral therapy is an option.[176] Although the early treatment of infants and young children will limit the duration of acute symptoms, the earlier institution of antimicrobial therapy has not been shown to decrease the subsequent development of renal scars.[177,178]

The Duration of Therapy and Follow-Up

The appropriate duration of therapy to achieve optimal cure rates in patients with acute pyelonephritis is uncertain, and may differ depending on the antimicrobial used. A minimum of 2 weeks of therapy has been routinely recommended, but 10 days is clearly sufficient in many clinical studies[172] and 7 days of ciprofloxacin[13] or 5 days of levofloxacin[170] have been as effective as longer courses of treatment in controlled clinical trials.

Behr et al.[179] reported, in a series of patients admitted with both complicated and uncomplicated acute pyelonephritis, that 26% remained febrile at 48 hours and 13% remained febrile at 72 hours. The median duration of fever was 34 hours. Johnson et al.[106] reported that 30% of women with acute uncomplicated pyelonephritis remained febrile at 2 days, but virtually all were afebrile by 72 hours. Thus, most patients become afebrile within 72 hours following the initiation of therapy; other clinical findings, including renal-angle tenderness, also rapidly improve.

Treatment in the Presence of Impaired Renal Function

In the management of patients with impaired renal function, antimicrobials, which are effective despite decreased renal perfusion, should be selected, whereas agents that might further compromise function should be avoided if possible. Antimicrobial therapy may ameliorate symptoms but frequently will not cure the infection in the presence of moderate-to-severe renal impairment, presumably because of the failure of antimicrobials to access the site of bacterial infection. Long-term suppressive therapy with an oral antimicrobial may be required in selected cases for the management of recurrent symptomatic episodes.

The β-lactam antibacterials have little dose-related toxicity and are relatively safe in patients with renal failure. Patients with impaired renal function are at increased risk of seizures with imipenem and encephalopathy with cefepime. Interstitial nephritis occurs rarely in patients receiving β-lactam antibacterial agents, but the risk of this complication is not increased by coexisting renal impairment. A dose adjustment for renal impairment is required for most β-lactam agents. No untoward consequences of trimethoprim prescribed without sulfonamide have been reported in patients with moderately advanced renal impairment. The fluoroquinolone antimicrobials—ciprofloxacin, ofloxacin, and levofloxacin—are also effective in renal failure. Dosage adjustments are required for patients with creatinine clearance rates less than 30 mL per minute.

Aminoglycosides should be avoided in patients with renal impairment. In the presence of unstable renal function, a rise in blood urea or creatinine levels may be incorrectly attributed to an aminoglycoside. Doxycycline is relatively safe in renal impairment but usually fails to achieve adequate urine levels. Other tetracyclines are contraindicated. Sulfonamides have been associated with a further loss of renal function and should not be used. Methenamine mandelate or other organic salts also are contraindicated in patients with renal impairment.

Recurrent Upper Tract Infection

In prospective studies, about 5% to 10% of women with acute pyelonephritis have a relapse with the initial infecting organism within 4 weeks of completing therapy.[13,14,170,171] Women with acute nonobstructive pyelonephritis are also

at increased risk of both upper and lower tract urinary reinfection, especially within the first year following the initial episode.[51,52] About 50% of patients with urinary infections in the setting of structural or functional genitourinary abnormalities (Table 23.2) recur with either upper or lower tract infection by 6 weeks after therapy, although most recurrences are asymptomatic. The pattern of recurrence is a predictor of infection site, with relapses predictive of renal infections in women and renal or prostate infections in men. For women with a symptomatic relapse, renal infection is presumed and retreatment with a 2-week course of antimicrobial therapy results in cure for most of those with a normal genitourinary tract. Longer courses of antimicrobial therapy (4 weeks or more) may be considered in patients with repeated relapsing symptomatic infections and chronic renal failure or where progressive renal damage is a concern. Men without upper tract abnormalities and with relapses should receive retreatment for 4 to 6 weeks for presumed prostate infection,[180] as prostate localization is the more likely source of relapsing infections in men.

Several principles should be considered in all patients with recurrent infections:

1. The urine culture becomes negative shortly after the institution of effective chemotherapy.[181] The isolation of any quantitative count of the initial infecting organism while antibiotics are being taken is a failure of therapy. Bacterial persistence with positive urine cultures occurs due to inadequate levels of the antimicrobial agent in the urine, the presence of resistant organisms, or patient noncompliance. Continuing the same antimicrobial regimen, even with a clinical response, is inappropriate if urine cultures remain positive with the same pretherapy isolate and if the patient has been compliant.
2. Relapse is frequently associated with urologic abnormalities. Infected renal cysts, calculi, indwelling devices, prostate infection, and a nonfunctioning kidney allow organisms to persist in sites where effective antimicrobial levels are not achieved.[180,182] Patients with relapses require a careful reevaluation including radiologic and urologic investigation. In the absence of urologic or radiologic abnormalities, many women who have a relapse can be cured with a sufficiently prolonged course of therapy. On the other hand, infection recurs in patients with calculi in the kidneys, prostate infection, or a nonfunctioning kidney, even following prolonged treatment courses of several months or years.
3. Clinical trials of the treatment of urinary infections in men have not generally localized infection to the prostate or kidneys; some may have infections at both sites. Owing to the frequency of complicating urologic abnormalities in men with urinary infection, attempts to define a homogeneous group with renal infections and to determine treatment responses have generally been unsuccessful. Treatment should be undertaken only if recurring symptoms or complicating disease suggest these men are at risk of morbidity from infection. A very prolonged course of therapy with TMP/SMX or a fluoroquinolone for 4 to 12 weeks should be prescribed to eradicate a persisting but curable renal or prostate focus. Even with prolonged fluoroquinolone treatment, however, a cure is obtained in 70% or less of men with chronic prostate infection.[180]
4. Antimicrobial concentrations in renal tissue and urine may be markedly diminished in patients with impaired renal function caused by acute or chronic parenchymal renal disease or obstruction. In patients with unilateral renal impairment, the antimicrobial concentration of some agents may be inadequate to inhibit bacterial growth or sterilize urine originating from the diseased kidney.[183] The contralateral normal or hypertrophied kidney may be excreting the antibacterial agent effectively, so the drug does not accumulate in the serum. Excretion of the antimicrobial agent in the urine from the healthy kidney may be adequate to sterilize the bladder urine and make it appear that the bacteriologic outcome is satisfactory despite persistent or continuing bacterial multiplication in the diseased kidney.
5. Patients with frequent reinfections have altered bacterial flora, reflecting the impact of repeated courses of antibacterial agents on the fecal reservoir.[163] Sulfonamides, penicillins, cephalosporins, and fluoroquinolones eradicate susceptible gram-negative organisms within the intestinal tract, which may be replaced by resistant Enterobacteriaceae or Pseudomonas spp. Broad-spectrum antimicrobial agents preferentially excreted in the bile have a greater impact on the fecal flora than do agents preferentially excreted in the urinary tract. The "next infection," if it occurs within a few months, often will be caused by an organism that is resistant to the therapeutic regimen previously prescribed. With frequent reinfections, particularly in patients with devices such as ureteric stents or an indwelling catheter, the pathogens become progressively resistant to antimicrobial therapy.
6. The treatment of asymptomatic bacteriuria should be avoided except for bacteriuria in pregnancy or prior to an invasive urologic procedure likely to be associated with trauma to the genitourinary mucosa.[3] Following from this, posttherapy urine cultures should only be obtained if there is a symptomatic recurrence.
7. Patients with long-term indwelling suprapubic or urethral catheters are always bacteriuric. Although transient suppression may occasionally yield a negative urine culture, bacteriologic failure is predictable. These patients should only be treated for symptomatic episodes, as efforts to prevent infection with continuous suppressive antibacterial regimens select multiply resistant organisms and have not been shown to prevent morbidity.[184]

8. The successful treatment of struvite stones requires the complete eradication of all stone material. Antimicrobial therapy is an adjunct to maintain sterile urine while a complete stone dissolution is achieved. Advances in the endourologic treatment of infected renal calculi make it possible for most patients with renal stones to be treated with complete removal of all calculous material. The necessary duration of antimicrobial therapy following lithotripsy, however, is controversial.

THE PREVENTION OF PYELONEPHRITIS

Some women with recurrent acute uncomplicated urinary infections may present as recurrent pyelonephritis, although this pattern is uncommon. Subsequent infections in these women can be effectively prevented by chemoprophylactic regimens. The most important intervention to prevent infections in patients with complicated urinary infections is to correct or optimize management of the underlying abnormality that is promoting infection. Recurrent symptomatic infections from a renal or prostate focus in selected patients with abnormalities that cannot be corrected may be suppressed indefinitely without "cure" by long-term treatment with suppressive antimicrobial regimens. Immunization has also been explored for the prevention of recurrent urinary infections. Animal studies have reported some success for the prevention of both cystitis and pyelonephritis through vaccination with E. coli antigens, but effectiveness in humans is not yet documented.[17,185]

Antimicrobial Prophylaxis

Prophylaxis of symptomatic acute uncomplicated cystitis or nonobstructive pyelonephritis in women is highly effective (see Chapter 22). Prophylactic antimicrobial therapy is an option for children[186] or women[187] who experience three or more episodes of symptomatic infections, either cystitis or pyelonephritis, within 1 year. Effective and widely used regimens include nitrofurantoin 50 mg monohydrate or 100 mg monohydrate/macrocrystals, TMP/SMX 0.5 tablet, or trimethoprim 100 mg, all taken once daily at bedtime, or postintercourse. TMP/SMX is also effective taken as a 0.5 tablet every second day. Both symptomatic and asymptomatic urinary infections are prevented with current strategies of TMP/SMX prophylaxis in renal transplant recipients.[188]

The need for and the efficacy of antimicrobial prophylaxis for children with vesicoureteral reflux is controversial. Although some guidelines have recommended continuous prophylactic antimicrobials for these patients, there remains considerable controversy whether this approach prevents the development of new or progressive renal scars, or renal impairment.[186,189,190] In an open randomized trial of Swedish boys and girls with reflux, prophylactic antimicrobial therapy significantly decreased subsequent febrile urinary infection, for girls only, during 2 years of follow-up.[191] Additional prospective, randomized clinical trials to answer the question of whether long-term prophylactic antimicrobial therapy prevents renal scarring and preserves renal function for children with vesicoureteral reflux compared with an optimal management of symptomatic episodes alone are ongoing.[190]

Prevention in Pregnancy

The prevention of acute pyelonephritis in pregnant women should be a part of the antenatal care of all patients.[91] The prevalence of asymptomatic bacteriuria during pregnancy has varied from 2% to 7%, with an incidence of acquiring bacteriuria about 1%—similar to the incidence of new infections in age matched women who are not pregnant.[91] In the absence of a screening and treatment program, acute pyelonephritis occurs in 20 to 30 per 1,000 pregnant women. With an intervention program for the treatment of asymptomatic bacteriuria, acute pyelonephritis is reduced to 3 to 5 per 1,000 pregnant women.[91,92] Pregnant women should be screened for bacteriuria once at 12 to 16 weeks' gestation, and those with positive cultures should be treated. Repeated screening cultures later in the pregnancy are not recommended for asymptomatic women whose initial culture is negative. Pregnant women who have had bacteriuria or symptomatic urinary infections should be followed with urine cultures throughout pregnancy, usually every 4 weeks. Continuous low-dose prophylaxis until 6 weeks after the delivery is recommended for patients with recurrent infections.

The choice of a regimen for the treatment of asymptomatic bacteriuria or for the prophylaxis of symptomatic or asymptomatic infections in a pregnancy must address the potential adverse effects for the fetus.[92] Although TMP/SMX is generally considered safe during pregnancy, concerns about a potential teratogenic effect from the trimethoprim component limits its use, especially during the first trimester. Penicillins and cephalosporins are safe in pregnancy; nitrofurantoin is safe, but is avoided at term because of the potential hemolysis of fetal hemoglobin. Ampicillin or a cephalosporin may be used if the organism is known to be susceptible. Cephalexin may also be used for prophylaxis, at 250 mg per day, and nitrofurantoin may be used for either treatment or prophylaxis. Fluoroquinolones are contraindicated because of the potential harmful effects on fetal cartilage development.

Prevention of Catheter-Associated Upper Tract Infections

Catheter-associated infections are the most common hospital-acquired infection.[184,192,193] Prophylactic antimicrobial therapy is not recommended because of the predictable emergence of infections with organisms with increased resistance.[184] The most important interventions to prevent these infections are to limit use of an indwelling urethral catheter or, if a catheter is necessary, to minimize the duration of catheterization. In addition, catheter insertion using sterile techniques and appropriate catheter maintenance, such as

maintaining a closed drainage system, are necessary. Infection control programs must ensure that prevention practices are current, and should monitor adherence to appropriate practice and patient infection rates.

The Prevention of Infection in Patients with Neurogenic Bladders

Bacteriuria is an anticipated complication following neurologic injury or disease complicated by a neurogenic bladder. Prophylactic antimicrobials are not recommended in spinal cord–injured patients managed with intermittent catheterization.[194] Although TMP/SMX, trimethoprim, or nitrofurantoin prophylaxis may prevent infections in the acute or early injury phase, prophylaxis is not effective in preventing symptomatic infections in the long term, and the induction of resistant bacteria in subsequent infections outweighs any short-term benefits. Maintenance of a low-pressure voiding system is essential to prevent complications of urinary infection.[104]

Continuous Suppression

Continuous long-term suppression may be considered for highly selected patients with recurrent symptomatic relapses despite optimal antimicrobial therapy. Such patients include those with renal calculi or obstructive lesions that cannot be corrected, infections in a nonfunctioning kidney, and men with chronic bacterial prostatitis.

There is relatively little evidence addressing optimal approaches to suppressive therapy. Sheehan and colleagues[195] compared 12 to 24 weeks of norfloxacin therapy for complicated recurrent urinary infections in a prospective, randomized, and blinded study. The longer antimicrobial course served as prophylaxis, suppressive, or curative therapy for different patients and, overall, led to fewer failures or reinfections from 12 to 24 weeks compared to placebo. Chinn and associates[196] demonstrated that antibacterial suppression is effective in patients with renal calculi in whom stones cannot be fully removed. No patients had further loss of renal function during a cumulative 77 years of continuous observation despite the presence of stones and partial obstruction. Renal calculi increased in size in only 4 of the 22 patients during the period of antibacterial suppression, and 4 of the 6 patients with impaired renal function had a decrease in serum creatinine levels while receiving suppressive therapy.

The antimicrobial dosage required for the maintenance of suppressive therapy is not well studied but generally, after an initial 2 to 4 weeks at full therapeutic doses, one-half the treatment dose is continued. In stable patients without a recurrence of bacteriuria, the dose may sometimes be reduced further. Patients on suppressive regimens should be reviewed periodically to ensure compliance and to monitor renal function. "Breakthrough" symptomatic infections occur occasionally. If the initial infecting organism has reappeared, then susceptibility testing will determine whether resistance has developed or if there is a suboptimal dose of medication. New infections may occur with reinfections with a new pathogen, and organisms isolated from a reinfection will usually be resistant to the antimicrobial used for the suppressive therapy. If this occurs, the patient should receive a 7- to 10-day course of an appropriate alternate antimicrobial to eradicate the new pathogen, without discontinuing the antimicrobial being taken for suppressive therapy. No guidelines have been developed to address the duration for which suppressive therapy is continued. If the initial indications for continuous suppressive therapy persist, the antimicrobial therapy may be continued indefinitely.

VIRAL INFECTIONS OF THE KIDNEY

Viruses causing systemic diseases are frequently isolated from the urine. Utz,[197] in 1974, described 16 viruses that were reported to have been isolated from the urine. The number is likely substantially greater now given the many new viruses described and the more sensitive diagnostic techniques. However, viruria commonly occurs during viremic infections as a manifestation of acute generalized diseases with limited, if any, involvement of the kidneys. Many viruses multiply in the tubular epithelium and are excreted in the urine as exfoliated infected cells. In only a few instances are there acute inflammatory changes in the renal tissue or in symptoms of clinical renal illness.

Clinical disease with parvovirus B19, cytomegalovirus, or adenovirus, usually following viral reactivation, occurs in some immunocompromised patients including renal transplant recipients, hematopoietic stem-cell transplant recipients, and occasionally, HIV patients. Hemorrhagic cystitis is the more common clinical presentation, but nephropathy is well described.[198,199] Viral infections of the kidney following a renal transplant are discussed more fully in another chapter.

The hemorrhagic fever viruses frequently cause renal impairment and are important health problems in many parts of the world.[200] Viral hemorrhagic fever with renal syndrome, which occurs in Korea, Scandinavia, the Soviet Far East, and the Balkans, is caused by members of the Bunyaviridae genera. The prototype agent is the Hantaan virus, originally isolated in Korea in 1978. Rodents are the reservoirs for these agents, and transmission to humans occurs by respiratory aerosols with no intermediary vector. Secondary cases have not been described in humans. High fever, myalgias, severe headaches, and a petechial rash characterize the illness. Thrombocytopenia is common. Hypotension and oliguria develop on about the fifth day of the fever. A pathologic examination discloses widespread capillary damage with extravascular leakage of plasma and red cells. Acute oliguric renal failure with massive proteinuria is a frequent complication. Renal biopsy specimens show extensive necrosis of the tubular epithelium with anatomically normal glomeruli except for the presence of extravasated red cells and protein-rich fluid. The overall mortality can be markedly reduced by supportive therapy, including dialysis, and in recent series has been 5% or less.

Rubella, varicella zoster, measles, and cytomegalovirus are commonly isolated during clinical illnesses with these viruses, but renal disease attributed to these agents has not been recognized.[197] Mumps frequently produce a transient renal impairment with a reduction in glomerular filtration together with significant proteinuria and hematuria. These abnormalities disappear within 1 month of resolution of the illness. Rare fatal cases with mumps interstitial nephritis have been reported.[201] Histologic studies suggest that viral multiplication in renal tubular cells induces these changes. Coxsackie B virus has also been associated with mild renal impairment. Infectious mononucleosis may have renal manifestations; hematuria and proteinuria occur in 11% and 18% of patients, respectively.[202] Acute renal failure owing to interstitial nephritis with few glomerular changes has also been described in isolated case reports.

CHAPTER

24 Renal and Perirenal Abscesses

Neha D. Nanda • Louise M. Dembry

Bacterial infections of the kidney and perinephric space include a spectrum of pathologic conditions that can be divided into intrarenal and perirenal abscesses. Both conditions are suppurative infections localized either within the parenchyma of the kidney (intrarenal abscess, i.e., renal cortical abscess and corticomedullary abscess) or within the perirenal fascia external to the kidney capsule (perinephric abscess), and each can be identified by specific diagnostic techniques. The incidence of intrarenal and perirenal abscesses ranges from one to 10 cases per 10,000 hospital admissions. In the preantibiotic era, most cases were caused by hematogenous seeding from distant foci of infection and were predominantly in young males without an antecedent history of renal disease. Currently, most cases occur as a complication of urinary tract infection and affect males and females with equal frequency. The incidence increases with age and if an abnormality of the genitourinary tract exists. This chapter covers only the more common types of these renal and perirenal infections.

INTRARENAL ABSCESS

Renal Cortical Abscess (Renal Carbuncle)

Etiology

A renal carbuncle (from the Latin, carbunculus, or "little coal") is a circumscribed, multilocular abscess of the renal parenchyma, which forms from a coalescence of multiple cortical microabscesses (Fig. 24.1). It is most commonly caused by staphylococci (Staphylococcus aureus) and is the result of metastatic spread from a primary focus of infection elsewhere in the body, most commonly the skin. Renal carbuncles were first described by Israel in 1905 in a presentation before the Free Society of Berlin Surgeons.[1] Although numerous reports and reviews[2–8] have been published since Israel's initial description, the total number of reported cases of renal carbuncle remains relatively small.

Pathogenesis

A renal cortical abscess results from a primary focus of infection elsewhere in the body. Common primary foci are cutaneous carbuncle, furunculosis, cellulitis, paronychia, osteomyelitis, endovascular infection, and infection of the respiratory tract. Important predisposing conditions that increase the risk of bacteremia and hematogenous spread are injection drug use, hemodialysis, and diabetes mellitus. S. aureus is the most common causative agent (90%) and infects the cortex of the kidney by hematogenous dissemination from the primary focus, often resulting in several interconnecting furuncles or microabscesses. Coalescence may occur with progression of the infection to a lesion consisting of a fluid-filled mass with a relatively thick wall. Rarely, the process may extend to the periphery of the renal cortex and rupture through the capsule, leading to formation of a perinephric abscess. The majority of renal cortical abscesses are unilateral (97%) single lesions (77%) occurring in the right kidney (63%), and are not associated with perinephric abscesses (90%). The reason for unilateral localization is not clear, although diminished resistance of the kidney resulting from previous disease or injury, including trauma, has been cited as a predisposing factor.[9] Infrequently, ascending infection causes a renal cortical abscess.[10,11] Because the interval between the original staphylococcal infection and the onset of clinical symptoms of a renal cortical abscess may vary from a few days to many months (average time of approximately 7 weeks),[9] the primary focus of infection may have healed and is not apparent in one third of affected patients.[5,7]

Clinical Features

Renal cortical abscesses are three times more common in males than females. The disease occurs at all ages but is most common between the second and the fourth decades of life.[9] The clinical picture of a renal cortical abscess is nonspecific. Most patients have chills, fever, and abdominal or back pain.[5,7,9] Some may have a palpable flank mass. Others present with a clinical picture of fever of undetermined origin, with few or no localizing signs.[12] Most patients have no urinary symptoms[9] because the abscess occupies a circumscribed area within the parenchyma of the kidney, which may not communicate with the excretory passages.

Physical examination often reveals tenderness in or near the region of the kidney. Pain on fist percussion of the

costovertebral angle is the most constant physical finding, often accompanied by moderate muscle rigidity in the upper abdominal and lumbar muscles. A flank mass or a bulge in the lumbar region, with loss of the natural concave lumbar outline, may be present. Examination of the chest on the affected side may be abnormal, with decreased respiratory excursion, tenderness over the lower ribs, dullness, diminished breath sounds, increased fremitus, or rales.

Basic laboratory data are variable. Peripheral white blood cell counts are moderately elevated in 95% of patients.[9] The urinalysis usually presents no pathognomonic findings. Proteinuria, pyuria, or microscopic hematuria are usually present and a Gram stain of the urine will demonstrate the pathogen if the abscess communicates with the collecting system of the kidney. However, negative urinalyses are seen in most patients and blood cultures are usually negative.[9]

Diagnosis

Renal cortical abscesses must be differentiated from other space-occupying lesions in the kidney. Renal tumors, cysts, intrarenal abscesses caused by aerobic gram-negative bacilli, and perinephric abscesses can mimic renal cortical abscesses. In the past, surgical exploration was performed to differentiate the renal mass from a carcinoma. The clinical presentation of a renal cortical abscess is nonspecific and not helpful in differentiating this disease from a renal tumor or perinephric abscess. Chills, fever, malaise, and back pain may be seen in each. A renal cortical abscess on the anterior surface of the kidney may produce abdominal symptoms and lead to an erroneous diagnosis of an intra-abdominal process. Renal cortical abscesses may also be confused with abscesses of the renal medulla, particularly in children.[7,9–11,13–15] Radiologic techniques can define the character of the renal mass and establish the correct diagnosis.[16–25]

In intravenous pyelograms, a renal cortical abscess appears as a mass of diminished density, frequently associated with distortion of the calyces, infundibulum, and renal outline. An abscess that extends to the periphery of the renal cortex may produce sufficient edema of the renal capsule to obliterate a segment of the perirenal fat shadow. However, there is no displacement of the kidney, as is frequently seen with a perinephric abscess. Thus, an abnormal intravenous pyelogram that demonstrates an intrinsic mass with calyceal distortion, but without displacement of the kidney in a patient with sterile urine, suggests a diagnosis of renal cortical abscess or tumor.

Ultrasonography has been extremely helpful in establishing the diagnosis of renal cortical abscess.[9] Renal ultrasonography is easily available, cost effective, and there is no exposure to radiation or contrast. Renal ultrasonography can provide morphologic detail of the kidneys; is capable of identifying cystic lesions, tumorlike masses, or abscess cavities; and can show the size and location of the lesion. Early in the development of a renal cortical abscess, however, internal echoes may be present, giving the appearance of a solid or semisolid mass. Because these findings are compatible with either a renal cortical abscess or tumor, computed tomography (CT) may be performed to define the lesion further and to establish the correct diagnosis.[26,27] Another disadvantage of renal ultrasonography is its dependence on the operator and the body habitus of the patient.[27] After coalescence, an abscess can be identified by ultrasound as a fluid-filled mass with a relatively thick wall (Fig. 24.2). Ultrasonography also can be used to guide aspiration of the lesion and to follow its resolution with antibiotic treatment[7,24,28] (Fig. 24.3).

CT is the most accurate noninvasive technique currently in widespread use and permits detection of abscesses smaller than 2 cm.[29–31] Contrast-enhanced CT is useful if ultrasonography is negative or equivocal and allows for the detection of pathologic lesions in the renal cortex and medulla in early stages. CT is also useful as a guide to percutaneous aspiration of an abscess and to follow a known lesion. An abscess appears as a sharply demarcated low-density lesion on CT. The abscess does not enhance with contrast because of its avascular nature; however, the wall of the abscess enhances because of the presence of dilated and inflamed vessels.[28,30,31] The finding of gas in a low density mass is pathognomonic for an abscess.[30]

Magnetic resonance imaging (MRI) is another noninvasive technique that is as accurate as CT to diagnose renal abscess and define the extent of involvement. With an MRI there is no exposure to radiation and ionizing contrast.[27] MRI with gadolinium and contrast-enhanced CT scans have comparable sensitivity to detect renal abscesses. Noncontrast CT and renal ultrasonography are not as good to detect renal parenchymal pathology.[32] To differentiate between a renal

malignancy and an isolated abscess in the kidney, MRI with diffusion-weighted images is helpful. The principle behind this is the diffusion of water molecules is reduced in the intracellular space compared to the extracellular space. Thus, highly cellular tumors may be more likely to have restricted diffusion than less cellular tumors/masses. This modality has been used extensively to characterize central nervous system lesions.[33] Several drawbacks to MRI are that it is expensive and time consuming to perform. Gadolinium use in patients with stage IV or V chronic kidney disease is also contraindicated.

Selective renal arteriography is an older modality used to differentiate renal cortical abscess from tumor. A renal cortical abscess can be identified angiographically as a mass that produces arcing, stretching, and attenuation of adjacent arteries, with the vessels located around the circumference rather than within the mass (Fig. 24.4). Early in the course, the rim around the abscess is poorly visualized, but arterial circulation to the periphery gradually increases with time so that a late study may identify a dense rim in the parenchymal phase. An untreated abscess may progress to a stage in which the rim is thick and poorly vascularized.

Renal and perirenal abscesses can be arteriographically distinguished from tumors because the major portion of an abscess is avascular whereas the wall of the abscess is hypervascular.

Renal carcinoma may be hypervascular or hypovascular (necrotic), but rarely both. In an abscess, the arteries retain their normal organization and branching pattern. Tumor neovascularity, in contrast, consists of abnormal vessels. Tumor vessels have no recognizable organization, may enlarge instead of taper as they course peripherally, and have an abnormal branching pattern.

Nuclear imaging was popular before CT and MRI became widely available. Renal scanning with gallium-67 (^{67}Ga) citrate (Fig. 24.5) also has been useful in localizing a renal abscess in adults.[17,28,34] A subtraction technique using ^{67}Ga citrate and technetium-99 (^{99}Tc) glucoheptonate can define the extent of perinephric involvement and eliminate any false-positive scans seen with gallium alone.[34] The latter may occur in patients with renal carcinoma, severe pyelonephritis without abscess formation, or ureteral obstruction. ^{111}In-labeled white cell scanning identifies a renal abscess but does not demonstrate renal carcinoma.

Noninvasive techniques such as ultrasound, CT, and MRI have reduced the need for intravenous pyelogram, selective angiography, and nuclear imaging to further define intrarenal masses.

Radiologic techniques can correctly establish a diagnosis of a renal cortical abscess only when this diagnosis is considered. Unfortunately, clinicians generally do not think of the diagnosis of renal cortical abscess early in its course. An average delay of 62 days before the correct diagnosis was established and proper treatment instituted has been reported.[9]

Treatment

Historically, the treatment of a renal cortical abscess has been surgical and has varied with the condition of the patient.[8] However, because a renal cortical abscess is usually hematogenous in origin, and caused by S. aureus, it often responds to antistaphylococcal antimicrobial therapy alone, thus obviating the need for surgical intervention.[9]

If the diagnosis of renal cortical abscess is suspected from the history, physical findings, and renal ultrasonography (abscess localized to the renal parenchyma) or CT, and gram-positive cocci or no bacteria are seen on microscopic examination of the urine, antimicrobial therapy should be directed against S. aureus. Choice of empiric antistaphylococcal therapy depends on the susceptibility patterns of S. aureus in the community. If methicillin-sensitive S. aureus (MSSA) is prevalent in the community, oxacillin or nafcillin 1 to 2 grams intravenously (IV) every 4 to 6 hours is appropriate initial therapy. If a history of nonanaphylactic penicillin allergy (i.e., rash) is present, cefazolin (2 grams every 8 hours) is an alternative. Patients with severe immediate penicillin allergy may manifest cross-reacting allergy when a cephalosporin is administered and should receive vancomycin (1 gram every 12 hours) instead. If the prevalance of community-associated methicillin-resistant S. aureus (MRSA) is high, empiric therapy with vancomycin

is justified. Historically, MRSA infections have been associated with exposures to health care settings; however, since 2001, community-associated MRSA has become an increasingly recognized and prevalent pathogen.[35] With the indiscriminate use of glycopeptides, vancomycin-intermediate S.aureus (VISA) and vancomycin-resistant S. aureus (VRSA) are a growing concern. Daptomycin (6 mg per kg IV every 24 hours) is the agent of choice in this setting. The prevalence of VISA and VRSA is not high enough at this time to warrant empiric therapy with daptomycin. Renal cortical abscesses can be cured with parenteral antibiotic therapy administered for a minimum of 10 days to 2 weeks, followed by oral antistaphylococcal therapy for at least an additional 2 to 4 weeks. The decision to pursue percutaneous drainage for therapeutic and/or diagnostic purposes is guided by the size of abscess and response to antimicrobial therapy. Renal abscesses less than 5 cm in size can be treated with antibiotic therapy alone.[36,37] If there is optimal response, fever gradually subsides over a 5- to 6-day period without recurrence. Flank or back pain abates rather quickly, and patients display significant clinical improvement within 24 hours of initiating antibiotic therapy. A prompt response to treatment justifies continuing antibiotic therapy without surgical intervention, and serial ultrasound or CT examinations can be used to show progressive reduction and ultimate disappearance of the renal mass. A contrary clinical course should suggest misdiagnosis or uncontrolled infection, with the development of perinephritis, perinephric abscess, or infection with an organism resistant to the antibiotics being administered. In such cases, modification of therapy may be required, based on the results of cultures of blood and urine. Nevertheless, a trial of intensive antibiotic treatment is warranted in lesions measuring less than 5 cm that are localized to the renal parenchyma. If the patient does not respond within 48 hours, percutaneous, ultrasonically, or CT-guided needle aspiration of the intrarenal fluid-filled lesion can be attempted.[38–41] If the renal abscess measures more than 5 cm, therapeutic and diagnostic percutaneous drainage along with antibiotics should be attempted.[37] If this treatment is unsuccessful, operative intervention should be undertaken.

Renal Corticomedullary Abscess

Etiology

Enteric aerobic gram-negative bacilli, predominantly Escherichia coli, Proteus spp., and, less commonly, Klebsiella spp., Enterobacter spp., and Pseudomonas spp. are usually responsible for intrarenal corticomedullary infections in association with vesicoureteral reflux or other urinary tract abnormalities.

Pathogenesis

Renal corticomedullary bacterial infections include a variety of acute and chronic parenchymal inflammatory processes. The more severe forms of these infections include acute focal bacterial nephritis, acute multifocal bacterial nephritis, and xanthogranulomatous pyelonephritis, which almost always involve only one kidney.

Acute focal bacterial nephritis is an uncommon, severe form of acute infectious interstitial nephritis presenting with a renal mass caused by acute focal infection without liquefaction.[42] This entity is also referred to as focal pyelonephritis or acute lobar nephronia, because the pathology consists of a heavy leukocytic infiltrate confined to a single renal lobe with focal areas of tissue necrosis.

Acute multifocal bacterial nephritis is also a severe form of acute renal infection in which a heavy leukocytic infiltrate occurs throughout the kidney with frank intrarenal abscess formation. Acute focal bacterial nephritis may represent an early phase of acute multifocal bacterial nephritis.[43]

Xanthogranulomatous pyelonephritis is a very rare and atypical form of severe chronic renal infection. Schlagenhaufer initially described the pathologic features of xanthogranulomatous pyelonephritis[44] in 1916. Grossly, the entire kidney or its involved segment is enlarged and may be fixed by perirenal fibrosis or retroperitoneal extension of the granulomatous process, which often resembles an inoperable tumor. Xanthogranulomatous pyelonephritis is classified into three stages based on the extent of involvement of renal and adjacent tissue by the xanthogranulomatous process.[45] In stage I (nephric), the xanthogranulomatous inflammatory process is confined to the kidney. Stage II lesions (perinephric) involve the renal parenchyma and Gerota's fat, whereas stage III lesions (paranephric) involve the renal parenchyma and its surrounding fat with widespread retroperitoneal involvement. Each stage is further divided into focal or diffuse, depending on the amount of parenchymal involvement. Microscopically, the disease is characterized by massive tissue necrosis and phagocytosis of liberated cholesterol and other lipids by xanthoma cells (macrophages). These foamy xanthomatous histiocytes appear to simulate clear-cell renal carcinoma.[46,47]

Acute focal bacterial nephritis, acute multifocal bacterial nephritis, and xanthogranulomatous pyelonephritis most commonly occur as a complication of bacteriuria and ascending infection, associated with tubular obstruction or scarring from prior infections, renal calculi, vesicoureteral reflux, urinary tract obstruction, or other abnormalities of the genitourinary system or in association with the endocrinopathies of diabetes mellitus or primary hyperparathyroidism.[9,11,14,15,42,43,47–51] These predisposing factors, particularly vesicoureteral reflux in children and renal calculi or other forms of urinary obstruction in adults, lead to intrarenal reflux and provide an avenue for bacteria to inoculate the renal parenchyma. Parenchymal infection develops with abscess formation because the kidney is unable to clear the infection in the presence of reflux, urinary obstruction, medullary scarring, or other causes of tubular obstruction. In adults, two thirds of intrarenal abscesses caused by aerobic gram-negative bacilli are associated with renal calculi or damaged kidneys, whereas in children this process is often associated only with vesicoureteral reflux. The incidence of renal abscesses in patients with diabetes mellitus is twice that in nondiabetic persons. In contrast to the staphylococcal renal cortical abscess of hematogenous origin, the gram-negative bacillary corticomedullary abscess of the kidney frequently produces severe renal infection. Although renal corticomedullary infections are confined within the substance of the kidney, they may perforate the renal capsule and form a perinephric abscess, extend toward

the renal pelvis and drain into the collecting system, or develop into a chronic abscess.[50] The etiology of xanthogranulomatous pyelonephritis is undefined; however, it appears to be related to a combination of chronic urinary tract infection and renal obstruction. The majority of the cases have renal calculi with staghorn renal calculi being the most common type.[52] Additional predisposing factors include chronic segmental or diffuse renal ischemia resulting in alterations in renal or lipid metabolism or both, lymphatic obstruction, abnormal immune response, diabetes mellitus, and primary hyperparathyroidism.[47,53,54]

Clinical Features

Renal corticomedullary abscesses affect males and females with equal frequency except for xanthogranulomatous pyelonephritis in adults, where females are more frequently affected than males.[53,54] Although these infections occur in all age groups, the incidence increases with advancing age. Peak incidence for xanthogranulomatous pyelonephritis occurs in the fifth to seventh decade and has been reported to occur in transplanted kidneys as well as native kidneys.[55] Most patients with acute focal bacterial nephritis, multifocal bacterial nephritis, or xanthogranulomatous pyelonephritis experience fever, chills, and flank or abdominal pain. Two thirds of patients have nausea and vomiting but dysuria is not necessarily present thus mimicking an abdominal process. Some patients may have a palpable flank or abdominal mass. Clinical signs of severe urinary tract infection with urosepsis may be seen in patients with acute multifocal bacterial nephritis, half of whom have diabetes mellitus. Nonspecific constitutional complaints of malaise, fatigue, and lethargy are particularly common (74%) in patients with xanthogranulomatous pyelonephritis, who may also complain of weight loss (24%). Significant physical findings include a renal mass (60%), hepatomegaly (30%), and, rarely, a draining flank sinus in patients with a past medical history of recurrent urinary tract infection (65%), renal stones (30%), or prior urinary tract instrumentation (26%). Peripheral white blood cell counts are elevated in most patients. The urinalysis is often abnormal, with pyuria, proteinuria, bacteriuria, and occasionally hematuria. However, the urinalysis may be normal in as many as 30% of patients. E. coli, Proteus mirabilis, and Klebsiella spp. are the most common organisms recovered from urine cultures. Blood cultures are also frequently positive in patients with acute focal bacterial nephritis or acute multifocal bacterial nephritis. Anemia is present in 75%, abnormal liver function tests (bilirubin, asparate transaminase [AST], alkaline phosphatase, and prothrombin time) in 38% to 63%, hypoalbuminemia in 60%, hypergammaglobulinemia (α_1- and α_2-globulin) in 79%, and hyperuricemia in 50% of patients with xanthogranulomatous pyelonephritis.[47,56] In general, the clinical and laboratory findings may or may not point to the urinary tract as the focus of infection and may not distinguish renal abscess from other abnormalities of the urinary tract.

Diagnosis
