HCT is an increasingly common treatment that offers the possibility of cure for a variety of once fatal malignant and nonmalignant disorders. Initially conceived in the late 1950s as a treatment for hematologic malignancies, the spectrum of illnesses treated with HCT has burgeoned to include solid tumors,[1] red blood cell dyscrasias,[2] inborn errors of metabolism,[3] and autoimmune disorders.[4] The coming years hold the potential of an even greater role for HCT including the tantalizing possibility of inducing tolerance in solid organ transplantation and treating chronic ailments such as Parkinson disease and diabetes mellitus.[5] Current common indications for transplantation are listed in Table 38.1. Overall, approximately 50,000 to 60,000 HCTs are performed annually worldwide with roughly 40% of these occurring in the United States (www.cibmtr.org). The 5-year survival rate has improved steadily and now stands at over 50%. Additional improvements have been achieved over the past two decades in engraftment time, graft-versus-host disease (GVHD), relapse or malignant progression, and nonrelapse mortality.[12] Much of this improvement is attributable to more accurate human lymphocytic antigen (HLA) matching, more effective and tolerable infection prophylaxis, and a reduction in the intensity of chemoradiation conditioning regimens. Despite these striking advances, the procedure remains fraught with potential complications, one of the most severe of which is AKI.

The development of AKI can be detrimental, beyond its own sequelae, because it interferes with the usual adequate dosing of immunosuppressants and thus predisposes for GVHD, rejection, and interruption of treatment. AKI can also contribute to other organ dysfunction, such as lung and liver, due to volume overload, coagulation abnormalities, and cytokine mediated pulmonary dysfunction. There are at present three types of transplantation: myeloablative autologous (autologous), myeloablative allogeneic (allogeneic), and nonmyeloablative allogeneic, or reduced intensity conditioning (RIC). In the United States, 57% of transplants are autologous with the remainder being conventional and reduced intensity allogeneic.[6,7] The incidence, risk factors for development, etiology, severity, and outcomes of AKI differ markedly among the three transplant modalities.

Sources of Cells

In the early days of HCT bone marrow was the source of cells for most transplants, reflected in the older term "bone marrow transplant." However, the potential sources of cells for HCT have expanded over time. The use of recombinant human granulocyte colony stimulating factor, which can increase the entry of stem cells into the peripheral blood by up to 1,000-fold, has allowed cytapheresis harvested peripheral cells to become the current dominant source for HCT. Autologous transplants involve the harvesting of one's own bone marrow or peripheral blood cells or, most recently, the use of banked umbilical cord cells. Allogeneic transplants utilize family members or HLA-matched unrelated donors and can again derive

38.1 Common Indications for Hematopoietic Cell Transplantation

Autologous	Allogeneic
Multiple myeloma	Acute myelogenous leukemia
Non-Hodgkin lymphoma[a]	Acute lymphocytic leukemia
Hodgkin lymphoma	Myelodysplastic syndrome/ myelodysplastic disorder
Other cancers[c]	Non-Hodgkin lymphoma[a]
Neuroblastoma	Nonmalignant disease[b]
Breast cancer	–AL amyloidosis –Paroxysmal nocturnal hemoglobinuria –Thalassanemia –Sickle cell disease –Systemic lupus erythematous Chronic myelogenous leukemia Aplastic anemia Multiple myeloma

[a]Non-Hodgkin lymphomas include lymphoblastic, Burkitt, diffuse large B cell, follicular, mantle cell, T cell.
[b]Nonmalignant disease includes Fanconi anemia, Blackfan-Diamond anemia, rheumatoid arthritis, Crohn disease, multiple sclerosis, systemic sclerosis, juvenile rheumatoid arthritis, Evan syndrome, chronic inflammatory demyelinating polyneuropathy, Niemann-Pick disease, Kostmann syndrome, osteopetrosis, Hurler syndrome, adrenoleukodystrophy (ALD)/metachromic dystrophy (MLD), Di-George syndrome, chronic granulomatous disease, common variable disease, severe combined immunodeficiency, Wiskott-Aldrich syndrome, POEMS syndrome, familial erythrophagocytic lymphohistiocytosis.
[c]Other cancers include chronic lymphocytic leukemia, Ewing sarcoma, rhabdomyosarcoma, medulloblastoma, Wilms tumor, osteogenic sarcoma, hepatic blastoma, juvenile chronic myeloid leukemia, desmoplastic small round cell tumor, germ cell, ovarian, renal cell, small-cell lung, soft cell sarcoma.
Data is from references 6 to 11.

cells from bone marrow, peripheral blood, or umbilical cord blood. By 2007, 80% of allogeneic and nearly 100% of autologous transplants involved the use of peripheral blood cells.[6,7] AKI has been found to be more common in recipients of marrow transplant as opposed to peripheral stem cells in some studies[11] but not in others.[13] Conversely, chronic GVHD (cGVHD) may be more prevalent in recipients of peripheral stem cell transplantation due to the greater dose of delivered T cells.[13,15–17] No association has been established between the number of infused stem cells per body weight and AKI.[18]

Myeloablative versus Nonmyeloablative

Conventional myeloablative allogeneic HCT involves high-dose chemotherapy and radiation to eradicate the underlying disease and immunosuppression to prevent rejection of the transplant graft. The allograft then serves to reconstitute the marrow and correct the treatment associated pancytopenia. Survival is contingent on recovery from the cytoablative therapy, successful engraftment, prevention and treatment of infections and GVHD, and eradication of the underlying disease. The potent myeloablative procedure is associated with significant rates of acute conditioning associated complications due to its high-dose chemotherapy and total-body irradiation (TBI), restricting its use to younger, healthier HCT recipients. However, many of the hematologic and malignant conditions wherein HCT holds the greatest potential for cure present primarily in patients older than the standard myeloablative cutoff of 55 to 60 years old or with baseline organ dysfunction or previous high-dose chemotherapy sufficient to render them ineligible for the procedure.

For years these patients were necessarily excluded from treatment. In 1997, a nonmyeloablative procedure was proposed wherein a reduced intensity conditioning regimen would allow its use in older patients and those with significant burdens of comorbidities.[19] Unlike in myeloablative transplant, the low dose chemoradiation in RIC is not intended to kill all residual cancer cells but to provide sufficient immunosuppression so as to allow engraftment of the transplanted stem cells, facilitating their subsequent eradication of the cancer via a donor mediated immune response known as the graft-versus-tumor effect.[19–23] RIC has demonstrated low toxicity and similar efficacy compared to conventional myeloablation in several malignancies without an increased rate of disease recurrence.[19,20] RIC constituted approximately 20% of allogeneic transplants in 2006 and it is increasingly employed in low-grade lymphoma, chronic leukemia, acute leukemia in remission, renal cell carcinoma, and multiple myeloma.[24] Utilization of RIC is likely to continue to increase given the aging population, expanded indications, and technologic advances for transplants across histocompatibility barriers. Distinguishing features of the three types of hematopoietic cell transplants are charted in Table 38.2.

Conditioning Treatments and Prophylaxis

Although all modalities of HCT expose recipients to potentially nephrotoxic medications in the course of conditioning and infection prophylaxis, the specific risks vary by type of transplant. Myeloablative allogeneic regimens typically are cyclophosphamide based along with either TBI or busulfan whereas autologous recipients receive a combination of cyclophosphamide or busulfan along with other agents. For RIC, a very low dose of TBI or fludarabine is substituted for cyclophosphamide or cyclophosphamide dosing is individualized. Allogeneic recipients receive prophylaxis against acute graft-versus-host disease (aGVHD) with

38.2 Distinguishing Features of the Three Modalities of Hematopoietic Cell Transplant

	Myeloablative Autologous	Myeloablative Allogeneic	Nonmyeloablative Allogeneic
Number in U.S. (annual)	21,000	4,300	2,700
Age % recipients age >60	Mostly younger 34%	Younger <10%	Older 40%
Conditioning regimen Radiation Cytotoxic therapy	 +/− High dose	 12 Gy High dose	 2 Gy Low dose
Donor cells	PB (98%) Other (2%)	PB (68%) BM (24%) CB (8%)	PB (96%) Other (4%)
GVT effect	None	Mild/moderate	Main effect
SOS (incidence)	4%–7%	2%–54%	Rare
TM (incidence)	0%–27%	0%–76%	Extremely rare
Pancytopenia	Shorter (~2 weeks)	Longer (~3 weeks)	Shorter (~2 weeks)
Acute GVHD (II-V) Timing Incidence Prophylaxis	 N/A N/A N/A	 Early (weeks) 7%–91% MTX/CsA ±Pred	 Later 13%–77% CsA or Tac ±Pred
Chronic extensive GVHD (incidence)	N/A	13%–71%	11%–73%
Overall mortality 100 days 1 year	 ~5%–20% ~25%–30%	 ~20%–25% ~40%–45%	 ~5%–15% ~35%–40%

immunosuppressive drugs, typically cyclosporine or tacrolimus plus methotrexate, although mycophenolate mofetil and sirolimus can also be used.[30] Prophylactic drugs may be withdrawn earlier in RIC to facilitate graft-versus-tumor effect. Prophylaxis for infection includes acyclovir for patients seropositive for herpes simplex virus (HSV), trimethoprim/sulfamethoxazole to prevent Pneumocystis jiroveci infection, oral fluconazole for fungal prevention, and preemptive ganciclovir or foscarnet for cytomegalovirus (CMV) infection in viremic recipients.[31,32] Amphotericin, voriconazole, or micafungin are used for patients at risk for aspergillus infection.[33] Comparing outcomes in allogeneic recipients in the periods between 1993 and 1997 and 2003 and 2007, there has been a significant decrease in bacterial, fungal, and CMV infections.[12] In addition to improvements in the use of prophylactic antimicrobials, the increased use of peripheral blood donor cells has resulted in significantly faster neutrophil engraftment and earlier reconstitution of immunity.

Epidemiology of Acute Kidney Injury

Estimates of the incidence of AKI post-HCT vary widely, ranging from 14% to 100%.[14,34] The likelihood of kidney injury is impacted by transplant type (allogeneic or autologous), donor type (related or unrelated), degree of HLA matching (full match or mismatched), conditioning regimen (myeloablative or nonmyeloablative), and specific

38.3 Commonly Utilized Definitions of Acute Kidney Injury in Hematopoietic Cell Transplant Studies

RIFLE	
Risk	Increase in Scr ≥ 1.5 × baseline or decrease in GFR ≥25%
Injury	Increase in Scr ≥ 2 × baseline or decrease in GFR ≥50%
Failure	Increase in Scr ≥ 3 × baseline or decrease in GFR ≥75% or an absolute Scr ≥4.0 mg/dL with an acute rise of at least 0.5 mg/dL
Loss	Persistent AKI >4 weeks
ESRD	ESRD >3 months
AKIN	
Stage 1	Increase in Scr ≥0.3 mg/dL or increase to 150%–199% (1.5–1.9 fold) from baseline
Stage 2	Increase in Scr 200–299% (>2.0–2.9 fold) from baseline
Stage 3	Increase in Scr ≥300% (≥3-fold) from baseline or Scr ≥4.0 mg/dL with an acute rise of at least 0.5 mg/dL
Parikh-Schrier	
Grade 0	Decrease in GFR <25% of baseline
Grade 1	Increase in Scr <2-fold from baseline with a decrease in GFR >25% but <50% of baseline
Grade 2	Increase in Scr ≥2-fold from baseline but not requiring dialysis
Grade 3	Increase in Scr ≥2-fold from baseline and need for dialysis

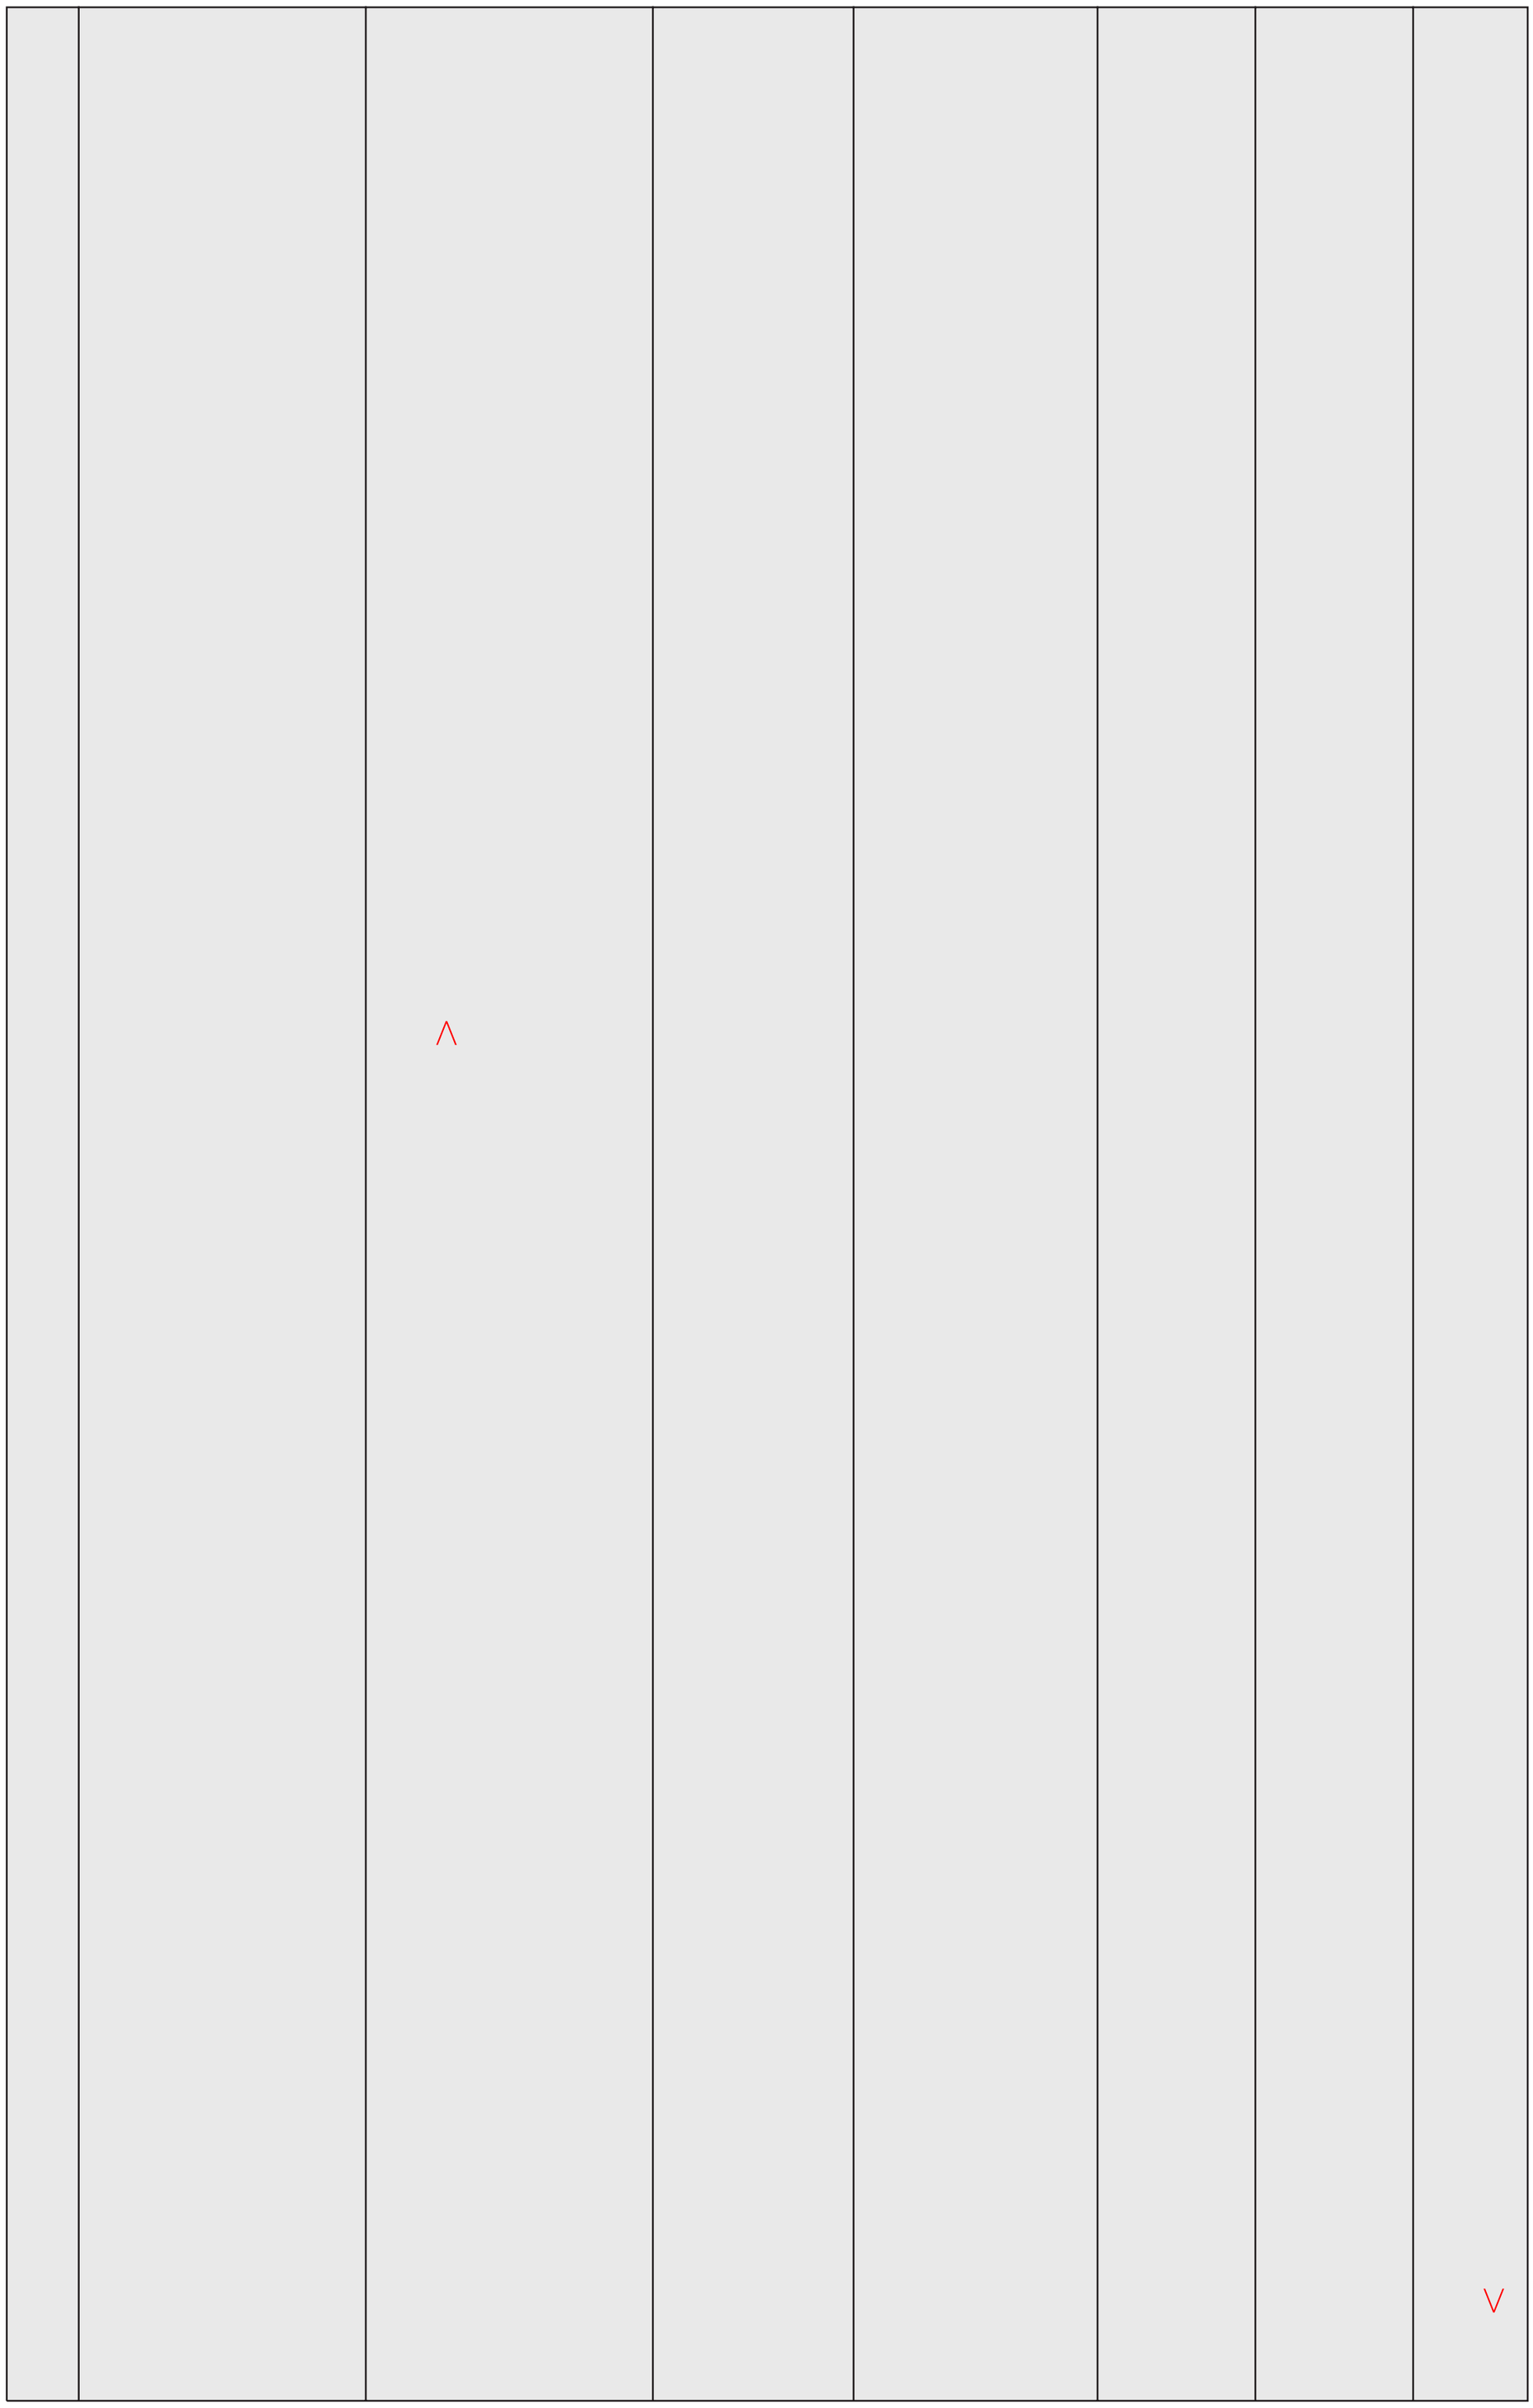
AKI, acute kidney injury; RIFLE, risk, injury, failure, loss, end-stage renal disease; Scr, serum creatinine; GFR, glomerular filtration rate; mg/dL; milligrams/deciliter; ESRD, end-stage renal disease; AKIN, Acute Kidney Injury Network.

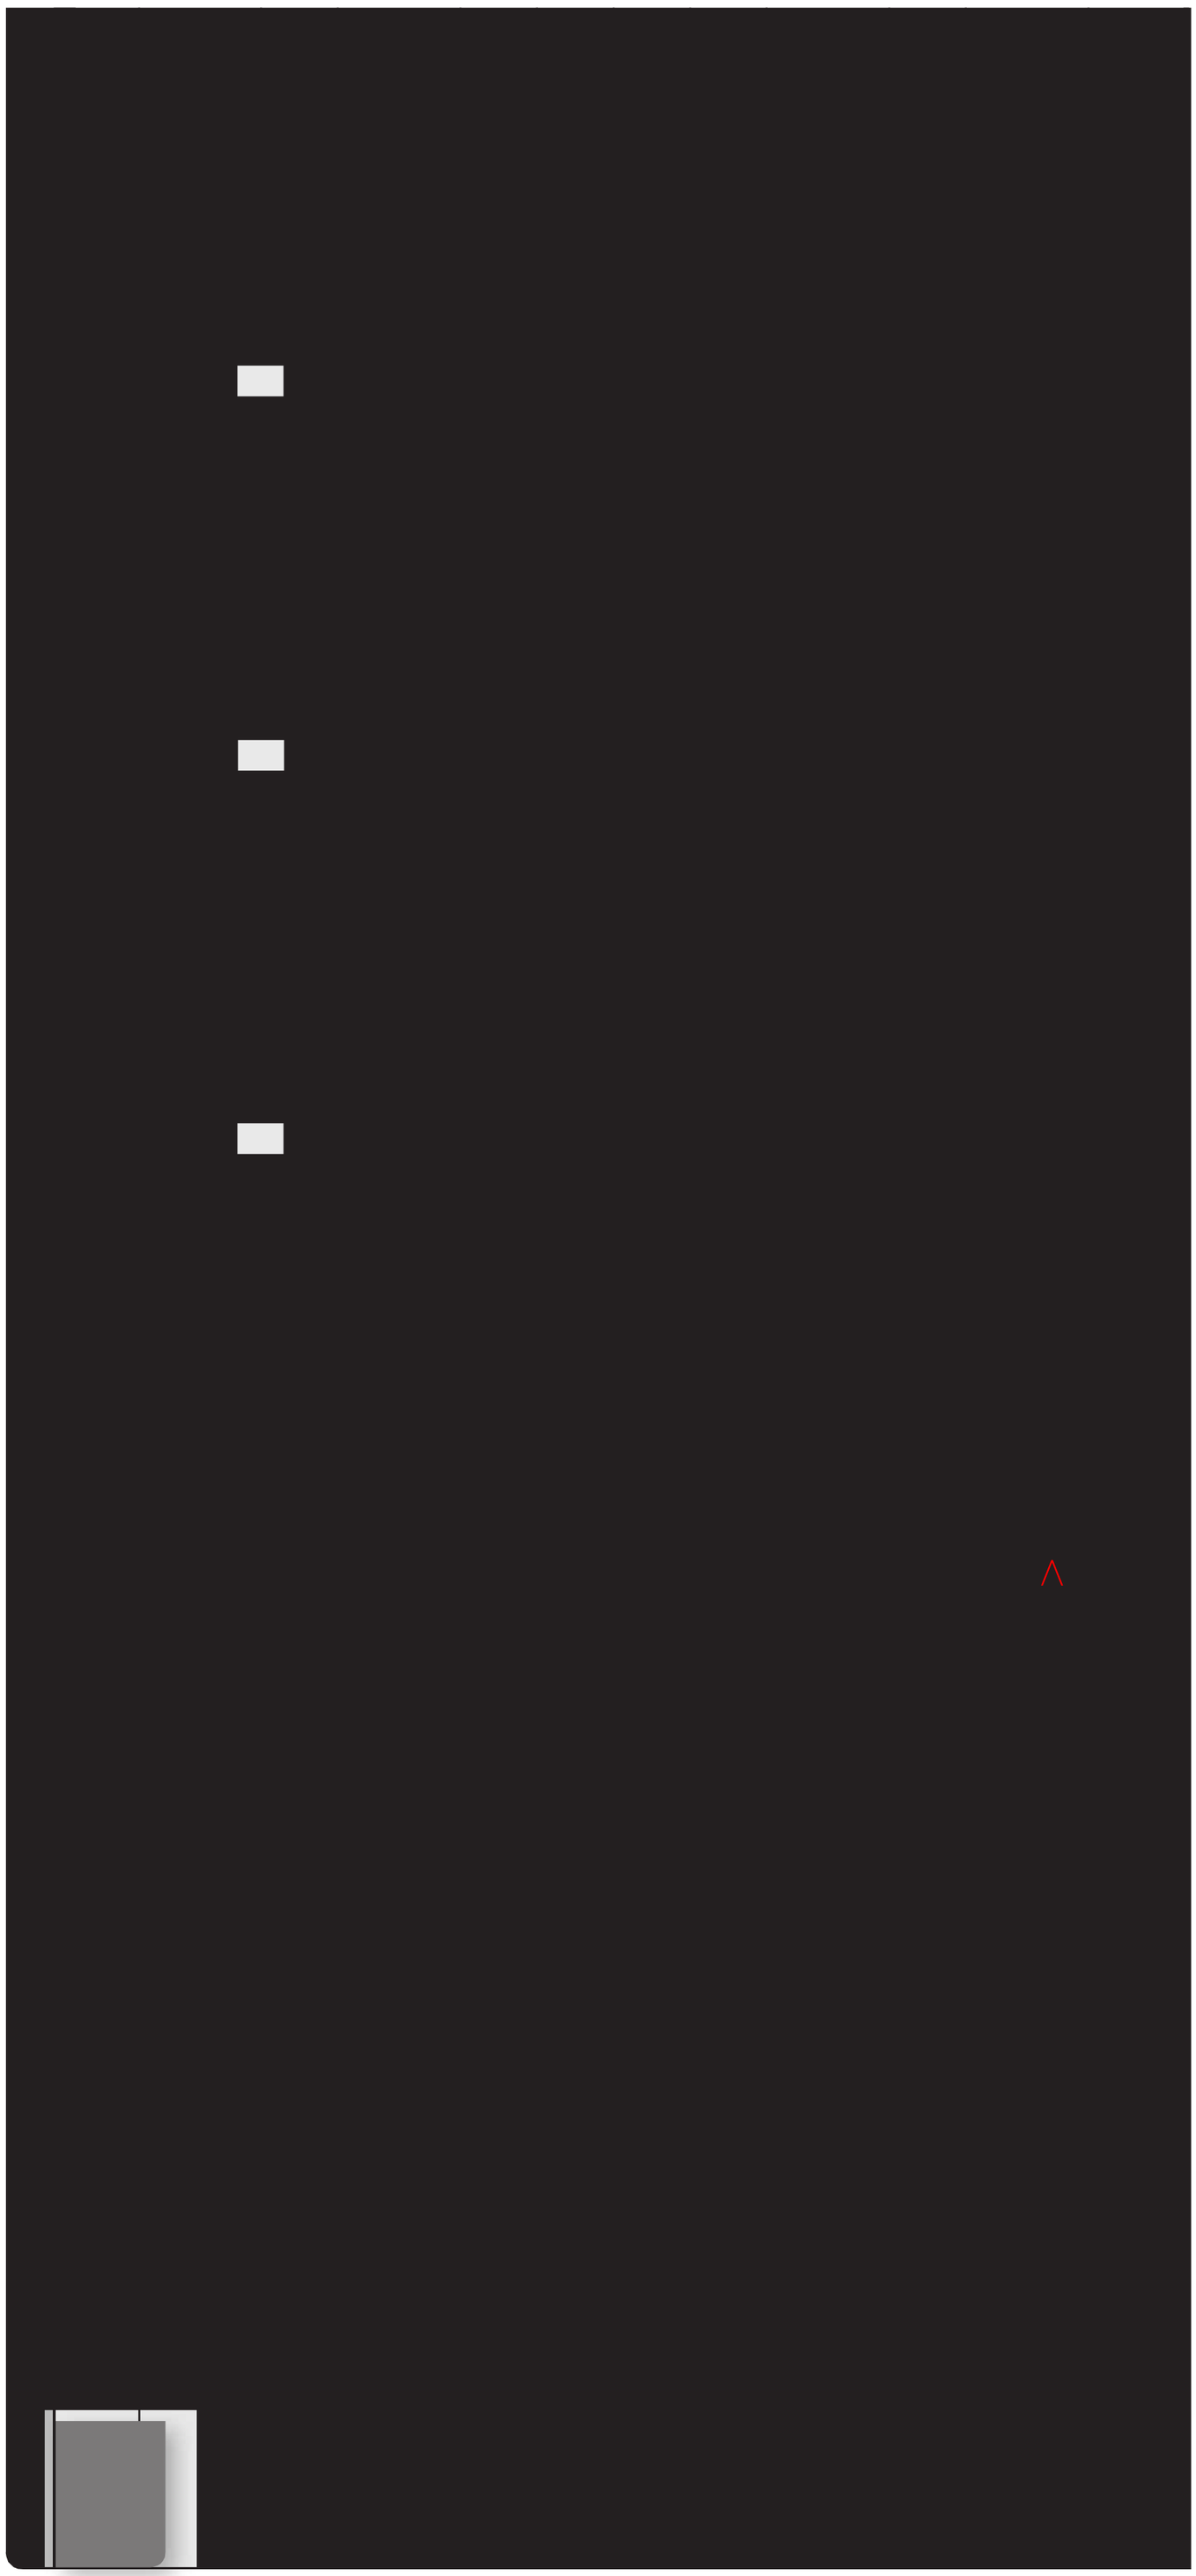
conditioning regimens, immunosuppressants, prophylactic medications, and length of follow-up. In addition, the lack of a standardized definition for AKI has been vexing to those seeking to understand the epidemiology of the disease. Two recently proposed sets of diagnostic criteria, RIFLE (risk, injury, failure, loss of kidney function, end-stage kidney disease)[35] and AKIN (Acute Kidney Injury Network),[36] have facilitated diagnostic standardization and allowed for significant advances in understanding the epidemiology and outcomes of AKI at large.[37] The definitions employed by three common classification systems for AKI following HCT are shown in Table 38.3. Although many studies of post-HCT AKI have used a variation of the classification system utilized by Parikh et al.,[38] the sensitivity of the RIFLE and AKIN criteria has recently been evaluated for diagnosis and prediction of long-term, all-cause mortality associated with post-HCT AKI.[39] AKIN identified the smallest number of patients as having AKI across all three modalities due to a reduced sensitivity for identifying the lowest category of AKI. For severe AKI, denoted as RIFLE ≥ injury, AKIN ≥ stage 2, or Parikh ≥ grade 2, all three systems performed identically. As seen in multiple other settings,[40,41] RIFLE and AKIN stages, along with those of the Parikh classification, were associated in a stepwise manner with mortality. The HCT-Comorbidity (HCT-CI) index is composed of cardiac, pulmonary, hepatic, gastrointestinal, and renal function tests that are sensitive for the detection of subclinical organ impairment and has been shown to predict nonrelapse mortality.[42,43] Both intermediate, hazard ratio (HR) 2.42, and high risk, HR 4.69, HCT-CI scores were independently associated with the development of RIFLE "I" and "F" in a combined cohort of myeloablative and RIC allogeneic recipients.[43]

INCIDENCE AND TIMING OF ACUTE KIDNEY INJURY

Myeloablative Allogeneic

Following the initial seminal study by Zager et al.,[44] AKI has been recognized as a common and devastating complication of myeloablative allogeneic HCT. In that initial cohort of 272 patients, 53% developed AKI at a median of 14 days. Numerous retrospective and prospective studies have since evaluated the incidence of AKI following myeloablative allogeneic HCT (Tables 38.4 and 38.5). Utilizing multiple definitions, AKI has been noted in 21% to 100% of patients with a weighted mean of 60%. Severe AKI occurs in a weighted mean of 40% of recipients. Although AKI following myeloablative allogeneic HCT has historically been thought to occur primarily in the first 2 to 3 weeks posttransplant, reflective of conditioning toxicity,[44,52] the median onset across all studies ranges from 15 to 60 days with a weighted mean of 30 days. The requirement for dialysis has ranged from 0% to 36%,[8,18,28,44,49,51–55,60,62,64,67,68] with some the lowest incidences[18,64] occurring more recently, perhaps reflecting refinements in conditioning and prophylactic regimens.





Befitting the discrepant patient populations, conditioning regimens, and prophylactic medications seen in these studies, myriad risk factors have been found for AKI. Conflicting results have been reported for multiple factors. Additionally, many studies have not utilized adjusted analysis, calling the true influence of postulated risk factors with potential colinearity into question. Those that have been found significant after adjustment in multiple studies include sinusoidal obstruction syndrome (SOS),[28,48,50,51,52,53,63,67,68] cyclosporine use/toxicity,[45,53,64] hyperbilirubinemia/jaundice,[46,48] amphotericin,[28,50] aGVHD,[48,51] and chronic kidney disease (CKD).[46,55] A full listing of risk factors for AKI in myeloablative allogeneic as well as autologous and RIC HCT are provided in Table 38.6.

Nonmyeloablative Allogeneic

Given the older age, poorer performance status, and increased comorbidities in those patients selected for RIC, a higher incidence of AKI than is seen with myeloablative transplant might be expected. Instead, when compared directly, RIC has consistently been associated with equal[14,43] or reduced rates of AKI.[39,63] Overall, the reported incidence is similar to myeloablative, ranging from 17% to 94% with a weighted mean of 65%. However, severe AKI is less common, occurring in a weighted mean of 30% of recipients. Reflecting this, the need for dialysis is lower and has been noted in 0% to 5% of patients.[14,25,26,29,38,39,43,58,59,63] Comparing the two modalities concurrently, myeloablative HCT was associated with an odds ratio (OR) of 4.8 for AKI.[14] Because the level of posttransplant immunosuppression and the rate of GVHD are similar between the two regimens, it appears to be the milder preconditioning regimen that reduces the incidence and severity of AKI. A gentler chemoradiation procedure alleviates both direct nephrotoxicity as well as damage indirectly caused by myeloablative associated SOS, infection, and thrombotic microangiopathy (TMA).[38] The median onset of AKI in RIC studies ranges from 17 to 60 days with a weighted mean of 46 days. This is 2 weeks later than in myeloablative, again reflecting the lesser role of conditioning toxicity in the etiology of RIC associated AKI. The onset of AKI is fairly evenly distributed over the first 3 months but subsequently tapers off significantly.[25,38] As with myeloablative allogeneic HCT, there has been little agreement between studies on independently significant risk factors for AKI following RIC HCT, with only aGVHD[25,58] noted in multiple studies.

An additional contribution to the discordant incidence and severity of AKI in MA and RIC may lie in the recipient's capacity to repair conditioning mediated tubular injury. Hematopoietic stem cells have shown the capacity to differentiate into renal tubular cells and home to the site of injury after ischemic renal insults.[69,70] It is possible such cells may contribute to the repair and regeneration of damaged tubular cells and thus mitigate AKI. Renoprotective activity of stem cell lineages has been documented in ischemically injured kidneys,[71,72] as well as with cisplatin-induced toxicity.[73,74] It is possible obliteration of endogenous stem cells in myeloablative regimens contributes to the higher observed rates of AKI.

Myeloablative Autologous

Although autologous transplants outnumber allogeneic worldwide,[6,7] comparatively few studies have investigated renal outcomes following this procedure.[29,35,40,44,58,59,61–64] The incidence of AKI after myeloablative autologous HCT is significantly lower than in either myeloablative allogeneic or RIC, ranging from 7% to 56%, with a weighted mean of 30%. Severe AKI occurs in a weighted mean of 19% of recipients. Dialysis is required following 0% to 9% of transplants.[29,35,44,58,59,61,63] Few studies have evaluated the timing of AKI onset following autologous transplantation. The lower incidence of AKI occurs despite an older patient population and the corresponding prevalence of more comorbidities.[8,9,39,67] This paradoxical outcome is due to several factors. First, autologous recipients receive comparatively mild chemoradiation conditioning regimens, thus affording protection from many conditioning associated complications. Second, autologous recipients by definition cannot suffer from acute or chronic GVHD, both of which expose the kidney to direct and indirect damage. Correspondingly, there is no need to treat autologous recipients with calcineurin inhibitors to prevent or treat GVHD and these patients are thus spared the risk of calcineurin inhibitor nephropathy (CIN). Third, associated with the milder conditioning and lack of GVHD, SOS and TMA are much less common.[13,38,75] Finally, there is more rapid engraftment without foreign cells, shortening neutropenia, lessening sepsis, and minimizing exposure to nephrotoxic antimicrobials.[64] No risk factors have been found across studies to independently associate with AKI following autologous HCT.

General Risk Factors

Chronic Kidney Disease

CKD is a well-established risk factor for AKI in the setting of potential kidney insults with nephrotoxins such as radiocontrast media[76] and aminoglycosides.[77] Surprisingly, the inverse has been found in multiple studies of HCT. Zager assessed the relationship in 3,325 patients between pretransplant eGFR and renal function at 1 year following HCT.[78] Outcomes included both "renal functional impairment," defined as a 25% reduction in eGFR from baseline, as well as absolute change. A striking inverse correlation was seen between baseline function and 25% decrease, $r = 0.92$, and absolute decrease, $r = 0.97$. The authors speculate it may be a form of acquired cytoresistance as seen in several animal models.[79–84] Although not universally noted,[55] a similar finding of elevated pretransplant GFR as a risk factor for AKI has been found in several RIC[38,58] and myeloablative allogeneic studies.[50] Although the concept of ischemic preconditioning to prevent AKI is intriguing,[85,86] some part of the effect in this setting is likely due to the utilized AKI definitions in that the

38.6 Risk Factors Independently Associated with Acute Kidney Injury Following Hematopoietic Cell Transplant

Risk Factors	MA	Autologous	RIC
SOS/liver toxicity	6 (8)[a]	1 (1)	– (0)

[a]Number of studies with statistically significant increased risk of AKI (number of studies where risk factor has been evaluated for independent association).
AKI, acute kidney injury; HCT, hematopoietic cell transplantation; MA, myeloablative allogeneic; RIC, reduced intensity conditioning allogeneic; SOS, sinusoidal obstruction syndrome, aGVHD, acute graft-versus-host disease; ICU, intensive care unit; GFR, glomerular filtration rate.

absolute change required for doubling of serum creatinine is less in patients with lower baselines, with the same following for GFR, and thus those patients with preserved baseline function require smaller changes to meet AKI criteria.

Genetics

SNPs in genes associated with the urea cycle (CPSI) and hemochromatosis (HFE) have been shown to influence susceptibility to SOS.[87–90] Additionally, donor–recipient genotype combinations in the killer immunoglobulin-like receptors (KIRs) present on NK and some T cells are important determinants of aGVHD.[91] Finally, the presence of the DD allele in the ACE gene may slow the decline in creatinine clearance in the year following HCT.[92]

Additional Markers of Kidney Injury

Despite the tremendous incidence of AKI documented in these studies, they are likely to be significantly underestimating the true occurrence of kidney injury following HCT. As is widely recognized in nephrology, serum creatinine is a poor and insensitive marker for kidney function. Due to renal functional reserve and tubular creatinine secretion, serum creatinine can remain in the normal range even when the glomerular filtration rate (GFR) has fallen to 50% of baseline. In addition to actual changes in GFR, creatinine levels are also influenced by body weight, race, age, gender, muscle mass, protein intake, and drugs. In HCT patients in particular, given the severity of their disease, it is common to see significant weight loss, loss of muscle mass, and decreased protein intake.

^{99m}Tc-DTPA was used to sequentially measure GFR in pediatric patients post-HCT.[47] GFR fell precipitously from baseline at 30 and 100 days but rebounded somewhat by 180 days. The estimated GFR utilizing creatinine was significantly higher than ^{99m}Tc-DTPA measured GFR. N-acetyl-β-D-glucosaminidase (β-NAG), a biomarker of tubular damage,[93] was significantly elevated at 30 days but returned to baseline by 180 days. Near ubiquitous early elevation in urinary α-1 microglobulin and β-NAG and a decrease in phosphate reabsorption after conditioning indicated rampant tubular damage.[28] After 2 years, although only 5% of the children had inulin measured GFR $<$90 mL/min, approximately 40% maintained elevated urinary α-1 microglobulin levels or decreased phosphate reabsorption. Based on these more sensitive markers it appears nonspecific tubular damage in the peritransplant period is ubiquitous and recovery is often incomplete, even if subclinically so.

Additional novel markers may assist in ascertaining the true incidence of injury. Cystatin C, a low molecular weight protein (13kDa) synthesized by all nucleated cells, freely crosses the glomerular filtration barrier and is almost completely reabsorbed by the cells of the proximal tubule. Cystatin C has demonstrated superior diagnostic sensitivity for the detection of AKI compared with creatinine.[94] Cystatin-C has retrospectively been assessed as a marker for post-HCT kidney dysfunction.[45] Although noting a strong inverse correlation between cystatin C and estimated GFR, the authors did not compare the ability of cystatin C and creatinine to detect AKI. A significantly higher rate of worsening of preexisting chronic kidney disease (CKD) was found during the first year post-HCT in patients with a pretransplant cystatin C level $\geq$0.90 mg per L relative to patients with levels below this cutoff.

In the context of validating the results of a urine proteomic study of novel markers predictive of clinical AKI, an AKI-specific peptide panel was assessed in 31 patients undergoing allogeneic HCT, 13 of whom developed AKI.[95] Although absolute peptide levels differed from those of patients studied in an intensive care unit (ICU) setting, the panel showed excellent discriminatory ability with an area under the receiver operating curve (AUC) of 0.90, a sensitivity of 94%, and a specificity of 82% to predict AKI as defined by a rise in serum creatinine of $\geq$50% within 48 hours.

ETIOLOGIES OF ACUTE KIDNEY INJURY

AKI seen in the context of HCT is often multifactorial and identifying a specific etiology can be challenging. Several factors unique to the transplant patient and procedure contribute to the extreme incidence and severity of AKI observed post-HCT. Various classification systems have attempted to distinguish between causes associated with early, middle, and late onset, as variably defined.[50,96–98] The most common etiologies will be discussed in chronological order, beginning at the time of induction.

Medullary Infusion Toxicity

Infusion of cryopreserved marrow or blood progenitor cells may lead to kidney injury via two mechanisms. Cell lysis products and debris associated with the freeze/thaw cycle can cause direct glomerular damage and proteinuria. Additionally, dimethyl sulfoxide, a cryopreservative primarily used in autologous cell storage, may cause hemolysis and hemoglobinuria mediated nephrotoxicity.[99–101]

Tumor Lysis Syndrome

Tumor lysis syndrome is a condition in which the rapid obliteration via radiation and chemotherapy of a high bulk of tumor cells results in a massive release of nephrotoxic debris. Renal injury is primarily mediated via hyperphosphatemia as well as urate and xanthine nephropathy. Precipitation of these products in the renal tubules leads to intratubular obstruction and AKI. Additionally, hyperuricemia has been associated with renal vasoconstriction and pro-oxidative and pro-inflammatory mediators.[102] Those at greatest risk are patients with high tumor bulk such as acute leukemias with high white cell counts and Burkitt's lymphoma.[103] Fortunately, due the fact that many patients are in remission at the time of therapy and are treated appropriately with

prophylactic intravenous fluids, urinary alkalinization, and allopurinol, the incidence of tumor lysis syndrome following HCT is rather low (approximately one in 400).[101]

Sepsis

Patients undergoing HCT are at tremendous risk for bacterial and fungal infection and resulting sepsis due to the profound neutropenia engendered by induction chemotherapy and radiation, which is then compounded by the use of immunosuppressants to prevent aGVHD. The inflammatory response to disseminated infection leads to systemic arterial vasodilatation and capillary leak, precipitating hypotension and renal hypoperfusion with resultant pre-renal azotemia and acute tubular necrosis. This hypoperfusion can be potentiated by vomiting and diarrhea associated with the intense conditioning regimens. However, even in the absence of hypotension, sepsis may provoke AKI via cytokine and chemokine mediated renal vasoconstriction and direct intrarenal inflammatory and complement associated kidney injury.[104] Additionally, the antimicrobials used in the prevention and treatment of sepsis are often nephrotoxic (see later).

Nephrotoxic Medications

Many of the chemotherapy agents used for induction have the potential to be nephrotoxic including carboplatin, vincristine, melphalan, busulfan, etoposide, carmustine, cytarabine, and cyclophosphamide.[100,105–107] The nephrotoxicity of antineoplastic medications is treated in depth elsewhere in this text. Amphotericin B is utilized for patients at risk for or with evidence of aspergillus infection and is a well-recognized nephrotoxin. Though liposomal amphotericin has generally been associated with lessened nephrotoxicity,[108] studies show both preparations confer an equal increase in risk of AKI following HCT.[28,50] The use of aminoglycosides has declined with the advent of alternative broad spectrum antibiotics but when utilized still carry a marked potential for nephrotoxicity. Additional medications found to associate with AKI following HCT include vancomycin[33,43] and methotrexate.[25] Given the potential nephrotoxicity of calcineurin inhibitors (see later), sirolimus has been investigated for GVHD prophylaxis. Although there is no data on monotherapy, sirolimus has been shown to potentiate the risk of TMA (OR 2.79)[109] and SOS (OR 2.76)[27] when used with calcineurin inhibitors without affecting mortality. The risk of SOS was even higher when sirolimus was used in conjuncture with busulfan.

Calcineurin Inhibitors

Calcineurin inhibitors (cyclosporine [CSA] and tacrolimus) are routinely used as immunosuppressants to prevent GVHD. In myeloablative allogeneic transplant patients, they are frequently combined with methotrexate or mycophenolate mofetil while they are used with steroids in non-myeloablative transplantation. Calcineurin inhibitors are well-known nephrotoxins, inducing potent renal vasoconstriction, direct endothelial injury, and provoking thrombotic microangiopathy. Toxicity has been thought to correlate well with serum drug concentration.[110] Although the expected association was seen between CSA exposure and AKI in several older studies,[19,20,111] the majority of recent studies have failed to replicate this finding.[25,38,44,49,50,58,112] There does not appear to be any difference in the incidence of AKI utilizing cyclosporine versus tacrolimus.[54] In two studies where the etiology of AKI was chart adjudicated, elevated CSA levels were associated with AKI in 67% of all patients[28] and 100% of patients with grade 2 AKI.[38] However, despite this clinical association and the biologic plausibility of causation, CSA levels were not found in either study to be independent risk factors for AKI on multivariable analysis.

This discordance between statistical analysis and chart reviewed diagnosis may be due to variability of levels and troughs within a given patient and the transient effect of CSA on short-term renal function. Additionally, targeted CSA therapeutic ranges vary significantly across studies (see Table 38.4) and, in analyzing CSA as a risk factor, it has sometimes been treated as a continuous variable based on levels and sometimes categorical regarding its use or the surpassing of the designated toxic threshold. Renal dysfunction may also lag peak concentration.[67] Finally, CSA toxicity can occur despite low or normal serum concentrations and thus may be complicated by a patient's genetic susceptibility. Woodhahl et al. investigated four single nucleotide polymorphisms (SNPs) in genes regulating cyclosporine metabolism and transport which may affect tubular intracellular drug levels in 121 patients following myeloablative transplant.[113] Although no findings reached statistical significance, there was a trend toward a higher OR for AKI with SNPs in ABCB1, encoding the transporter P-glycoprotein.

Sinusoidal Obstruction Syndrome

SOS, formerly known as hepatic veno-occlusive disease, is initiated by chemoradiation-induced injury to sinusoidal epithelial cells. Damage to these cells leads to activation of stellate cells and deposition of extracellular matrix in sinusoids and zone 3 hepatocytes with resulting thrombosis and necrosis. Subsequent portal hypertension stimulates a shift in fluid from the intravascular to extravascular space, increased activation of the renal-angiotensin-aldosterone system, sodium and water retention, ascites formation, and ultimately AKI in a presentation similar to hepatorenal syndrome.[75] However, patients with SOS and AKI have also been found to have higher β-NAG, α-1 microglobulin, and albumin excretion than those without AKI, implying there is a component of tubular and perhaps glomerular injury as well.[100] Signs and symptoms include hepatomegaly, right upper quadrant pain, ascites, weight gain, and increased serum aminotransferase and bilirubin levels.[114] SOS is only rarely seen with RIC[14] and is less common in autologous than allogeneic transplants.[62] In myeloablative regimens, the development of SOS is strongly associated with post-HCT AKI,[14,44,52,68] with an incidence of 0% to 60%,[8,30,114] and

increases with AKI severity. Ileri et al. documented SOS in 6% of pediatric recipients without AKI, 8% with grade 1, 22% with grade 2, and 100% with grade 3.[28]

Risk factors for the development of SOS include age, preexisting hepatic disease, hepatitis C, TBI, CMV seropositivity, and multiple medications including cyclophosphamide, busulfan, vancomycin, amphotericin B, acyclovir, and methotrexate.[64,114,115] Although the exact contribution of individual medications can be difficult to untangle in overlapping regimens, cyclophosphamide in particular is thought to directly contribute to liver injury.[116] Using personalized dosing based on measurement of carboxyethylphosphoramide mustard, a metabolite that functions as a reporter molecule for hepatotoxins from cyclophosphamide, and utilizing Bayesian parameter estimates, patients that received reduced cyclophosphamide had lower bilirubin levels, and suffered less AKI, 62% vs 77% ($P = .03$), than those receiving conventional dosing.[117]

HCT Associated Thrombotic Microangiopathy

Thrombotic microangiopathies (TMA) are characterized by systemic or intrarenal platelet aggregation, thrombocytopenia, and microvascular fragmentation of erythrocytes. Diagnostic evaluation divulges schistocytes on peripheral smear and increased serum lactate dehydrogenase (LDH). In the archetypal TMA, thrombotic thrombocytopenia purpura (TTP), abnormalities in ADAMTS-13 von Willebrand factor cleaving protease activity have been associated with inherited and acquired disease. Decreased ADAMTS-13 activity results in a preponderance of large multimers of von Willebrand factor and subsequent platelet aggregation.[118] However, ADAMTS-13 deficiency is not involved in the pathophysiology of HCT associated TMA.[119–123] Additionally, autopsy studies have demonstrated post-HCT TMA to be primarily renally dominant, similar to hemolytic uremic syndrome rather than TTP.[119,124] Correspondingly, the neurologic features of TTP are typically absent.[124]

The inciting event in post-HCT TMA is endothelial damage initiated by the conditioning regimen, particularly TBI and busulfan.[121,125] The initial injury is potentiated by infections, lipopolysaccharides, calcineurin inhibitors, sirolimus, and aGVHD.[122,126,127] GVHD may mediate endothelial damage in the kidney via circulating inflammatory cytokines related to systemic disease or may inflict direct injury to endothelial cells in the kidney due to localized activated donor cells.[128] This kidney specific GVHD may also be associated with reduced VEGF function.[128–130] Owing to this damage, a loss of endothelial resistance to thrombus formation, subsequent leukocyte adhesion, and an increased vascular shear stress ensue and augment the injury. In addition to AKI, patients often present with anemia, thrombocytopenia, hypertension (HTN), edema, proteinuria, and hematuria. Disease onset typically is within 100 days of HCT. The clinical spectrum of kidney disease in HCT patients with TMA ranges from an indolent course resulting in CKD to a fulminant presentation with AKI and death.[128] Different forms of overlapping thrombotic microangiopathic syndromes have been described. Patients with TMA after HCT have thus been diagnosed with HCT nephropathy, radiation nephropathy, hemolytic uremia syndrome, TTP, or transplant associated microangiopathy.[127] Making a confident diagnosis is challenging because anemia, thrombocytopenia, and elevations in LDH and creatinine are common post-HCT due to delayed engraftment, fungal and viral infections, medications, and GVHD.[121,131] Biopsy is often contraindicated due to patient instability and thrombocytopenia. Confounding the confusion, no fewer than 28 different sets of diagnostic criteria have been proposed in 35 articles detailing post-HCT TMA.[124] Two distinct consensus definitions have also been set forth.[120,131]

Not surprisingly, the estimated incidence of TMA in the setting of HCT varies widely from 0.5% to 76%[34,122,128] with the alleged mortality ranging from 0% to 100%. Changsirikulcai et al. retrospectively analyzed autopsy samples from 322 patients who had died a median of 43 days posttransplant; 41% had suffered AKI within 2 weeks preceding their deaths.[128] On biopsy, 20% met criteria for TMA whereas an additional 15% had a singular glomerular or vascular thrombus. There was no statistically significant difference in serologic abnormalities (hematocrit, platelets, LDH, elevated creatinine) between patients with these findings and those with negative biopsies. Histologic evidence of TMA in the kidney did not correlate with the laboratory evidence of AKI in the 2 weeks prior to death. On chart review, a clinical diagnosis or suspicion of TMA correlated with histologic evidence of TMA in 35.5% of the positive samples versus 4.5% of the negative ($P < .001$). Other studies have shown mixed results in the correlation between TMA as diagnosed by clinical criteria and histologic findings on autopsy.[99,119,124] An extensive litany of risk factors for post-HCT TMA have been described including advanced age, female sex, female recipient–male donor, unrelated donor, HLA-mismatch, T-cell depletion, high intensity conditioning regimens, high dose busulfan, fludarabine, TBI, sirolimus, calcineurin inhibitors, sirolimus with calcineurin inhibitors, aGVHD, methylprednisolone therapy, adenovirus, fungal or viral infection, and SOS.[38,109,128,132–137]

Treatment options for post-HCT TMA, outside of withdrawing any identifiable inciting agents, are scarce. Indeed a review article found that any attempt at treatment led to increased mortality as opposed to no treatment at all, although this finding may suffer confounding by indication.[121] Although plasma exchange, a staple of treatment in ADAMTS-13 associated TMA, has been reported to be effective in rare instances,[138,139] the majority of studies have seen little or no benefit.[124,131,140–143] Rituximab, an anti-CD20 monoclonal antibody, showed promise in a small series treating post-HCT TMA which had failed plasma exchange.[144] In patients who have developed GVHD and TMA, withdrawal of calcineurin inhibitors and treatment with daclizumab, a humanized anti-CD25 antibody, have shown promise in the treatment of TMA but poor response in terms of complete remission of

GVHD.[126] Defibrotide, a polydeoxyribonucleotide salt, protects against endothelial damage by inhibiting tumor necrosis factor (TNF)-α mediated endothelial cell apoptosis and exhibits profibrinolytic, antithrombotic, and anti-inflammatory activity.[122] It has been used in treating SOS associated with HCT and with some success in small studies in TMA.[145]

Graft-versus-Host Disease

GVHD has classically been thought not to involve the kidney. aGVHD develops in 50% to 60%[146] of sibling-matched allografts and cGVHD involves 30% to 60%.[147] Any association between GVHD and AKI in these patients has been attributed to volume depletion due to gastrointestinal tract involvement with diarrhea and an increased need of nephrotoxic drugs for GVHD treatment. Recent evidence, however, suggests that GVHD may affect the kidney directly. aGVHD has been found an independent risk factor for post-HCT AKI in multiple studies.[25,48,58,63] Such toxicity may be due to cytokine mediated inflammatory injury, glomerular deposits leading to nephrotic syndrome (see later), and tubulitis secondary to activated cytotoxic T cells. Documentation of severe renal infiltration by cytotoxic T cells during GVHD has been documented in mice,[148] but confirmation of the role of GVHD in human AKI awaits further study.

Biopsy Data for Etiologies

Biopsies are rarely performed in patients with AKI following HCT due to thrombocytopenia, hemodynamic instability, and infection. Several series have been performed, often retrospectively, in patients with AKI or worsening CKD months to years out from transplant.[149–153] Among frequently overlapping pathology, findings consistent with TMA, polyoma virus nephropathy, ATN, interstitial nephritis, tubulointerstitial scarring, and podocytopathy are commonly found. El-Seisi et al. performed an autopsy study of 26 patients who had died a median 3 months after transplant; 15 had AKI.[99] Global segmental sclerosis, tubular epithelial atypia, tubular calcification, mild tubulitis, interstitial fibrosis, and thrombotic microangiopathy were all common. Despite the expected renal insults common in hospital-based death, very little classical ATN was noted. No association was seen between clinical SOS and histology consistent with TMA. Interestingly, only 1/12 patients with TMA on biopsy had clinical evidence of the disease on retrospective chart review. In assessing the generalizability of these findings to all AKI post-HCT, the study suffers from selection bias in that patients would have been much less likely to be autopsied if they died of disease relapse or at home.

PROGNOSIS

Mortality

Nonrelapse mortality after HCT occurs primarily due to complications of the HCT procedure, with AKI being one of the most prominent. The pathway linking HCT associated

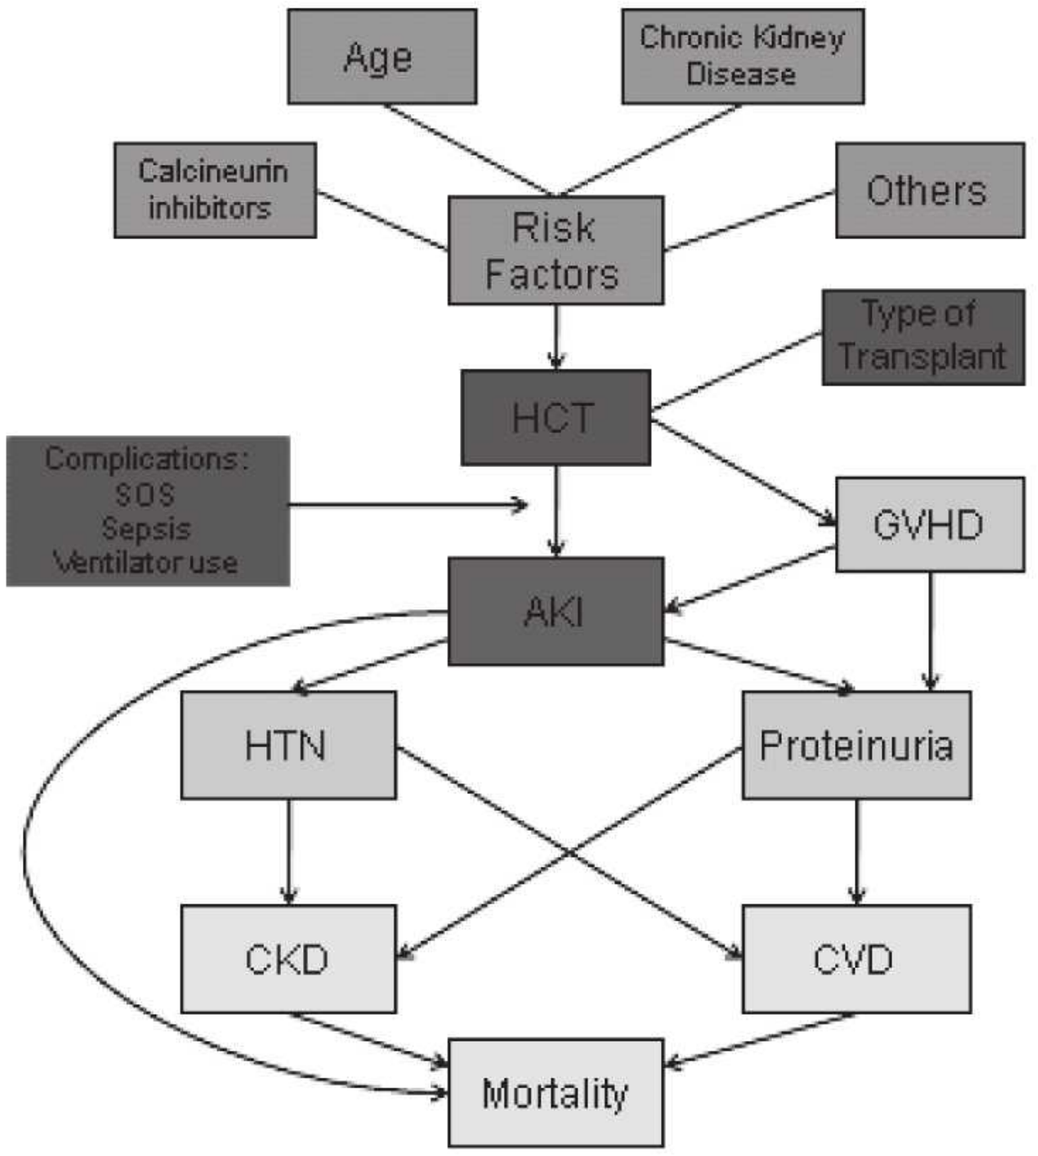

FIGURE 38.1 Mechanisms and outcomes of hematopoietic cell transplant associated acute kidney injury. AKI, acute kidney injury; CKD, chronic kidney disease; CVD, cardiovascular disease; GVHD, graft-versus host disease; HCT, hematopoietic cell transplant; HTN, hypertension; SOS, sinusoidal obstruction syndrome.

AKI with mortality and other long-term outcomes is shown in Figure 38.1. AKI can cause mortality directly via consequences of compromised renal function including metabolic acidosis, cardiac dysrhythmias, HTN, electrolyte imbalances, gastrointestinal dysfunction, and hemorrhage.[154] AKI can also contribute to dysfunction in other organ systems such as lung and liver via volume overload and confers an increased risk of sepsis due to altered leukocyte function.[154–156] Additionally, cytokine or immune-mediated injury may be culpable for the dysfunction in distant organs seen with AKI.[157] Finally, AKI interferes with adequate dosing of immunosuppressants and may predispose to GVHD and rejection while complicating their treatment.[158]

Across modalities, AKI following HCT has consistently been linked with an increased risk of death on both short- and long-term follow-up. Overall mortality following AKI has been found to range from 4% to 61%.[34,64] In one of the earliest studies involving myeloablative allogeneic transplant, Zager et al. found an index hospitalization mortality of 17% in those without AKI, 37% in non–dialysis-requiring AKI, and a whopping 84% in dialysis-requiring AKI.[44] AKI has since been found to confer a significant independent risk for mortality in myeloablative allogeneic,[14,33,49,50,52,67] myeloablative autologous,[67,114] and RIC[25,28,38] transplants. The strength of this association has consistently been found to be dose dependent and contingent on the severity of the

AKI as well as the length of follow-up.[14,25,43,52,58,59,66,67,112,159] Increased mortality has been found at 100 days,[28,52,67] 6 months,[46,49] 1 year,[25,38] and 5 years.[26] Patients with AKI have significantly decreased 1-, 2-, and 3-year survival when stratified by AKIN stage.[66] Utilizing the Parikh scale, Yu et al. found 29% mortality without AKI, 57% with Grade 1. and 79% with Grade 2-3.[63] In a prospective study evaluating the RIFLE, AKIN, and Parikh diagnostic criteria in 249 patients receiving a mixture of myeloablative allogeneic, RIC, and myeloablative autologous transplants, the mortality rates at 1,000 days for patients with AKI were approximately 54% in myeloablative allogeneic, 48% to 50% in RIC, and 11% to 20% in autologous recipients.[39] The variance in mortality rates may be due to the previously noted different etiologies of AKI in these three modalities. A very significant stepwise increase in mortality hazard ratio was seen in all three classification systems. On multivariable analysis, RIFLE "I" and "F" were associated with overall nonrelapse mortality, HR 2.1 ($P = .01$) and 6.15 ($P < .01$). Finally, a meta-analysis of over 1,200 patients receiving a myeloablative allogeneic transplant revealed a doubling of the relative risk of death 6 months after AKI.[86] The adjusted odds of 6-month mortality were elevated nearly sevenfold. The outlook for patients requiring dialysis is especially grim, with mortality ranging from 75% to 100%.[10,25,38,43,44,49,51,54,58,60,62,68,112]

Significantly, AKI is an independent predictor of overall and nonrelapse 5-year mortality even in RIFLE stage "R," demonstrating that small changes in creatinine may be associated with long-term mortality.[26] Such a connection between mild AKI and mortality has also been demonstrated in cardiac surgery, acute myocardial infarction (MI), and the critically ill.[160–163]

AKI has been postulated to drive mortality by means of instigating HTN, CKD, and increased cardiovascular disease. Specific to HCT, AKI interferes with dosing of immunosuppressive medications, including calcineurin inhibitors, and may thus contribute to the development of cGVHD and resultant mortality.[155] The extent to which the association between AKI and long-term mortality is causal remains unknown.[164] Although it plausibly could be a direct mediator through the above mechanisms, AKI may associate with mortality merely as a surrogate for unappreciated or inadequately adjusted comorbidities. Additionally, many of the causes of AKI, including SOS, infection, and GVHD, independently lead to mortality.[97] In one study where AKI had a marked dose response association with mortality, correcting for aGVHD, SOS, TMA, and ICU admission abrogated the association.[49] However, another study showed AKI continuing to confer a robust OR of 6.8 for mortality even on a model adjusted for comorbidities and complications.[112]

Chronic Kidney Disease

The increased incidence of CKD following AKI has been well established.[162–165] The first report of CKD following HCT was in 1978.[166] Since then, estimates of the incidence of CKD in survivors of AKI have ranged from 3.6% to 89%.[153] The marked discrepancy in these estimates is due to variation in the definition of CKD, changes in conditioning regimens and posttransplant prophylactic and therapeutic medications, as well as evolving patient populations. Additionally, autologous, conventional allogeneic, and RIC transplants all confer different risks for AKI and their proportional representation among cohorts will influence the observed CKD rate. AKI following HCT has been identified as an independent risk factor in the development of CKD in multiple studies.[45,50,53,153,167,168] Indeed, in some pediatric populations, AKI has been identified as the only consistently significant risk factor for post-HCT CKD.[53,55] A systematic review by Ellis et al. identified 28 studies containing 5,337 patients who survived at least 100 days following HCT and who were evaluated for CKD.[169] With significant heterogeneity in definitions, 16.6% of all patients were reported to have developed CKD with 0.8% progressing to end-stage renal disease (ESRD). AKI following HCT was assessed as a risk factor for the development of CKD in four studies involving 2,038 patients. The cumulative OR for CKD after AKI was found to be 2.57. Worldwide, 5,100 post-HCT patients develop CKD annually whereas 300 progress to ESRD.[170] Survival in patients with HCT associated ESRD may be worse than in the general ESRD population.[171]

On systematic review, the incidence of CKD following allogeneic and autologous transplants is similar.[169] In addition to AKI, multiple risk factors for post-HCT CKD have been identified, although inconsistently, including age, prior transplant, aGVHD, cGVHD, calcineurin use >60 days, baseline GFR, microalbuminuria, multiple myeloma, and female gender.[31,32,153,167,169] Although TBI has often been found to be weakly, if at all, associated with CKD,[32,167,172,173] other studies have found a strong and indeed preeminent association.[169,174,175]

Post-HCT CKD can be secondary to glomerular (see later) or interstitial and vascular disease. Although many cases of interstitial CKD are readily attributable to TMA (often associated with TBI), from 17.5% in myeloablative to 66% in nonmyeloablative recipients have idiopathic disease.[32] This CKD is multifactorial but it seems likely that AKI plays a prominent role in its development. In a retrospective study of 123 patients receiving allogeneic transplants, CKD developed in 40% within 24 months.[167] The occurrence of AKI post-HCT conferred an OR of 4.54. Additional risk factors included age and baseline GFR <90 mL per minute. Patients who would and would not go on to develop CKD had a near identical drop in GFR at 3 months (28 vs. 26). However, by 24 months, GFR had dropped further to −36 mL per minute from baseline in CKD patients but rebounded to −17 mL per minute in those not destined for CKD. Only 3% of recipients developed CKD subsequent to 24 months. It may be that much of this "early" CKD is secondary to progression of AKI in patients with lower baseline GFR and less renal functional

reserve.[168] Indeed, nonrecovery of GFR by 100 days post-HCT has been documented even in mild AKI.[62]

Proteinuria

On systematic review, the rate of proteinuria following HCT is 7.8%[169] but was rarely reported. Thought to be a marker of endothelial dysfunction and inflammation, proteinuria post-HCT may reflect systemic endothelial injury. As such, proteinuria is intricately associated with SOS and GVHD. Hingorani et al. prospectively followed 142 patients receiving myeloablative allogeneic, RIC and autologous transplants.[31] Microalbuminuria was present in 37% at baseline and 64% at day 100, with an overall prevalence of 94% in the first 100 days post-HCT. Overt proteinuria was seen in 4% at baseline and in 15% by day 100. Mean proteinuria peaked at 35 days and declined at 100 days and again by 1 year. The development of SOS was associated with a markedly higher level of albuminuria in the first week post-HCT. Median albuminuria was significantly higher in allogeneic recipients than autologous at 35 and 100 days. Interestingly, albuminuria was not associated with the development of AKI but was, as a time-varying term, a risk factor for the development of aGVHD. On multivariable analysis, overt proteinuria at 100 days conferred an HR 2.4 for overall mortality and 6.8 for nonrelapse mortality.

The presence of albuminuria prior to the clinical presentation of aGVHD suggests it as an early marker of systemic and renal inflammation and endothelial damage. It also implies the kidney as a target of aGVHD. Such targeting is also insinuated by the association between SOS, strongly associated with aGVHD, and proteinuria. Both membranous nephropathy and minimal-change disease post-HCT are thought to be renal manifestations of GVHD. In minimal change, the lack of infiltrates on biopsy and the increased production of tumor necrosis factor-α and interferon-γ suggest cytokine mediated glomerular injury in response to extrarenal alloantigens.[176] In contrast, in membranous nephropathy, subepithelial immune complex deposition is present along the basement membrane, consisting of antigen-antibody complexes that resemble GVHD. GVHD may thus cause proteinuria via both inflammation and direct glomerular and tubular injury. The near universal incidence of microalbuminuria see by Hingorani and others[57] may thus suggest ubiquitous subclinical immune mediated kidney injury in HCT despite the observation that only 30% of patients in this study met clinical diagnostic criteria for AKI.

Frank nephrotic syndrome is rare after HCT, with an incidence of 0.4% to 0.8%.[96,177] The most common etiology, membranous nephropathy (MN), was first reported in 1989,[178] and has been documented in nearly 60 cases.[151] Although the antigenic target has yet to be elucidated, MN following HCT is intimately associated with cGVHD. Much like chronic allograft nephropathy, cGVHD is increasingly recognized to feature a role for B cells and antibodies in its pathophysiology, altering the classically understood T-cell centric paradigm.[45] Additional glomerulopathies reported after HCT include MCD, focal segmental glomerular sclerosis, membranoproliferative glomerulonephritis, diffuse proliferative glomerulonephritis, antineutrophil cytoplasmic antibody (ANCA)-associated GN, and IgA nephropathy.[151,179–186] Case reports suggest nephrotic syndrome associated with post-HCT MN may be responsive to treatment with angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs).[187]

Hypertension

HTN is an integral component of the classically described transplant nephropathy. Few prospective studies have evaluated the incidence of new-onset HTN following HCT. Hoffmeister et al. followed 689 pediatric patients receiving a mixture of myeloablative allogeneic, RIC, and autologous transplants.[188] Seventeen percent of recipients developed new-onset HTN during a median follow-up of 16 years. In those who experienced AKI within 100 days of transplant, HTN developed in 22% versus 14% in those without AKI. On multivariable analysis, the hazard ratio for HTN given post-HCT AKI was 2.53 ($P < .0001$). Additional risk factors for the development of HTN were high dose TBI, autologous transplant, and time-dependent obesity, diabetes, and growth hormone usage. Overall rates of HTN on follow-up were found to be two to three times higher than the age appropriate population prevalence. In 73 autologous recipients, 72% developed new-onset or worsening of prevalent HTN at 1 year post-HCT. HTN rates were higher in those patients that had developed CKD. Although HTN was also associated with calcineurin inhibitor use, elevated blood pressure persisted in 64% of hypertensive patients 6 months after stopping calcineurin inhibitors.[153] A systematic review showed HTN developing in 108/873 (12.4%) patients across modalities but was unable to assess risk factors or the time frame of HTN onset in HCT recipients.[169]

Conclusion

AKI is remarkably prevalent following all modalities of HCT and is independently associated with mortality. The etiology is multifactorial and varies by conditioning regimen. Although the incidence of AKI has fallen over the past two decades,[12] it remains one of the most common and devastating complications of HCT. Given the data on biomarkers for tubular damage, it is likely that the incidence of subclinical injury following HCT far outstrips even the remarkable rates noted in studies to date. With the survival rate following HCT improving, the importance of the long-term effects associated with peritransplant complications such as AKI will become increasingly preeminent. The relationship between even mild AKI and both CKD and mortality is now well established.[189] It is possible that strategies to minimize AKI post-HCT, while improving short-term outcomes, may also mitigate the subsequent incidence of these devastating long-term sequelae.

ACUTE KIDNEY INJURY FOLLOWING SEVERE BURNS

In the United States, approximately 45,000 people are hospitalized annually for burn injuries.[190,191] The prognosis for these patients depends substantially on the extent of their burns. Although burn patients are increasingly receiving specialized care in dedicated burn units, their hospitalizations continue to be associated with significant complications resulting in a mean length of stay of 9 days and mean hospital costs of $60,000. One of the most devastating of these complications is AKI. Indeed, it was not until 1965 that a patient was reported to survive the combined insults of a severe burn and AKI.[192] As seen in general critical care, AKI following burns is often the heralding sign of impending multiorgan failure. The impact of severe AKI requiring renal replacement therapy (RRT) on postburn outcomes has long been recognized but only recently has the significant sequelae of milder disease been appreciated. Over the past 20 years, survival rates following severe burns have improved modestly associated with evolving critical care techniques and burn specific therapeutic protocols,[193,194] but the diagnosis of AKI complicating a severe burn continues to portend a grim prognosis. For the purposes of this review, severe burns will be understood to involve at least 10% of total body surface area (TBSA), with more stringent requirements present as noted.

Epidemiology and Risk Factors

Estimates of the incidence of AKI following severe burns vary widely. A portion of this variance can be attributed to differences amongst the literature in what constitutes a "severe" burn and to heterogeneous patient populations, types of burns, and ranges of TBSA percentage burns included in different studies. However, the primary source of the discordant findings in the epidemiology of AKI following burns has been the lack of a standardized definition for AKI. A recent systematic review identified 57 pediatric and adult studies providing data on the prevalence and mortality of AKI in patients with severe burn injuries, 9 of which were prospective.[195] An astounding 23 different definitions of AKI were used, illustrating the difficulty in comparing results across the literature. Definitions were founded on fixed serum creatinine cutoffs, relative increases in creatinine, urine output, blood urea nitrogen (BUN) levels, and need for RRT.

In this review, a total of 34,868 patients were evaluated across studies. In those studies permitting assessment of AKI prevalence, 1,872/34,771 (5.4%) patients developed AKI. The prevalence of AKI varied considerably and ranged from 0.2% to 64%. Unsurprisingly, AKI rates are highly contingent on diagnostic criteria, ranging from 34.9% in those studies utilizing a fixed serum creatinine cutoff to 3.5% in those identifying AKI based on urine output. When employing the sensitive RIFLE criteria, AKI was seen in 608/2,111 (30.9%) of patients versus 334/9,443 (17%) where AKI was more stringently defined by a requirement for RRT. It is likely that even those studies utilizing a definition involving relative changes in serum creatinine, such as the RIFLE system, may actually underestimate the true prevalence of AKI. Major burn patients are often initially resuscitated at an outside hospital prior to transferring to a specialized burn center and patients' initial presenting creatinine may thus already be elevated from their true baseline. Overall, the median prevalence was noted to be 14.5%, which is lower than that seen in ICU populations at large.[196,197] This discrepancy may be due to burn patients often being younger and with fewer comorbidities than are present in the general ICU population.

Across studies, RRT was performed in 30% of AKI patients or 3% of the total population with burn injuries.[195] This is slightly less than seen in studies of general ICU populations. This lower utilization of RRT may again reflect younger, healthier patients who are better able to withstand AKI without progressing to a requirement for RRT. However, the mortality of burn patients on RRT (see below) is worse than even the dreadful rates of 50% to 70% witnessed in general ICUs,[196–199] indicating the extreme severity of these patients' critical illness. It is thus possible that lower prevalence of RRT use in burn patients may alternatively be related to withholding of treatment for perceived therapeutic futility. Finally, difficulties in obtaining access or concerns of possible catheter associated infection may induce a reluctance to initiate RRT in patients with severe burns.

Utilizing a Pearson correlation test, Brusselaers et al. found the prevalence of AKI has increased over time ($r = 0.31$; $P = .02$) but the prevalence of AKI requiring RRT has declined ($r = 0.36$; $P = .05$).[195] This discrepancy can be explained by changes in the sensitivity and specificity of AKI definitions concurrent with improvements in critical care techniques and protocols for the treatment of burn victims.

The primary risk factor for the development of AKI following a severe burn is the size of the burn itself, as expressed in TBSA percentage.[200–204] Greater burn size predisposes to greater fluid and albumin loss as well as increasing the likelihood of infection. The incidence of AKI begins to increase with burns of >10% TBSA.[200] AKI is associated with burn size in a dose-dependent manner, with each 10% increase conferring an increased risk of death up until approximately 60%, when mortality levels off, albeit at a level of close to 50%.[200] A burn size of >65% of TBSA is associated with RR for AKI of 9.9 compared to <65% on multivariable analysis.[203]

Additional risk factors noted in the literature include sepsis,[190,202,204,205] inhalation injury (IHI),[190,200,204] age,[201,205,206,207] overall severity of critical illness or multiorgan dysfunction (acute physiology and chronic health evaluation II [APACHE II], pediatric risk of mortality [PRISMA]),[204,206–208] catheter infections,[190] adequacy of preadmission fluid resuscitation,[205] percentage of full thickness burns (FTB),[201] and admission thrombocytopenia and elevated bilirubin.[201] Interestingly, whereas Steinvall et al. noted age, TBSA percentage, and extent of FTB to be associated with

the development of AKI, these factors did not correspond to severity by RIFLE stages.[201]

ETIOLOGIES

Early Acute Kidney Injury

Renal Hypoperfusion

AKI associated with burns is bimodal, occurring either within the first 7 days after injury or during the second to third week. Causes of AKI in these early and later periods are listed in Table 38.7. Burns lead to an intense inflammatory response and release of vasoactive agents, increasing capillary permeability to fluid and albumin.[209] Albumin exhibits a significant leak within 6 to 18 hours postburn.[210] As compared to other critically ill patients, burn victims experience inflammation of a greater intensity and significantly longer duration.[211] The resulting loss of oncotic pressure is compounded by a decrease in albumin synthesis after severe burns.[212] As a result, fluid is shifted from the intravascular to extravascular space. Additionally, compromise of the barrier integrity of the skin engenders massive insensible fluid losses. The resulting intravascular hypovolemia and subsequent renal hypoperfusion are the primary cause of early AKI. Severe burns with extensive tissue destruction also decrease cardiac inotropism via endotoxin mediated apoptosis[213] while simultaneously elevating local and systemic stress-related hormones such as catecholamines, angiotensin II, aldosterone, and vasopressin with resulting systemic and renal vasoconstriction, a condition known as burn shock.[200,202,203,214–216]

These physiologic responses to a severe burn occur within hours and thus compel rapid and aggressive fluid resuscitation to prevent renal hypoperfusion and resulting oliguria. Indeed, a delay in adequate fluid resuscitation has been associated with poor prognosis in burn associated AKI.[217,218] Fluid requirements are contingent on the patient's initial weight, burn size, and need for mechanical ventilation.[193] With recognition of the importance of timely resuscitation and the adaptation of aggressive, standardized protocols[219,220] early AKI following severe burns has become less frequent.[200] In modern studies, however, there is not always an association between resuscitation volume and the development of AKI.[205] It may be that once a critical volume threshold is reached, no further benefit may be realized as etiologies other than hypovolemia come to predominate. Indeed, administration of fluid >25% more than that predicted as appropriate by the Parkland burn formula has been associated with increased odds of pneumonia, acute respiratory distress syndrome (ARDS), multisystem organ failure (MOF), and death.[221]

38.7 Common Causes of Acute Kidney Injury Following Severe Burns

Early
Volume depletion/hypoperfusion
Inhalation injury
Rhabdomyolysis/hemolysis
Late
Sepsis
Abdominal compartment syndrome
Nephrotoxic medications
Hypercalcemia

Inhalation Injury

Early AKI is often preceded by or concurrent with systemic inflammatory response syndrome (SIRS) and respiratory disease.[201] Pulmonary injury associated with trauma or burns promotes pathogenic systemic inflammation and the development of MOF, including AKI.[222] The extravasation of intravascular fluid initiated by the burn may be potentiated by inflammation triggered by IHI. Supporting this, burn victims with IHI have been documented as having significantly higher fluid and sodium replacement requirements than those without IHI.[223] IHI associated respiratory failure results in hypoxia and acidemia, further compromising vascular tone. Renal dysfunction is more common among patients with the most severe respiratory dysfunction.[224] Prevalence of inhalation injury is higher and the number of days on mechanical ventilation is greater in pediatric burn patients with AKI than in those without.[204]

Rhabdomyolysis/Hemolysis

Rhabdomyolysis (RML) and hemolysis can result in AKI via the release of free hemoglobin and myoglobin. Both molecules are freely filtered by the glomerulus, absorbed by tubular epithelial cells, and degraded into heme and globin, respectively. Each of these pigment molecules can be directly toxic to tubular cells via generation of oxygen free radicals as well as causing cast precipitation and tubular obstruction. AKI is associated with RML in one third of patients with myoglobinuria due to this oxidative stress and myoglobin cast nephropathy.[225,226] In patients with RML, myoglobinuria is strongly associated with the development of AKI, with an area under the receiver operating curve (AUC) of 0.88 and an optimal cutoff of 3865 ng per mL.[227] In the early period following a severe burn, patients are at substantial risk for AKI secondary to RML and, to a lesser degree, hemolysis.

RML is most frequently associated with electrical burns.[228–230] However, RML can also follow deep flame burns which produce direct myocyte damage or else induce limb ischemia and secondary RML through circumferential burns resulting in eschar formation and compartment syndrome.[231] Burn victims are at additional risk for RML due to prolonged immobilization, IHI, sepsis, pharmacologic

agents, obesity, and large surgical surface areas, which promote the destruction of striated muscle cells.[206,232] Once present, the nephrotoxic effects of RML are potentiated by such frequent comorbidities of burns as acidosis, intravascular volume depletion, and oliguria.[202]

In a retrospective study of 714 burn victims, RML, diagnosed by serum creatinine phosphokinase (CPK) and myoglobin levels as well as the documented presence of pigmented urine, was noted in 8/714 (1%) of patients,[206] six of whom (75%) developed AKI. Although serum CPK levels were similar between those with and without AKI, myoglobin trended toward being higher in the AKI patients, 10,600 μg per L versus 4989 μg per L, but the results were not statistically significant. While RML can develop several weeks after a severe burn, it is a significantly more common cause of AKI in the early period. Patients with AKI due to RML are more likely to present with early injury, 12/16 (75%), than those with AKI secondary to other causes, 31/77 (40%), and RML induced AKI requires RRT more frequently 9/16 (56%) than other AKI etiologies 23/77 (30%).[233] In a study of 48 patients with AKI requiring RRT, myoglobinuria occurred significantly more frequently in those with AKI <5 days postburn than those with later injury ($P < .0001$).[200] Although not statistically significant, Steinvall et al. examined 31 patients with burn-associated AKI and found mean myoglobin levels were higher in those with early AKI as opposed to late, 1,167 μg per L versus 220 μg per L.[201]

Outcomes following RML are better after electric burn than flame due to the severity of burn required to cause RML with thermal injury.[233] Early escharotomies and fasciotomies so as to minimize tissue ischemia are key to reducing the incidence of RML.[233] Although of unproven benefit, urine alkalinization and forced diuresis using lactated Ringer's (LR) solution, sodium bicarbonate, and mannitol or furosemide is typically employed. Myoglobin has a molecular weight of 17 kD and can theoretically be eliminated by ultrafiltration but the half-life of systemic myoglobin has not been shown to differ in burn-associated AKI patients treated with continuous venovenous hemodiafiltration (CVVHDF) as compared to LR alone.[206,234]

Proteinuria

Burn shock associated with sepsis may incite lesions in the glomerulus and tubules and is often associated with high and low molecular weight proteinuria.[235] Plasma from septic burn victims with AKI induces a pro-apoptotic effect in tubular cells and podocytes that correlates with the extent of proteinuria. Specifically, alteration of polarity in tubular cells and reduced expression of megalin, nephrin, and the tight junction protein ZO-1 have been demonstrated.[236]

The development of proteinuria may be a more sensitive indicator of kidney injury than definitions predicated on serum creatinine. Kang et al. evaluated 24-hour urine protein excretion daily for 3 days and then weekly for 3 weeks in 12 patients following a severe burn injury.[237] None of the patients experienced a rise in serum creatinine or a decrease in urine output. Mean proteinuria rose from 139 mg per 24 hours on day 0 to 835 mg per 24 hours by day 3 and remained above baseline at 3 weeks with the majority of protein being nonalbumin. Additional confirmation of tubular injury was found by a sustained elevation in N-acetyl-β-D-glucosaminidase (NAG), a specific marker of renal tubular pathology.[238] Sabry evaluated 40 patients with TBSA burns >20%, nine (22.5%) of whom developed AKI.[202] Although serum creatinine in those patients with AKI was not significantly higher than in those without AKI until hospital day 7, the patients with AKI were found to have significantly higher microalbuminuria at admission. It is unclear if this is an example of microalbuminuria being an early biomarker of tubular injury or if these patients had microalbuminuria at baseline and hence were at higher risk for AKI.

Late Acute Kidney Injury

Patients who develop AKI in the later period following burns are younger with lower TBSA percentage burns and less FTB.[201] Due to the profound and prolonged inflammation engendered by burns, patients 2 to 3 weeks postinsult continue to express elevated cytokines, including TNF-α and IL-1, with resulting vasoconstriction and renal hypoperfusion. These ongoing physiologic derangements render them highly susceptible to the predominant renal insults, sepsis, and nephrotoxic medications, encountered in this period. The resulting development of ATN compromises the kidney's ability to retain sodium and concentrate urine and thus perpetuates intravascular volume depletion. With improved resuscitation protocols having minimized hypoperfusion associated early AKI, late-onset injury now predominates.[200] The factors influencing the development of late AKI are shown in Figure 38.2.

Sepsis

The primary causes of late AKI following severe burns are sepsis and associated MOF.[200,203,217,218,239] Sepsis has been noted in 64% of late-onset AKI compared to 28% in early AKI[233] although such a disparity is not always seen.[201] Holm et al. found sepsis to be present in 30/33 (91%) of burn victims whose AKI developed >5 days postinjury but in 0/15 of those with AKI within the first 5 days.[200] Despite the extensive use of topical and systemic antibiotics, the nidus of infection in postburn sepsis remains the burn itself. However, as seen in ICU populations at large, impairment of the GI mucosal barrier with subsequent bacterial translocation and endotoxemia may be an additional contributor to late onset sepsis after burns.

The onset of sepsis in a burn patient is an ominous development. In a study of 76 patients with AKI, sepsis was seen in 96% of nonsurvivors versus 44% of survivors ($P < 0.001$).[217] However, not all episodes of severe sepsis cause AKI and the chronology is not always consistent. Among survivors of AKI, Chrysoloulo et al. found kidney injury often preceded clinical evidence of sepsis, rather than following

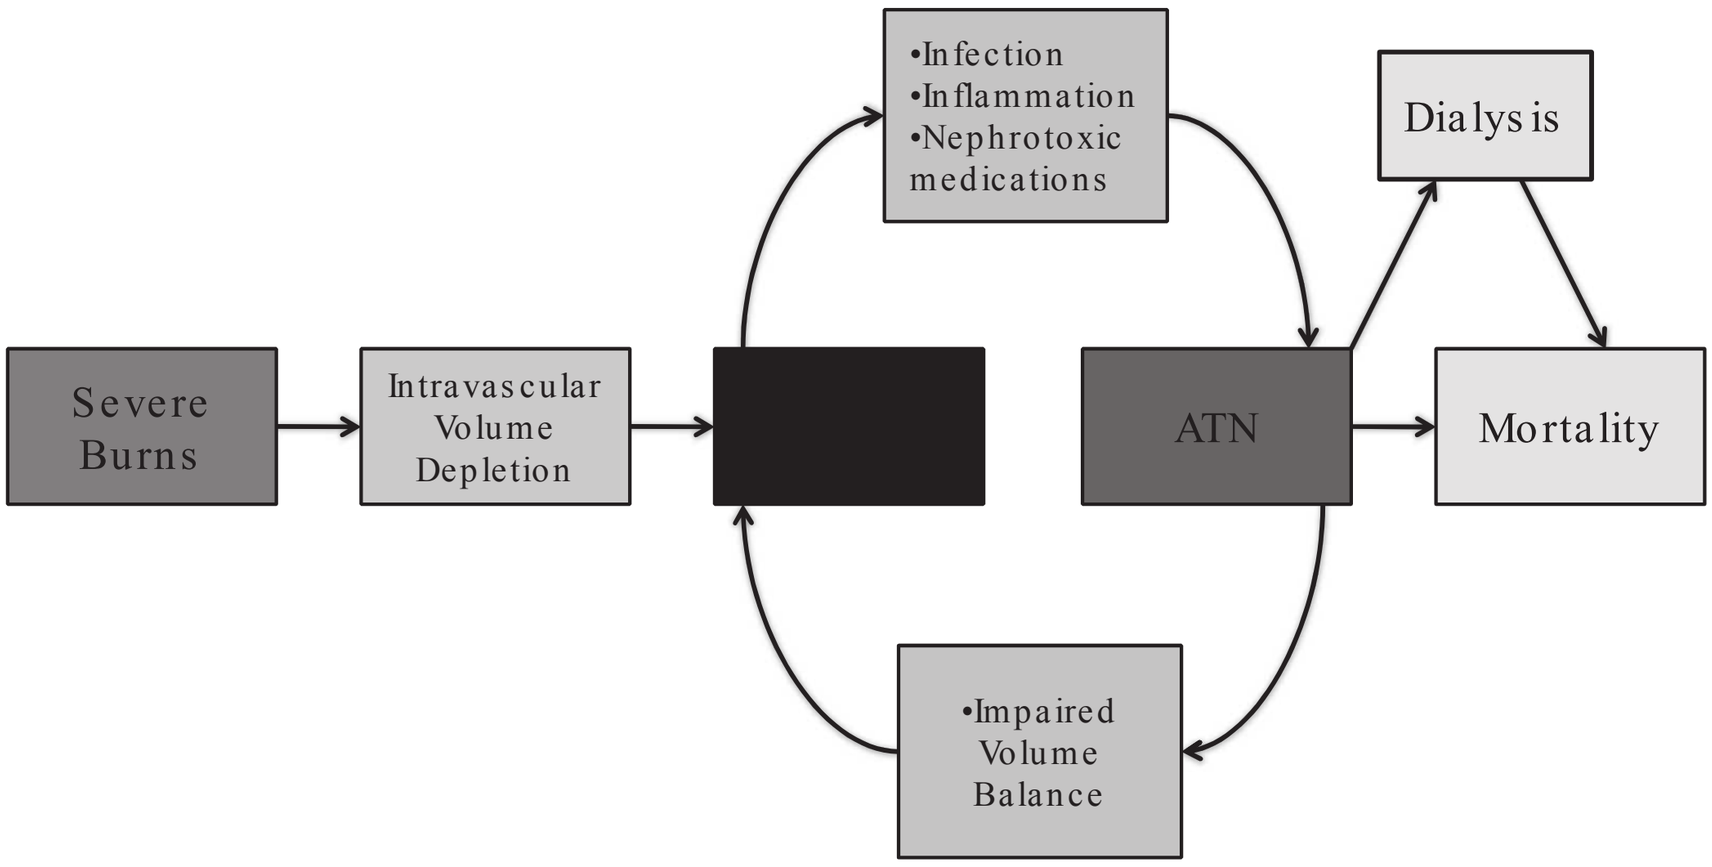

FIGURE 38.2 Progression of late kidney injury after severe burns. AKI, acute kidney injury; ATN, acute tubular necrosis.

it.[217] Remarkably, all diagnoses of sepsis occurred after onset of AKI in survivors whereas nonsurvivors were stricken both before and after inception of AKI. Taken together, these findings suggest that when AKI follows sepsis, it is part of MOF and results in the expected devastating mortality. The mere development of sepsis in the setting of prevalent AKI, however, allows for the possibility that the AKI's initial etiology was primarily hemodynamic and thus may be associated with more favorable outcomes.

Abdominal Compartment Syndrome

Aggressive volume resuscitation, although minimizing early intravascular hypovolemia, hypotension, and renal hypoperfusion, may ultimately lead to a significantly positive fluid balance. In the setting of increased capillary permeability and subsequent fluid translocation, excessive extravascular volume puts patients at risk for intra-abdominal hypertension and abdominal compartment syndrome.[240–242] First reported following a burn in 1994,[243] abdominal compartment syndrome has been diagnosed in 40% of patients meeting RIFLE "F,"[204] although the temporal relationship between intra-abdominal hypertension and AKI is not always clear. Abdominal compartment syndrome impairs cardiac function, reduces pulmonary compliance, and truncates renal perfusion.[243–245] In a study of 123 burn victims, 9/56 (16%) of those with AKI were diagnosed with compartment syndrome whereas none of the 67 without AKI developed this complication.[204] Surgical decompression has been shown to improve APACHE scores and increase urine output in post-burn compartment syndrome.[244]

Nephrotoxic Medications

Nephrotoxic medications, particularly antibiotics, are well-known risk factors for AKI. The use of potentially nephrotoxic antibiotics has been reported as nearly ubiquitous in late onset AKI after severe burns.[200,233] Additionally, in patients diagnosed with AKI by RIFLE criteria, use of known nephrotoxic medications was much more prevalent in those patients who ultimately progressed to a higher stage of AKI severity (86%) than in those who did not (27%) ($P = .02$).[208] However, the concurrent presence of sepsis in nearly all patients on antibiotics is an obvious potential confounder and confirmation of the independent role of nephrotoxic medications in the development of late AKI awaits future controlled studies. The use of nephrotoxic antibiotics has also been reported in up to 57% of early AKI cases but the drugs were only initiated 1 to 3 days prior to occurrence of AKI and thus cannot be said to be causal.[233]

Hypercalcemia

Burn injuries and their management frequently result in hypercalcemia. Kohut et al. found hypercalcemia in 22/73 (30%) of patients with TSBA >20% burns and/or ICU stay >20 days.[246] Elevation of calcium in this setting is multifactorial but primarily related to prolonged immobility, with subsequent increase in bone resorption, and high protein feeds stimulating calcium mobilization and hypercalciuria.[247] Hypercalcemia leads to renal hypoperfusion both through direct vascular action causing renal vasoconstriction and by stimulation of natriuresis and aquaresis. Treatment of hypercalcemia involves aggressive hydration, volume expansion, and early mobilization. Bisphosphonates have also proven successful in preserving bone mass following severe burns.[248]

Treatment

Volume Resuscitation

The critical impact of volume depletion on outcomes following severe burns has long been recognized.[249] Immediate and aggressive fluid resuscitation so as to maintain circulating

blood volume and ensure adequate tissue perfusion and oxygenation is a critical component of the acute treatment of burn patients. The time between burn injury and fluid resuscitation is significantly less in survivors than nonsurvivors.[217] Of multiple proposed resuscitation formulas,[219,220] the Parkland formula[250] is one of the most widely utilized. This protocol calls for the administration of LR at 4 mL/kg/TBSA percentage burned, half to be given in the first 8 hours and the remainder over the next 16 hours. Fluids are then adjusted to maintain urine output of 0.5 to 1.0 mL/kg/hr. Resuscitation guided by the Parkland formula has been shown to result in less volume administered without difference in cardiac output parameters than that guided by pulmonary artery catheter.[251] Colloid solutions have increasingly fallen out of favor as they have not been shown superior to saline in general ICU patients[252] and a decrease in GFR following colloid administration has been observed in burn victims.[253]

Early wound excision and grafting may temporize the inflammatory response and subsequent release of inflammatory mediators, thereby improving renal blood flow and mitigating AKI. However, the effect of early excision on mortality has been variable.[217,218]

Vitamin C

Vitamin C has been utilized following thermal injury due to its antioxidant properties. Activation of mast cells is instigated by burns, resulting in histamine release, increased xanthine oxidase activity, and resultant free radical production.[254] By serving as a free radical scavenger, vitamin C may reduce postinjury membrane lipid peroxidation and attenuate vascular permeability.[255] Concerns have been expressed about the potential of vitamin C to initiate an osmotic diuresis and worsen renal injury. However, addition of vitamin C to resuscitation fluids has been shown to reduce fluid requirements, minimize weight gain, and lessen wound edema.[256] Patients receiving vitamin C experienced fewer ventilator days and demonstrated improved PaO2:FiO2 ratios.[256] Kahn et al. prospectively compared conventional LR resuscitation and LR with vitamin C at 66 mg/kg/hr.[257] The vitamin C group displayed a decreased fluid requirement but increased urine output. Although no difference was noted in mortality, the study involved only 33 patients and was likely underpowered for such hard outcomes.

Fenoldopam

Fenoldopam, a highly selective dopamine-1 receptor agonist, decreases renal vascular resistance, increases glomerular filtration rate (GFR), stimulates natriuresis through inhibition of the Na/H exchanger and Na/K/ATPase mediated sodium reabsorption, and facilitates aquaresis via antagonism of antidiuretic hormone (ADH).[258] Fenoldopam administration has been associated with increased cortical and medullary renal blood flow via nonnitric oxidase mediated arterial dilitation.[259,260] In a retrospective study of 758 patients admitted to an intensive care burn unit, 76 diagnosed with AKI on AKIN criteria were treated with fenoldopam.[258] Serum creatinine improved within 48 hours across all AKIN stages and urine output increased without adjustment in fluid administration in AKIN stages 2 and 3. The study, however, was not powered to assess RRT requirement, length of stay, or mortality.

Outcomes

Progression/Resource Utilization

Palmieri et al. evaluated the prognostic ability of the RIFLE criteria in 60 patients, 32 of whom (53%) were diagnosed with AKI.[208] Following initial fulfillment of criteria, 13 patients subsequently progressed over a mean of 9 days to a higher class. Mortality was 0% in those without AKI, 8% in those who did not progress beyond their initial stage ("R" or "I"), and 46% in those who progressed to a higher class. Progression was not associated with age, comorbidities, or severity of illness scores at admission but rather factors arising subsequent to admission such as sepsis, use of nephrotoxic drugs, cumulative fluid balance, and number of surgeries.

Evaluating the impact of AKI on length of hospital stay is difficult due to the competing risk of death associated with AKI. Nonetheless, significantly longer ICU,[200,204,208] and overall hospital[201,204] stays have been noted in patients with AKI. Similarly, the number of required ventilator days has also been demonstrated to be higher with AKI[200,204,208] and to increase in a stepwise manner with AKI severity.[200]

Dialysis

Although the first report of survival in a burn victim with AKI requiring RRT was in 1965,[192] the subsequent 20 years continued to produce very poor outcomes. Burn patients typically have massive obligatory fluid input in the service of maintaining hemodynamics, providing parenteral nutrition, and administering medications. Given these patients' low oncotic pressure and increased capillary permeability, much of this fluid is extravasated into third spaces, resulting in anasarca and placing patients at risk for impaired wound healing, skin breakdown, and pulmonary edema. During the period preceding the mid-1980s, the only treatment option was standard intermittent hemodialysis, which typically was employed daily in an attempt at aggressive ultrafiltration. With sepsis often compounding patients' hypotension and intravascular volume depletion, intermittent intense fluid removal was often impossible and outcomes were very poor. In the mid-1980s, continuous arteriovenous, followed by continuous venovenous, methods of RRT were introduced and are now preeminent in ICUs. Continuous RRT offers the advantage of gentle yet large volume ultrafiltration, allowing for aggressive nutritional support. The physiology of burn patients makes such techniques an especially appealing option in this setting.

Multiple venovenous therapeutic modalities (hemodialysis, hemofiltration, hemodiafiltration) have been successfully employed in patients with AKI and severe burns.[261] In a review of 16 studies, the incidence of renal replacement therapy after severe burns ranged from 0.7% to 14.6%.[201] A 10-year experience at a large burn unit showed 1% of all admissions, and 2.7% of patients with TBSA >10% burns, required RRT.[239] A systemic review found RRT was performed in 30% of AKI patients or 3% of the total population with burn injuries.[195] RRT is typically initiated approximately 2 weeks after hospital admission, consistent with the period of late onset sepsis/MOF associated AKI.[201,239,261,262] Reported mean duration of treatment has ranged from 10 to 24 days.[201,239,261,262]

Early studies reported a significantly higher rate of bleeding complications in burn patients receiving CRRT than in general ICU CRRT patients, 56% versus 15% (P = .002).[261] This increased risk may have resulted from the interaction of anticoagulation and the frequent thrombocytopenia and consumptive coagulopathy seen following burns. The patients in this study received a mixture of arteriovenous and venovenous dialysis. When the same investigators assessed a later cohort using only venovenous techniques, no bleeding complications were noted.[262] Encouragingly, survival improved from 18% in the first time period (1987–1994) to 50% in the second (1995–1998) within the same institution.

Inpatient Mortality

Prior to the widespread availability of RRT, the survival rate in patients with severe burns and AKI was abysmal. Of 119 patients in the literature published between 1953 and 1979, only 8/119 (7%) survived.[216] In the ensuing years, outcomes have improved considerably but the diagnosis of AKI following a severe burn still portends a grim prognosis. Analyzing data culled from nearly 30 years of experience at a single center, Jeschke et al. identified 60 children who had experienced AKI following a severe burn. Dividing the patients into those presenting before and after 1984, they found that the mortality rate had decreased from 100% to 56%.[218]

On systematic review, mortality rates vary by AKI definition, ranging from a median of 35% in studies utilizing RIFLE criteria to 88% in three older studies where AKI status was determined by elevations in BUN levels.[195] The overall mean mortality in severely burned patients with AKI was 55%, with a median across studies of 77%. The median mortality in burn patients not afflicted with AKI was 13%. In the 30 studies with data available on control populations, AKI was clearly associated with an increased risk for mortality with an RR of 4.85. An increased risk of mortality has been documented with both early and late AKI. Retrospectively examining 62 patients meeting RIFLE criteria within 24 hours of admission, Mosier et al. found hospital mortality significantly elevated compared to burn patients without early AKI, 36% versus 13% (adjusted OR 2.32).[205] Forty-seven out the remaining 159 study patients (30%) developed AKI later in their hospital stay with a mortality of 16/47 (34%). As compared to mortality in burn victims who would be discharged without AKI, 6/112 (5%), late AKI conferred an unadjusted OR for death of 10.9.

The RIFLE criteria have been shown to provide incremental prognostic value regarding mortality in several settings of AKI.[263–267] In eight studies examining the utility of the RIFLE criteria following severe burns, mean mortality across categories was 42% with a median of 35%.[195] Mortality increased in a stepwise manner, both across studies with fixed serum creatinine cutoffs as well as across RIFLE stages.[195,201,204] Although the RR for mortality with AKI was 6.17 in those studies employing the RIFLE criteria, there was not a statistically significant increase in mortality for patients in the "R" category.[195] However, in 62 patients who developed RIFLE "R" or "I" within 24 hours of admission, 18 of whom progressed from their initial RIFLE stage to a more advanced one, Mosier et al. found mortality was significantly elevated in those who progressed versus those who stabilized or improved, 72% versus 20%.[205]

Despite refinements in continuous RRT techniques, the outlook for patients requiring dialysis remains harrowing and the need for dialysis is the strongest predictor of death in burn victims with AKI.[233] In a study of 1,360 burn patients admitted over 13 years to an ICU, mortality was found to be 6.9% in patients without AKI, 34.4% with AKI without RRT, and 62.5% in patients requiring dialysis.[233] Mortality in burn patients requiring RRT ranges across reported studies from 63% to 100%.[200,203 205,233,261,268–270] The median mortality in studies defining AKI by the need for RRT is 80%.[195]

Although need for RRT is the dominant risk factor for death in burn patients with AKI, multiple additional associations been reported including sepsis/MOF,[205,208,217] TBSA%,[190,233] RIFLE "F,"[190,208] age,[233] IHI,[190] serum albumin on presentation,[203] and SOFA score.[208] Burn size >65% TBSA confers a dramatic RR of 14.2 on multivariable analysis for mortality.[203] In 76 diagnosed with AKI, Chrysopoulo et al. noted 64/67 (94%) nonsurvivors as compared to 4/9 (44%) survivors were diagnosed with sepsis (P < .001).[217] As with AKI at large,[271] the development of oligo/anuria following a severe burn is predictive of worse outcomes. Mustonen et al. examined 32 patients requiring RRT.[233] Although 20/20 (100%) nonsurvivors were oliguric and 18/20 (90%) were anuric, only 6/12 (50%) survivors were oliguric and 2/12 anuric (17%). Mortality rates have alternatively been reported as higher in early AKI[200,233] and in late AKI[217] with another study finding them nearly identical.[205] With early AKI having larger TBSA percentage burns and higher rates of RML whereas late AKI involves more prevalent comorbidities and sepsis, both findings are plausible and the question awaits resolution in larger, multicenter studies.

It is interesting to note that in several studies only more severe AKI as evidenced by RIFLE "I" or "F" is associated with increased mortality.[190] This finding stands in clear distinction to that seen in multiple other populations where even

minor AKI confers an elevated risk for mortality.[163,272–275] It may be that other risk factors for mortality in burns such as TBSA percentage burned and IHI are so overwhelmingly impactful that the association between milder forms of AKI and death is overshadowed. Similarly, although TBSA percentage burned is an extremely strong predictor of mortality in multivariable models, once AKI develops, survival is similar across ranges of TBSA percentage burns. Especially in the late period, AKI is often associated with sepsis and MOF. It is possible that once such devastating complications have arisen, the power of TBSA percentage burned as a predictor of mortality is overwhelmed.

Encouragingly, there has been a strong trend toward decreasing mortality overall ($r = -0.5$; $P < .001$) and in those patients requiring RRT ($r = -0.6$; $P = .001$).[195] No prospective studies have evaluated long-term proteinuria, hypertension, or renal function in this patient population. Full inpatient renal recovery, variably defined, has been reported in multiple studies for many if not all survivors of burn associated AKI.[201,261,262] However, evidence is now overwhelming that even mild AKI is associated with increased risk for long-term CKD.[276–278] In light of this data, such optimistic findings seem premature and the long-term renal outcomes in survivors of postburn AKI await eliciting in future longitudinal studies.

Conclusion

AKI following burns is highly prevalent and conveys a grim prognosis. As the etiology is frequently multifactorial, interventions to reduce the incidence and severity of AKI must necessarily involve multiple targets. The prognosis following the onset of AKI has improved, even for those patients requiring dialysis, but remains poor. It remains to be seen whether the continued application and refinement of specialized burn therapies and RRT techniques will appreciably impact prevalence and mortality. Early, aggressive fluid resuscitation, control of infection, timely excision of eschars, and minimizing nephrotoxic medications remain the cornerstones of prevention for this devastating complication of an already horrific injury.

CHAPTER 39

Role of the Kidneys in Hypertension

Joey P. Granger • Eric M. George

Over 40 years ago Guyton and Coleman[1–3] proposed that if an increase in arterial pressure could produce sustained elevations in sodium and water excretion through a mechanism of renal pressure natriuresis and diuresis, then this system would have a near infinite gain for the long-term control of arterial pressure by regulating blood volume. Thus, whenever arterial pressure is elevated, renal arterial pressure would enhance the excretion of sodium and water until blood volume is reduced sufficiently to return arterial pressure to control values. According to the renal–body fluid system concept, hypertension can develop only when something impairs the excretory ability of the kidney and shifts the relation between sodium excretion and arterial pressure toward higher levels.[1–4] Although there is strong theoretical and experimental evidence that the kidney is a major determinant of the long-term control of arterial pressure, the initial abnormality of the kidney need not be intrinsic to the development of hypertension.[4–6] A shift of pressure natriuresis can occur as a result of intrarenal abnormalities such as enhanced formation of angiotensin II or genetic defects that enhance renal sodium transport mechanisms. In other instances, the altered kidney function is caused by extrarenal disturbances, such as increased sympathetic nervous system activity or excessive formation of antinatriuretic hormones such as aldosterone.[4–6]

RENAL-BODY FLUID FEEDBACK SYSTEM FOR LONG-TERM BLOOD PRESSURE REGULATION

According to the renal–body fluid feedback mechanism for long-term control of arterial pressure, extracellular fluid volume is determined by the balance between intake and excretion of salt and water by the kidneys (Fig. 39.1). A temporary higher intake than output would lead to an increase in extracellular volume and arterial pressure. If the excretory ability of the kidney is not impaired, the increase in arterial pressure raises sodium excretion and extracellular fluid volume would then decrease, thereby reducing venous return and cardiac output until blood pressure returns to normal and fluid intake and output are reestablished. Conversely, when sodium output exceeds intake and extracellular fluid volume and blood pressure fall below normal, the kidneys retain sodium and water until arterial pressure is restored to the normal set-point. Thus, according to the renal–body fluid feedback mechanism concept, the set-point for long-term blood pressure control is the arterial pressure at which sodium and water intake and output are at equilibrium.[4–7]

A key component of this mechanism for regulating salt and water balance is pressure natriuresis/diuresis, which is the effect of increased arterial pressure to raise sodium and water excretion. An important feature of pressure natriuresis is that various hormonal and neural control systems can amplify or blunt the pressure natriuresis mechanism.[5,7,9–11] For example, in most individuals, chronic increases in sodium intake are associated with only small changes in arterial pressure. The lack of significant increases in arterial pressure in response to elevations in sodium intake results in decreased formation of antinatriuretic hormones and/or increased formation of natriuretic factors, which enhance the effectiveness of pressure natriuresis and allow sodium balance to be maintained with little or no increase in arterial pressure. On the other hand, excessive activation of antinatriuretic systems or abnormalities in natriuretic systems can reduce the effectiveness of pressure natriuresis, thereby necessitating greater increases in arterial pressure to maintain sodium and water balance. Thus, excessive activation of antinatriuretic systems or abnormalities in natriuretic systems impairs the excretory ability of the kidney and shifts the relation between sodium excretion and arterial pressure toward higher levels and resets the set-point for long-term blood pressure control (Fig. 39.2).

Although total peripheral resistance and cardiac output are determinants of arterial pressure, one prediction of the renal–body fluid feedback mechanism is that if the pressure natriuresis mechanism is not impaired, a primary increase in total peripheral resistance or increases in cardiac pumping ability would not result in long-term alterations in arterial pressure.[2–6] For instance, an increase in total peripheral resistance would result in an immediate elevation in arterial

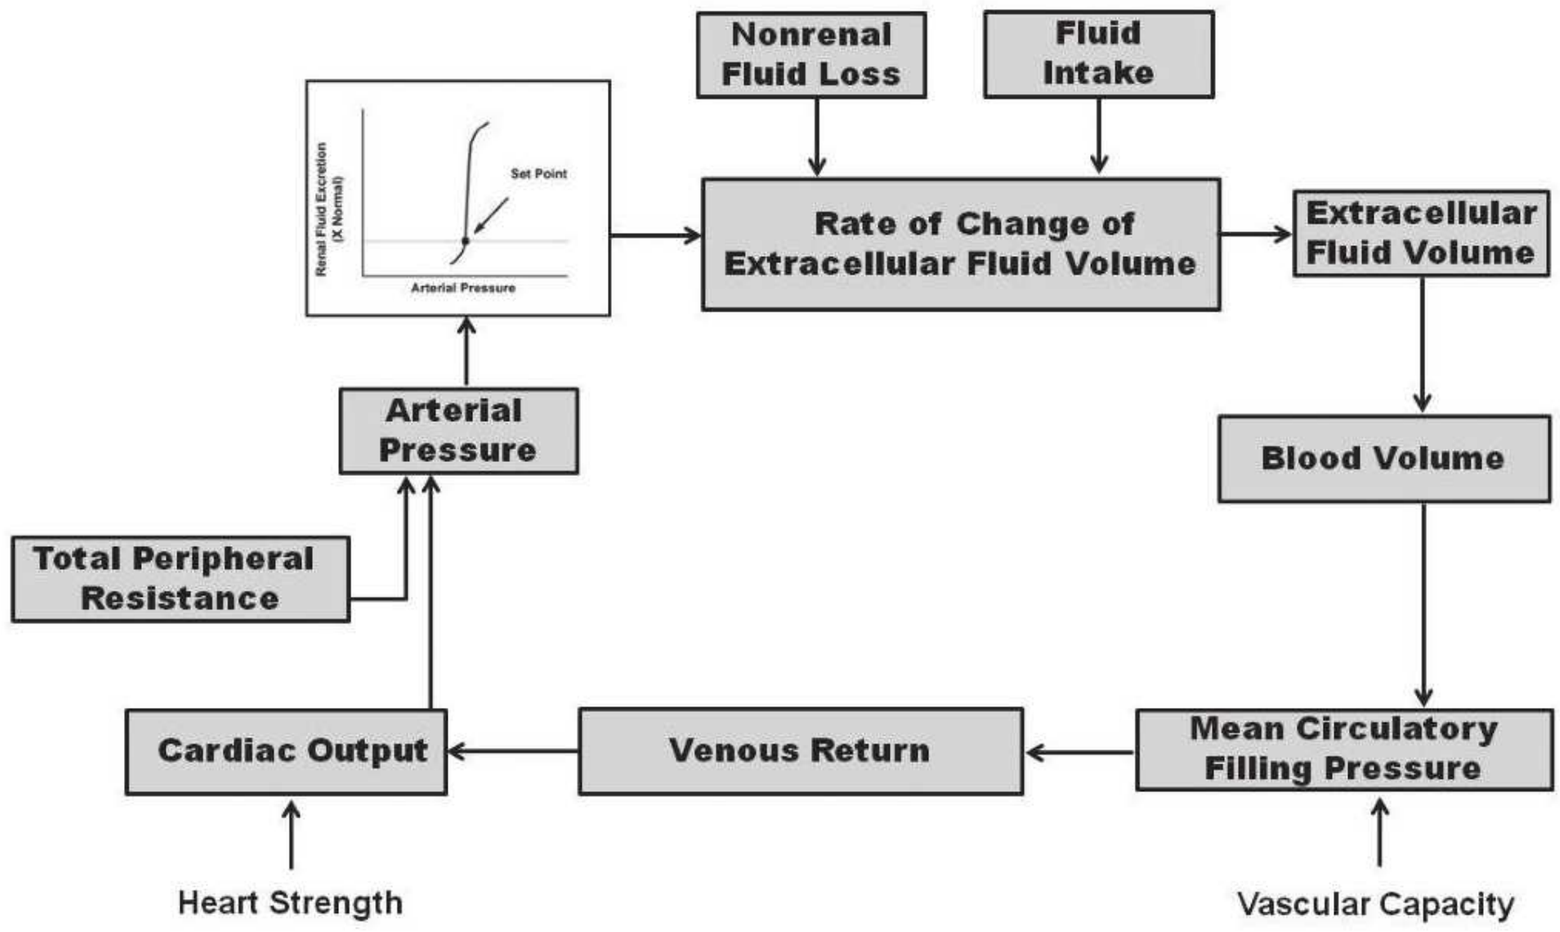

FIGURE 39.1 Basic renal–body fluid feedback mechanism for long-term regulation of blood pressure and body fluid volumes. (Redrawn from Granger JP, Hall JE. Role of the kidney sodium and fluid excretion in hypertension. In: Lip GYP, Hall JE, eds. *Comprehensive Hypertension*. New York: Elsevier; 2007.)

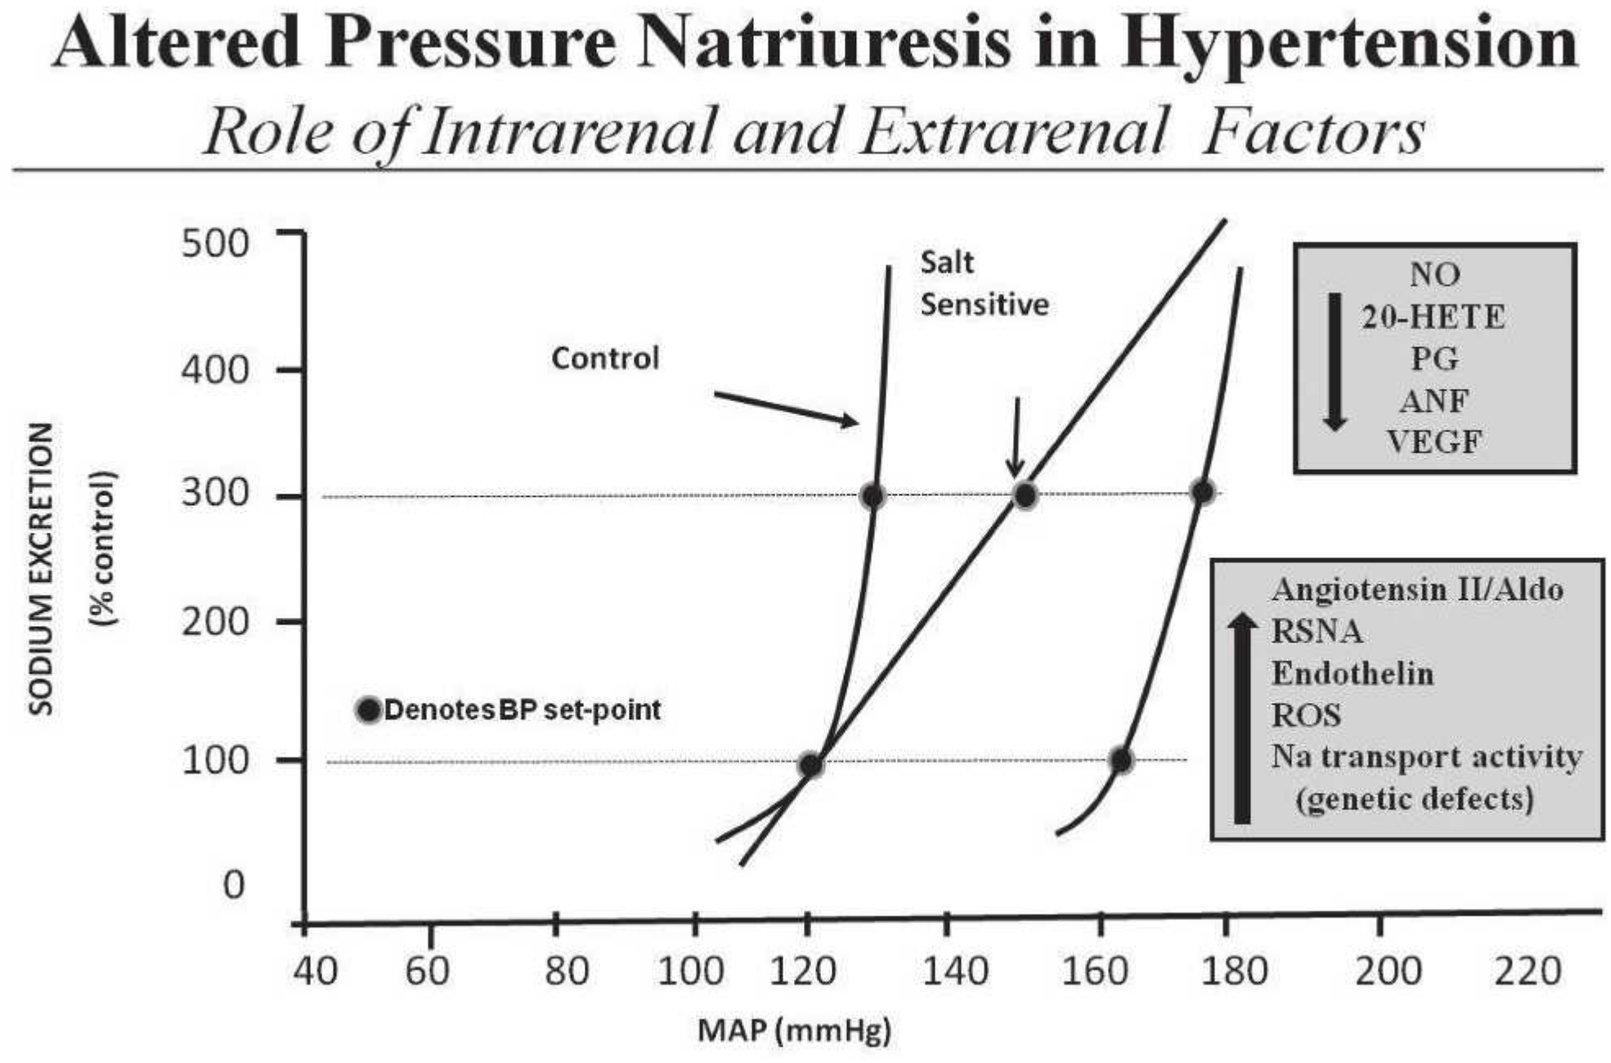

FIGURE 39.2 Steady-state relationships between arterial pressure and urinary sodium excretion and sodium intake for control subjects with normal kidneys and for subjects with a rightward hypertensive shift in the pressure-natriuresis relationship. A shift in the pressure natriuresis relationship can occur as a result of *intrarenal* abnormalities such as enhanced formation of angiotensin II (ANGII), reactive oxygen species (ROS), inflammatory cytokines and endothelin (via ET_A receptor activation), or decreased synthesis of nitric oxide (NO), natriuretic prostanoids (PG), vascular endothelial growth factor (VEGF), or even genetic defects that enhance renal sodium transport mechanisms. In other instances, the altered kidney function is caused by *extrarenal* disturbances, such as increased sympathetic nervous system (SNS) activity or excessive formation of antinatriuretic hormones such as aldosterone (Aldo) or decreased atrial natriuretic peptide (ANP).

pressure. The increase in arterial pressure would increase sodium and water excretion, via pressure natriuresis. As long as fluid excretion exceeds fluid intake, extracellular fluid volume will continue to decrease, reducing venous return and cardiac output, until blood pressure (BP) returns to normal and fluid balance is reestablished. Thus, according to the renal–body fluid volume control system concept, primary increases in total peripheral resistance or increases in cardiac pumping do not result in long-term alterations in arterial pressure and hypertension can develop only when something impairs the excretory ability of the kidney and shifts the relation between sodium excretion and arterial pressure toward higher levels.[2–6]

Although hypertension is a result of a reduction in the kidney's ability to excrete sodium and water (reduced pressure natriuresis), the hypertension may not necessarily be associated with increases in extracellular fluid volume. Indeed, many forms of hypertension are associated with increased total peripheral resistance and reduced rather than increased extracellular fluid volume. This occurs when a vasoconstrictor, such as norepinephrine, has a potent extrarenal vasoconstrictor effect to increase total peripheral resistance but a relatively weak antinatriuretic action. The antinatriuretic effect of norepinephrine shifts pressure natriuresis and the set-point for arterial pressure to a higher level. However, because norepinephrine has a more powerful extrarenal vasoconstrictor effect, arterial pressure initially increases above the renal set-point for sodium balance and causes transient natriuresis and decrease in extracellular fluid volume. Eventually arterial pressure stabilizes at a point where sodium intake and output are balanced. Thus, sodium retaining actions of norepinephrine are masked by peripheral vasoconstriction which raises BP above the renal set-point at which sodium balance is maintained causing increased renal excretion and decreased extracellular fluid volume. It is important to reiterate that the maintenance of high blood pressure chronically depends on norepinephrine's renal actions because norepinephrine's extrarenal effects to increase total peripheral resistance would in itself, as pointed out previously, only result in a transient increase in blood pressure.

PRESSURE NATRIURESIS: A KEY FACTOR IN MAINTAINING SODIUM BALANCE IN HYPERTENSION

Another important prediction of the renal–body fluid feedback control system concept is that an increase in BP in hypertensive states is an essential compensatory mechanism that allows sodium balance to be maintained in the face of an underlying sodium retaining defect.[5–7] The importance of the pressure-natriuresis mechanism in the regulation of sodium excretion can best be illustrated under conditions in which a sodium-retaining abnormality exists within the kidney and an increase in arterial pressure occurs to compensate for this abnormality. Such a condition is illustrated in the hypertension caused by aldosterone excess. To determine the importance of the pressure-natriuresis mechanism in achieving sodium balance during aldosterone-induced hypertension, Hall and colleagues[12] examined the long-term effects of aldosterone on sodium excretion and arterial pressure in normal dogs and in dogs in which renal artery pressure was prevented from increasing with an electronically servocontrolled aortic occluder. In dogs in which renal artery pressure was permitted to increase during chronic aldosterone infusion, sodium excretion decreased markedly on the first day and then returned to control levels on days 2 to 3 of aldosterone infusion as arterial pressure increased (Fig. 39.3). In contrast, in dogs in which renal artery pressure was prevented from increasing, sodium excretion decreased on the first day and remained below sodium intake for the 7 days of aldosterone infusion. The sustained sodium retention resulted in dramatic increases in cumulative sodium balance and systemic arterial pressure. The results from this study clearly demonstrated that an increase in renal arterial pressure is essential in allowing the kidneys to escape from the chronic sodium-retaining actions

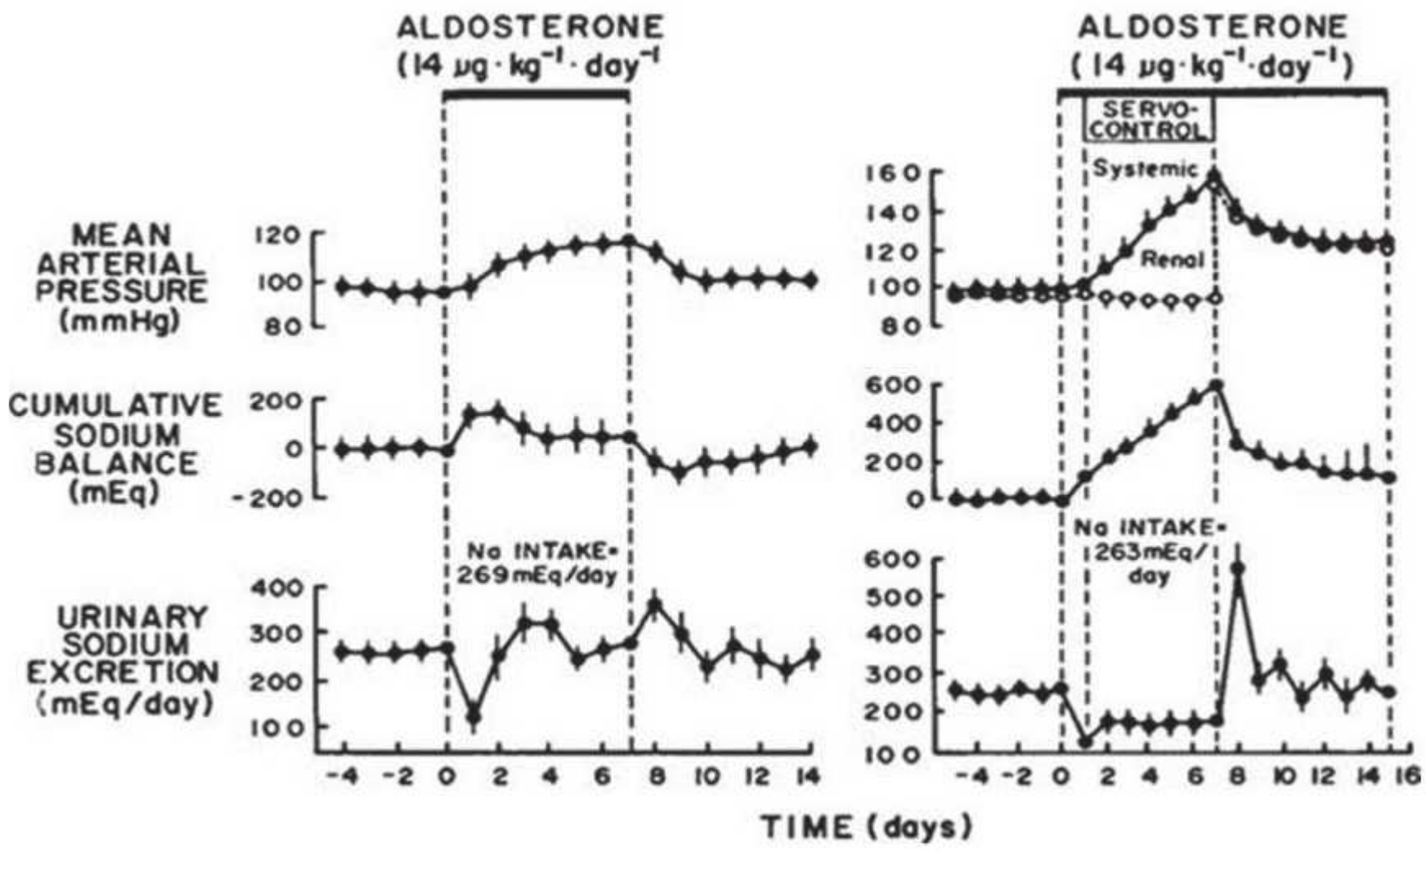

FIGURE 39.3 Effects of chronic aldosterone infusion on sodium excretion when renal perfusion pressure was allowed to increase (*left panel*) and was servo-controlled (*right panel*). Notice that when renal perfusion pressure was prevented from increasing, "escape" from sodium retention did not occur and cumulative sodium balance and systemic arterial pressure continued to increase. (Redrawn from Hall JE, Granger JP, Smith MJ, et al. Role of renal hemodynamics and arterial pressure in aldosterone "escape." *Hypertension*. 1984, 6(suppl I): I-183–I-192.)

of aldosterone and to achieve normal sodium balance. Similar findings were reported from the same group during chronic administration of other sodium-retaining hormones, such as angiotensin II and norepinephrine.[13,14] Thus, it appears that during pathophysiologic conditions associated with excess levels of sodium-retaining hormones, such as aldosterone or angiotensin II, the pressure-natriuresis mechanism is important for the maintenance of sodium balance.[15,16]

MECHANISM UNDERLYING RENAL PRESSURE NATRIURESIS

The ability of the kidney to alter urine flow and sodium excretion in response to acute changes in renal perfusion pressure has been of interest to investigators for many years.[17–19] Changes in sodium excretion in response to changes in renal perfusion pressure are thought to be due to alterations in tubular reabsorption of sodium, because glomerular filtration rate (GFR) and the filtered load of sodium are usually well autoregulated.[20] Thus, a decrease in renal perfusion pressure results in an increase in tubular reabsorption of sodium and a decrease in sodium excretion. In contrast, increases in renal perfusion pressure lead to decreases in tubular reabsorption of sodium and increases in sodium excretion, a phenomenon commonly referred to as pressure natriuresis.

The specific intrarenal mechanism responsible for the decrease in tubular reabsorption in response to increases in renal perfusion pressure appears to be related to increases in hemodynamic factors such as medullary blood flow and renal interstitial hydrostatic pressure (Fig. 39.4).[20–25] The mechanism whereby renal interstitial hydrostatic pressure (RIHP) increases in the absence of discernible changes in whole kidney renal blood flow and peritubular capillary hydrostatic and/or oncotic pressures may be related to increases in renal medullary flow as a result of nitric oxide-induced reductions in renal medullary vascular resistance.[26] Preventing RIHP from increasing in response to increases in renal perfusion pressure markedly attenuates pressure natriuresis.[24] Furthermore, direct increases in RIHP, comparable to increases measured in response to increases in renal perfusion pressure, have been shown to significantly decrease tubular reabsorption of sodium in the proximal tubule and increase sodium excretion.[20–24] The exact mechanism whereby RIHP influences tubular reabsorption is unknown but may be related to alterations in tight junction permeability to sodium in proximal tubules, redistribution of apical sodium transporters, and/or release of renal autacoids such as prostaglandin E2.[27–31]

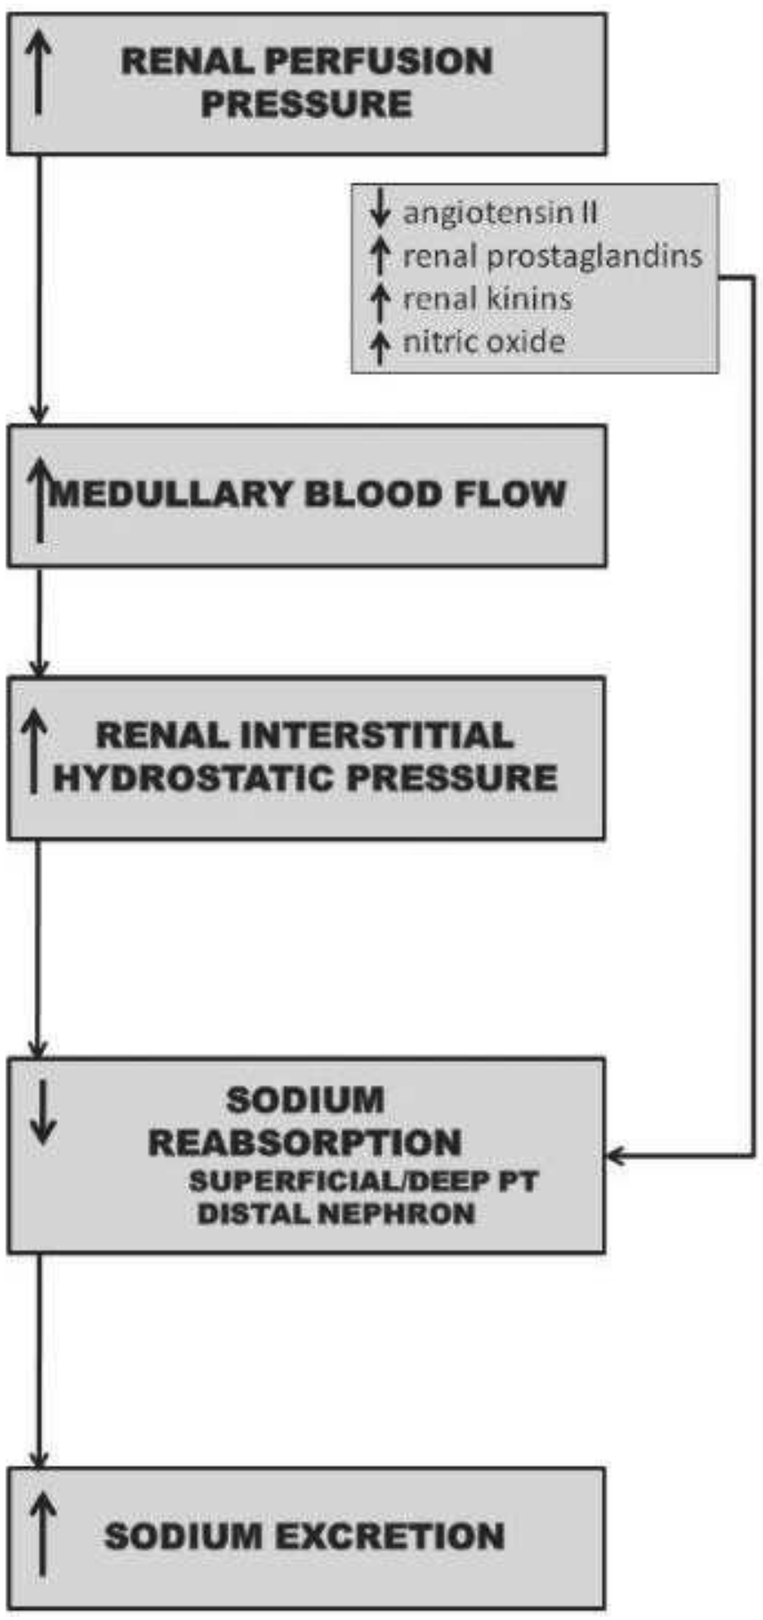

FIGURE 39.4 Mechanisms whereby increases in renal perfusion pressure enhance sodium excretion.

MECHANISMS OF IMPAIRED RENAL-PRESSURE NATRIURESIS IN HYPERTENSION

Several lines of evidence support an important role for the kidneys in the development and maintenance of hypertension. Some of the strongest evidence for a key role of the kidneys in hypertension derives from renal cross-transplantation studies.[4] Transplantation of a kidney from a hypertensive donor into a normotensive recipient has been demonstrated to produce sustained elevations in arterial pressure in numerous genetic models of hypertension (e.g., SHR, Dahl).[32] Of particular relevance to human hypertension is the study of Curtis et al.[33] demonstrating that BP returns to normal levels in hypertensive patients who were recipients of kidneys from normotensive donors. Another observation that points toward abnormal kidney function as a key factor in causing hypertension is that almost all forms of experimental hypertension are caused by perturbations to the kidneys that alter renal hemodynamics or tubular reabsorption and reduce the kidney's ability to excrete sodium and water. For example, constriction of the renal arteries (e.g., Goldblatt hypertension), compression of the kidneys (e.g., perinephritic hypertension), or administration of sodium-retaining hormones (e.g., ANG II) are all associated with either initial reductions in renal blood flow and GFR or increases in renal tubular reabsorption prior to development of hypertension.[7,34] Further evidence

supporting an important role for the kidneys in the development and maintenance of hypertension is that in all known monogenic forms of human hypertension, the common pathway to hypertension appears to be increased renal tubular reabsorption caused by mutations that directly increase renal electrolyte transport (e.g., Liddle or Gordon syndromes) or the synthesis and/or activity of antinatriuretic hormones (e.g., glucocorticoid remediable aldosteronism).[8]

Although specific abnormalities of kidney function are difficult to identify in most patients with primary hypertension, the one aspect of kidney function that is abnormal in all types of experimental and clinical hypertension is renal pressure natriuresis.[4,5,7,15,16,34] A shift in the pressure natriuresis relationship can occur as a result of intrarenal abnormalities such as enhanced formation of angiotensin II, reactive oxygen species (ROS), inflammatory cytokines, and endothelin (via ET_A receptor activation) or decreased synthesis of nitric oxide and natriuretic prostanoids or even genetic defects that enhance renal sodium transport mechanisms (Fig. 39.2). In other instances, the altered kidney function is caused by extrarenal disturbances, such as increased sympathetic nervous system (SNS) activity or excessive formation of antinatriuretic hormones such as aldosterone. The remaining portion of this chapter discusses how these intra- and extrarenal factors impair renal pressure natriuresis and lead to chronic hypertension.

The Renin-Angiotensin System

The renin-angiotensin system (RAS) plays a critical role in the long-term regulation of blood pressure and is involved in the pathogenesis of various forms of hypertension including renovascular hypertension and human essential hypertension.[10,15,34] Although the RAS has many components, its most important effects on renal hemodynamics and sodium reabsorption are exerted by angiotensin II (ANGII) via an ANGII type 1 (AT1) receptor (Fig. 39.5). ANGII also acts on ANGII type 2 receptors to cause renal vasodilation and natriuresis; however, the relative importance of this antihypertensive pathway is equivocal.[35–37] More recently, fragments of ANGII such as ANG 1–7 have also been suggested to have physiologic effects within the kidney, often opposing the actions of ANGII.[35–37] An isoform of angiotensin-converting enzyme (ACE), known as ACE2, appears to be involved in the formation of angiotensin 1–7.[35–37] Although experimental findings on Ang 1–7 are equivocal, ANG 1–7 has been shown to induce renal vasodilation, an effect that is thought to occur independently of binding to AT_1 or AT_2 receptors

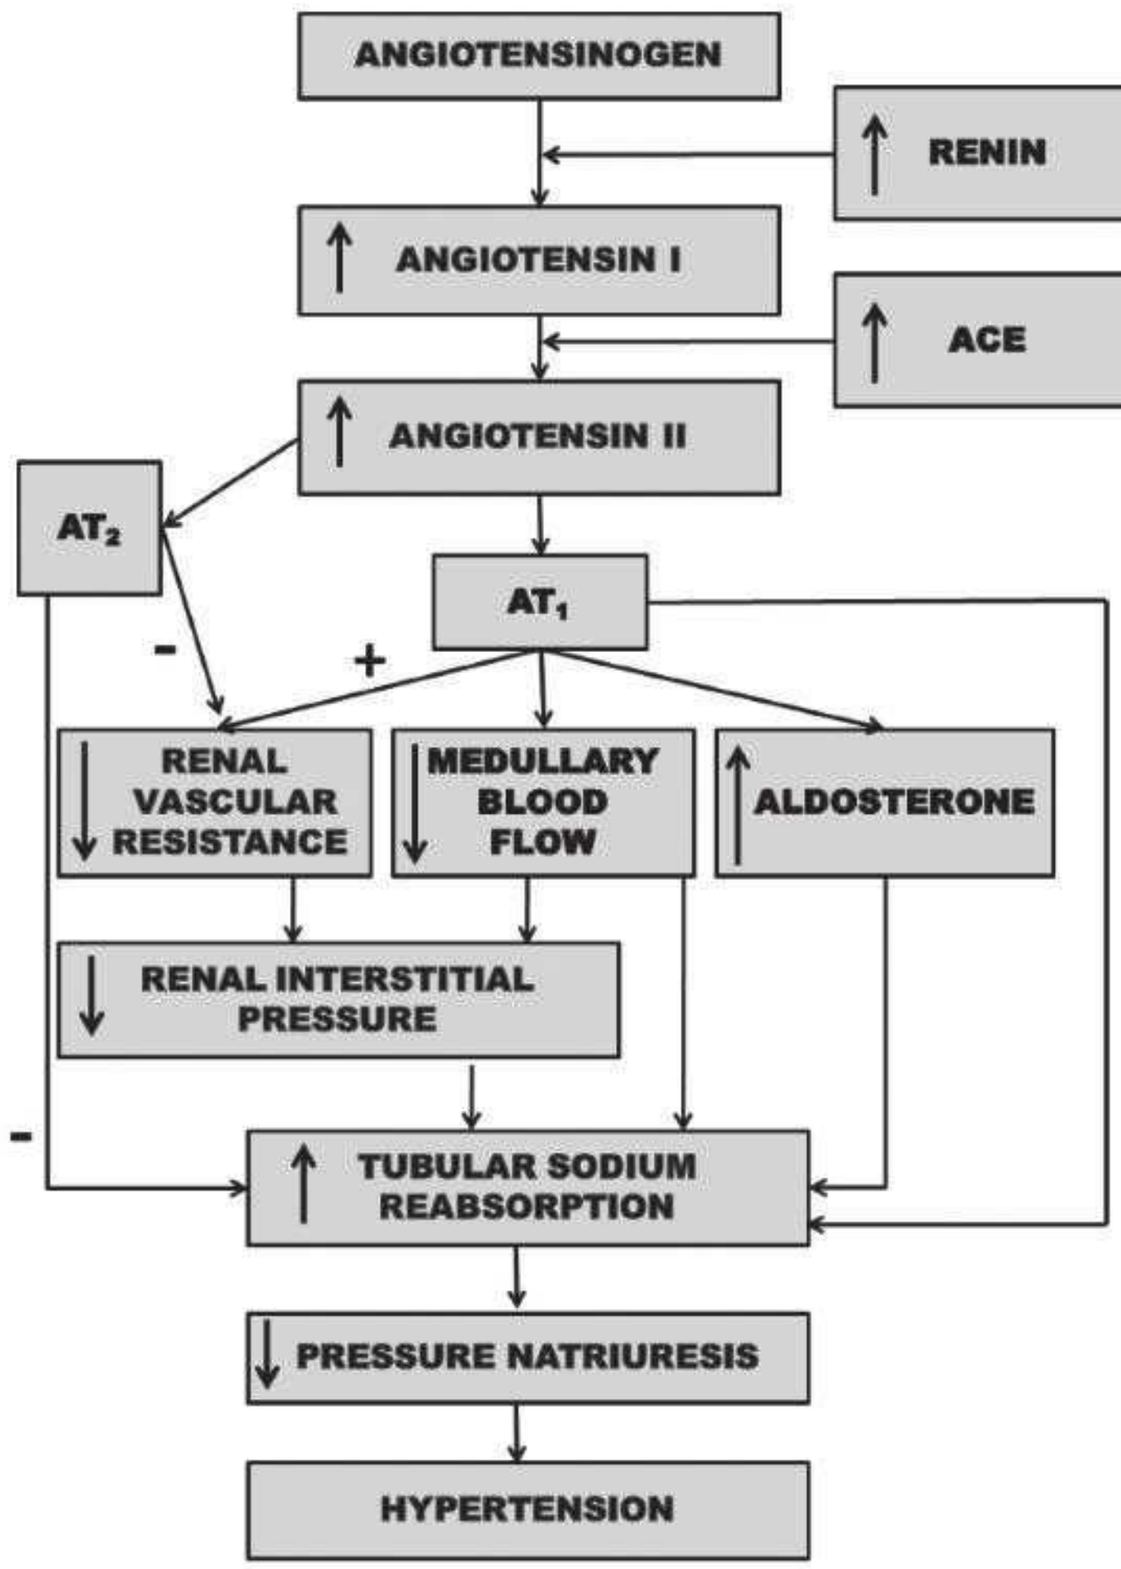

FIGURE 39.5 Renal mechanism whereby activation of the renin-angiotensin system reduces pressure natriuresis relationship and leads to hypertension.

but rather through a G protein–coupled Mas receptor.[35–37] Although ANG 1–7, ACE2, and the Mas receptor have all been detected within the kidney and an imbalance of these peptides, enzymes, or receptors have been reported to occur in various cardiovascular and renal diseases, the physiologic and pathophysiologic importance of ANG 1–7 has yet to be fully elucidated.[35–37]

The RAS, via AT1 receptor, plays an important role in maintaining sodium balance and a relatively normal pressure as sodium intake is altered from low to high levels.[9] As sodium intake is increased to high levels, ANGII levels are suppressed allowing sodium excretion to increase to match sodium intake. Conversely, when sodium intake is restricted ANGII levels increase and sodium excretion is reduced to match the low sodium intake. Thus, with a fully functional RAS, sodium balance is maintained in response to changes in sodium intake without the need to invoke significant changes in blood pressure. An inability to suppress the RAS in response to increases in sodium intake could be one potential mechanism for salt-sensitive hypertension in humans.[7,10]

The importance of the RAS in controlling blood pressure during changes in sodium intake is highlighted by the study of Hall and colleagues[9] where they reported that blockade of the RAS, with ANGII receptor blockers (ARB) or ACE inhibitors, increases renal excretory capability so that sodium balance can be maintained at reduced BPs (Fig. 39.6). However, blockade of the RAS also reduces the slope of pressure natriuresis and makes BP salt-sensitive.[9] Inappropriately high levels of Ang II reduce renal excretory capability and impair pressure natriuresis, thereby reducing the slope and necessitating increased blood pressure to maintain sodium balance.

The effect of ANGII to reduce renal pressure natriuresis and cause hypertension is the result of its effects to directly or indirectly stimulate sodium transport (Fig. 39.5). Infusion of a physiologic dose of ANGII is usually accompanied by an increase in renal vascular resistance and filtration fraction which favors tubular reabsorption.[10,38,39] In addition, acute administration of an ANGII antagonist or converting enzyme inhibitor under conditions where BP is not dramatically reduced results in a natriuresis that is associated with increases in renal blood flow and a reduction in filtration fraction.[10] ANGII has been shown to reduce peritubular capillary pressure, whereas converting enzyme inhibition increases peritubular capillary and renal interstitial hydrostatic pressure.[10] Thus, alterations in Starling forces across the peritubular capillaries provide an important mechanism whereby the RAS affects the tubular reabsorption of sodium.

Alterations in medullary blood flow may be another renal hemodynamic mechanism whereby ANGII could influence tubular reabsorption of sodium.[7,10,40] Ang II-induced constriction of efferent arterioles of the juxtamedullary nephrons or pericytes of descending vasa recta would decrease inner medullary blood flow. This, in turn, would enhance sodium reabsorption by increasing medullary interstitial tonicity. In support of this mechanism are studies demonstrating that ANGII, at a dose that does not alter whole-kidney GFR or renal blood flow, markedly reduces medullary blood flow and sodium excretion.[10] Studies by Cowley and associates have also shown that inner medullary blood flow is reduced in sodium-depleted dogs, a condition associated with enhanced activity of the RAS.[40] Moreover, ANGII blockade has been shown to improve medullary blood flow and enhance pressure natriuresis in various animal models of hypertension.[7,10,40]

Experimental evidence also suggests an important direct tubular action of ANGII.[10,38,39] Various studies suggest that increased proximal tubule transport in response to physiologic concentrations of ANGII is mediated by changes in HCO_{3-} coupled with Na transport.[38] This effect of ANGII has been attributed to activation of Na/H exchange. In addition to a proximal tubule effect on sodium transport, evidence also indicates ANGII may have direct actions on more distal parts of the nephron.[10,38,39]

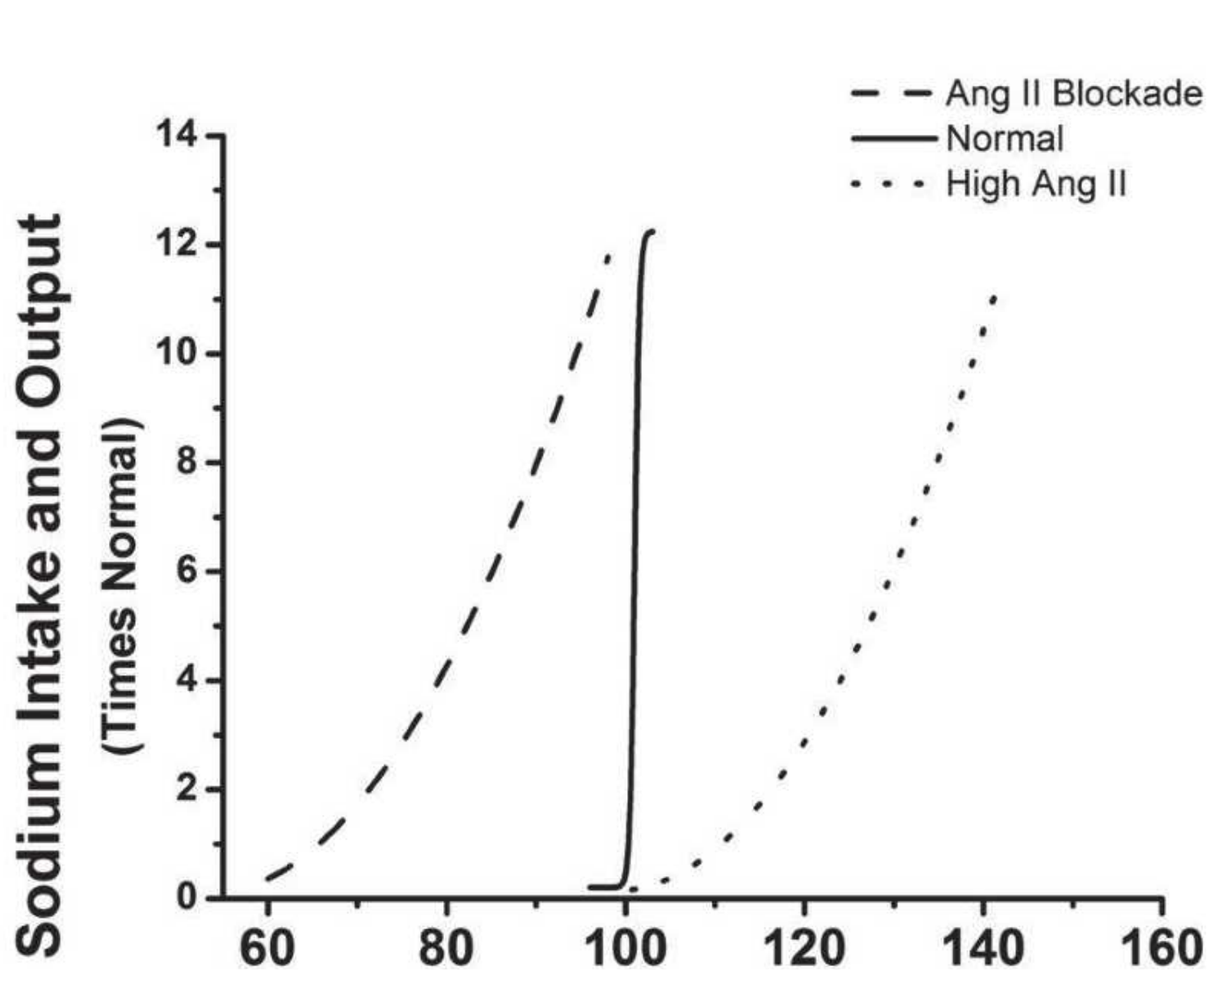

FIGURE 39.6 Effect of changes in mean arterial pressure during chronic changes in sodium intake after angiotensin-converting enzyme (ACE) inhibition, or when angiotensin II was infused at a constant low dose (5 ng/kg/min) to prevent angiotensin II from being suppressed when sodium intake was raised. (Redrawn from data in Hall JE, Guyton AC, Smith MJ Jr, et al. Blood pressure and renal function during chronic changes in sodium intake: Role of angiotensin. *Am J Physiol.* 1980;239:F271–F280.)

Although AT1 receptors are prominently expressed in the kidney, they are also expressed in the heart, blood vessels, adrenal glands, and the brain.[10] Because AT1 receptors are ubiquitously expressed, dissecting the quantitative importance of each individual organ system, including the kidney, in the long-term regulation of blood pressure has been difficult. Utilizing a combined gene targeting with renal cross transplantation approach, Coffman and colleagues examined the role of AT1 receptors in the kidney and their contribution to the development of ANGII-induced hypertension.[41–44] They found that ANG II causes hypertension primarily through effects on AT1 receptors in the kidney associated with reduced urinary sodium excretion, independent of actions of the sympathetic nervous system or aldosterone. When AT1 receptors are eliminated from the kidney, the extrarenal AT1 receptors are not sufficient to induce hypertension (Fig. 39.7). Thus, despite the fact that ANGII activates extrarenal vascular receptors and increases total peripheral resistance, when AT1 receptors are eliminated from the kidney, ANGII does not alter the pressure natriuresis relationship or increase arterial pressure.

More recently Coffman and colleagues reported that abrogation of AT1 receptors in the proximal tubule alone reduces proximal fluid reabsorption, alters expression of key sodium transporters, improves pressure-natriuresis, and significantly attenuates ANGII hypertension.[42] Collectively, the findings of Coffman and colleagues highlight the critical role of the kidney in the pathogenesis of ANGII-dependent hypertension. In addition, they suggest that the major mechanism of action of RAS inhibitors in hypertension is attenuation of ANG II effects in the kidney.

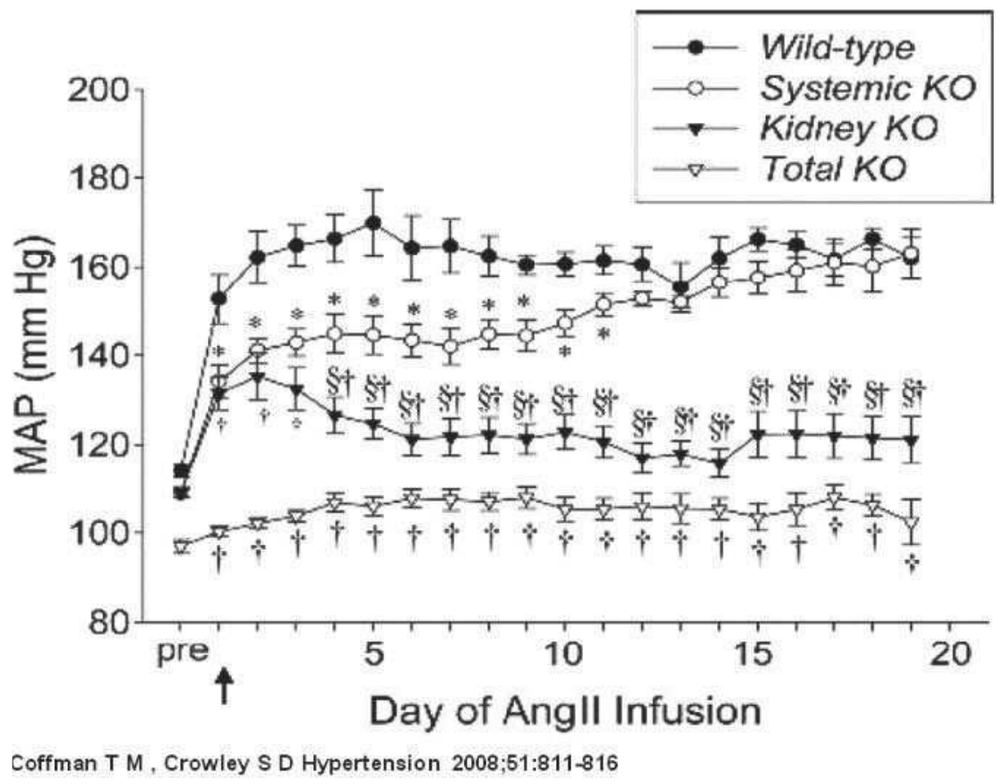

FIGURE 39.7 Blood pressures in cross-transplanted mice during 21 days of AngII infusion. Blood pressure response to AngII in systemic knockout (KO) recapitulates that of the wild-type group by day 12 of AngII infusion. Absence of renal AT_{1A} receptors in kidney KO animals ameliorates AngII–induced hypertension. Total KO blood pressure shows minimal response to AngII infusion. (Coffman TM, Crowley SD. Kidney in hypertension: Guyton redux. *Hypertension*. 2008;51(4):811–816.)

Aldosterone

Aldosterone also plays an important role in the chronic regulation of BP via its sodium-retaining actions on the kidney.[10,45–47] Aldosterone alters the renal pressure natriuresis relationship by enhancing sodium transport in the distal tubules and cortical collecting ducts. The sodium retaining effect of aldosterone is due to binding of aldosterone to the intracellular mineralocorticoid receptor and activation of transcription by target genes. These target genes, in turn, stimulate synthesis or activation of the sodium-potassium ATP-ase pump on the basolateral epithelial membrane and activation of amiloride-sensitive sodium channels on the luminal side of the epithelial membrane.[47,48]

As sodium intake is increased to high levels, aldosterone levels are suppressed allowing sodium excretion to increase to match sodium intake. Conversely, when sodium intake is restricted aldosterone levels increase and sodium excretion is reduced to match the low sodium intake. Thus, a change in aldosterone production in response to changes in sodium intake is another important hormone in the maintenance of sodium balance. An inability to suppress aldosterone production in response to increases in sodium intake therefore is another potential mechanism for salt-sensitive hypertension in humans.[46] In addition to primary hyperaldosteronism, excess activation of the mineralocorticoid receptor by aldosterone has also been implicated in several forms of human hypertension including renovascular hypertension, patients with resistant hypertension, and obesity-related hypertension.[46–51]

The Sympathetic Nervous System

Another antinatriuretic system that can reduce the renal pressure natriuresis relationship and cause chronic hypertension is the renal sympathetic nervous system.[52–56] The kidneys receive extensive sympathetic innervation and increases in renal sympathetic nerve activity reduce sodium excretion by increasing tubular reabsorption or decreasing the filtered load of sodium via alpha adrenergic receptor activation (Fig. 39.8).[52] Renal nerves can act directly on the tubule to increase sodium reabsorption or indirectly by increasing renal vascular resistance and reducing medullary blood flow and renal interstitial pressure. In addition, increased renal sympathetic nerve activity can enhance tubule reabsorption by activating the RAS.

Excessive activation of the renal SNS has been implicated in the pathogenesis of several experimental and genetic forms of hypertension.[52–56] Evidence for a role of the renal nerves in hypertension derives from animal studies showing that renal denervation attenuates or delays the development of hypertension in several forms of experimental hypertension.[56] One particular experimental form of hypertension that is mediated via enhanced renal sympathetic nerve activity is obesity-related hypertension.[56,57] Obesity is often associated with increased sympathetic activity.[56,57] To determine the role of renal nerves in mediating the sodium retention

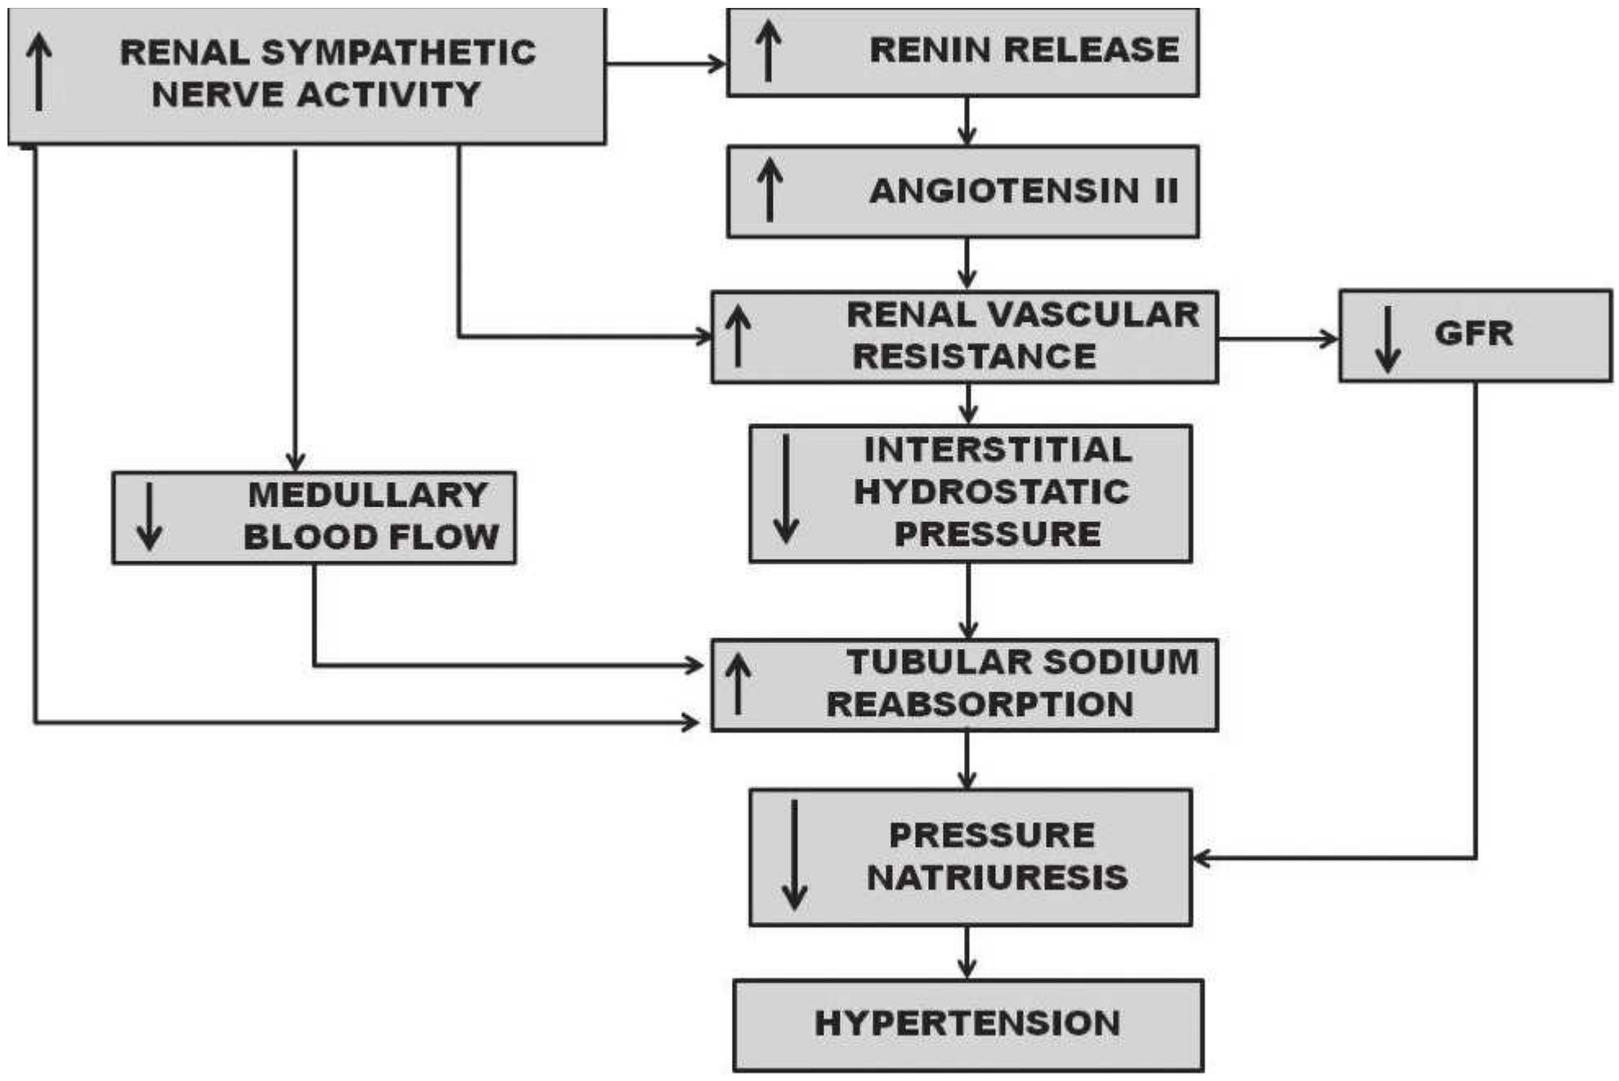

FIGURE 39.8 Renal mechanisms whereby activation of the sympathetic nervous system reduces pressure natriuresis relationship and leads to hypertension.

and hypertension associated with obesity, Kassab and colleagues[58] determined the hemodynamic and renal excretory responses to a high-fat diet in control and bilaterally renal-denervated dogs (Fig. 39.9). In response to a high-fat diet, body weight increased similarly (about 40%) in the control and bilaterally renal-denervated groups. Arterial pressure increased by 15% in the control group but in sharp contrast, 5 weeks of a high-fat diet in the bilaterally renal-denervated group did not significantly increase arterial pressure. Furthermore, after 5 weeks of a high-fat diet, cumulative sodium retention was 455 ± 85 mmol in the control group and only 252 ± 47 mmol in the bilaterally renal-denervated

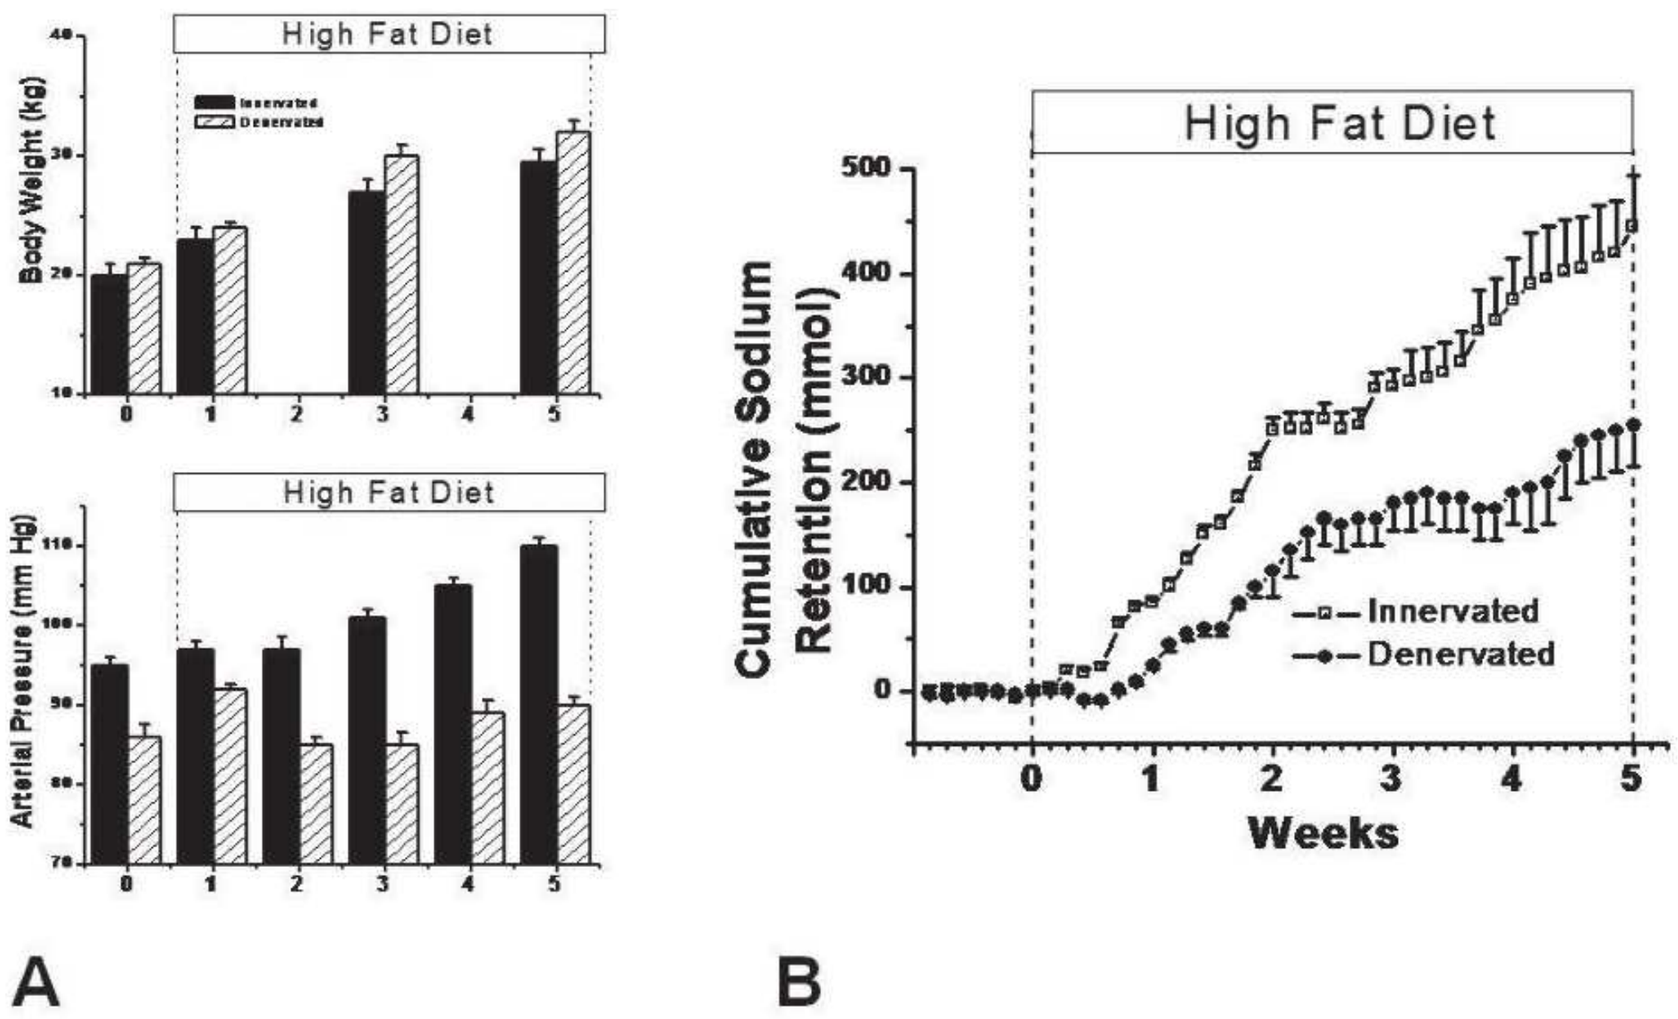

FIGURE 39.9 Changes in body weight and arterial pressure **(A)** and cumulative sodium balance **(B)** in response to a high-fat diet in dogs with innervated and denervated kidneys. (Redrawn from Kassab S, Kato T, Wilkins FC, et al. Renal denervation attenuates the sodium retention and hypertension associated with obesity. *Hypertension*. 1995;25:893–897.)

group. Similar increases in GFR and renal plasma flow occurred in both groups in response to the high-fat diet, indicating that the sodium retention in response to a high-fat diet was due to enhanced sodium reabsorption.[58] The results of this study indicate that the renal nerves play an important role in mediating the sodium retention and hypertension associated with obesity.

Although there is growing evidence for a role of the renal SNS in the development of several animal models of hypertension, the importance of renal nerves in the pathogenesis of human hypertension has yet to be fully elucidated.[56] Application of the norepinephrine spillover methodology in humans has demonstrated activation of the sympathetic nervous outflow to the kidneys in humans with essential hypertension.[56] Renal norepinephrine spillover, on average, is elevated two- to threefold in both normal weight patients with essential hypertension and in obesity-related hypertension.[56] The most compelling evidence for a role of renal nerves in human hypertension are the recent findings that ablation of the renal sympathetic nerves with a radiofrequency-emitting catheter inserted percutaneously significantly reduces BP in patients with resistant hypertension.[59] The level of BP reduction achieved in the resistant hypertensive patients undergoing renal nerve ablation was a mean reduction of 24/10 mm Hg at 3 months and 29/16 mm Hg at 12 months (Fig. 39.10). In a more recent study, the Symplicity HTN-2 trial,106 patients with treatment-resistant hypertension were assessed and renal denervation resulted in impressive reductions in mean office-based measurements of BP (32/12 mm Hg at 6 months), whereas BP remained almost unchanged in the control group.[60] Home and ambulatory measurements of BP followed a similar pattern; the corresponding reductions were 20/12 mm Hg and 11/7 mm Hg with renal denervation, whereas no significant reductions were observed in the control group. It is interesting to note that the average body mass index (BMI) of patients in the study was in the obesity range. Although these data support a potential role for renal nerves in patients with resistant hypertension, it remains unclear as to the relative importance of destruction of renal afferent versus efferent nerves in the antihypertensive effect achieved by the radiofrequency ablation procedure.[56]

The Endothelin System

Endothelin-1 (ET-1) is derived from a 203 amino acid peptide precursor, preproendothelin, which is cleaved after translation to form proendothelin.[61–65] Proendothelin is cleaved in the presence of a converting enzyme to produce the 21 amino acid peptide, ET-1. ET-1 receptor binding sites have been identified throughout the body with the greatest numbers of receptors in the kidneys. ET-1 can either elicit a prohypertensive, antinatriuretic effect by activating endothelin type A (ET_A) receptors and causing renal vasoconstriction or an antihypertensive, natriuretic effect via endothelin

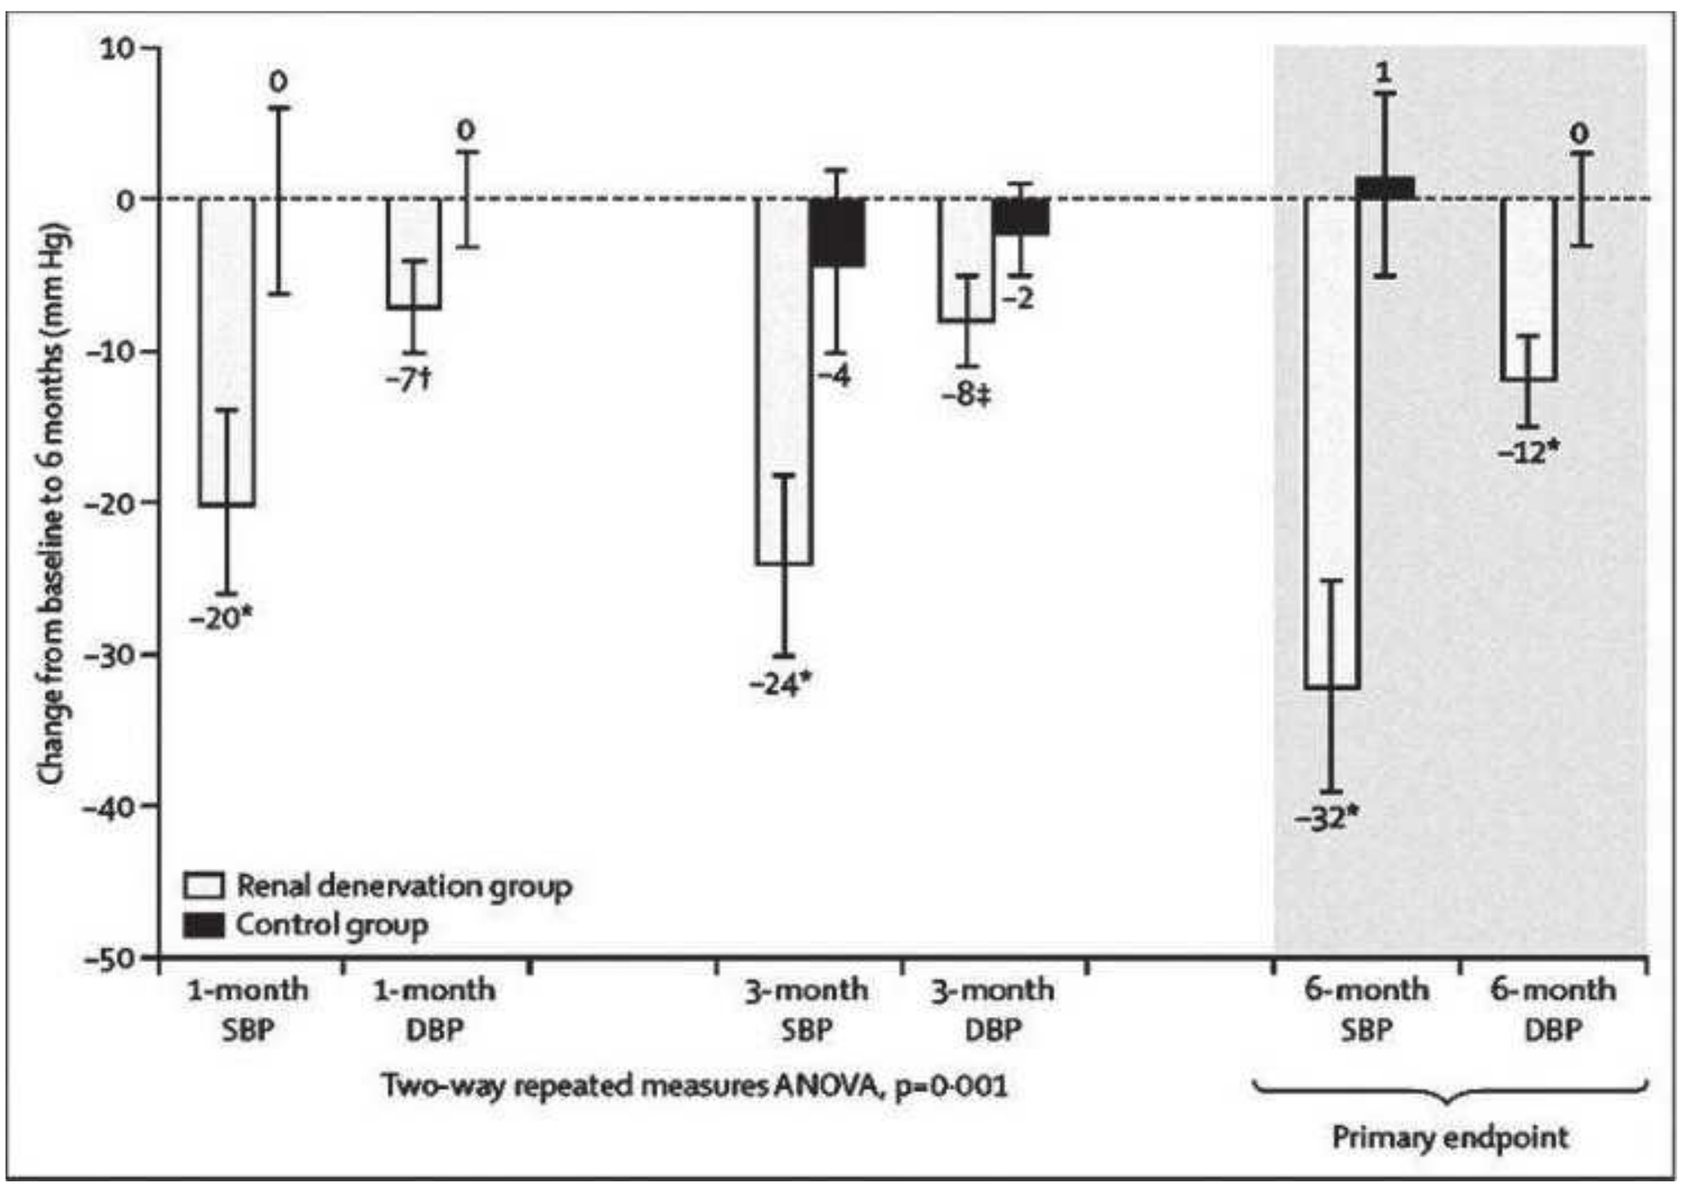

FIGURE 39.10 Blood pressure (BP) lowering effect of radiofrequency ablation of the renal sympathetic nerves for 18 months (M) in patients who were resistant to the usual antihypertensive drugs. *SBP*, systolic blood pressure; *DBP*, diastolic blood pressure. FIGURE 39.11 Summary of the pro- and antihypertensive actions of endothelin-1 (ET-1). The ability of ET-1 to influence blood pressure regulation and renal pressure natriuresis is highly dependent on where ET-1 is produced and which renal ET receptor type is activated. ET-1 can elicit a prohypertensive, antinatriuretic effect by activating ET_A receptors in the kidneys. Activation of renal ET_A receptors increases renal vascular resistance (RVR), which decreases renal plasma flow (RPF) and glomerular filtration rate (GFR), and enhances sodium reabsorption by decreasing peritubular capillary hydrostatic pressure (Pc). The net effect of renal ET_A receptor activation would be increased sodium retention and blood pressure. Conversely, ET-1 can elicit an antihypertensive, natriuretic effect via ET_B receptor activation. Activation of the renal ET_B receptor leads to enhanced synthesis of nitric oxide (NO) and prostaglandin E2 (PG) and suppression of the renin-angiotensin system. The net effect of renal ET_B receptor activation would be decreases in sodium retention and blood pressure.

type B (ET_B) receptor activation (Fig. 39.11). Thus, the ability of ET-1 to influence BP regulation and renal pressure-natriuresis is highly dependent on where ET-1 is produced in the kidney and which renal ET receptor type is activated.[66]

ET-1, via ET_A receptor activation, exerts a variety of actions within the kidney that, if sustained chronically, could contribute to the development of hypertension and progressive renal injury.[66] ET-1 decreases GFR and renal plasma flow.[66,67] Long-term effects of ET-1 on the kidney include stimulation of mesangial cell proliferation and extracellular matrix deposition as well as stimulation of vascular smooth muscle hypertrophy in renal resistance vessels.[68] Previous studies have indicated that expression of ET-1 is greatly enhanced in animal models of severe hypertension with renal vascular hypertrophy and in models of progressive renal injury.[66–68] In addition, treatment with endothelin receptor antagonists attenuated the hypertension and small artery morphologic changes and improved kidney function in these models.[66–68]

Several lines of evidence suggest that ET-1 may play an important role in salt-sensitive forms of hypertension. Dahl salt-sensitive (DS) rats placed on a high-sodium diet are characterized by an attenuated pressure natriuresis; development of hypertension and extensive renal lesions in the form of glomerulosclerosis, renal arteriolar, and tubular injury; and progressive renal failure in late phases of the disease.[69,70] Prepro-ET-1 mRNA and vascular responsiveness to ET-1 are increased in the renal cortex of DS rats compared with Dahl salt-resistant (DR) rats and a positive correlation between ET-1 generation in the renal cortex and the extent of glomerulosclerosis has been reported in DS hypertensive rats.[69,70] Acute infusion of a nonselective ET_A-ET_B receptor antagonist directly into the renal interstitium improves renal hemodynamic and excretory functions in DS rats but not in DR rats.[69,70] Moreover, chronic blockade of ET_A receptors attenuates the hypertension and proteinuria and ameliorates the glomerular and tubular damage associated with high salt intake in DS rats (Fig. 39.12). An interesting unanswered question that emerges is whether the beneficial effect of the ET_A blockade in reducing renal injury is mediated through reducing BP or through direct renal mechanisms.

Although ET-1 clearly plays a significant role in the pathogenesis of some forms of experimental hypertension, especially salt-sensitive models, its role in human hypertension has yet to be fully elucidated. Selective ET_A receptor blockade in hypertensive patients with chronic kidney disease produces a significant reduction in BP, suggesting an upregulation of the ET-1 system in chronic kidney disease–associated hypertension.[71] Krum and colleagues reported that bosentan, a nonselective ET receptor antagonist, reduces BP in patients with essential hypertension as much as did enalapril 20 mg.[72] In another study, 6 weeks of darusentan, a selective ET_A receptor antagonist, lowered both systolic and diastolic BP.[73] Bakris et al.[74] and Weber et al.[75] also showed that darusentan reduced mean 24-hour systolic BP more than placebo in patients with treatment-resistant

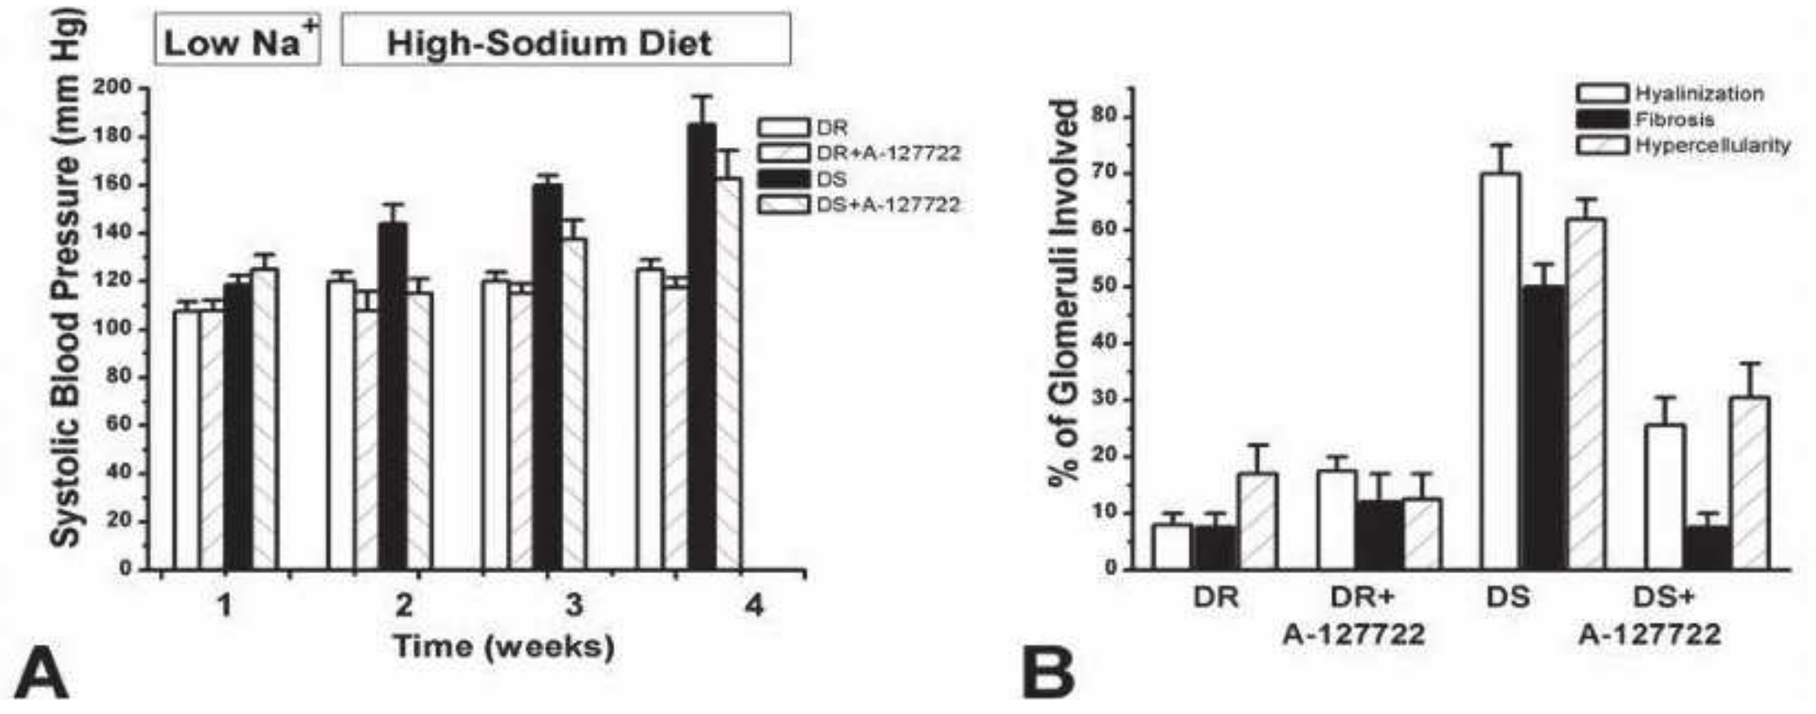

FIGURE 39.12 **A:** Systolic pressures in DS and DR control rats and in those chronically treated with a selective endothelin type A receptor antagonist, A-127722. **B:** Histopathologic changes within the glomeruli of DS and DR rats and in those chronically treated with A-l27722 . Data are expressed as percentage of glomeruli involved with fibrosis, hyalinization, or hypercellularity. (Redrawn from data in Kassab S, Miller M, Novak J, et al. Endothelin-A receptor antagonism attenuates the hypertension and renal injury in Dahl salt-sensitive rats. *Hypertension*. 1998;31:397–402.)

hypertension. Although these clinical studies suggest a potential role for ET-1 in several forms of human hypertension, the importance of ET-1 in human hypertension deserves further investigation.[76–78]

Although much attention has been given to the role of ET-1 in the pathophysiology of cardiovascular and renal disease acting via an ET_A receptor, recent studies indicate an important physiologic role for ET-1 in the regulation of sodium balance and arterial pressure via ET_B receptor activation.[68] The most compelling evidence that the endothelin system may play a significant role in the regulation of sodium balance and arterial pressure are the reports that transgenic animals deficient in ET_B receptors develop a severe form of salt-sensitive hypertension.[79,80] Additional evidence comes from studies indicating that pharmacologic antagonism of ET_B receptors produces significant hypertension in rats.[81]

Although systemic ET_B receptor blockade produces significant hypertension that is salt-sensitive, the physiologic mechanisms involved in mediating the hypertension are still unknown. Because ET_B receptors are located on multiple cell types through the body, including endothelial cells and renal epithelial cells, both intrarenal and extrarenal mechanisms may mediate the hypertension produced by chronic disruption of the ET_B receptor. However, several recent studies suggest that the renal endothelin system plays a major role in controlling BP under high sodium intake conditions. To examine the role of endothelial cell ET_B receptors in salt-sensitive hypertension, Bagnall and colleagues generated an endothelial cell-specific ET_B receptor in knockout mice using a Cre-loxP approach.[82] They reported that ablation of ET_B receptors exclusively from endothelial cells produces endothelial dysfunction in the absence of hypertension. In contrast to models of total ET_B receptor ablation, the BP response to a high-salt diet was unchanged in endothelial cell-specific ET_B receptor knockouts compared to control mice. These important findings suggest that nonendothelial cell ET_B receptors are important for regulation of BP.

There is growing evidence to suggest that ET-1, acting through the renal medullary ET_B receptors, is involved in the regulation of sodium balance and BP under normal physiologic conditions. The kidney is an important site of ET-1 production, and ET_B receptors are expressed at important renal sites of ET-1 synthesis, particularly in the renal medulla.[68] Some of the first studies using synthetic ET-1 demonstrated that nonpressor doses of ET-1 produced significant natriuresis and diuresis.[68] It is now known that ET_B receptors are located in various parts of the nephron, including the proximal tubule, medullary thick ascending limb, collecting tubule, and the inner medullary collecting duct.[68] The highest concentration of ET_B receptors appears to be on the inner medullary collecting duct in the renal medulla.[68] Activation of ET_B receptors has been reported to inhibit sodium and water reabsorption along various parts of the nephron.[68] Taken together, these data indicate that ET-1, via ET_B receptors, may influence the renal handling of sodium and water. The exact mechanism whereby ET_B receptor activation inhibits sodium reabsorption is unclear but could involve other autocoid factors such as nitric oxide, PGE2, and/or 20-HETE.

For the renal ET-1 system to be an important control system for the regulation of sodium balance, the production of renal ET-1 should change in response to variations in sodium intake. Moreover, blockade of ET_B receptors should result in a salt-sensitive form of hypertension. Although there is ample data showing that ET-1 can influence sodium reabsorption, there is a paucity of data in the literature examining the relationship between sodium intake and renal production of ET-1. A recent study by Pollock and Pollock,[81] however, has shown a positive correlation between sodium intake and renal excretion of ET-1. The most convincing

evidence for a role of the renal ET-1 in controlling sodium excretion and arterial pressure during chronic changes in sodium intake is the result of several recent studies. Gariepy and colleagues demonstrated that rats deficient in ET_B receptor expression display salt-sensitive hypertension.[80] Likewise, Pollock and Pollock reported that chronic pharmacologic blockade of the ET_B receptor in rats resulted in hypertension that was sensitive to dietary sodium intake.[80] Moreover, Ohuchi et al. reported elevation in BP by genetic and pharmacologic disruption of the ET_B receptor in mice.[83]

In a recent report by Ge and colleagues,[84] disruption of the ET_B receptor in the collecting duct cells of mice was found to produce significant hypertension that was salt-sensitive. Collecting duct ET_B knockout mice on a normal sodium diet were hypertensive.[84] Collecting duct ET_B knockout mice on a high-sodium diet had worsened hypertension, reduced urinary sodium excretion, and excessive weight gain.[84] Similar findings were found in mice with combined ET_B and ET_A receptor knockout in the collecting duct cells (Fig. 39.13).[85] These findings provide strong evidence that the collecting duct ET_B receptor is an important physiologic regulator of renal sodium excretion and blood pressure.

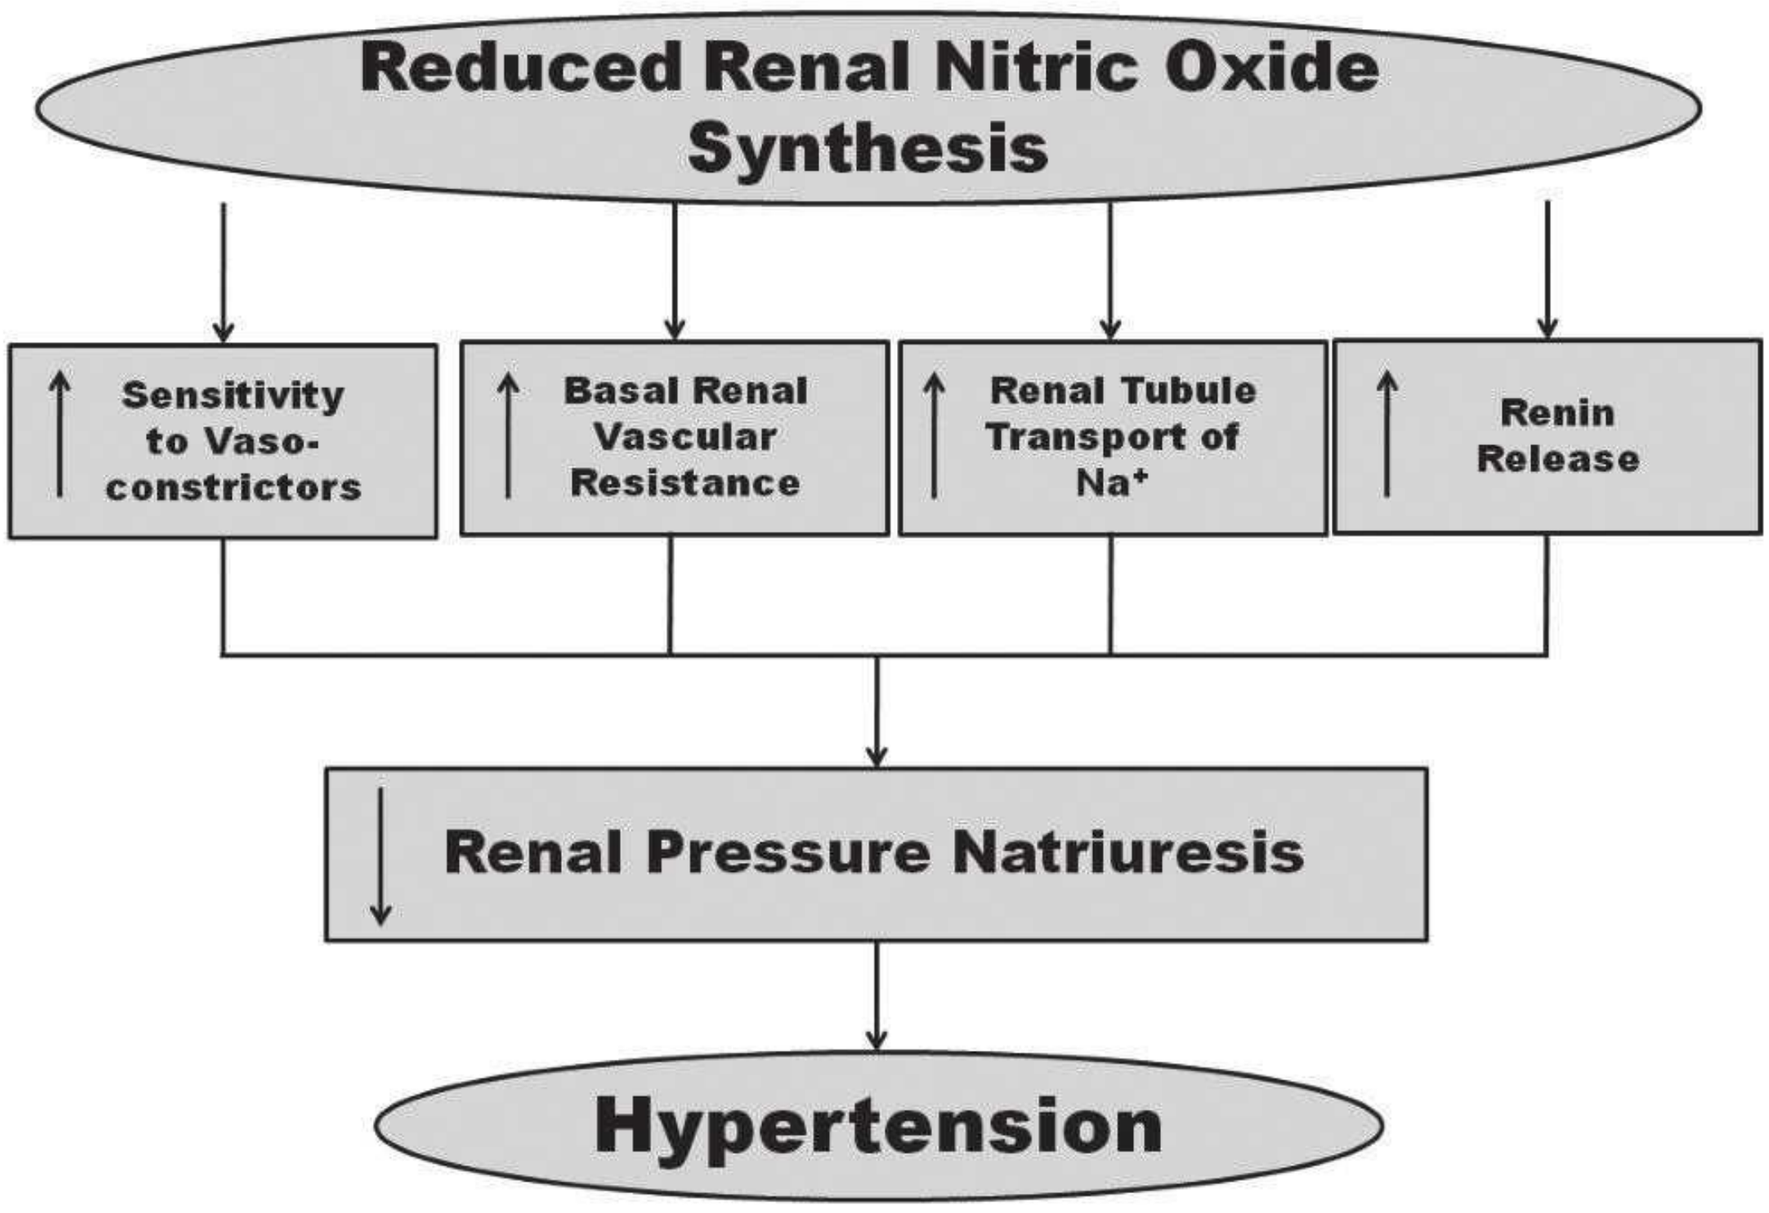

FIGURE 39.14 The renal effector mechanisms whereby reductions in NO synthesis decrease pressure natriuresis and increase blood pressure. A reduction in endothelial derived nitric oxide (EDNO) synthesis leads to a decrease in renal sodium excretory function by directly increasing basal renal vascular resistance, enhancing the renal vascular responsiveness to vasoconstrictors such as ANGII or norepinephrine, or activating the renin-angiotensin system. Reductions in NO synthesis also reduce sodium excretory function either through direct effects on tubular transport or through changes in intrarenal physical factors such as renal interstitial hydrostatic pressure or medullary blood flow.

Combined knockout of collecting duct endothelin A and B receptors causes hypertension and sodium retention. *Am J Physiol Renal Physiol.* 2008;295(6):F1635–1640.)

Nitric Oxide

All components of the nitric oxide (NO) system are located within the kidney and pharmacologic or genetic disruption of this system results in a sustained hypertension associated with reductions in renal hemodynamics and pressure-natriuresis.[85–87] The magnitude of the increase in BP is also dependent on the dietary sodium intake.[85–87] These findings have led to the concept that NO is not only important in the long-term regulation of sodium balance and BP but also to the notion that abnormalities in NO production result in altered pressure natriuresis and a salt-sensitive form of hypertension.

The renal effector mechanisms whereby reductions in NO synthesis alter pressure natriuresis can be divided into hemodynamic and tubular components each of which may be modulated by processes that are intrinsic and extrinsic to the kidney (Fig. 39.14). For example, reductions in NO synthesis could lead to a decrease in renal sodium excretory function by directly increasing basal renal vascular resistance or by enhancing the renal vascular responsiveness to vasoconstrictors such as AngII or norepinephrine (Fig. 39.15).[87–90] Reductions in NO synthesis also reduce sodium excretory function either through direct effects on tubular transport or through changes in intrarenal physical factors such as renal interstitial hydrostatic pressure or medullary blood flow.[85,86,91,92] Consistent with this hypothesis are observations that the acute infusion of an NO synthase (NOS) inhibitor directly into the renal medulla significantly reduces papillary blood flow, renal interstitial hydrostatic pressure (RIHP), and decreases urinary sodium and water excretion without affecting GFR or systemic pressure.[91–93] Chronic medullary interstitial infusion of NOS inhibitors in conscious rats results in sustained reductions in medullary blood flow, sustained sodium and water retention, and hypertension which are reversed when the infusion is discontinued (Fig. 39.16). These findings demonstrate that

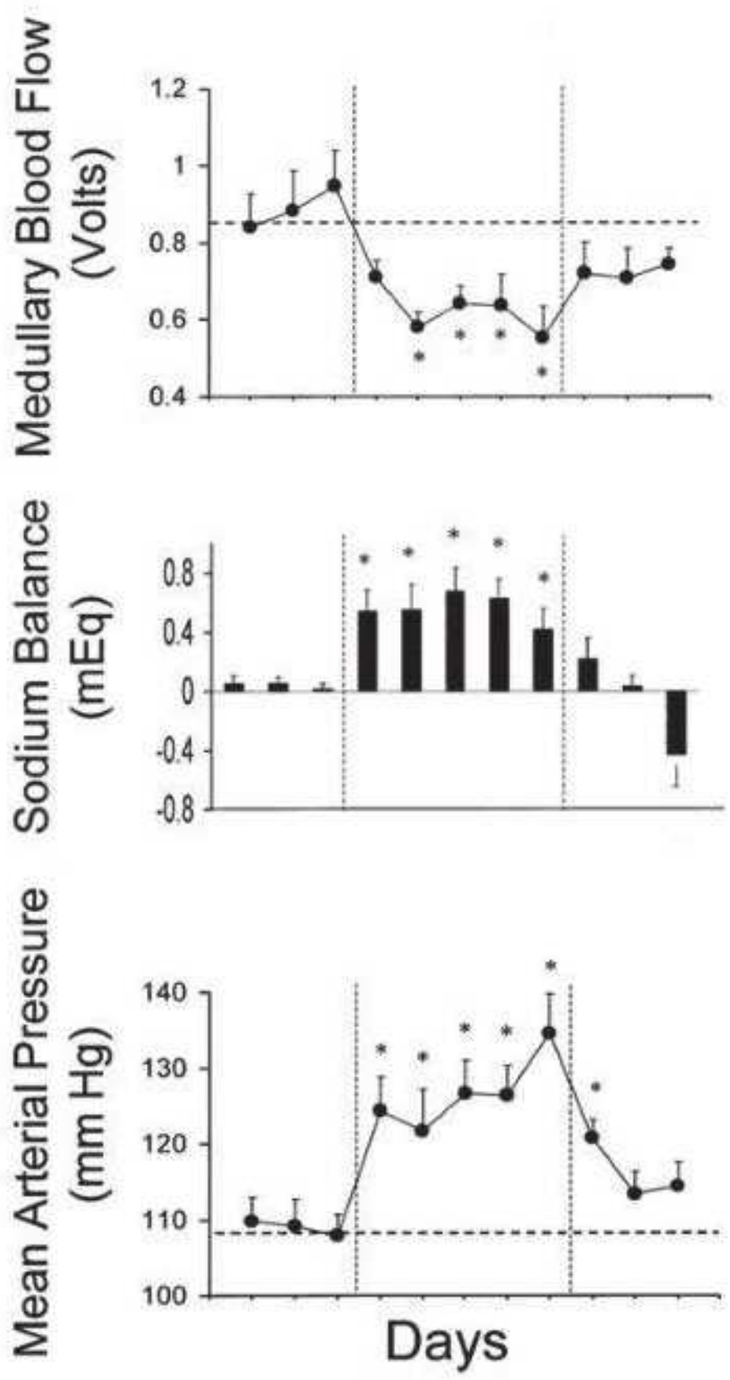

FIGURE 39.16 Chronic effect of renal medullary interstitial infusion of the nitric oxide synthase inhibitor L-NAME (8.6 mg · kg^{-1} · day^{-1}) on renal medullary blood flow (*top*), daily sodium balance (*middle*), and mean arterial blood pressure (*bottom*) in conscious Sprague-Dawley rats. Vertical dashed lines indicate the L-NAME infusion period. *Significant difference from control ($P < 0.05$). (Mattson DL, Lu SH, Nakanishi K, et al. Effect of chronic renal medullary nitric oxide inhibition on blood pressure. *Am J Physiol Heart Circ Physiol.* 1994;266:H1918–H1926.)

reductions in medullary blood flow may be another important mechanism whereby inhibition of NO in the kidney leads to a hypertensive shift in pressure natriuresis.[91]

Inhibition of NO synthesis may have direct effects on renal tubule transport.[86,94] NO has direct effects on sodium uptake in cultured cortical collecting duct cells by altering apical sodium channels.[86] Sodium transport in the cortical collecting duct in vivo is mediated through changes in cyclic GMP. Micropuncture studies have shown NOS inhibitors decrease proximal tubule reabsorption in anesthetized rats.[86] This effect has been attributed to antagonism of Ang II–mediated sodium transport. An effect of NO on proximal reabsorption has also been inferred from changes in lithium clearance induced during inhibition of NO production.[86] Thus, NO can affect sodium reabsorption via direct effects on tubular transport or indirectly via alteration in medullary blood flow or renal interstitial hydrostatic pressure.

Another mechanism whereby NO synthesis inhibition may reduce pressure natriuresis is via activation of the RAS.[85] Inhibition of NO production enhances renin release from rat cortical kidney slices.[85] Inhibitors of NO synthesis also increase plasma renin activity. Intrarenal inhibition of NO increased renin release in dogs, an effect that is dependent on the macula densa mechanism.[95]

Several lines of evidence suggest that NO may play an important role in the regulation of sodium balance and in pathogenesis of salt-sensitive hypertension.[84,94] An increase in renal NO production or release as evidenced by increased urinary excretion of NO metabolites or the NO second messenger, cyclic GMP, has been reported to be essential for the maintenance of normotension during a dietary salt challenge. Prevention of this increase in renal NO production results in salt-sensitive hypertension.[84,85,94]

There is also ample in vitro evidence demonstrating that NO synthesis is impaired in some vascular beds in human essential hypertension. The extent to which these observations reflect effects of the hypertensive process or reflect important mechanisms for the pathogenesis of the hypertensive condition remains unclear.

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) elicits an antihypertensive, natriuretic effect via its receptors (NPR-A). ANP is a 28 amino acid peptide synthesized and released from atrial cardiocytes in response to stretch.[96,97] Once ANP is released from the atria, it enhances sodium excretion through extrarenal and intrarenal mechanisms.[96] ANP increases GFR while having no effect on renal blood flow.[96,98] However, increased GFR is not a prerequisite for ANP to enhance sodium excretion. A deficiency in ANP production or a defect in its receptors may reduce pressure natriuresis and lead to hypertension by enhancing tubular sodium reabsorption either directly by enhancing the active tubular transport of sodium or indirectly via alterations in medullary blood flow, physical factors, and intrarenal hormones (Fig. 39.17).

ANP also has actions at several sites of the RAS cascade.[96,98] Intrarenal or intravenous infusion of ANP reduces the renin secretion rate, presumably by a macula densa mechanism because ANP failed to reduce renin secretion in nonfiltering kidneys. The reduction in renin secretion would decrease intrarenal levels of AngII, which could contribute to ANP-induced natriuresis. When intrarenal levels of AngII were prevented from decreasing the natriuretic effects of ANP were blunted.[96]

ANP also decreases aldosterone release from the adrenal zona glomerulosa cells.[96] Two mechanisms for ANP-induced suppression of aldosterone release have been suggested: (1) a direct action on adrenal glomerulosa cells and (2) reduced circulating levels of AngII due to suppressed renin secretion under in vivo conditions.[96] Although the suppression

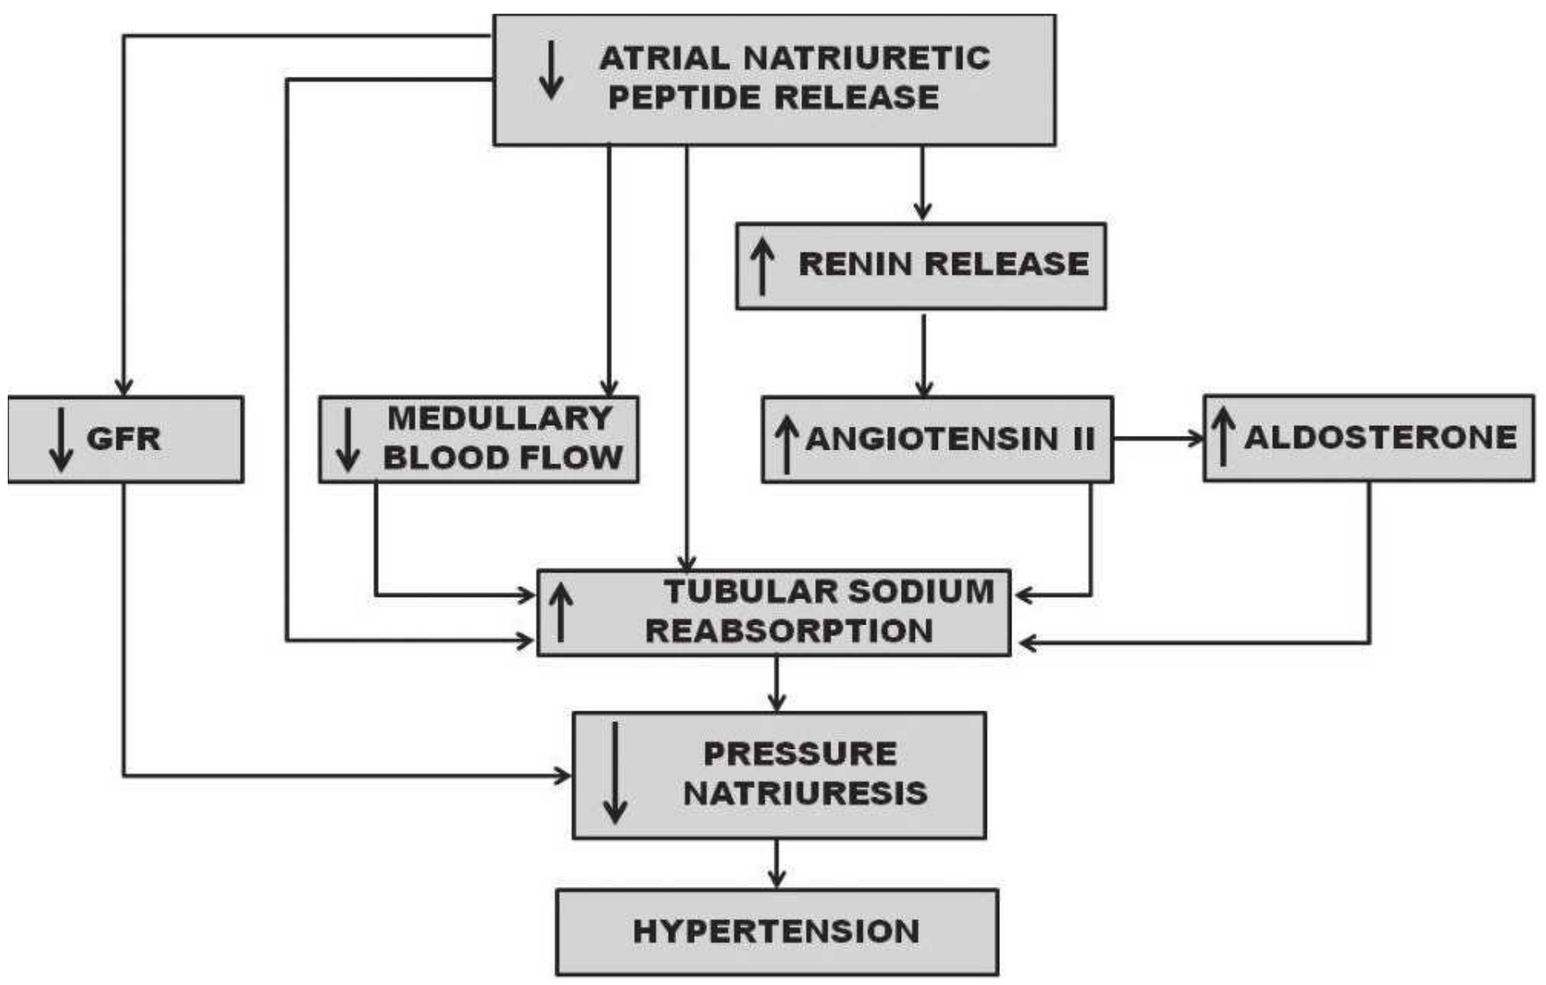

FIGURE 39.17 Renal mechanisms whereby reductions in atrial natriuretic peptide synthesis or atrial natriuretic peptide receptor defects reduce pressure natriuresis relationship and lead to hypertension.

of aldosterone release would not play a role in mediating the acute natriuretic responses to ANP, decreases in circulating levels of aldosterone could contribute to the long-term actions of ANP on sodium balance and arterial pressure regulation.

Plasma levels of ANP are elevated in numerous physiologic conditions associated with enhanced sodium excretion.[96,97] Acute saline of blood volume expansion consistently elevates circulating levels of ANP. Some, but not all, investigators have reported that chronic increases in dietary sodium intake raise circulating levels of ANP. Several studies have reported that infusions of exogenous ANP at rates that result in physiologically relevant plasma concentrations, comparable to those observed during volume expansion, have significant renal and cardiovascular effects.[96,97] Infusion of ANP at a rate that causes a twofold increase in plasma ANP elicits significant natriuresis, especially in the presence of other natriuretic stimuli, such as high renal perfusion pressure.[96] Long-term physiologic elevations in plasma ANP also shift the renal-pressure natriuresis relationship and reduce arterial pressure.[98]

The development of genetic mouse models that exhibit chronic alterations in expression of the genes for ANP or its receptors (NPR-A, NPR-C) have also provided compelling evidence for a role of ANP in chronic regulation of renal pressure natriuresis and BP.[99] Transgenic mice overexpressing ANP gene are hypotensive relative to the nontransgenic littermates, whereas mice harboring functional disruptions of the ANP or NPR-A genes are hypertensive. The ANP gene knockout mice develop a salt-sensitive form of hypertension in association with failure to adequately suppress the RAS (Fig. 39.18). These findings suggest that genetic deficiencies in ANP or natriuretic receptor activity could play a role in the pathogenesis of salt-sensitive hypertension.[100] Indeed, common genetic variants at the NPPA-NPPB locus associated with circulating natriuretic peptide concentrations may contribute to interindividual variation in blood pressure and hypertension.

Arachidonic Acid Metabolites

Cyclooxygenase metabolizes arachidonic acid into prostaglandin (PG) G_2 and subsequently to PGH_2, which is then further metabolized by tissue-specific isomerases to PGs and thromboxane.[101,102] Although the kidney produces many types of PGs with multiple functions, the major renal prostaglandin controlling sodium excretion is probably PGE_2.[101,102] However, production of other arachidonate acid metabolites, such as prostacyclin, thromboxane, and 20-HETE, may also influence renal-pressure natriuresis and BP regulation. The largest production of PGE_2 occurs in the medulla with decreasing synthesis in the cortex. PGE_2 is synthesized and rapidly inactivated and, once synthesized, is released and not stored. Once released, PGE_2 influences sodium transport by several intrarenal mechanisms.

Despite numerous reports that PGs may contribute to the natriuresis of acute physiologic perturbations, the importance of endogenous renal PGs in the long-term

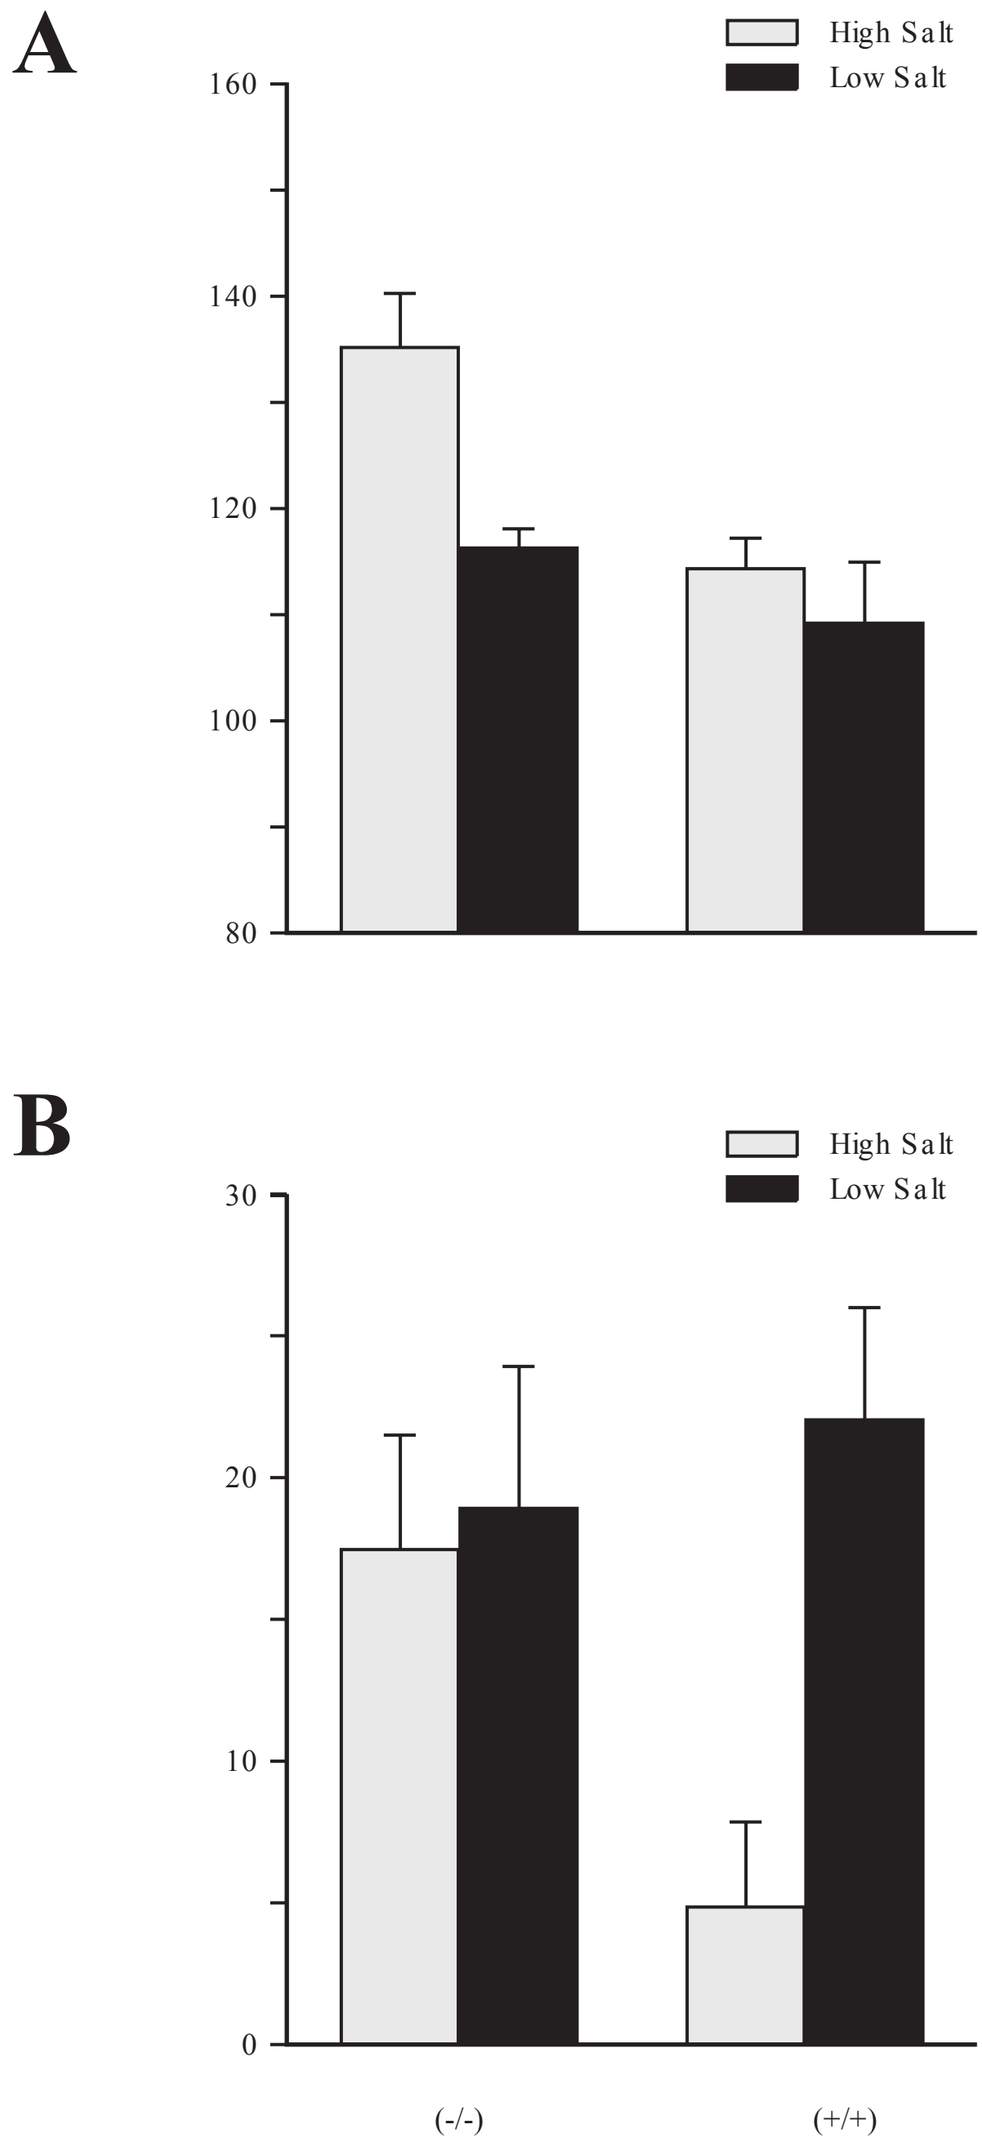

FIGURE 39.18 Mean arterial pressure (MAP) and plasma renin activity (PRA) in atrial natriuretic peptide knockout mice fed on HS or LS diets for 3 to 4 weeks. (Redrawn from Melo LG, Veress AT, Chong CK, et al. Salt-sensitive hypertension in ANP knockout mice: potential role of abnormal plasma renin activity. *Am J Physiol.* 1998; 274: R255–R261.)

regulation of sodium balance remains unclear.[101] Increases in dietary sodium intake have little or no effect on urinary PG excretion. In addition, nonspecific cyclooxygenase inhibitors do not affect the sodium excretory or BP responses to chronic alterations in dietary sodium intake. Thus, it appears that endogenous renal PGs may not play a major role

in regulating sodium excretion during chronic changes in sodium intake.[101]

Although long-term administration of PG synthesis inhibitors has very little effect on volume and/or arterial pressure regulation under normal physiologic conditions, renal PGs may be important in pathophysiologic states associated with enhanced activity of the RAS.[101] In vitro and in vivo studies indicate that renal PGs protect the preglomerular vessels form excessive AngII-induced vasoconstriction.[101] In the absence of this protective mechanism in pathophysiologic states the renal vasculature could be exposed to the potent vasoconstrictor actions of AngII. This could lead to significant impairment of renal hemodynamics, reduced excretory function, and hypertension.

It is now known that there are at least two distinct cyclooxygenases, COX-1 and COX-2.[53] COX-1 is called the constitutive enzyme because of its wide tissue distribution, whereas COX-2 has been termed as inducible because of its more restricted basal expression and its upregulation by inflammatory and/or proliferative stimuli.[101] COX-2 inhibition has been shown to decrease urine sodium excretion and induce mild to moderate increases in arterial pressure. In addition, nonsteroidal anti-inflammatory drugs (NSAIDs) in general and COX-2 inhibitors in particular can aggravate preexisting hypertension. Moreover, blockade of COX-2 activity can have deleterious effects on renal blood flow and GFR.[101] In addition to physiologic regulation of COX-2 expression in the kidney, increased renal cortical COX-2 expression is seen in experimental models associated with altered renal hemodynamics and progressive renal injury. Thus, NSAIDs can cause acute kidney injury in patients with compromised renal hemodynamics.

In addition to renal PGs generated via the COX pathway, other eicosanoids that inhibit tubular sodium transport are produced by cytochrome P450 (CYP) monooxygenase metabolism of arachidonic acid.[102] CYP enzymes metabolize arachidonic acid primarily to 20-HETE and EETs. 20-HETE is a potent constrictor of renal arterioles that may have an important role in autoregulation of renal blood flow and tubuloglomerular feedback (Fig. 39.19).[102] 20-HETE and EETs also inhibit sodium reabsorption in the proximal tubule and thick ascending loop of Henle (TALH). Compelling evidence suggests that the renal production of CYP metabolites of arachidonic acid is altered in genetic and experimental models of hypertension and that this system contributes to the resetting of pressure natriuresis and the development of hypertension. In the SHR, the renal production of 20-HETE is increased and inhibitors of the formation of 20-HETE decrease arterial pressure.[102] Blockade of 20-HETE synthesis also reduces BP or improves renal function in deoxycorticosterone acetate (DOCA)-salt, angiotensin II-infused, and Lyon hypertensive rats.[102] In contrast, 20-HETE formation is reduced in the thick ascending limb

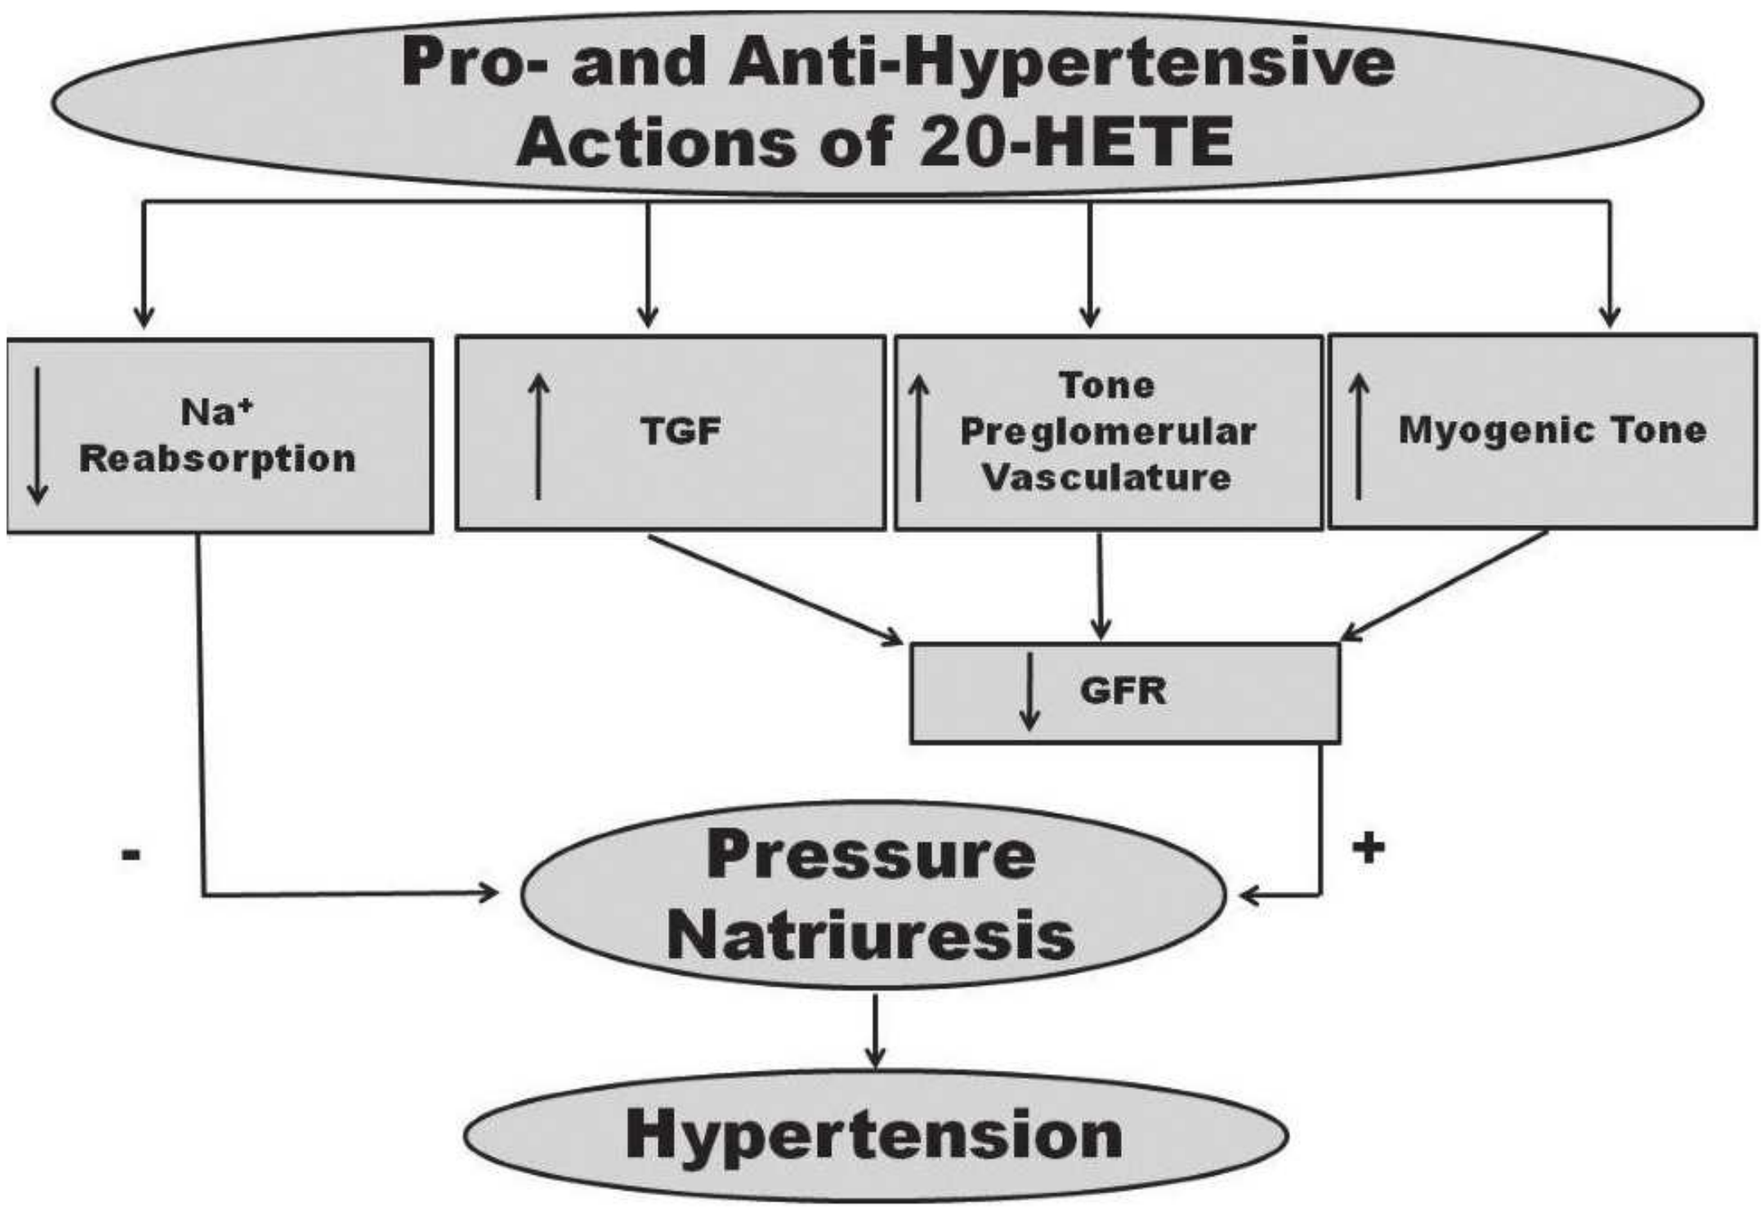

FIGURE 39.19 Summary of the pro- and antihypertensive actions of 20-HETE. 20-HETE produced in the renal tubules inhibits sodium transport and lowers blood pressure. In the renal vasculature and glomerulus, 20-HETE is a constrictor that lowers glomerular filtration rate, promotes sodium retention, and increases arterial pressure. In the peripheral circulation, 20-HETE increases vascular tone and increases blood pressure. *TGF*, tubuloglomerular feedback; *TPR*, total peripheral resistance.

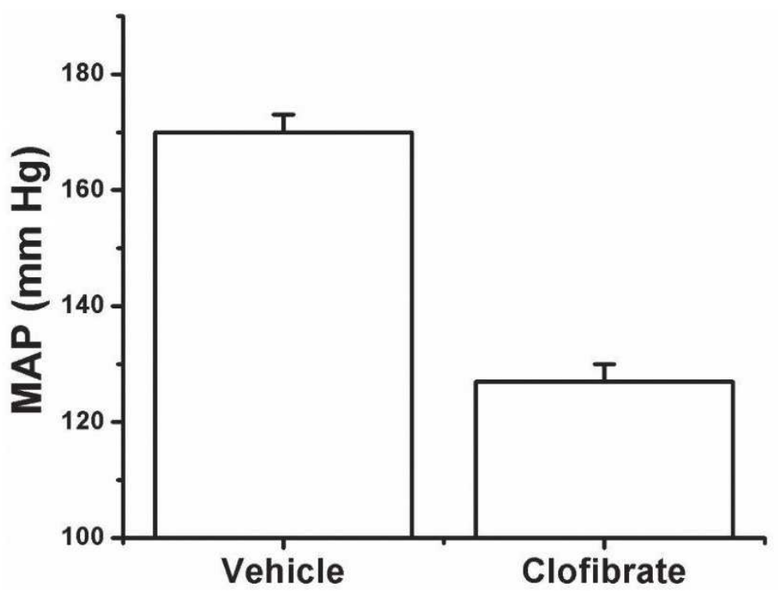

FIGURE 39.20 Left: effect of induction of the renal production of 20-HETE and expression of CYP4A protein with clofibrate on mean arterial pressure (MAP) of Dahl S rats fed a high-salt diet for 4 weeks. (Redrawn from Roman RJ. P-450 metabolites of arachidonic acid in the control of cardiovascular function. *Physiol Rev.* 2002;82:131–185.)

of Dahl S rats and this contributes to elevated sodium reabsorption.[102] Enhanced 20-HETE synthesis improves pressure-natriuresis and lowers BP in Dahl S rats (Fig. 39.20) whereas inhibitors of 20-HETE production promote the development of hypertension in Lewis rats.[102]

Studies in humans also suggest that CYP metabolites may play a role in sodium homeostasis. Urinary 20-HETE excretion is regulated by salt intake and is differentially regulated in salt-sensitive versus salt-resistant subjects.[103,104] Moreover, there appears to be a strong negative relationship between the excretion of 20-HETE and body mass index (BMI), suggesting that some factor related to obesity may be responsible for decreased synthesis or excretion of this eicosanoid in hypertension.[103,104] These observations support the possibility that impaired renal production of 20-HETE could contribute to impaired renal-pressure natriuresis in human hypertension, especially when associated with obesity. However, further mechanistic studies are needed to test the importance of 20-HETE in human hypertension.

Oxidative Stress

Recent studies suggest that ROS may play a role in the initiation and progression of cardiovascular dysfunction associated with diseases such as hyperlipidemia, diabetes mellitus, and hypertension.[105–108] In many forms of hypertension, the increased ROS are derived from NAD(P)H oxidases, which could serve as a triggering mechanism for uncoupling endothelial NOS by oxidants.[105,106]

ROS produced by migrating inflammatory cells and/or vascular cells have distinct functional effects on each cell type.[105] These effects include endothelial dysfunction, renal tubule sodium transport, cell growth, migration, inflammatory gene expression, and matrix regulation. ROS, by renal hemodynamics and renal tubule cell function (Fig. 39.21),

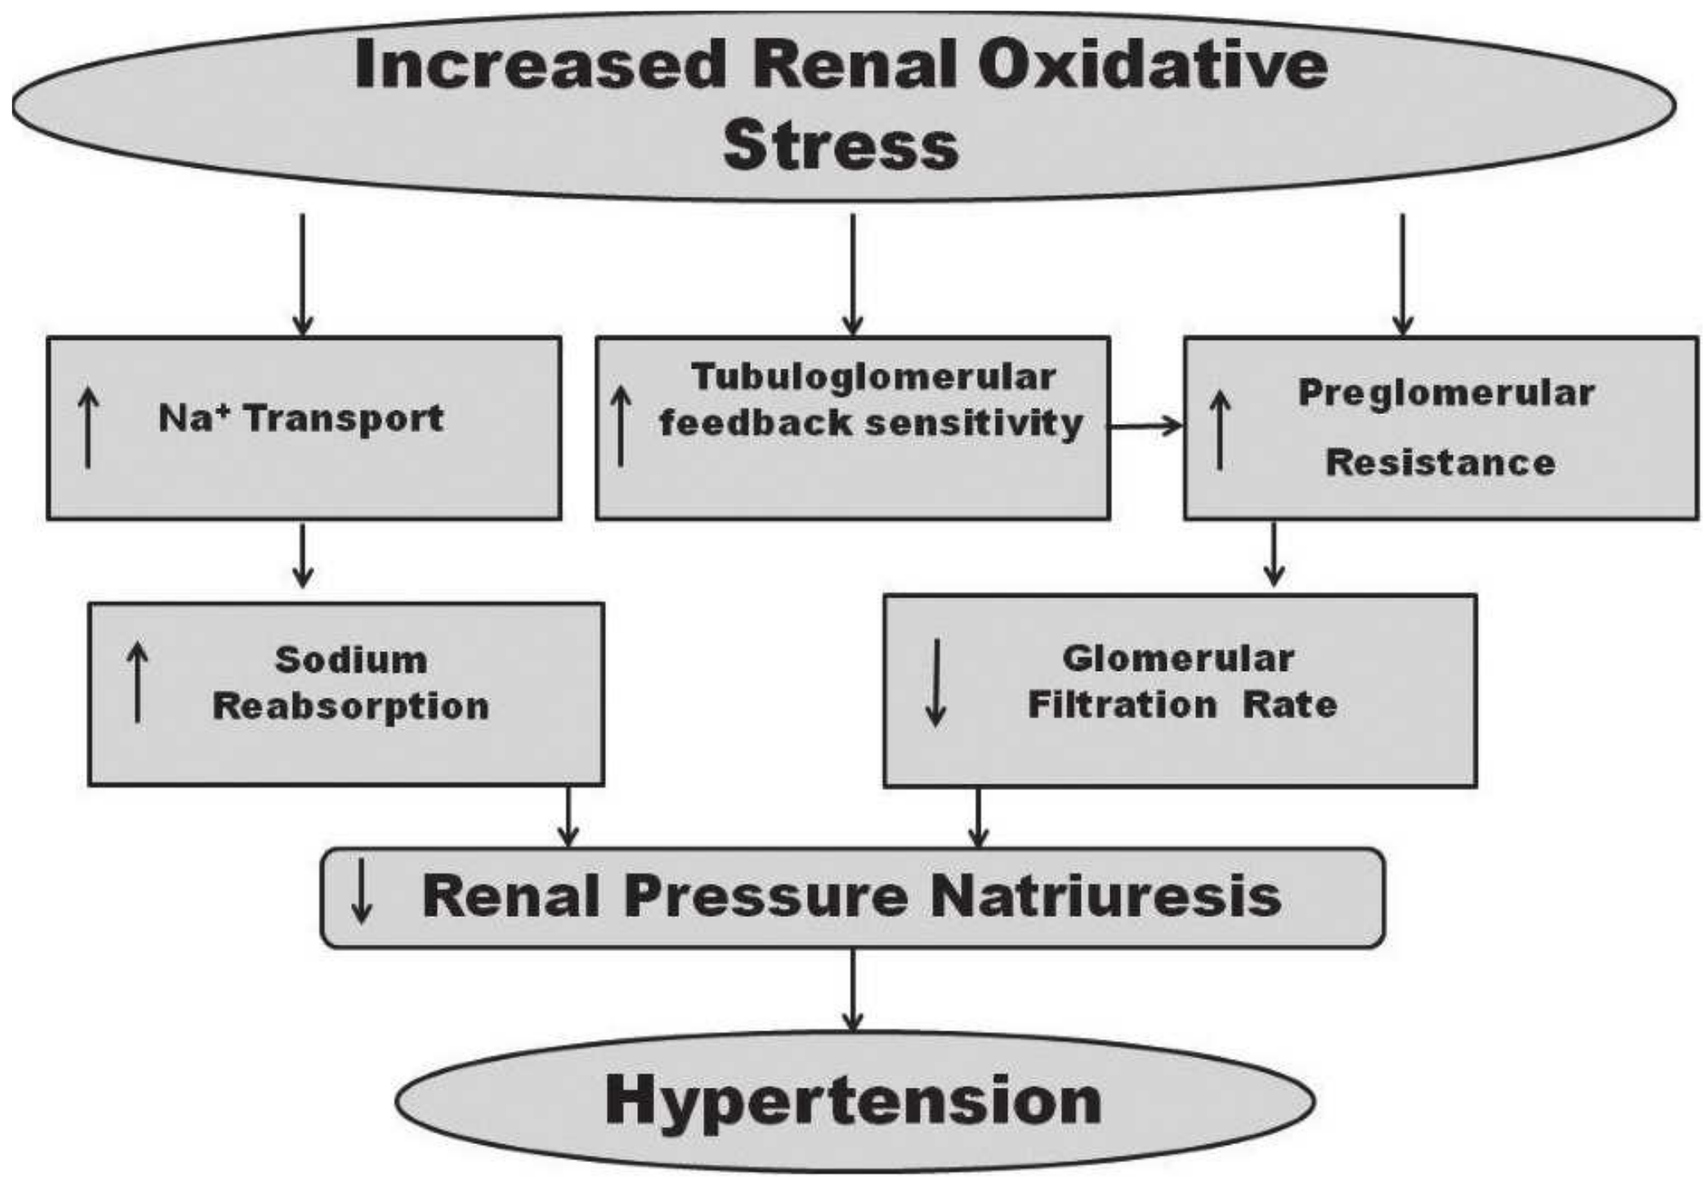

FIGURE 39.21 Renal mechanisms whereby reactive oxygen species impair pressure natriuresis and increase blood pressure. An increase in renal oxidative stress impairs renal pressure natriuresis by increasing renal vascular resistance or enhancing tubuloglomerular feedback, both of which decrease the glomerular filtration rate. Renal oxidative stress also reduces sodium excretion by direct effects to increase renal tubular reabsorption.

can play a role in altering renal pressure natriuresis and BP regulation.[105,108–111]

Growing experimental evidence supports a role for ROS in various animal models of sodium-sensitive hypertension.[105–111] The Dahl salt-sensitive (S) rat has increased vascular and renal superoxide production and increased levels of H_2O_2. The renal protein expression of superoxide dismutase (SOD) is decreased in the kidney of Dahl S rats, and long-term administration of Tempol, a superoxide mimetic, significantly decreases arterial pressure and renal damage. Another salt-sensitive model, the stroke-prone spontaneously hypertensive rat (SP-SHR), has elevated levels of superoxide and decreased total plasma antioxidant capacity. Superoxide production is also increased in the deoxycorticosterone acetate (DOCA)-salt hypertensive rat. Treatment of the DOCA-salt rats with apocynin, an NADPH oxidase inhibitor, decreases aortic superoxide production and arterial pressure.

The importance of oxidative stress in human hypertension is unclear. An imbalance between total oxidant production and the antioxidant capacity in human hypertension has been reported to occur in some but not all studies.[105,106] The equivocal findings in human studies are most likely due to difficulty of assessing oxidative stress in humans. Moreover, most recent human studies have found that vitamin E and C supplementation has little or no effect on BP.[105,106] However, the relatively low doses of vitamin E and C used in many of these studies are weak antioxidants. Thus, further clinical studies are necessary to determine the quantitative role of oxidative stress in human hypertension.

Inflammatory Cytokines and the Immune System

Although inflammation and the immune system were first associated with hypertension over four decades ago, growing evidence over the last 5 years have shown that both innate and adaptive immunity directly contribute to hypertension and renal injury.[112,114–116] Inflammatory cells, including macrophages and T cells, have been reported to accumulate in the kidney of hypertensive animals.[116] Additional support for a role for cytokines in hypertension are findings that plasma levels of proinflammatory cytokines correlate with increased BP in human hypertension and in some experimental animal models of hypertension.[117,118] Moreover, several studies have demonstrated that chronic increases in plasma cytokines, comparable to concentrations observed in the hypertension associated with hypertension preeclampsia, cause significant and sustained increases in BP.[117,118]

Lee and coworkers[119] found that hypertension caused by chronic ANGII excess may depend, at least in part, on

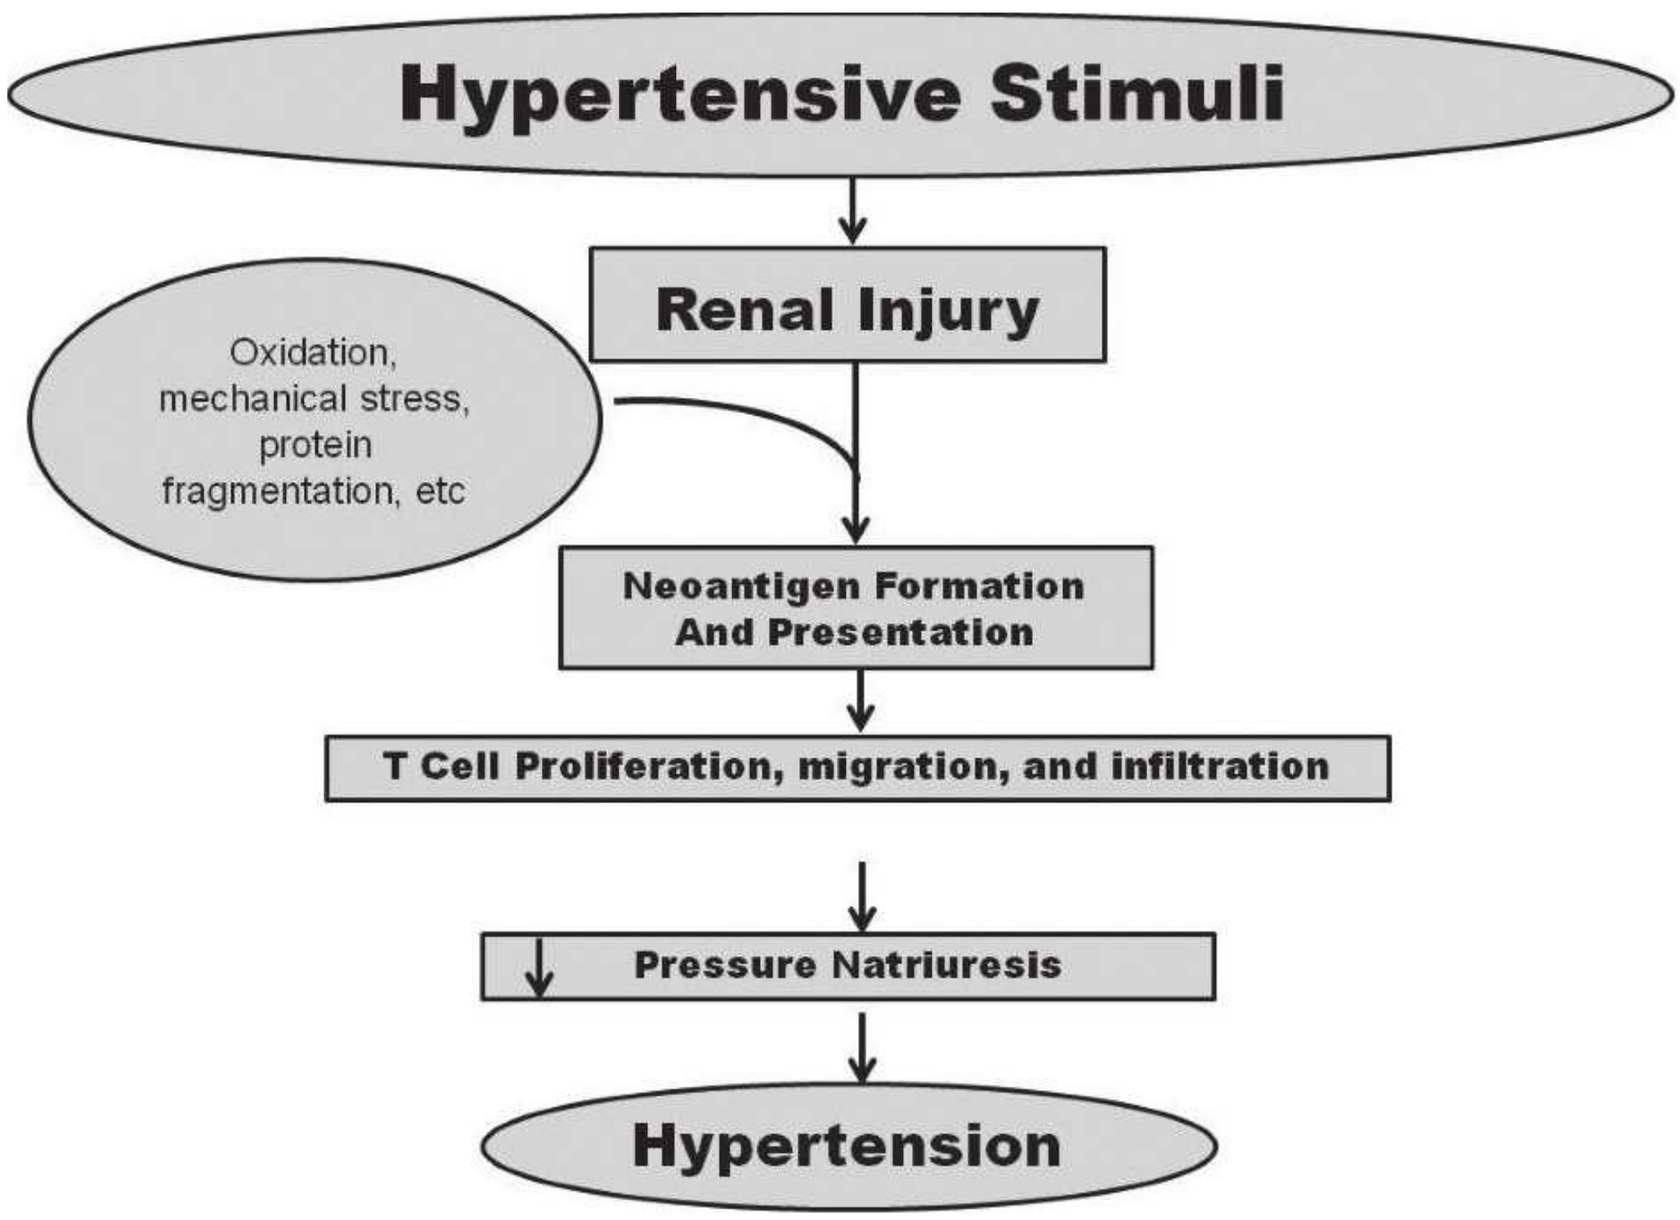

FIGURE 39.22 Proposed role of T cells and inflammation in progression of chronic hypertension. Initial hypertensive stimuli leads to renal injury, neoantigen formation, and eventual T cell activation within the kidney. T cell–derived signals promote entry of other inflammatory cells such as macrophages which result in renal vasoconstriction and sodium reabsorption, thereby increasing the severity of hypertension. (Redrawn from Granger JP, Hall JE. Role of the kidney sodium and fluid excretion in hypertension. In: Lip GYP, Hall JE, eds. *Comprehensive Hypertension*. New York: Elsevier; 2007.)

the presence of interleukin 6 (IL-6). Mice with knockout of IL-6 had significantly lower BP than wild-type mice during 2 weeks of ANGII infusion. Although these findings demonstrate a significant role for IL-6 in mediating the chronic hypertensive response to ANGII in mice, the importance of inflammatory cytokines in the pathogenesis and progression of the various forms of human hypertension is unclear and is currently an area of active investigation.

Several recent studies have demonstrated that T cells play an important role in the progression of hypertension.[115,120] Harrison and colleagues proposed that hypertensive stimuli lead to renal injury, neoantigen formation, and eventual T cell activation within the kidney.[120] T cell–derived signals promote entry of other inflammatory cells such as macrophages which result in renal vasoconstriction and increased sodium reabsorption, thereby increasing the severity of the hypertension (Fig. 39.22). Supporting this concept is a recent report that RAG-1–/– mice, which lack T cells and B cells, do not develop the degree of hypertension in response to ANGII infusion as the wild type mice, an observation that was attributed to lack of T cells (Fig. 39.23).[121] Moreover, chronic ANGII infusion was associated with a greater number of activated T cells as well as increased Rantes, a chemotoxic protein, in the vasculature and perivascular fat. These observations were confirmed by Crowley et al. using a model very similar to the RAG-1–/– mice.[121] They reported that ANGII hypertension, renal injury, left ventricular hypertrophy, and cardiac fibrosis were prevented in SCID mice lacking T cells.

Although there is growing evidence that the immune system may play a role in the progression of hypertension, the mechanisms by which hypertension stimulates an immune response remain unclear, but might involve the formation of neoantigens that activate adaptive immunity. Moreover, although findings in experimental models of hypertension are intriguing, the importance of the immune system in the pathogenesis of essential hypertension in humans remains to be determined.

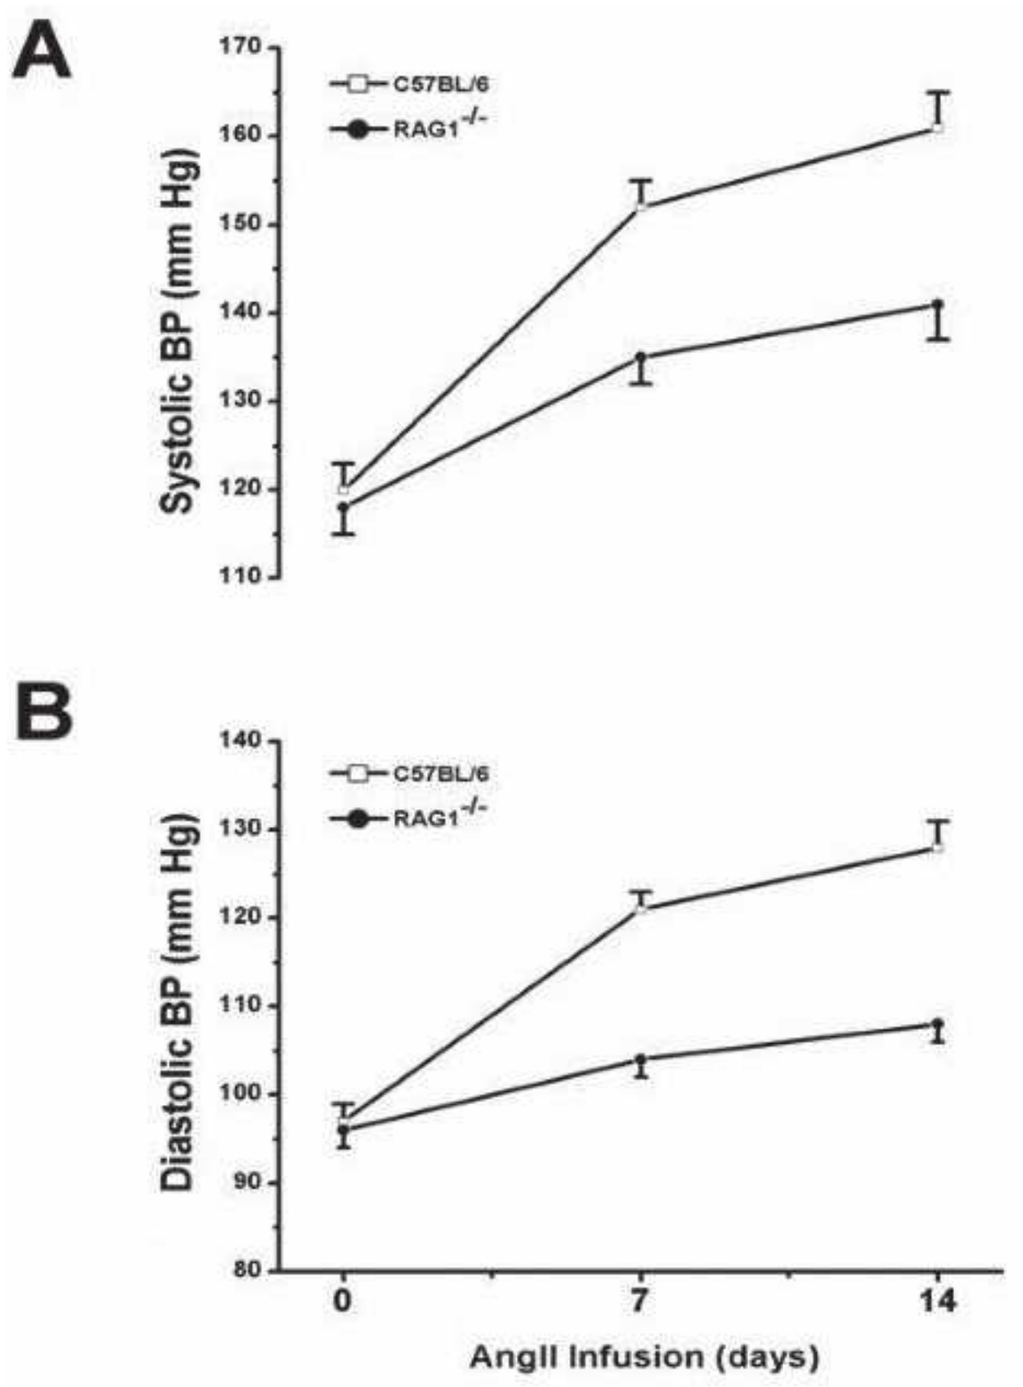

FIGURE 39.23 C57BL/6 and RAG-1–/– mice were treated for 14 days with 490 ng/min/kg angiotensin II, which was administered subcutaneously via osmotic minipump. (Redrawn from Guzik TJ, Hoch NE, Brown KA, et al. Role of the T cell in the genesis of angiotensin II induced hypertension and vascular dysfunction. *J Exp Med*. 2007;204:2449–2460.)

Vascular Endothelial Growth Factor

Although vascular endothelial growth factor (VEGF or VEGF-A) is known to regulate angiogenesis and arteriogenesis, experimental studies over the last decade have suggested that VEGF may also affect renal function and BP regulation.[123,124] VEGF belongs to a family of secreted glycoproteins, including VEGF-B, C, D, and placenta growth factor (PlGF). VEGF signaling is mediated via two receptors, VEGFR1/Flt1 and VEGFR2/Flk1. An array of VEGF pathway inhibitors have been developed to block formation of tumor blood vessels and cause tumor regression. Although hypertension appears to be one of the most common side effects of VEGF inhibitors, the mechanisms underlying the increase in BP in response to VEGF pathway inhibitors have not been fully elucidated.[125,126] Because the endothelium is a major target for the actions of VEGF, it is likely that decreases in the production of endothelium-derived relaxing factors such as NO or enhanced production of vasoconstricting factors such as endothelin play a role in the hypertensive response to drugs that block the VEGF pathway (Fig. 39.24). Facemire and colleagues reported that administration of a specific antibody against the major VEGF receptor, VEGFR2, to normal mice caused a rapid and sustained increase in BP that was associated with reductions in expression of endothelial and neuronal NO syntheses in the kidney (Fig. 39.25).[127] They also reported that L-NAME administration abolished the difference in BP between the vehicle- and anti-VEGFR2–treated groups.[127] These findings suggest that VEGF, acting via VEGFR2, plays a critical role in influencing basal levels of BP control by enhancing NOS expression and NO activity. Moreover, the results suggest that reducing NO production and/or availability may be one mechanism underlying hypertension caused by anti-angiogenic agents targeting VEGF.[122]

Another important endothelial-derived factor that may play a role in mediating the hypertension produced by VEGF inhibition is the vasoconstrictor ET-1.[122] A study by Murphy et al. suggests an important role of ET-1 in mediating the hypertension in a model of preeclampsia that has elevated levels

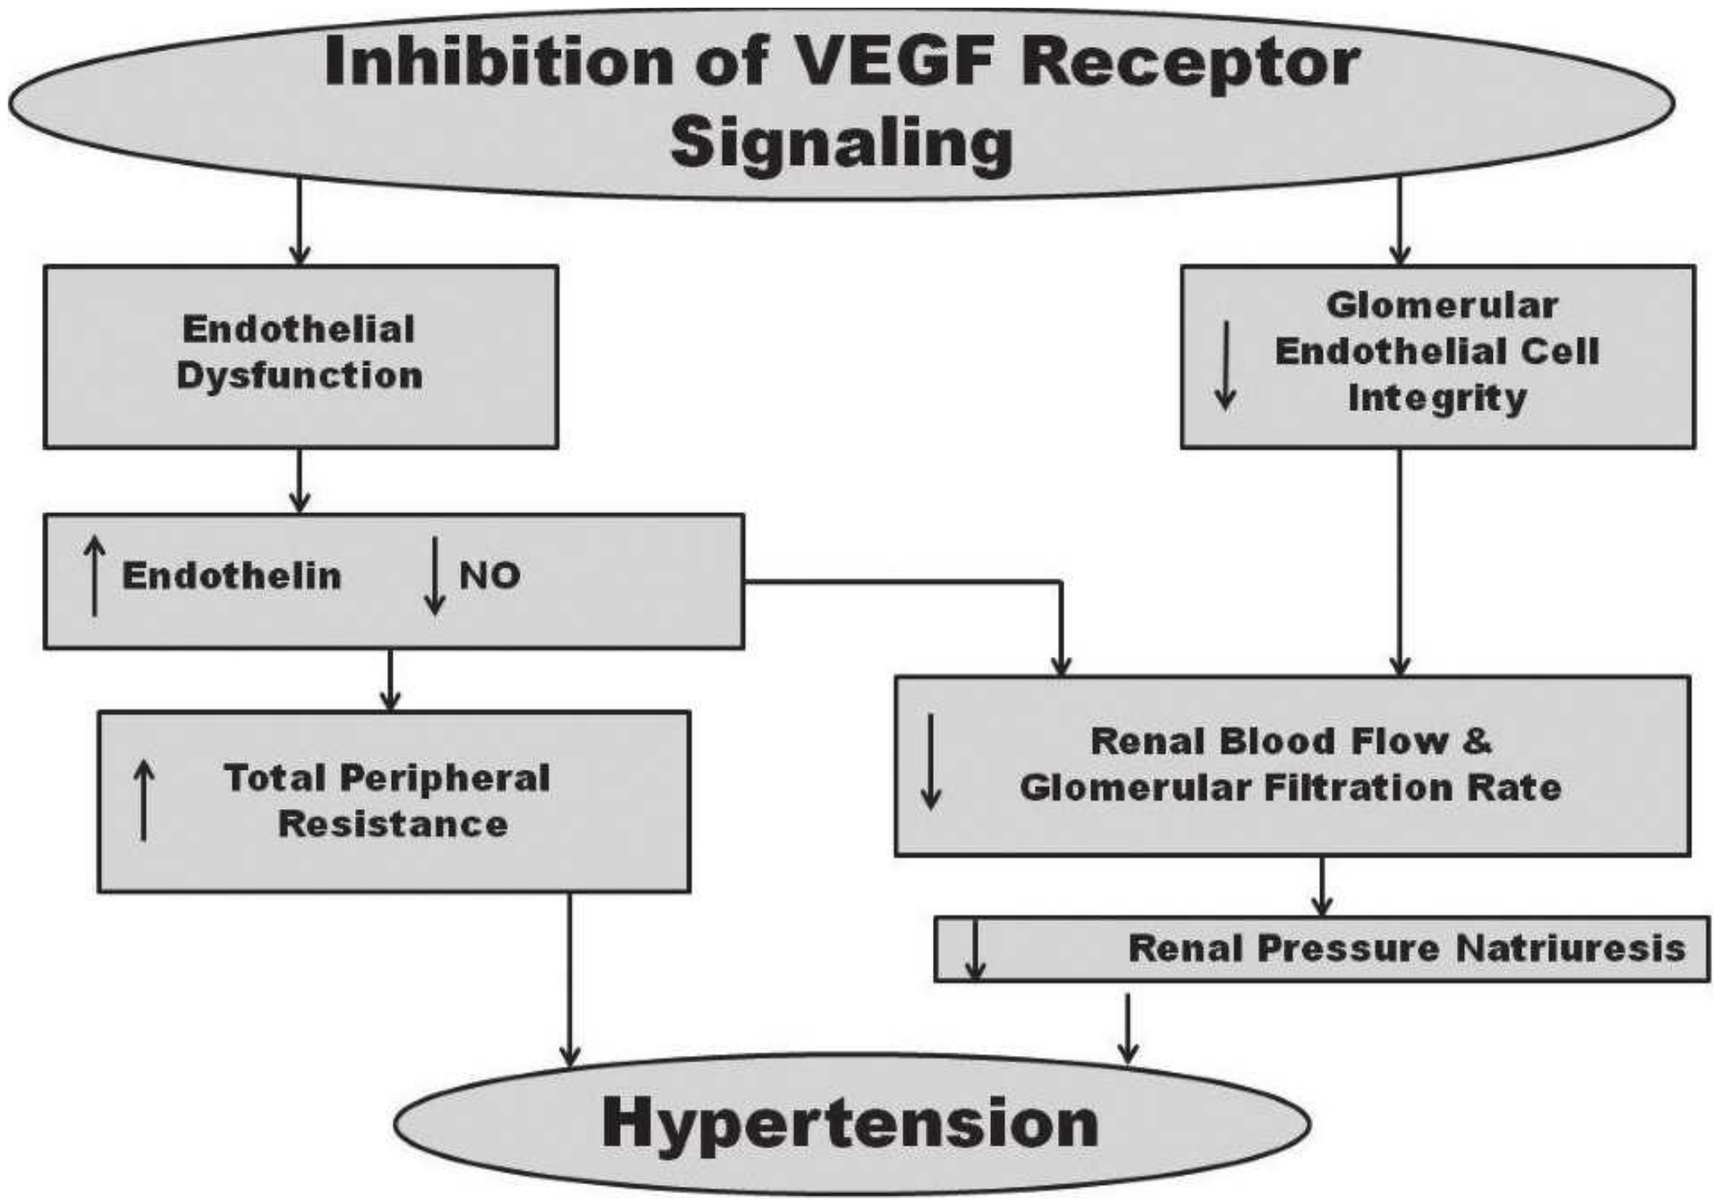

FIGURE 39.24 Potential mechanisms whereby inhibitors of vascular endothelial growth factor (VEGF) receptor signaling raise blood pressure. Blockade of VEGF receptors results in endothelial dysfunction leading to decreased production of endothelium-derived relaxing such as nitric oxide and prostaglandin or enhanced production of vasoconstrictor factors such as thromboxane and endothelin. Inhibitors of VEGF signaling may also result in alterations in glomerular structure and function. These changes may elevate blood pressure by reducing renal blood flow and GFR and impairing the kidney's ability to excrete sodium and water (depicted by a decrease in the pressure natriuresis relationship).

of the soluble VEGF receptor antagonist, sFlt-1.[128] Kappers et al. also reported that sunitinib, an inhibitor of tyrosine kinases including the VEGF receptor, induces a reversible rise in BP in patients and in rats associated with activation of the endothelin-1 system and generalized microvascular dysfunction.[129] Finally, deBeers and colleagues recently reported that VEGF inhibition with sunitinib in pigs results in endothelin-mediated hypertension.[130] Thus, another potential mechanism whereby VEGF blockade could increase BP is by enhancing ET-1 synthesis.[122,131]

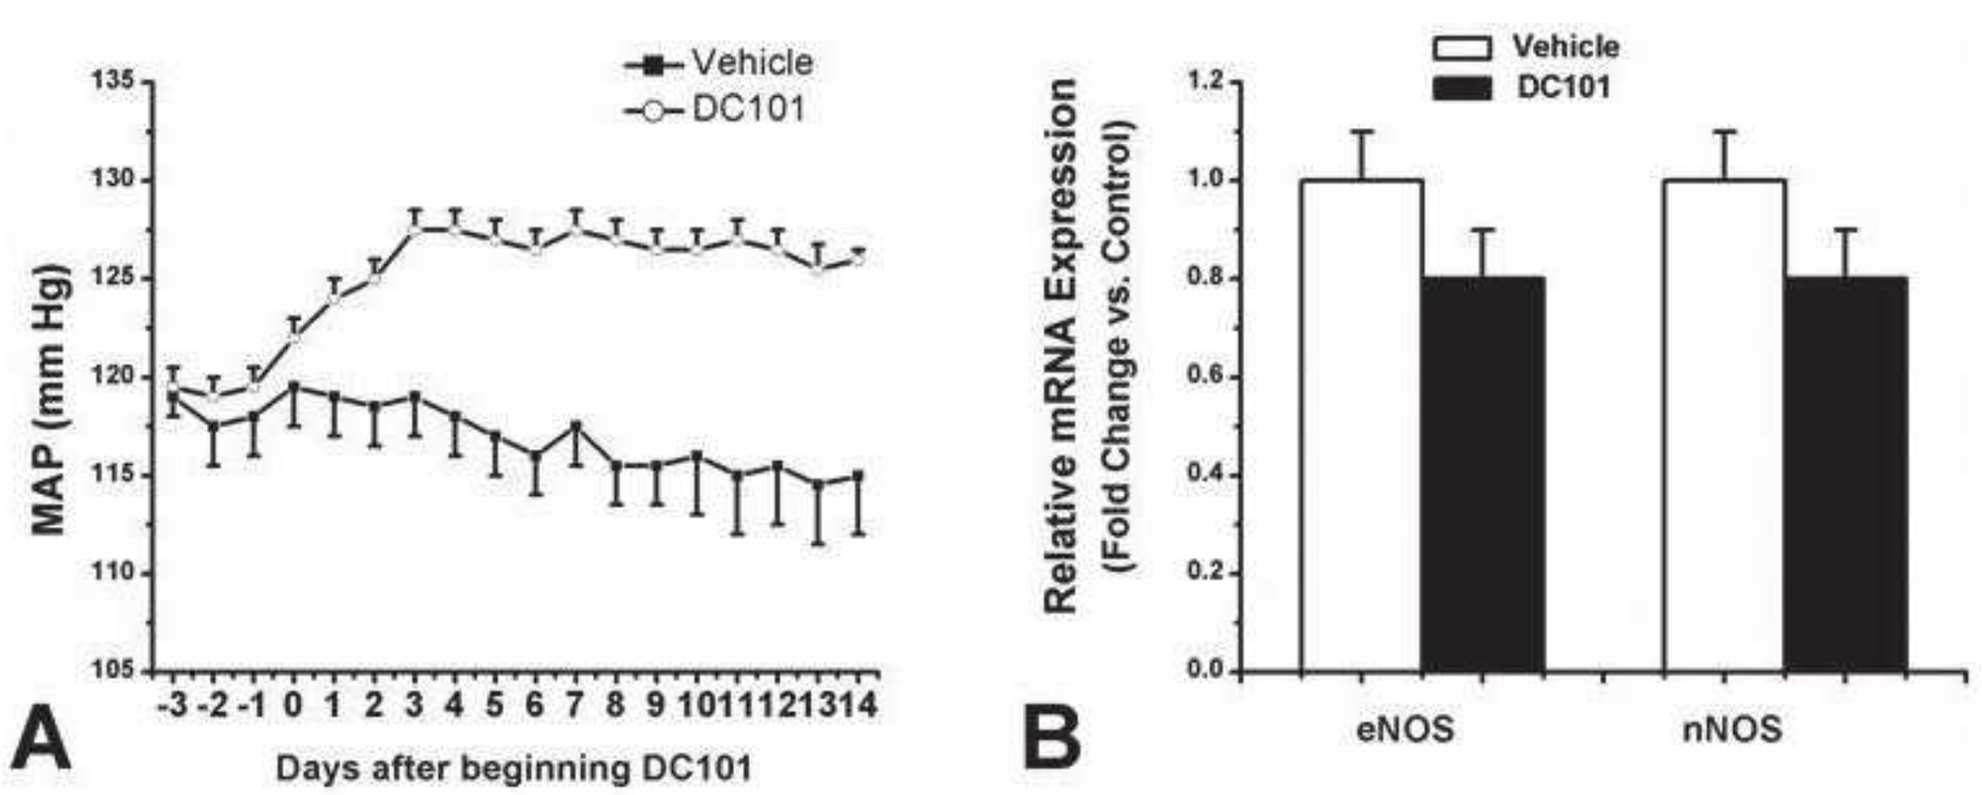

FIGURE 39.25 Effect of vascular endothelial growth factor receptor 2 inhibition on mitogen-activated protein and nitric oxide synthase mRNA expression in kidney in mice. (Redrawn from Facemire CS, Nixon AB, Griffiths R, et al. Endothelial growth factor receptor 2 (VEGFR2) controls blood pressure by regulating nitric oxide synthase expression. *Hypertension*. 2009;54(3):652–658.)

Although it is thought that the blockade of VEGF-A signaling pathway plays a critical role in the hypertension produced by VEGF inhibitors, a study by Machnik and colleagues suggests a role for VEGF-C.[132] The authors propose that macrophages regulate salt-dependent volume and BP by a VEGF-C dependent buffering mechanism. They suggest that VEGF-C, which is produced by macrophages, stimulates lymphatic vessel growth, creating a third fluid compartment that buffers the increased total body sodium and volume and buffers the high BP in response to increases in sodium intake.[132] This novel mechanism could potentially serve as an additional extrarenal mechanism that prevents changes in BP in response to increases in sodium intake. Moreover, loss or abnormalities in this putative sodium buffering pathway could be another potential mechanism for salt-sensitive hypertension. Indeed, Machnik and colleagues reported that macrophage depletion or inhibition of VEGF-C signaling increased BP in response to a high-sodium diet. The authors suggested that increase in BP was due to a decrease in lymphatic vessel growth and a reduction in the fluid compartment.[132] However, the fact that macrophage depletion or inhibition of VEGF-C signaling caused a chronic increase in BP indicates that inhibition of VEGF-C signaling also reduces the kidney's ability to excrete sodium and water. Future studies will be necessary to discern the renal mechanisms whereby macrophage depletion or inhibition of VEGF-C signaling alters the pressure natriuresis relationship.

CONCLUSION

Experimental and theoretical evidence strongly support a central role for the kidneys in the long-term regulation of body fluid volume and arterial pressure. A pivotal part of the renal–body fluid feedback control system for long-term BP regulation is the renal-pressure natriuresis mechanism. Increases in renal perfusion pressure lead to significant increases in sodium and water excretion, an effect that is thought to be mediated by increases in medullary blood flow and renal interstitial pressure. Renal pressure natriuresis is abnormal in all types of experimental and clinical hypertension. Hypertension is an important compensatory mechanism that allows maintenance of sodium balance when renal pressure natriuresis is impaired. Impaired renal pressure natriuresis and chronic hypertension can be caused by factors that either reduce GFR and/or increase tubular reabsorption. A shift of pressure natriuresis can occur as a result of intrarenal abnormalities such as enhanced formation of angiotensin II, ROS, and endothelin (via ET_A receptor activation) or decreased synthesis of NO or natriuretic prostanoids. In other instances, the altered kidney function is caused by extrarenal disturbances, such as increased SNS activity or excessive formation of antinatriuretic hormones such as aldosterone.

CHAPTER

40 Hypertension in Chronic Kidney Disease

Peter N. Van Buren • Robert D. Toto

INTRODUCTION

The prevalence of hypertension in patients with chronic kidney disease (CKD) exceeds that of the general population. Although hypertension is believed to be the etiology of kidney disease in many of these patients, hypertension is often the consequence of kidney disease stemming from any etiology. The pathophysiology of hypertension in CKD is related to multiple factors, including expanded extracellular volume from sodium retention, activation of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS), and imbalances in vasoconstrictor and vasodilator substances that regulate peripheral vascular resistance. Untreated or poorly controlled hypertension in CKD patients is associated with adverse outcomes including deterioration of renal function, development of left ventricular hypertrophy (LVH), and increased mortality. Recent clinical trials have investigated the role of various antihypertensive treatments and blood pressure targets in preventing these outcomes. The purpose of this chapter is to review the epidemiology, pathophysiology, and management of hypertension in patients with CKD. Because diabetic nephropathy is the leading cause of end-stage renal disease (ESRD) in the United States, the unique aspects of its pathophysiology and the treatment of hypertension in this setting warrant a separate discussion. Although mentioned briefly herein, the reader is referred to a recent extensive review of this topic.[1]

EPIDEMIOLOGY

Chronic Kidney Disease

Hypertension is a prevalent comorbidity associated with CKD. The prevalence of hypertension in the overall U.S. population, according to the National Health and Nutrition Examination Survey (NHANES) data from 2007 to 2008, is 29%.[2] Data published by the United States Renal Data System (USRDS) according to NHANES data collected from 1999 to 2006 indicate that the prevalence of hypertension in the non-CKD population is 23.3%.[3] In contrast, the prevalence of hypertension in the CKD population is much higher. The prevalence of hypertension increases with each stage of CKD and is estimated to be 35.8%, 48.1%, 59.9%, and 84.1% in patients with stage I, II, III, and IV/V CKD, respectively. Although the awareness of hypertension among patients with stage III and IV CKD was similar to that in the non-CKD population, the failure to control hypertension (defined as blood pressure [BP] 130/80 mm Hg for those with CKD and 140/90 mm Hg for those without CKD) is higher among the CKD patients.

The Chronic Renal Insufficiency Cohort (CRIC) is a National Institutes of Health (NIH) sponsored prospective observational study among 3,612 patients with an estimated glomerular filtration rate (GFR) of 20 to 70 mL per minute designed to better understand factors responsible for CKD progression and cardiovascular disease.[4] Although the sample population for CRIC is smaller than NHANES, the detailed ascertainment of individual demographics, comorbidities, medication use, and laboratory analysis provides useful information for understanding the relationship between CKD and hypertension control in a population that is established in the health care system. In this population, 85.7% of patients are hypertensive based on the definition of a BP >140/90 mm Hg or with the use of an antihypertensive medication. The percentage of patients from CRIC that are aware of their diagnosis of hypertension (98.9%) and who are treated for hypertension (98.3%) is higher than in the NHANES data. However, the control of hypertension in CRIC patients is still suboptimal, with 67.1% having BP >130/80 mm Hg and 46.7% having BP >140/90 mm Hg. The CRIC data indicate that older age, African American race, and a greater amount of proteinuria are risk factors for a failure to control BP to either 140/90 or 130/80 mm Hg.[5] Overall, the epidemiologic evidence from NHANES and CRIC identifies that hypertension is a significant burden for patients with CKD and the health care providers responsible for managing these patients.

The long-term consequences of uncontrolled hypertension highlight the significance of this disease in CKD patients. Studies have reported that elevated systolic BP increases the incidence of CKD,[6,7] the progression of CKD,[8] and the incidence of ESRD.[9] Furthermore, hypertension is reported to be the second leading cause of ESRD in the

United States based on USRDS data.[10] However, it has been difficult to establish the independent effect of BP in CKD from effects related to the degree of baseline proteinuria.[11]

Elevated BP is also a risk factor for cardiovascular events, including stroke and myocardial infarction among CKD patients; however, the exact relationship between BP and outcomes is not consistent among studies. A J-shaped relationship between cardiovascular morbidity and BP has been shown,[12] suggesting that the highest risk for an outcome occurs at the highest and lowest BP, whereas the lowest risk for an outcome occurs at an intermediate BP. In one longitudinal study of patients with stage III and IV CKD, systolic BP >130 mm Hg was a predictor for an incident stroke; however, those with systolic BP <120 mm Hg had a greater risk than those with a systolic BP between 120 and 129 mm Hg.[12] In contrast, a post hoc analysis of the Perindopril Protection Against Recurrent Stroke Study (PROGRESS), a prospective randomized placebo controlled trial of the effects of perindopril on stroke among patients with a prior history of cerebrovascular disease, CKD patients had a reduced risk for a recurrent stroke across all strata of systolic BP. Moreover, there was no increase in the risk for recurrent stroke in those who achieved a systolic BP <120 mm Hg compared to higher achieved BP levels.[13]

When considering mortality as an outcome, some observational data confirm the association with low BP and events.[14,15] One study showed an increased mortality risk in subjects with baseline systolic BP in the lowest quartile (<133 mm Hg) compared to the other quartiles, and another study showed the highest mortality risk with a systolic BP <110 mm Hg and >180 mm Hg in a cohort of CKD patients inclusive of both diabetic and nondiabetic CKD. The effect from the latter study was strongest in older patients with advanced CKD and without proteinuria, thus limiting the generalizability of this finding.

In summary, observational studies demonstrate an increased risk for cardiovascular morbidity and mortality at BP levels considered hypertensive for the general population. However, it is unclear if an aggressive reduction of BP translates into decreased cardiovascular morbidity and mortality in the CKD population. The evidence from randomized clinical trials on specific BP targets is discussed in the treatment section of the chapter.

Ambulatory Blood Pressure Measurements and Chronic Kidney Disease

Although CKD patients frequently have BP measured in an office setting, it is important to recognize some of the limitations that can arise in this context. Of utmost importance to the topic of hypertension is the relationship between home and clinic BP measurements. Home and ambulatory measurements better predict the presence of end organ damage such as proteinuria compared to clinic measurements.[16] Ambulatory BP measurements also predict which CKD patients with an elevated clinic BP have a greater risk for progression to ESRD or reaching the composite outcome of ESRD or death.[17] Thus, a comprehensive ascertainment of BP burden requires the consideration of more than measurements obtained in the office.

Hemodialysis Patients

ESRD patients on hemodialysis (HD) have an annual mortality rate close to 20%, with cardiovascular disease and infections accounting for the highest percentage of deaths.[18] Although the prevalence of hypertension in the HD population is near 90%,[19] a target BP to improve outcomes has yet to be identified. Early epidemiologic studies showed that for BP measurements obtained in the HD unit, low systolic BP and systolic BP in excess of 200 mm Hg were associated with the highest mortality, particularly in older patients and diabetics.[20,21] However, it has also been shown that uncontrolled hypertension with systolic BP in excess of 140 mm Hg results in the increased incidence of LVH, de novo ischemic heart disease, and de novo cardiac failure.[22] It must be considered that low systolic BP can be a manifestation of decreased cardiac output, resulting from the structural and functional consequences of long-standing uncontrolled hypertension, which would explain its association with increased mortality.

Similar to pre-ESRD CKD patients, the timing and location of BP measurements are also important considerations in HD patients. Home and ambulatory BP measurements during the interdialytic time period, in comparison to individual HD-unit measurements, are better predictors of mortality.[23] The significance of BP changes during HD treatments has also been recently investigated. Intradialytic hypertension, increases in BP from pre- to post-HD, has been associated with increased short-term (6 month) morbidity and mortality in prevalent HD patients and decreased 2-year survival in incident HD patients.[24,25] There is evidence that mechanisms responsible for the phenomenon include extracellular volume overload[26] or increased vasoconstriction related to intradialytic endothelin-1 surges as a manifestation of endothelial cell dysfunction.[27–29] Patients with intradialytic hypertension have also been shown to have increased ambulatory blood pressure and greater impairment in underlying endothelial cell function during the interdialytic time period.[30,31] Additional mechanisms that have been proposed, but that have yet to be confirmed, include increased activity of the RAAS and SNS, changes in electrolytes during HD, and removal of antihypertensive medications during the course of HD.[32]

PATHOPHYSIOLOGY

The etiology of hypertension in CKD is multifactorial and related to both increases in cardiac output and increased peripheral vascular resistance (Table 40.1). Positive sodium balance can affect either component (Fig. 40.1), and achieving sodium balance remains a primary target of managing hypertension in patients with CKD. Multiple other mechanisms, including activation of the SNS and RAAS, endothelial cell dysfunction related to imbalances in vasodilator and vasoconstrictor substances, and increased oxidative stress, can modify the effects of each other and result in hypertension, particularly when these systems are disrupted in the context of CKD. A comprehensive summary of these processes is outlined in Figure 40.2.

40.1 Etiology of Hypertension in Chronic Kidney Disease

Extracellular volume overload
Increased renin-angiotensin-aldosterone system activity
Increased sympathetic nervous system activity
Endothelial cell dysfunction
    Increased endothelin-1 release
    Accumulation of asymmetric dimethylarginine
    Decreased production of nitric oxide
Oxidative stress
Increased vasopressin release
Hypertensinogenic drugs (erythropoietin)

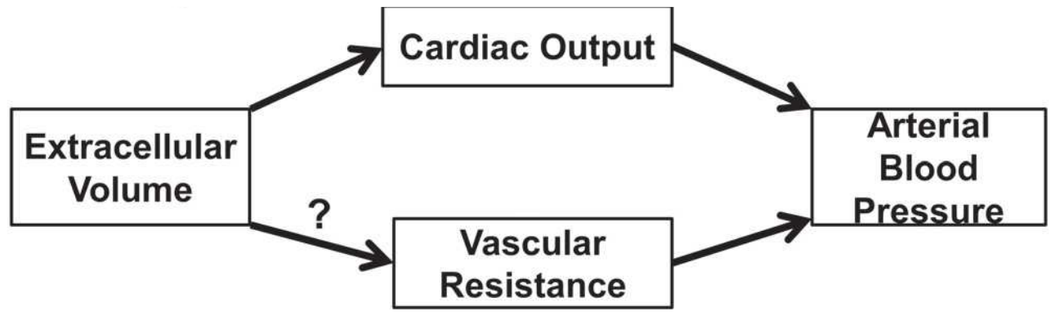

FIGURE 40.1 Blood pressure is directly related to cardiac output and vascular resistance. Extracellular volume increases cardiac output and, potentially, vascular resistance in patients with chronic kidney disease and end-stage renal disease. The achievement of euvolemia and a reduction in vascular resistance remain the primary target of blood pressure reduction in these patient populations.

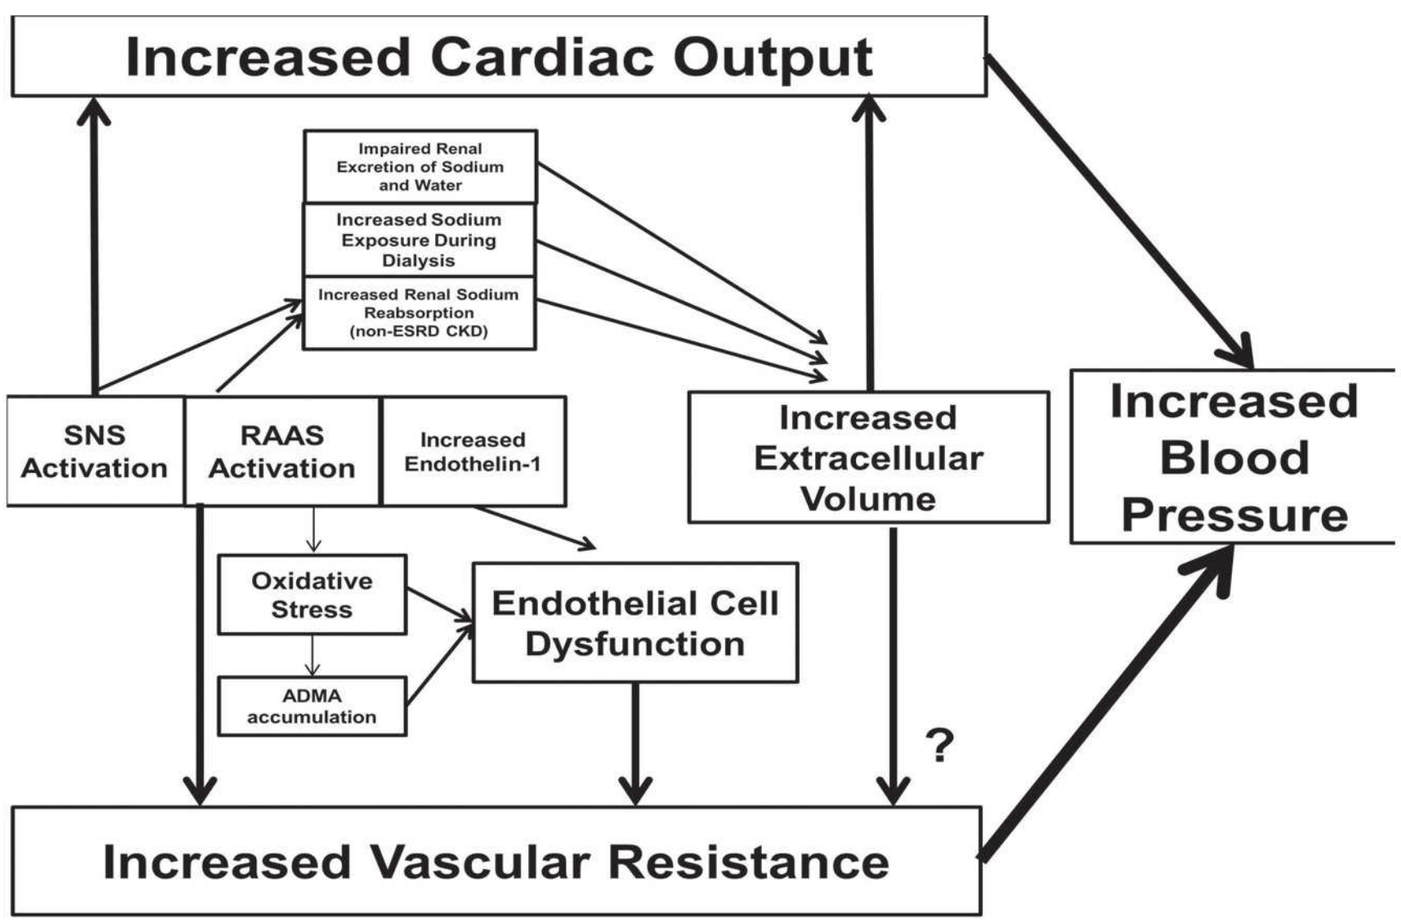

FIGURE 40.2 Both increased cardiac output and increased vascular resistance contribute to increased blood pressure in patients with chronic kidney disease (CKD) and end-stage renal disease (ESRD). Increased cardiac output results primarily from increased extracellular volume. Activation of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS) contributes to renal sodium reabsorption in non-ESRD CKD patients. In both CKD and ESRD patients, the decreased renal excretion of sodium and water from the decreased glomerular filtration rate also contributes to increased extracellular volume. Finally, in ESRD patients on hemodialysis, the transfer of sodium from the dialysate to the plasma can promote thirst and interdialytic weight gain.

Vascular resistance can be increased by the activation of the SNS and the RAAS, as well as by enhanced vasoconstriction caused by endothelial cell dysfunction. Increased RAAS activity increases angiotensin (Ang) II, which binds to receptors on vascular smooth muscle cells and causes vasoconstriction. Ang II also activates nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and increases oxidative stress, which is believed to be responsible for the increase in the inhibitor of endothelial nitric oxide synthase, asymmetric dimethylarginine. Endothelial cell dysfunction refers to an imbalance in mediators released from the endothelial cells of which one of the results is increased vasoconstriction. An increase in asymmetric dimethylarginine (ADMA) interferes with the production of the vasodilator nitric oxide (NO). Reactive oxidative species also combine with NO to form peroxynitrite and to prevent NO that has already been produced from binding to its receptor. In the context of impaired production and function of NO, there is less opposition to the vasoconstrictive effects of endothelin (ET)-1. Extracellular volume overload has varying effects on vascular resistance, but there is evidence that there is a delayed increase in vascular resistance that follows volume-induced increases in blood pressure and acts to sustain hypertension.

Basic Concepts

BP in humans is determined both by the cardiac output and by peripheral vascular resistance. Cardiac output is dependent on the intravascular component of the extracellular space as well as the heart rate; and peripheral resistance is dependent on functions of the vascular endothelial and smooth muscle cells in response to the actions of various vasoactive mediators (both vasoconstrictors and vasodilators). Although alteration of either cardiac output or vascular resistance would initially be expected to affect BP in a concordant direction, a healthy kidney can adapt to short-term changes in BP to restore normotension. An increase in renal sodium excretion is the expected response to increased BP in healthy individuals. This pressure natriuresis allows for the restoration of extracellular volume and BP following an increase in cardiac output. However, in CKD, this homeostatic mechanism is impaired, and the kidney fails to sufficiently excrete sodium loads. In CKD and ESRD, it is hypothesized that an increase in cardiac output initiates the increase in BP, but ultimately, an increase in vascular resistance sustains the BP elevation.[33,34] Accordingly, addressing both volume status and the degree of peripheral vasoconstriction are necessary to control BP in these patient populations.

Sodium Balance and Volume Overload

Sodium balance is an important aspect in BP control in CKD and ESRD. Because of the kidney's ability to excrete sodium, healthy individuals can tolerate large amounts of sodium intake without significant increases in BP.[35] However, in the presence of kidney disease, BP is highly dependent on extracellular volume. Rats that have undergone 70% renal ablation develop severe hypertension on a high sodium diet, but hypertension is completely prevented in these animals while on a low sodium diet.[36] A lower hematocrit found in the animals on a high sodium diet suggested that extracellular volume overload was present and likely the mechanism responsible for the increased BP. Another experiment with a renal ablation model demonstrated that increased cardiac output is responsible for the initial increase in BP during acute salt loading, but increased peripheral resistance (which occurs after BP has already become increased) is responsible for the maintenance of elevated BP even after cardiac output has returned to normal.[37]

Chronic Kidney Disease Patients Not on Hemodialysis

Because CKD patients are limited in the amount of renal sodium excretion, BP and sodium balance are interrelated. Among CKD patients, those with more severe renal impairment experience greater increases in BP in response to a sodium load. Although the pressure natriuresis curve serves to maintain sodium balance in healthy individuals, CKD patients require much higher BP increases than healthy individuals to augment their renal sodium excretion. Similarly, the degree of blood volume expansion required to induce a natriuresis is higher in patients with severe renal impairment compared to those with moderate renal impairment. Overall, these findings show that the effects on BP related to sodium intake ("salt sensitivity") are augmented with the progression of renal disease.[38] During the early stages of CKD, despite suboptimal renal sodium excretion, some patients remain normotensive despite an increase in cardiac output because of a reduction in peripheral resistance.[33] Although BP is sustained in the normotensive range, these patients, who are already limited in their sodium excretion because of reductions in GFR, fail to induce the necessary pressure natriuresis to re-establish sodium balance. Consequently, further increases in sodium loading result in increased cardiac output, peripheral resistance, and BP.

When subjects with CKD increase dietary sodium ingestion from 20 to 120 mEq per day, they experience an increase in BP that is not seen even in healthy subjects who increase their dietary sodium ingestion to levels as high as 1200 mEq per day.[39] Although both groups have a similar suppression of RAAS at moderate amounts of sodium ingestion, plasma renin activity (PRA) and angiotensin (Ang) II decreased drastically in healthy subjects during periods of high sodium ingestion (1200 mEq per day).[39] Although vascular resistance could not be measured directly in this study, increased vasoconstriction in the CKD subjects appeared to be the likely mechanism responsible for the increased BP and the reduced distribution of fluid into the interstitial space. Even under clinical conditions of pharmacologic RAAS blockade, salt balance has an important role in BP. In nondiabetic proteinuric subjects with creatinine clearance ranging from 33 to 110 mL per minute ingesting a low sodium diet, a reduction in BP and proteinuria during the chronic administration of fixed doses of angiotensin converting enzyme (ACE) inhibitors is reversed during periods of increased dietary sodium ingestion.[40] As further evidence of the importance of sodium intake in relation to BP and proteinuria in CKD patients, the coadministration of hydrochlorothiazide during a high salt intake period reduces both BP and proteinuria back to values seen during the low sodium diet.

Chronic Kidney Disease On Hemodialysis

In ESRD patients with little or no renal sodium excretion, sodium removal through ultrafiltration during HD is the primary means to maintain extracellular volume status because a pressure natriuresis is not possible. Consequently, compared to healthy controls, HD patients have a significantly higher cardiac output.[41] However, the presence of hypertension among HD patients is also highly dependent on elevations in vascular resistance.[41] Extracellular volume potentially impacts both of these parameters to influence BP. When subjected to sodium loading, HD patients typically respond with an increase in both BP and cardiac output. The pattern of vascular resistance following sodium loading is more variable, but increases typically do not occur until after the elevated cardiac output has already led to an

increase in BP.[34,42] In between HD treatments, during the interdialytic period, HD patients gradually gain weight with their routine dietary intake of sodium and water. The BP patterns during a typical interdialytic period show rhythmic oscillations superimposed on a general linear increase in BP over time.[43] This pattern is modified by interdialytic weight gain such that greater weight gain is associated with an increase in the slope of BP rise.[44] Subsequently, greater increases in interdialytic weight gain have been associated with increased pre-HD systolic BP at the next HD treatment.[45] However, that increased interdialytic weight gain is also associated with a greater reduction in BP during the course of that treatment (likely as a response to the ultrafiltration required to remove the interdialytic fluid gain).[45] Such evidence supports the hypothesis that extracellular volume (through either increases in cardiac output or vascular resistance) is primarily responsible for hypertension in this population. Consequently, one HD center has described a 98% success rate in withdrawing antihypertensive medications while using the ultrafiltration that can be achieved during a cumulative weekly dialysis time of 24 hours.[46] Thus, recognition and successful attainment of a patient's dry weight can facilitate the initial BP management in most, but not all, HD patients.

Therefore, HD treatment with adequate ultrafiltration should normalize BP in many HD patients. However, the basis for this practice assumes that interdialytic sodium and fluid intake is not excessive. An insufficient time on HD needed to completely restore normal extracellular fluid volume and achieve dry weight without inducing symptomatic hypotension limits this practice. A cross-sectional study found that major differences between ultrafiltration-sensitive and ultrafiltration-resistant HD patients were the pre- and post-HD atrial natriuretic peptide (ANP) levels between groups.[47] The ultrafiltration-sensitive group had reductions in ANP during HD (as well as lower pre-HD ANP), whereas the higher pre-HD ANP levels in the ultrafiltration-resistant group persisted despite similar amounts of ultrafiltration, suggesting that this group had remaining extracellular volume contributing to the elevated BP. It should be recognized, however, that extracellular volume overload may not always manifest itself overtly. In some cases, patients may have additional extracellular volume despite appearing euvolemic on clinical exam. The Dry Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) study was a randomized clinical trial in which hypertensive HD subjects were randomized to either continue their current HD and ultrafiltration prescription or have their dry weight challenged during each HD treatment over several weeks by 0.1 kg per 10 kg dry weight until symptoms developed. The subjects randomized to additional ultrafiltration demonstrated significant decreases in ambulatory systolic BP after 4 weeks and 8 weeks.[48]

The dialysate used during HD is another important factor that may contribute to hypertension in ESRD patients. Although ultrafiltration effectively removes water and sodium concurrently through convection, there may be an additional exchange of sodium from the dialysate to the patient's plasma depending on the sodium concentration gradient between the two compartments. Directly programmable ultrafiltration enables greater convective sodium removal in shorter periods of time, but increases the risk of intradialytic hypotension related to the abrupt hemodynamic changes. Although the use of higher dialysate sodium concentrations may reduce the risk of intradialytic hypotension, it may increase the risk of hypertension.[49] In contrast, the use of individualized dialysate sodium concentrations (as opposed to standardized concentrations, which may exceed the pre-HD plasma sodium of the patient) have been associated with lower pre-HD systolic BP in the context of decreased thirst and interdialytic weight gain.[50]

The Renin-Angiotensin-Aldosterone System and Hypertension

The RAAS has local and systemic effects that control BP by altering renal sodium reabsorption and vascular resistance. Renin released from juxtaglomerular cells cleaves angiotensinogen to Ang I, which is ultimately converted to Ang II by the ACE. Ang II causes vasoconstriction upon binding to angiotensin type 1 (AT1) receptors in vascular smooth muscle cells (VSMCs). Ang II increases proximal tubular reabsorption of sodium and stimulates aldosterone release from the adrenal gland, which is responsible for further sodium reabsorption in the distal nephron. Although this proposed sequence applies to the levels and activity of RAAS components in the plasma, there is also local RAAS activity. Consequently, measurements of RAAS mediators in the plasma may not always identify a disruption of the axis at the tissue level.[51]

Early evidence for systemic RAAS activation in CKD stems from studies in patients with autosomal dominant polycystic kidney disease (ADPKD). It has been shown that PRA and plasma aldosterone were higher in hypertensive ADPKD patients compared to patients with essential hypertension, and plasma aldosterone is higher in normotensive ADPKD patients compared to healthy controls (despite similar creatinine clearance between the groups).[52] Autosomal dominant polycystic kidney disease patients also manifest an accentuated response to ACE inhibitors compared to unaffected family members, further supporting the role of RAAS in the hypertension seen in ADPKD even prior to the onset of significant renal impairment.[53] However, the findings from these studies may not be entirely generalizable to more heterogeneous groups of CKD patients because the proposed renal ischemia induced by large cyst formation in ADPKD does not necessarily apply to CKD from other etiologies. There is evidence that PRA and aldosterone are higher in hypertensive CKD patients compared to healthy controls, essential hypertension patients, or even normotensive CKD patients.[54,55] However, there is also evidence that CKD patients have lower PRA compared to healthy

controls, although the values were similar to subjects with essential hypertension and normal renal function.[56] Despite these conflicting findings, increased intrarenal RAAS activity has been described in patients with hypertension and varying etiologies of CKD, including immunoglobulin A (IgA) nephropathy, membranous nephropathy, and diabetic nephropathy.[57–59]

As mentioned previously, success in managing BP can be achieved in many ESRD patients by appropriately using ultrafiltration for volume removal.[46] However, there are HD patients who remain quite hypertensive despite achieving their estimated dry weight. Previous reports have shown both increased or normal PRA in groups of HD patients compared to controls, and PRA did not consistently correlate with BP.[60,61] However, increased PRA has been demonstrated in HD patients with hypertension that is ultrafiltration resistant compared to those whose BP responds to ultrafiltration.[61] Bilateral nephrectomy, a procedure previously used for ultrafiltration-resistant hypertension in ESRD patients, has been shown to reduce PRA, Ang I and II, along with reductions in BP in these ultrafiltration-resistant hypertensive patients.[62]

Renin and Aldosterone

Although the primary action of angiotensin converting enzyme (ACE) inhibitors and ARB is to decrease the production and action of Ang II via the inhibition of the ACE enzyme or Ang II receptor, a complete perspective on the role of RAAS in hypertension associated with kidney disease warrants a discussion of the other components of the RAAS, including aldosterone and renin. Following the use of an ACE inhibitor or ARB, serum aldosterone levels typically decrease. However, in up to 40% of patients receiving these medications, aldosterone levels can rebound to pretreatment levels through a process referred to as aldosterone escape.[63] Aldosterone increases BP via enhanced sodium reabsorption in the distal nephron, but it is also likely involved in vasoconstriction via interaction with the Ang II receptor.[64] Despite evidence that CKD patients experiencing aldosterone escape may have worse control of proteinuria, systemic BP does not seem to be different from CKD patients whose aldosterone levels remain depressed following ACE inhibitor or ARB treatment.[65,66] These studies included patients with IgA nephropathy who were normotensive and had creatinine clearance >50 mL per minute or patients with early diabetic nephropathy and hypertension; such investigations have not been performed in broader groups of CKD patients. Evidence regarding the potential benefit of mineralocorticoid receptor blockers is included in the Treatment section of this chapter.

In contrast to the expected decrease in aldosterone following ACE inhibitor or ARB use, renin levels and PRA are expected to increase as a result of the blockade in events downstream from the main actions of renin. It has been demonstrated in vivo that Ang II can be generated by enzymes other than ACE.[67] This presents a potential obstacle to complete RAAS blockade if renin levels are sufficiently elevated in the context of an ACE inhibitor or ARB administration, and the possible use of add-on therapy to ACE inhibitors or ARB with a direct renin-inhibitor is further discussed in the Treatment section.

Angiotensin Converting Enzyme 2

Understanding of the RAAS continues to expand, and attention has been drawn to another enzyme in this pathway. ACE2 is a monocarboxypeptidase homolog of ACE that decreases Ang II levels by (1) increasing the degradation of Ang II to Ang 1-7, a vasodilatory and antiproliferative mediator, and (2) converting Ang I to Ang 1-9. This latter process not only prevents the conversion of Ang I to Ang II via ACE, but the increase in Ang 1-9 acts as a substrate for additional enzymatic conversion to Ang 1-7. Infusion of human recombinant ACE2 (rACE2) does not alter BP significantly in normotensive mice.[68] However, rACE2 prevents BP increases induced by the infusion of Ang II when they are infused together. Consistent with the proposed mechanism of ACE2, Ang II levels were significantly lower and Ang 1-7 levels were higher in mice receiving Ang II plus rACE2 compared to Ang II alone. ACE2 is highly expressed in the kidney and is believed to play a role in the progression of CKD via local activity of the renal RAAS. Mice that have undergone 5/6 nephrectomy have significantly reduced renal ACE2 expression and a trend toward reduced renal ACE2 activity compared to sham-operated mice.[69] Although BP was similar in nephrectomy and sham-operated mice, there was greater proteinuria in the nephrectomy mice. The proteinuria was further increased following administration of the ACE2 inhibitor. The major implications of these studies are that there may be further opportunities to reduce Ang II levels beyond the currently implemented strategies.

Sympathetic Nervous System and Hypertension

The SNS has been studied extensively as a possible contributor to hypertension in CKD and ESRD patients. In CKD patients, there is evidence for multiple pathways that the SNS may affect to increase BP. In support of the previous discussion of the effects of salt balance on BP, renal sympathetic nerve stimulation increases proximal tubular reabsorption of sodium and water.[70] Additionally, the systemic effects of the SNS include increased cardiac output and vasoconstriction. Although evidence of activated SNS activity based on elevated catecholamine levels in CKD is inconsistent and possibly confounded by decreased renal clearance of these compounds, other estimates of SNS, such as muscle sympathetic nerve activity (MSNA), confirm the hyperactive state in CKD and ESRD. The mechanisms responsible for hyperactive SNS are thought to be related to increased renal nerve activity. The kidney possesses baroreceptors and chemoreceptors that increase renal nerve firing secondary to pressure changes or metabolites produced in response to ischemia

or uremia. Animal models of renal artery stenosis, arterial ligation causing partial renal ablation, or intrarenal phenol injection all reveal increased nerve activity.[71–73] Activation of renal nerves results in a centrally mediated hypertension via activation of the SNS, which can ultimately be interrupted by a blockade of neural signals. For example, Sprague-Dawley rats that have undergone a 5/6 nephrectomy experience an attenuation in hypertension following a dorsal rhizotomy with a concurrent reduction in the turnover of norepinephrine in the hypothalamic nuclei and locus coeruleus.[72] In humans, there is evidence for SNS activation even prior to overt renal impairment if a potential cause for renal ischemia is present. Hypertensive ADPKD patients have increased MSNA compared to controls despite preserved renal function in both groups.[74] Muscle sympathetic nerve activity was even higher in ADPKD patients with decreased GFR, but was not different between normotensive ADPKD patients and controls. Given the experimental association with bilateral renal ischemia, the possibility exists that the increased MSNA is related to increases in RAAS activation. One study confirmed the presence of increased MSNA in CKD patients, and showed that the administration of the ACE inhibitor enalapril caused a reduction in MSNA (relative to the decrease in BP it caused), whereas amlodipine increased MSNA.[75] In a small study including patients with various etiologies of nondiabetic CKD and matched control, MSNA changed similarly in the patients and controls with variability in volume status, but MSNA was persistently higher in the CKD patients.[76]

The evidence for the role of increased SNS activity in the etiology of hypertension in renal disease is best supported by the findings of Converse et al.[77] Twenty years ago it was established that ESRD patients had increased MSNA compared to healthy controls and other ESRD patients that had undergone bilateral nephrectomies. Higher mean arterial BP was also seen in the ESRD patients whose native kidneys were still present, and the hypothesis was that afferent signaling from the ischemic kidneys modulated an overall SNS response best managed by surgical removal of the kidneys. This is further supported by the fact that reversing the uremic state of ESRD patients with renal transplantation does not decrease MSNA, but a native kidney nephrectomy in the transplant recipient does.[78] The fact that nondiabetic HD patients have a normal arterial and cardiopulmonary baroreflex response weakens any suggestion that uremia-induced impairments in these reflexes might further contribute to abnormally elevated SNS activity in this population.[79]

Renalase

Adding to the evidence that CKD patients, particularly those with hypertension, have increased MSNA and circulating catecholamine levels is the recent discovery of a protein that may facilitate higher levels of catecholamines. Renalase is an amine oxidase that contributes to catecholamine degradation, which, in comparison to other common amine oxidases, can circulate in the plasma. Renalase is secreted into the circulation by the kidneys, and patients with ESRD on HD have nearly undetectable levels, supporting the role of adequate renal function to maintain its presence.[80] Although in CKD patients, there is no direct evidence how circulating renalase is responsible for hypertension, animal models demonstrate the development of hypertension following knockout of the renalase gene and a reduction in BP following the infusion of recombinant renalase in Sprague-Dawley rats.[80]

ENDOTHELIAL CELL DYSFUNCTION AND HYPERTENSION

Because the increase in peripheral vascular resistance also contributes to the elevated BP in patients with kidney disease, it is important to understand the mechanisms responsible for vasoconstriction. Blood vessels are lined with endothelial cells, which release mediators that exert their actions on VSMC receptors. The balance between vasoconstricting mediators and vasodilating mediators dictates the ultimate response of the VSMC and the amount of resistance. Endothelial nitric oxide synthase (eNOS) uses arginine as a substrate to produce the vasodilator nitric oxide (NO). This process is dependent on the presence of the cofactor tetrahydrobiopterin (BH4), and production of NO can be inhibited by the arginine analog asymmetric dimethylarginine (ADMA). One of the primary vasoconstrictive agents is endothelin-1 (ET-1), but the ultimate response of the vascular tone is dependent on which ET receptor is being bound. The interplay between all of these mediators is complex. Substances such as Ang II modify the activity of ET-1, and NO release is sensitive to the relative state of oxidative stress and inflammation.

Endothelin

ET-1 is a 21 amino acid mitogenic peptide that is produced ubiquitously, but to a large extent in vascular endothelial cells. Its original description demonstrated that it had more potent vasoconstrictive effects than other vasoconstrictive peptides including Ang II, vasopressin, and neuropeptide Y while having a longer lasting effect on vascular tone than the endothelial-derived relaxing factor NO.[81] Additionally, ET-1 has been shown to promote vascular cell hypertrophy and increase nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity, resulting in oxidative stress and endothelial cell dysfunction.[82] There are two primary receptors for ET-1: ET-A and ET-B. ET-1 binding to ET-A and ET-B receptors found on VSMC causes vasoconstriction, whereas binding to ET-B receptors on the endothelial cells causes vasodilation, suggesting a mechanism for feedback inhibition to stimulation by ET-1. Because ET-1 has paracrine behavior and migrates from the endothelial cells to VSMC (away from the lumen), plasma levels of ET-1 have proven to be unreliable in establishing a clear causal relationship with hypertension. However, mRNA expression of ET-1 in the endothelium of resistance vessels is higher in patients with moderate-to-severe hypertension compared to those with mild hypertension

or controls.[83] Its role in hypertension in humans is further implicated by its effects on arterial tone. Following an infusion of ET-1, forearm blood flow decreases (increased tone) in both hypertensive and healthy humans, although the effect is greater in hypertensive patients. The pharmacologic inhibition of ET-A receptors alone or the combined inhibition of ET-A and ET-B receptors results in significant increases in forearm blood flow in the hypertensive patients, but not the healthy subjects.[84] The administration of a nonselective ET receptor blocker in a dose of >500 mg per day resulted in reductions in systolic and diastolic office and ambulatory BP as compared to placebo; the BP reduction from the drug was similar to that achieved with the ACE inhibitor enalapril.[85]

In patients with CKD, both systemic and local renal effects are proposed to contribute to hypertension in this population. Partial nephrectomy Sprague-Dawley rat models suggest that there is an imbalance of ET expression and degradation in the uremic state. In these animals, there were increased ET-1 levels (related to increased expression) in the endothelial cells of the thoracic aorta and renal cortex.[86] It was also found that the number of ET-B receptors was decreased in these locations, but there was a mild increase in ET-A receptor expression in the VSMC. Downregulation of ET-B receptors disables a mechanism for ET-1 degradation and can further contribute to the increased presence and action of ET-1.[87,88]

In CKD, there is also increased urinary and plasma levels of ET-1, independent of BP.[89,90] The renal excretion rate of ET-1 is increased in hypertensive CKD patients, but not in subjects with normal renal function who have increased plasma ET-1 levels accompanying essential hypertension. These findings suggest that renal production of ET-1 increases as renal function declines and contributes to hypertension in CKD.[91] Mechanisms through which ET-1 can increase BP include vasoconstriction, salt/water retention, and activation of the RAAS. ET-A receptor inhibitors have been shown to decrease systemic BP in CKD patients and controls.[92] They also increased renal blood flow and decreased renal vascular resistance in CKD patients, and this effect dissipated with a concurrent administration of an ET-B receptor inhibitor. These findings and the evidence that ET-A receptor antagonists reduce proteinuria in diabetic patients have already been further investigated in a clinical trial. The ASCEND study was a randomized double-blind placebo-controlled trial studying the effects of avosentan in patients with diabetic nephropathy.[93] Subjects were randomized to avosentan 25 mg daily, 50 mg daily, or placebo while being continued on current therapy with an ACE inhibitor or ARB. There were trends toward lower sitting and standing systolic BP in the low dose group, and this difference was statistically significant compared to placebo. However, the study was terminated early because of increased cardiovascular events in the avosentan group, particularly from congestive heart failure exacerbations and pulmonary edema. A smaller randomized placebo-controlled trial in 27 nondiabetic proteinuric CKD patients compared the effects of a selective ET-A receptor antagonist, sitaxsentan, with either the calcium channel blocker nifedipine or placebo.[94] Sitaxsentan significantly lowered BP and arterial stiffness compared to placebo. There was no difference in these outcomes compared to nifedipine, but proteinuria reduction was greater. Thus, the practical use of inhibiting various endothelin receptors remains to be fully established in CKD.

Nitric Oxide and Asymmetric Dimethylarginine

NO is one of the primary vasodilators released from the endothelium and counteracts the effects of the vasoconstrictors. NO also plays an important role in modifying renal blood flow and sodium excretion. Infusion of L-arginine, the substrate for NO production, decreases renal vascular tone in hypertensive patients who are either salt sensitive or salt resistant, but this effect is diminished in salt-sensitive patients with increasing sodium intake.[95] This suggests increased dietary sodium impairs NO release in salt-sensitive patients, and there is additional evidence that impaired renal response to arginine predicts an increased prevalence of end-organ damage in patients with salt-sensitive hypertension.[96] Furthermore, transition from a low sodium diet to a high sodium diet decreases plasma NO levels in salt-sensitive hypertensive patients compared to salt-resistant hypertensive patients where there was an inverse relationship between changes in plasma NO and BP changes.[97] These findings demonstrate that, in essential hypertension, there is impaired NO production and this impairment is associated with increased BP and long-term consequences related to uncontrolled BP.

Animal models of renal ablation have consistently identified a reduction in renal NO production, but not systemic NO production.[98,99] Differences in these studies may be related to the method of renal ablation and the consequential effects on systemic BP that could confound overall production of NO in the aorta.[98] In humans, total body NO production assessed by varying techniques has been noted to be lower in CKD patients and ESRD patients compared to healthy controls.[100–102] Although decreased NO synthase activity may be responsible for these findings, CKD patients were more hypertensive and had increased serum levels of the eNOS inhibitor ADMA.[101]

The association between ADMA and renal function has also been demonstrated in animal CKD models. Rats that have undergone a 5/6 nephrectomy have increased ADMA, and these levels correlate with increased BP.[103] Urinary ADMA excretion was increased in these animals, but the enzyme responsible for the metabolism of ADMA, dimethylarginine dimethylaminohydrolase (DDAH) was found to be decreased, suggesting that mechanisms beyond impaired renal excretion are responsible for ADMA accumulation in CKD. Further support for the role of ADMA in hypertension comes from evidence that transgenic mice overexpressing DDAH have lower BP and ADMA than controls, and that the administration of DDAH attenuates the increase in BP that

occurs following a 5/6 nephrectomy in animal models.[104,105] Infusion of ADMA into healthy humans causes an increase in systolic BP associated with decreased cardiac output, but increased vascular resistance.[106,107] In patients with nondiabetic CKD (IgA nephropathy and ADPKD) elevated ADMA levels can be seen even in the early stages of CKD prior to a significant reduction in GFR compared to healthy controls.[108] However, in this study, there were no significant differences in ADMA between hypertensive and normotensive CKD patients. Elevated ADMA has been confirmed in ESRD patients on HD where the increased levels were predictive of cardiac structure and function, as well as cardiovascular morbidity and mortality.[109–112] Cumulatively, these studies fail to consistently show a direct correlation with ADMA and BP in CKD and ESRD patients, but ADMA is associated with adverse events in this population.

Oxidative Stress

A common aspect related to many of the previously described mediators of hypertension in CKD is oxidative stress. Oxidative stress refers to an imbalance of reactive oxygen species (ROS) and naturally occurring antioxidant enzymes that favor an elevation of ROS. Chronic kidney disease is a state of both relative ROS excess and antioxidant depletion. Increased RAAS activity can generate ROS via the Ang II–induced activation of NADPH oxidase, which may be one explanation for the degree of oxidative stress seen in CKD and ESRD. Furthermore, it has been demonstrated that the enzyme responsible for the degradation of ADMA, DDAH, can be influenced by increased oxidative stress.[113] Following a 5/6 nephrectomy, Sprague-Dawley rats have increased BP that is attenuated by the administration of an antioxidant and lipid peroxidation inhibitor.[114] The BP increases again following withdrawal of the antioxidant. The levels of plasma malondialdehyde, a marker of lipid peroxidation, increased in the CKD animal models and correlated with BP. Again, malondialdehyde levels decreased when the animals were given the antioxidant, but increased when the antioxidant was withdrawn.

Additionally, ROS can interact with NO that has already been synthesized by eNOS and deplete the amount of NO available to induce vasodilation. This was shown in an experiment using a 5/6 nephrectomy in Sprague-Dawley rats where a diet fortified in the antioxidant vitamin E attenuated BP increases that occurred following the nephrectomy.[115] There was an increase in plasma and tissue nitrotyrosine, a measure of the effects of ROS on NO, in all CKD animals; this effect was reduced in the CKD animals receiving a diet high in vitamin E. Similarly, NO production from isolated vascular tissues was higher in the animals receiving vitamin E compared to the animals on a regular diet.

Numerous studies in humans with CKD and ESRD have aimed to determine if intervention with antioxidant therapy is capable of improving outcomes. A retrospective analysis of the Heart Outcomes Protection Evaluation (HOPE) study, which included nonproteinuric CKD subjects with serum creatinine (Cr) <2.3 mg per deciliter, found no difference in the composite of cardiovascular outcomes between subjects taking vitamin E 400 units daily or placebo.[116] Hemodialysis patients receiving antioxidants including vitamin E or N-acetylcysteine in randomized placebo-controlled trials showed improved cardiovascular outcomes, but there was no difference in mortality between these groups.[117,118]

Arginine Vasopressin

Experimental evidence suggests that vasopressin may also contribute to hypertension in CKD patients, although currently no therapy is aimed at decreasing its effects. Arginine vasopressin (AVP) is a peptide released from the hypothalamus in response to increases in plasma osmolarity. Receptors for vasopressin include the V1a, V1b, and V2 receptors. Traditionally, V1a receptors were believed to be responsible for vasoconstriction via VSMC, and V2 receptors responsible for water reabsorption through the insertion of aquaporin channels in the collecting duct of the nephron. Based on animal studies, the V1a receptor may mediate other effects on BP related to decreases in circulating blood volume, baroreflex sensitivity, and RAAS activity.[119,120] In CKD patients, AVP levels are higher and increase in response to osmolarity changes with a greater slope than in controls.[121] Vasopressin levels are also elevated in HD patients, and BP decreases following infusion of an AVP inhibitor in HD patients that have been saline loaded.[122,123]

Secondary Hyperparathyroidism

Secondary hyperparathyroidism is a complication of CKD that contributes to many comorbidities associated with CKD. The increased production and secretion of parathyroid hormone (PTH) is triggered in part as a response to the accumulation of serum phosphorus caused by decreased renal phosphorus excretion in CKD. Furthermore, in CKD, there is decreased renal 25-hydroxyvitamin D_3 1α-hydroxylase activity, which results in the reduced production of active vitamin D. Previous in vitro studies have investigated the role of secondary hyperparathyroidism in the etiology of hypertension, but recent clinical trials have added to the data available in human studies. One study in adult CKD patients demonstrated an association with increased BP and elevated serum PTH levels proposed to be related to higher cytosolic calcium in the subjects with elevated PTH levels.[124] This association was supported by the improvement in mean BP following treatment with the vitamin D analog alfacalcidol. Treatment with vitamin D also decreased PTH and cytosolic calcium levels along with the decrease in BP. It has since been demonstrated that although treatment with 1,25 dihydroxyvitamin D in spontaneously hypertensive rats (SHR) achieves a reduction in BP mediated through the attenuation of endothelium-dependent VSMC contraction, the administration of vitamin D had no effect on the amount of free cytosolic calcium,[125] suggestive of an effect downstream from the increase in calcium.

Although the exact mechanisms remain under debate, further evidence has been generated to support the use of active vitamin D treatment in CKD. The selective vitamin

D receptor activation with paricalcitol for a reduction of albuminuria in patients with type 2 diabetes (VITAL) study was a clinical trial where patients with diabetic nephropathy (mean estimated glomerular filtration rate: 39 to 42 mL per minute) were randomized to receive placebo versus 1 μg paracalcitol versus 2 mcg paricalcitol.[126] In this study there was a reduction in albuminuria following the administration of the larger dose of vitamin D compared to placebo. Additionally, there was a significant reduction in systolic BP in patients receiving vitamin D compared to placebo. The identification of inactive vitamin D deficiency and insufficiency in the general population and in CKD patients with secondary hyperparathyroidism has generated further interest in the effects of BP response to inactive vitamin D repletion/supplementation. A recent meta-analysis of the effects of vitamin D on the cardiovascular system among healthy individuals showed a trend toward reductions in systolic BP.[127]

Drug Related

Erythropoietin-Stimulating Agents

Beyond the disruption of endogenous mediators of hypertension that occurs in CKD patients, it is also important to consider the iatrogenic effects of commonly implemented interventions in this patient population. Anemia is another prevalent comorbidity in CKD. Though iron deficiency contributes to decreased hemoglobin levels in CKD and ESRD patients, the underlying erythropoietin deficiency has prompted widespread use of erythropoiesis-stimulating agents (ESAs) as commonly used therapeutic agents to correct anemia. Increases in BP in both previously hypertensive and nonhypertensive patients is one of the reported adverse effects of ESA use.[128] Despite the recognition that ESA administration increases BP, several meta-analyses have failed to consistently show significant differences in hypertension-related adverse events in ESA use versus nonuse or high or low target hemoglobin groups using ESA in CKD and ESRD patients.[129–131] Proposed mechanisms of ESA-induced hypertension include increased ET-1 release and increased sensitivity to Ang II and adrenergic stimuli.[132,133] Furthermore, acute and chronic ESA administration in pre-HD CKD patients resulted in impairment of flow-mediated dilatation as a measurement of endothelial cell function.[134] Current guidelines recommend treating hypertension that arises during treatment with an ESA as opposed to withholding ESA treatment in anemic patients.[135]

HYPERTENSION IN SPECIFIC ETIOLOGIES OF CHRONIC KIDNEY DISEASE

Because diabetic nephropathy and CKD attributed to hypertension are the two leading causes of ESRD in the United States, it is important to consider what aspects of the underlying disease processes make CKD-associated hypertension unique in these cases.

Hypertension in Diabetic Nephropathy

Diabetic nephropathy is the leading cause of ESRD in the United States. The timing of the onset of hypertension in patients with diabetic nephropathy is related to whether type 1 or type 2 diabetes is the underlying cause. The onset of hypertension correlates with the development of microalbuminuria in type 1 diabetics and is rarely present before that time. However, a "non-dipping" nocturnal BP pattern, where BP fails to decrease at night from the daytime values, predicts the onset of microalbuminuria in patients with type 1 diabetes and normoalbuminuria.[136] There is also evidence of genetic factors that determine whether hypertension will be present in type 1 diabetics because there is a higher prevalence of hypertension in the family members of patients with type 1 diabetes and microalbuminuria.[137] Conversely, hypertension is frequently already present in patients with type 2 diabetes before the onset of microalbuminuria.[138,139] The overlap between risk factors for hypertension and type 2 diabetes in patients with obesity and the metabolic syndrome may explain why hypertension occurs before renal disease in this population.

There are many similarities in the pathophysiology of hypertension in diabetic nephropathy and nondiabetic kidney disease. It should be recognized that in addition to the impact that impaired renal function has on sodium excretion, RAAS activation, SNS activation, endothelial cell dysfunction, and oxidative stress, the metabolic derangements present in diabetes further accentuate the role these factors have in causing increased vasoconstriction and BP.

Hypertensive Nephrosclerosis

Although diabetic nephropathy is the leading cause of ESRD in the United States, the second leading cause of ESRD is hypertensive nephrosclerosis, with an incidence rate of 100 per million in 2010 according to the USRDS.[3] Because hypertensive nephrosclerosis frequently presents with a normal urinary sediment and a lack of sonographic changes beyond decreased kidney size, many cases of CKD/ESRD attributed to hypertensive nephrosclerosis are never confirmed with a renal biopsy. Often, the identification of hypertension as the sole risk factor for CKD accounts for the designation of hypertension as the etiology. Kidney biopsies from nondiabetic hypertensive individuals with proteinuria and/or increased serum Cr revealed thickened and hyalinized arterioles with an exaggeration of arteriolar smooth muscle hypertrophy in excess of that typically seen from normal aging.[140] Additionally, both hypertrophic and sclerotic glomerular lesions can be seen in hypertensive nephrosclerosis with both autoregulatory dysfunction and ischemia possibly playing a role.[141] Because the number of patients in the general population who have a diagnosis of hypertension far exceeds the number of those who go on to develop kidney disease, there must be certain risk factors that predispose some individuals to hypertensive nephrosclerosis.

In particular, African Americans are more susceptible to renal disease than other races and often develop CKD at

younger ages. Additionally, the severity of hypertension does not correlate with renal function as well as in non-African American patients.[142] There are differences in the renal biopsy findings in African American and Caucasian patients with hypertensive nephrosclerosis, although the etiology of these differences remains unexplained.[143] Genetic variants that predominate in African Americans are sought after as possible explanations for the pattern of CKD in this population. An association between nonmuscle myosin heavy chain 9 (MYH9) gene polymorphisms and the pathologic diagnosis of focal segmental glomerulosclerosis and HIV nephropathy in African Americans has been detected.[144] In several cohorts of African American patients, it has also been shown that the presence of some MYH9 gene polymorphisms is associated with the presence of nondiabetic ESRD previously diagnosed as hypertensive nephrosclerosis.[145] Because MYH9 is expressed in podocytes, mesangial cells, and renal capillary beds, such evidence suggests the possibility that hypertension alone is not sufficient to cause progressive renal disease, but in fact, a genetic susceptibility that primarily affects the kidneys predisposes individuals to the onset of renal disease in the context of other inciting factors, including hypertension.

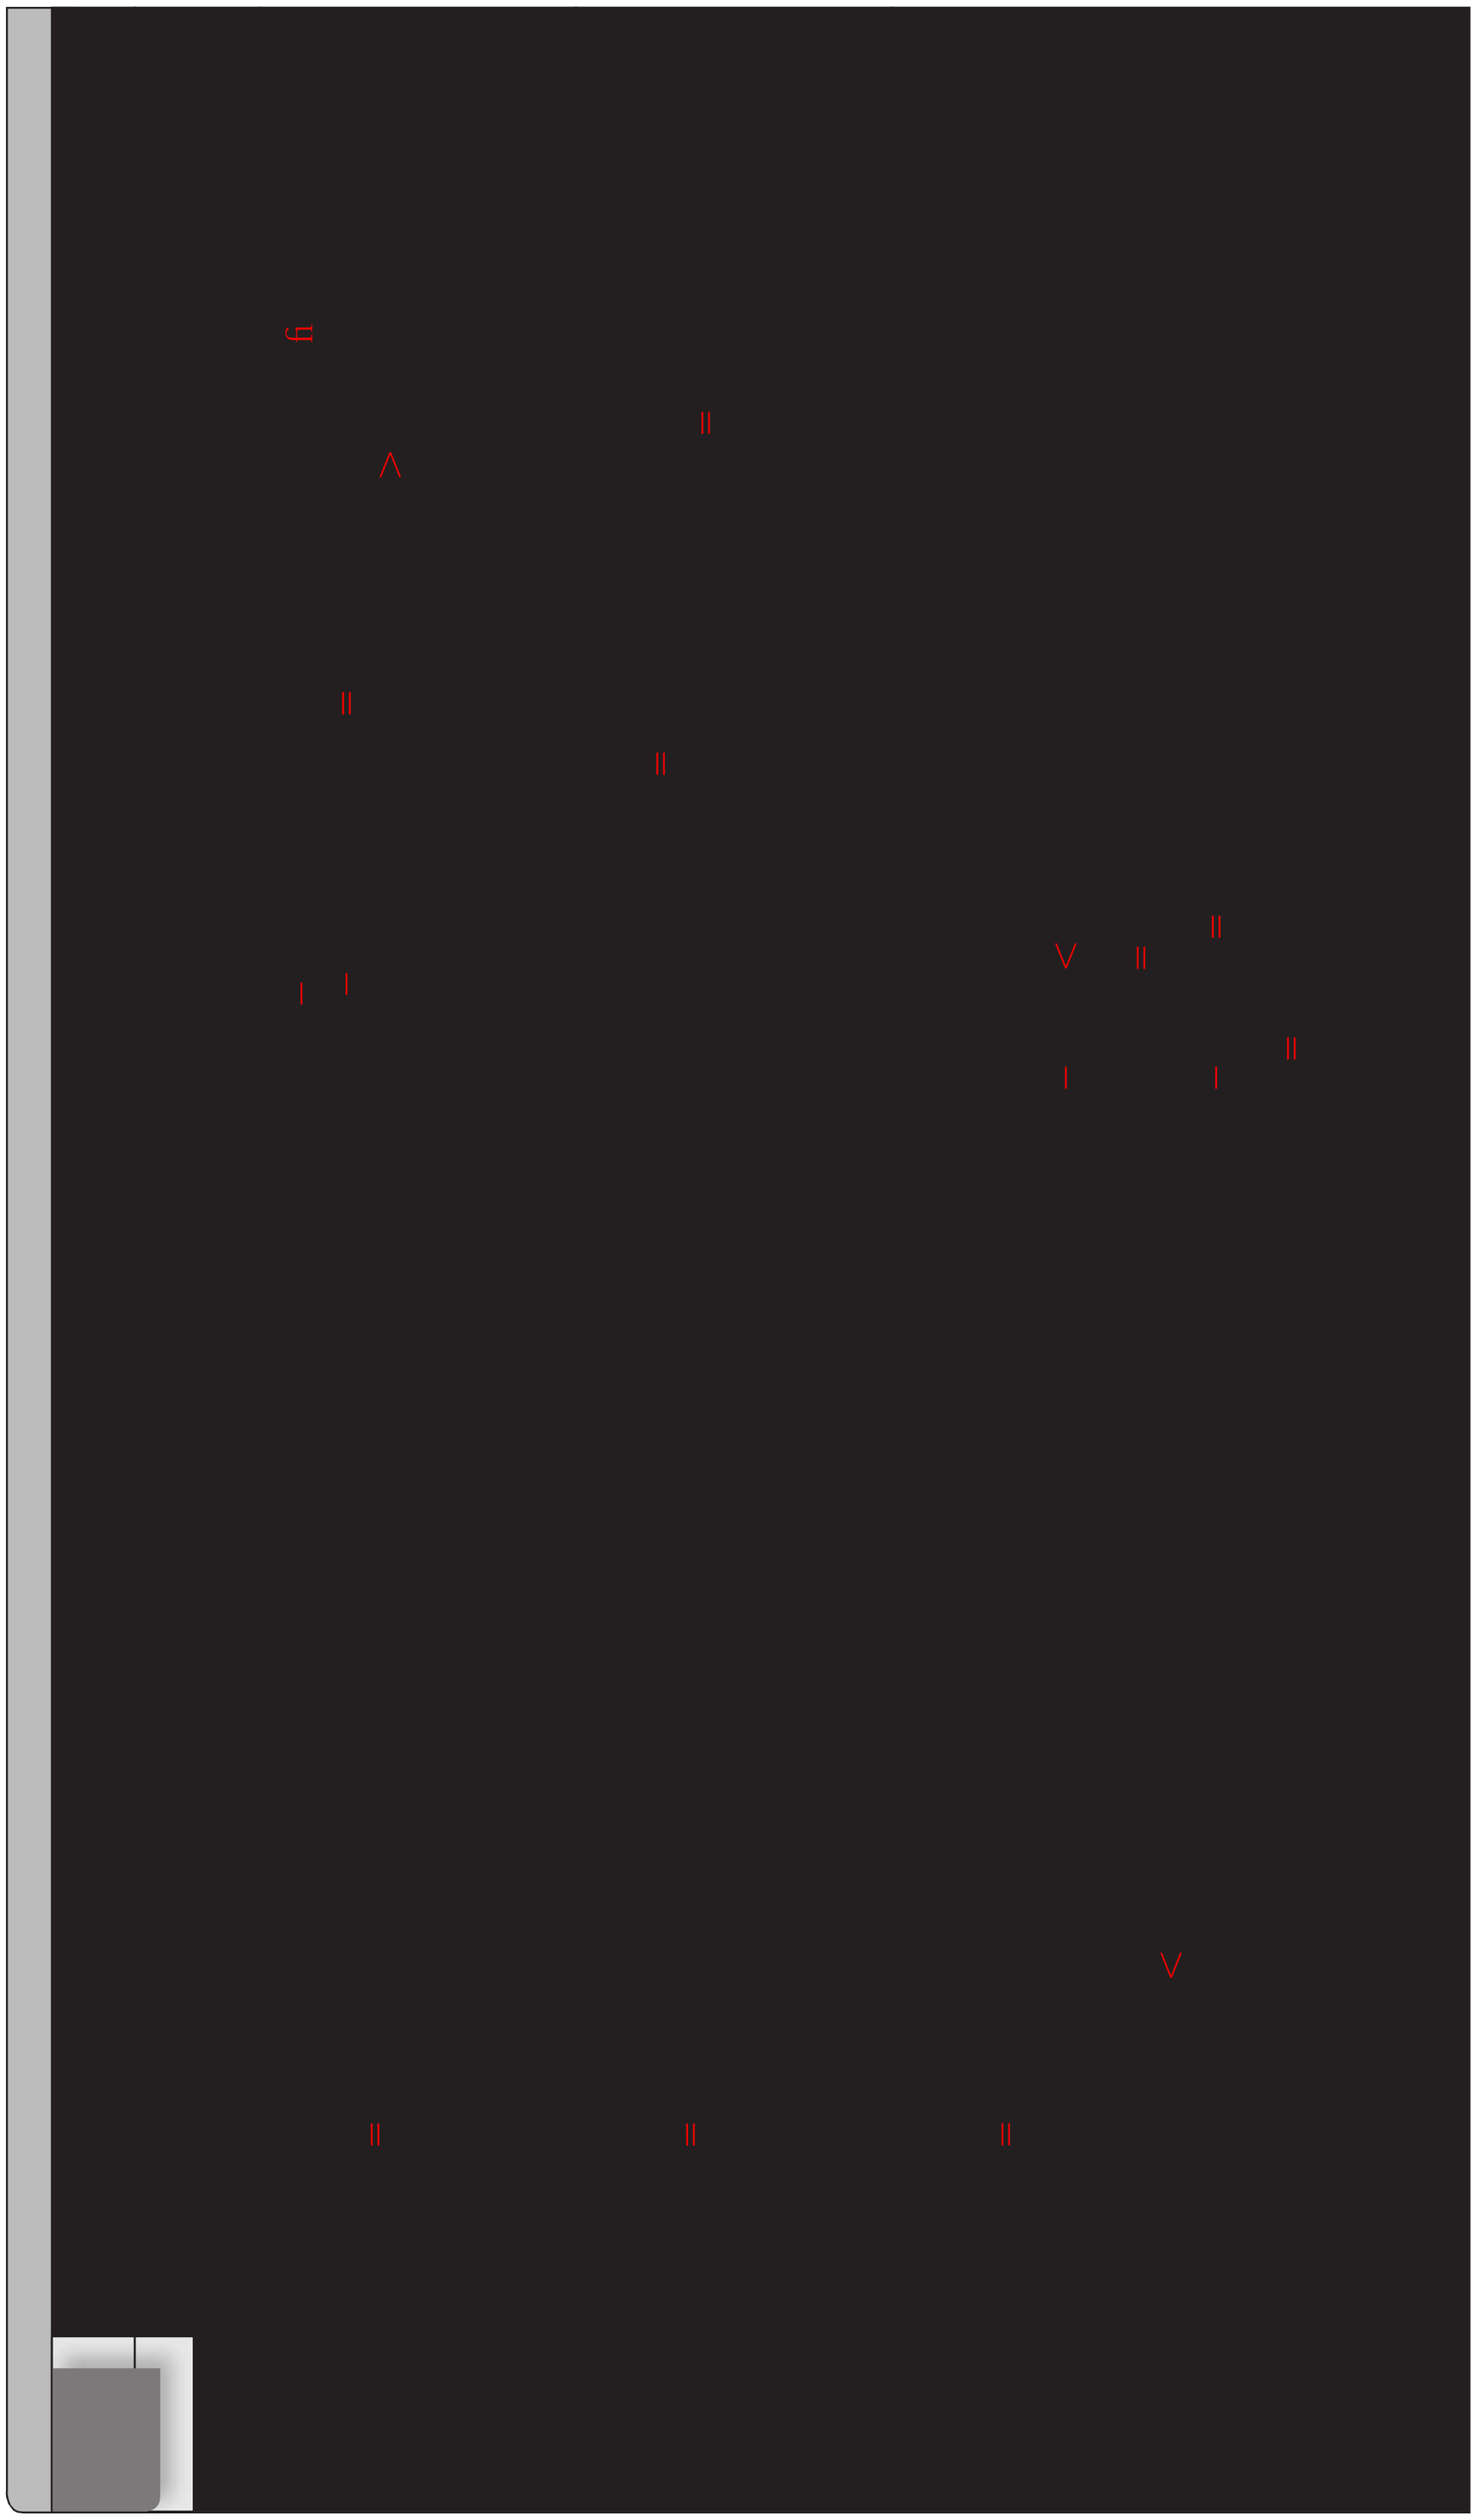
Further investigation into this topic has shown that the risk for kidney disease associated with the MYH9 gene is related to polymorphisms in another nearby location on chromosome 22q. The apolipoprotein 1 (ApoL1) gene encodes a serum factor that lyses Trypanosoma brucei rhodesiense. Case-control studies of African Americans with focal segmental glomerulosclerosis compared to African American controls reveal that the risk for renal disease was dependent on the presence of the ApoL1 alleles.[146] This has also been confirmed in African Americans patients with ESRD attributed to hypertensive nephrosclerosis.[146] This concept has important implications expanding from risk stratification of patients to expectations for managing hypertension in patients with nondiabetic kidney disease.

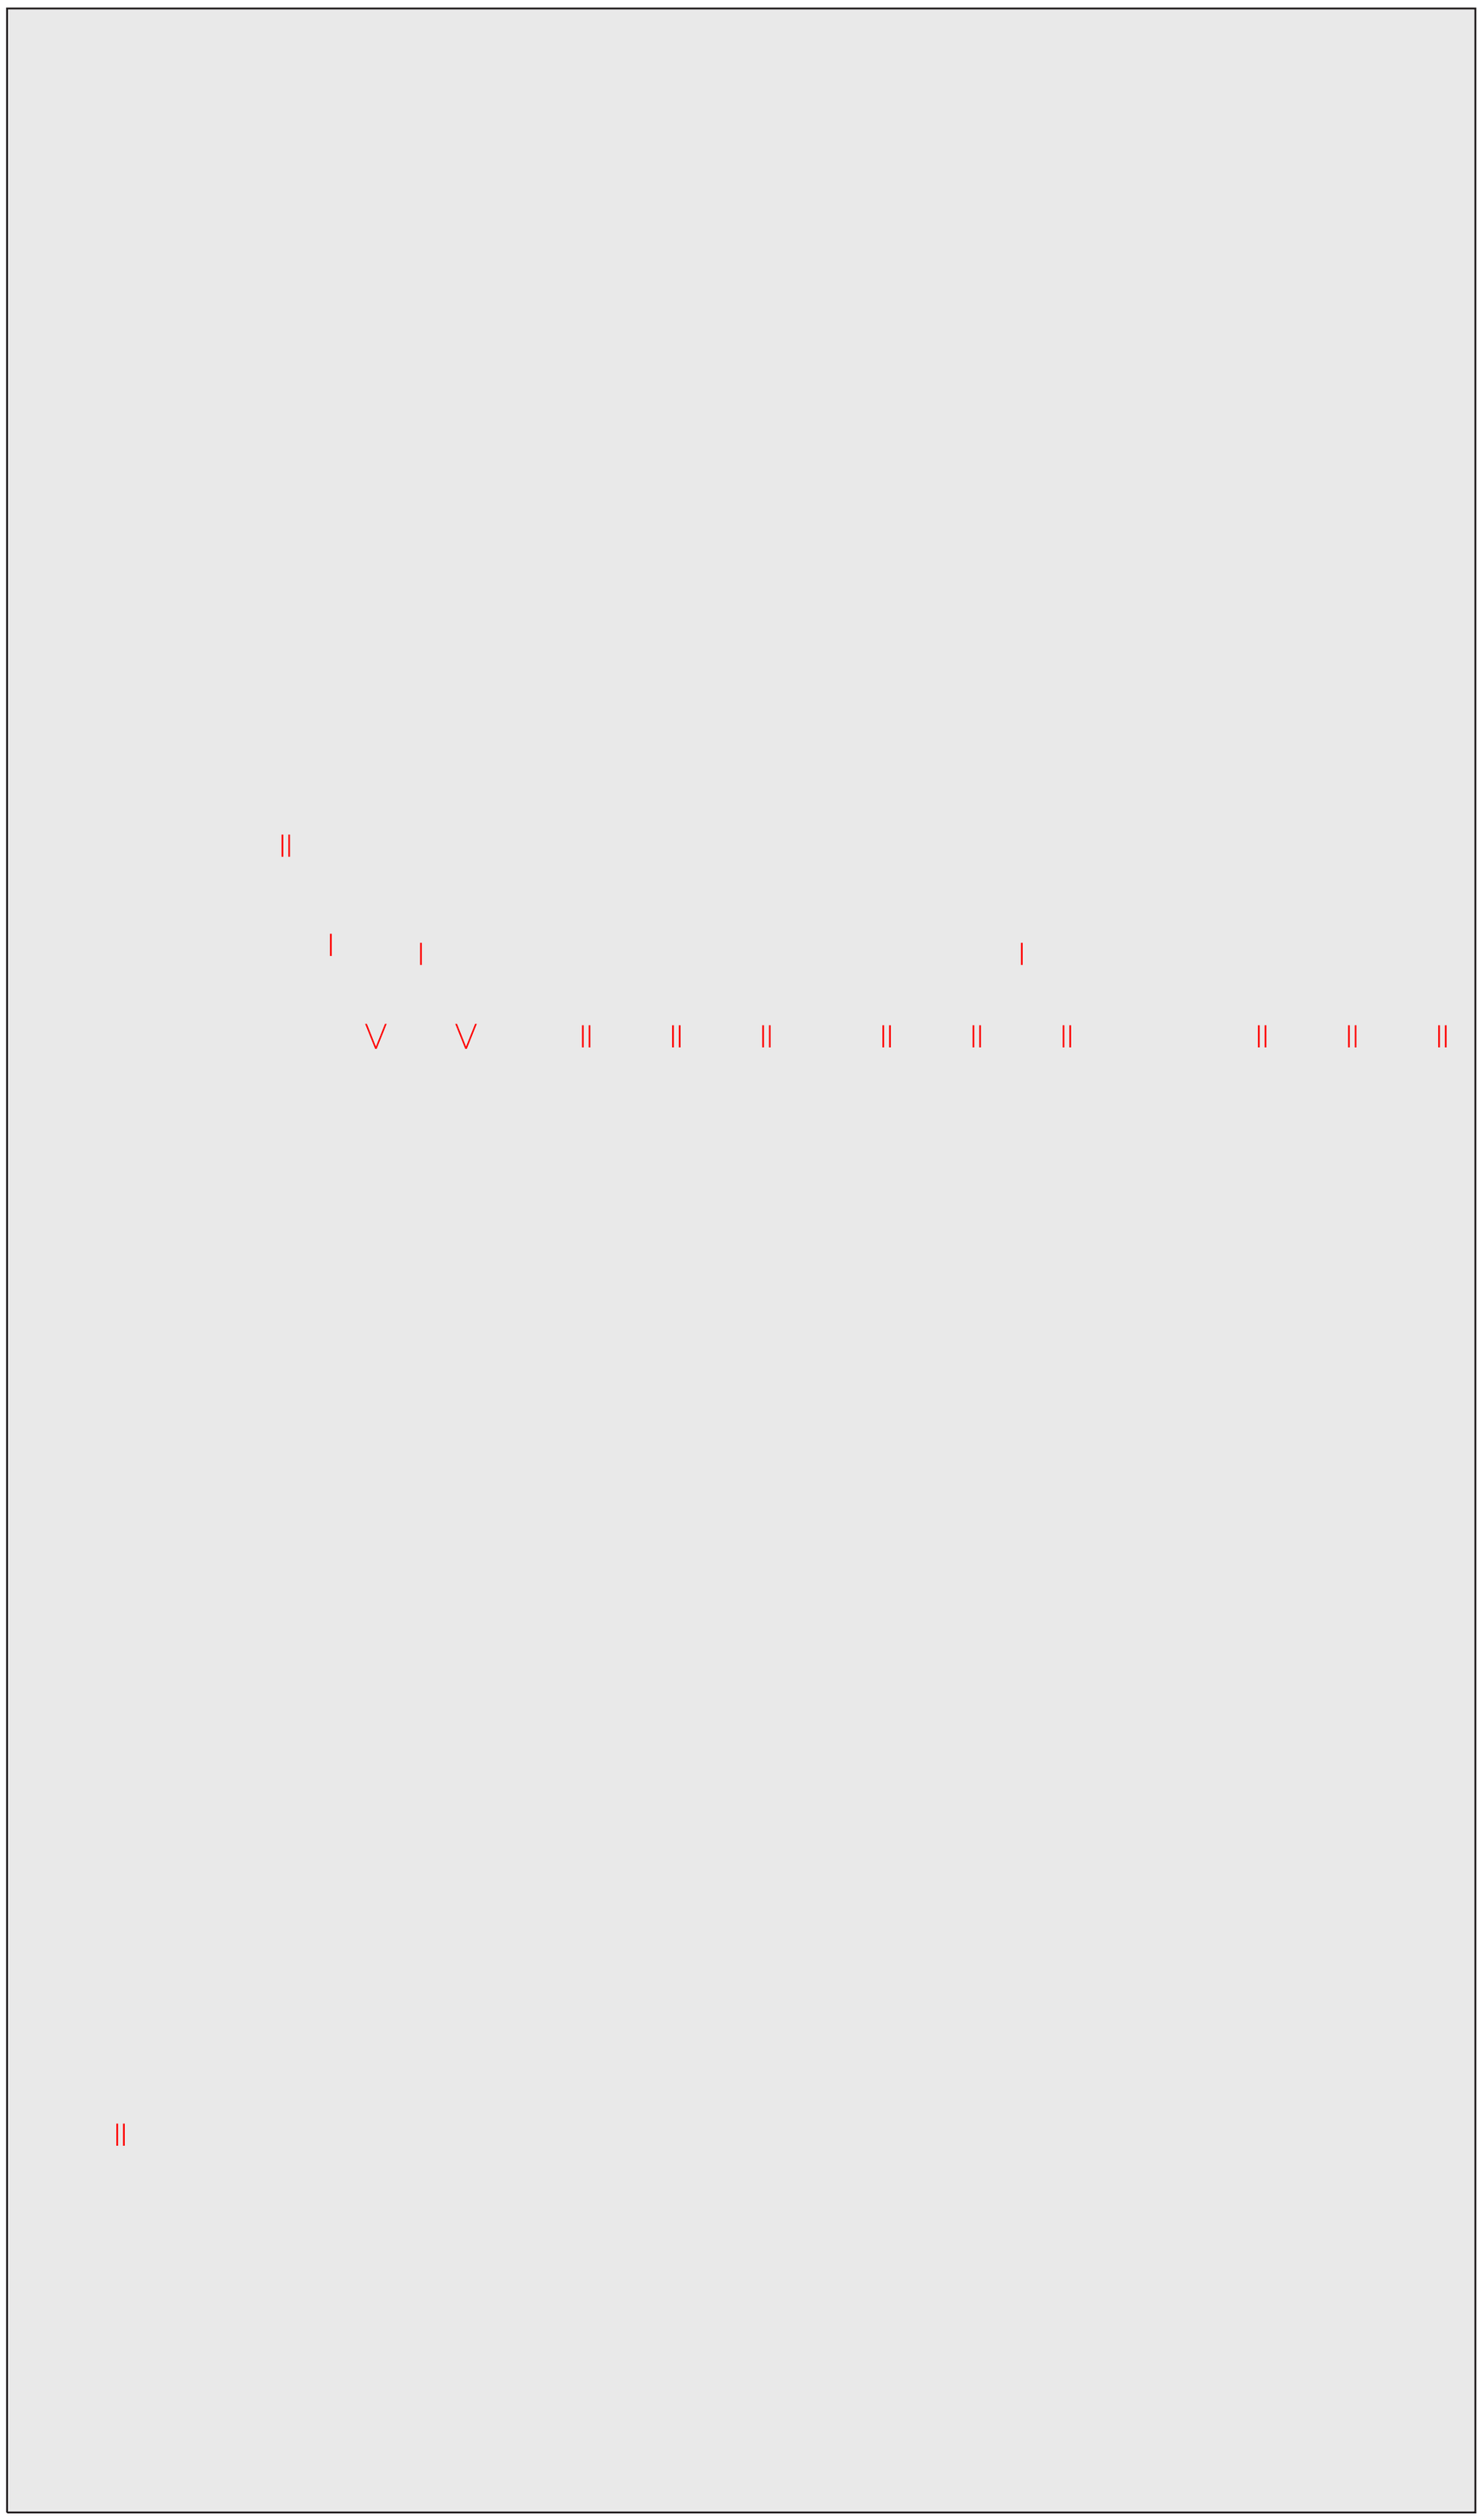
TREATMENT

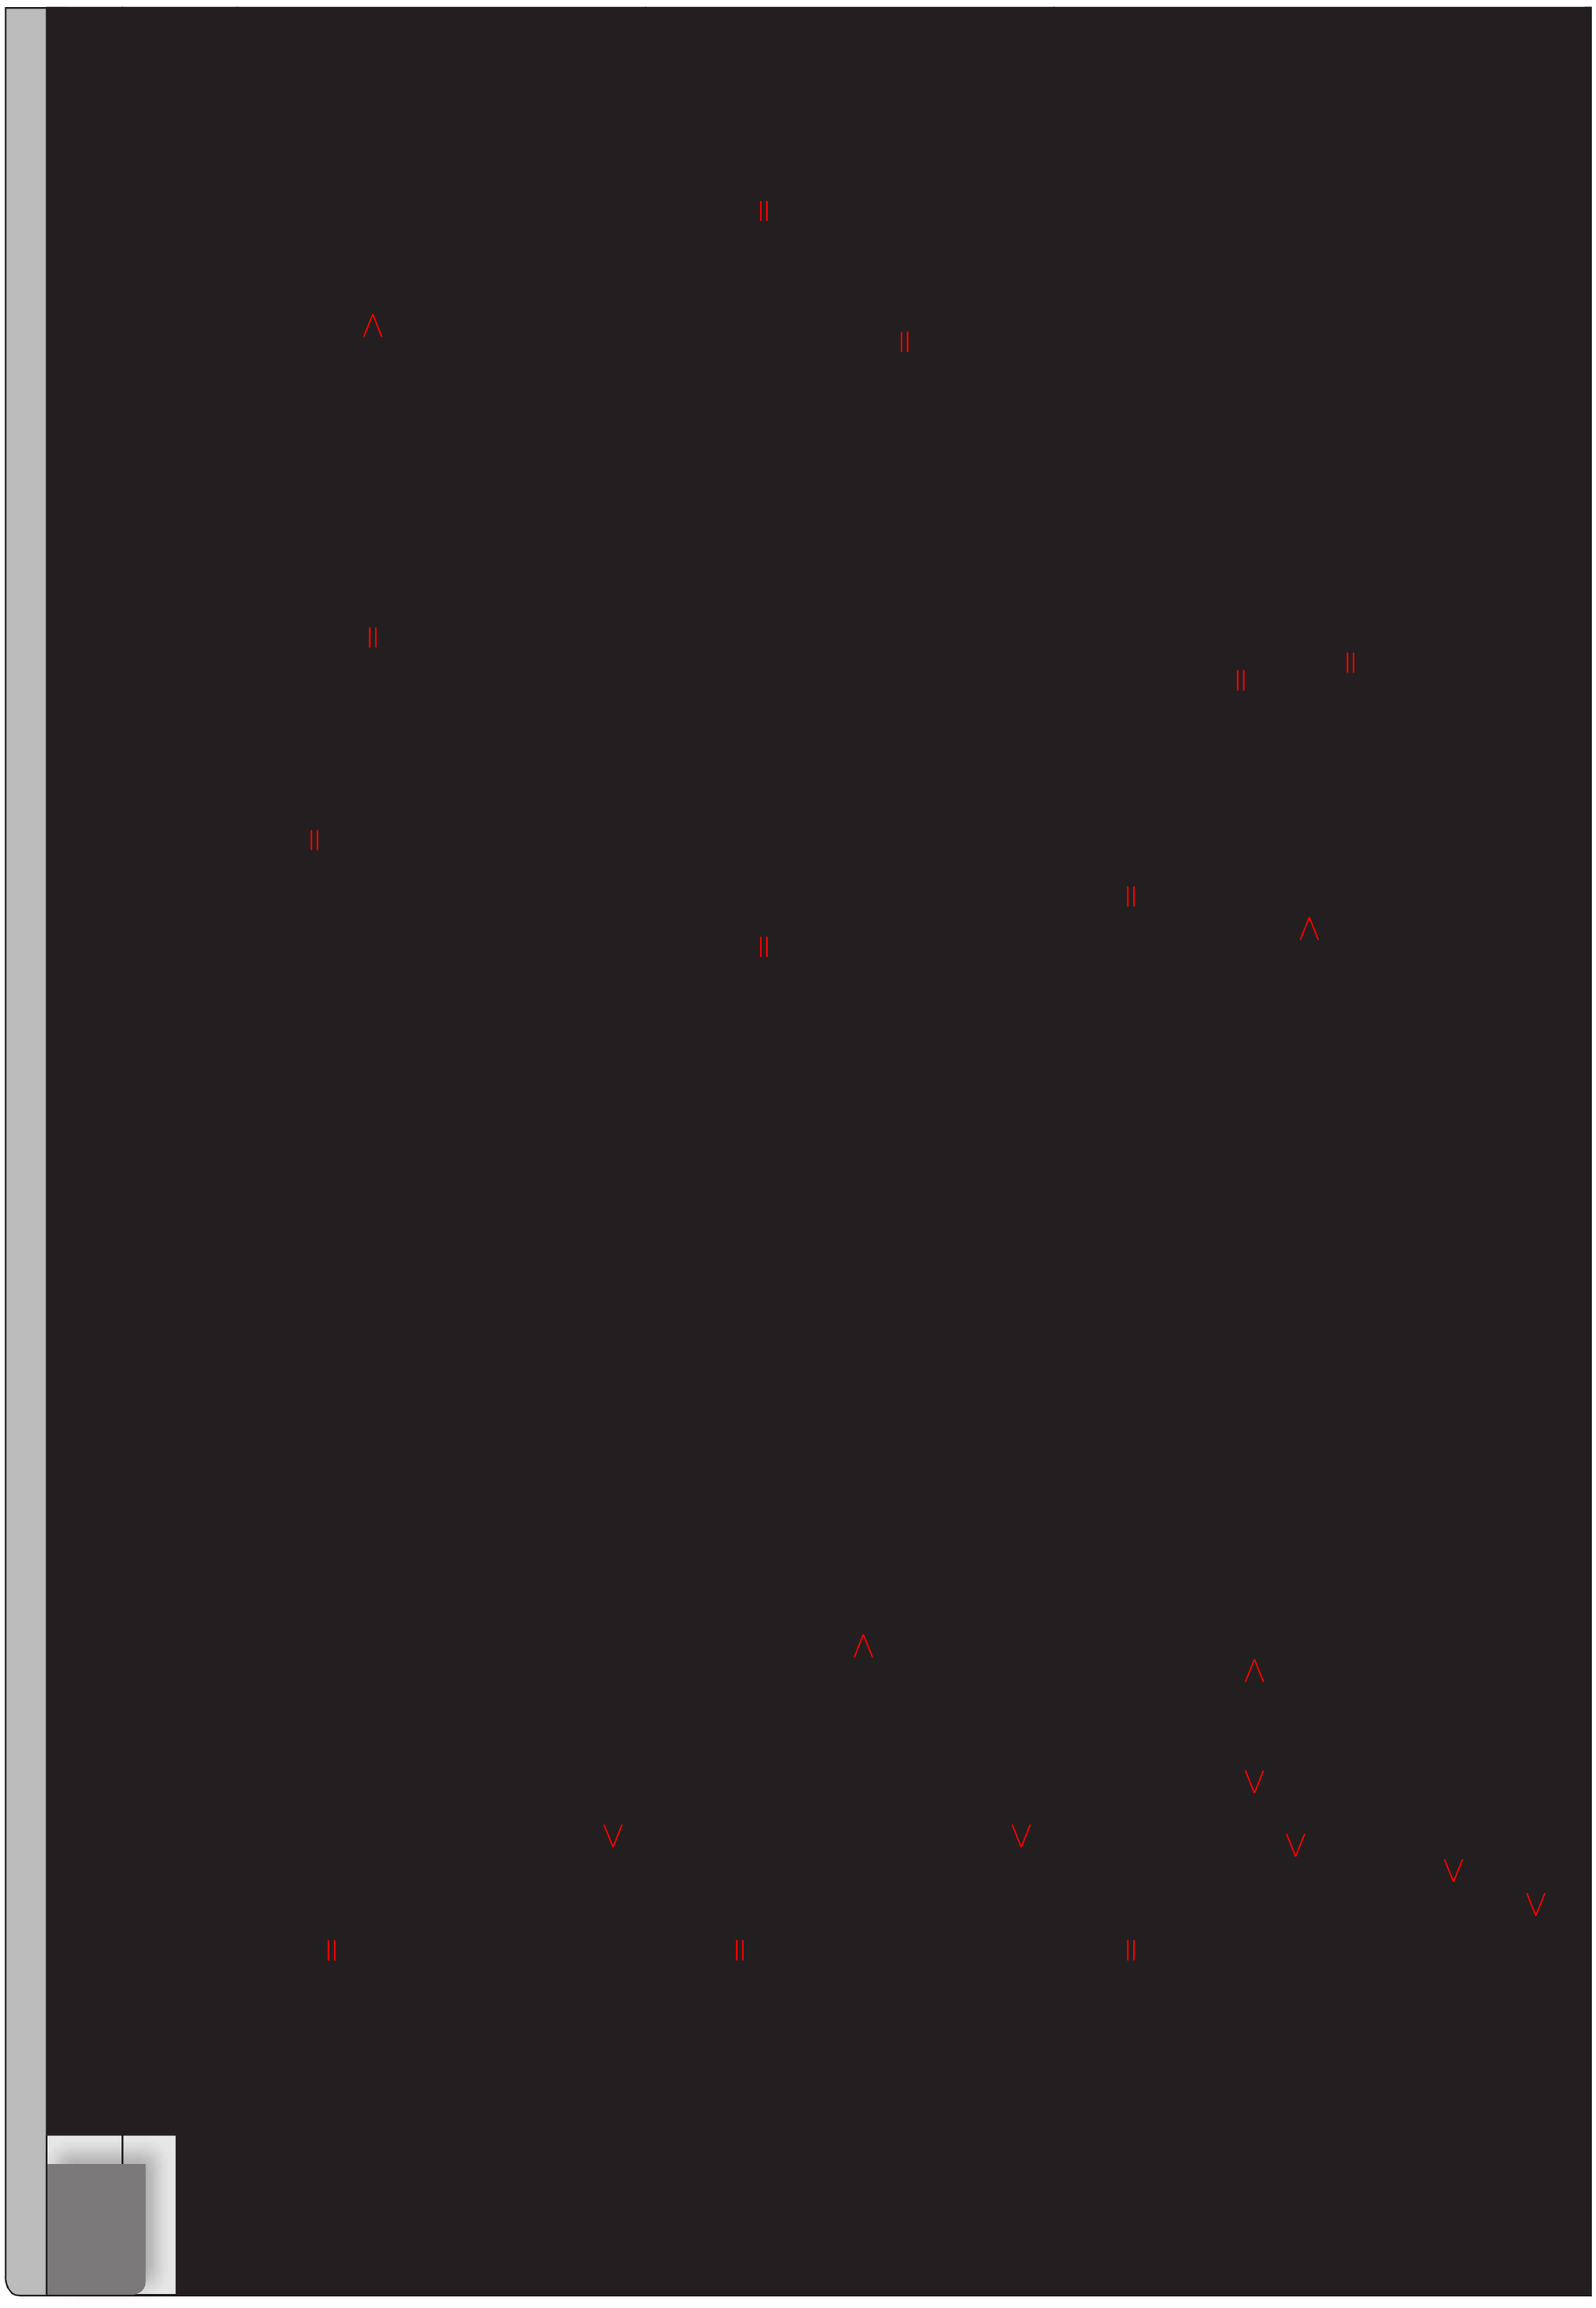
Pre–End-Stage Renal Disease

The management of hypertension in pre-ESRD CKD patients should be aimed at lowering the risk for progression to ESRD as well as reducing the risk for cardiovascular events and death. Current recommendations are to target a BP of 130/80 mm Hg in all CKD patients with consideration of a BP of 125/80 mm Hg in those with significant proteinuria.[147] These guidelines are based on the results and post hoc analyses of randomized clinical trials, which are summarized in Table 40.2. The Modification of Diet in Renal Disease (MDRD) studies randomized patients with GFR of 25 to 55 mL per minute (Study 1) and 13 to 24 mL per minute (Study 2) to a mean arterial pressure (MAP) <107 mm Hg or a MAP <92 mm Hg.[148] Although there was no difference between groups in the change in GFR with a mean follow-up of 2.2 years, a further analysis demonstrated that there was a significant reduction in GFR decline in those subjects with proteinuria randomized to the lower MAP goal.[149] The African-American Study of Kidney Disease and Hypertension (AASK) study randomized nondiabetic African American patients with a GFR of 20 to 65 mL per minute to either a MAP of 102 to 107 mm Hg or a MAP of <92 mm Hg. During the initial 3 months, there was a faster decline of GFR in the intensive BP group, but there was no difference between groups in the chronic or overall slope of GFR over time.[150] For patients with higher baseline proteinuria, there was a trend toward a slowed reduction in GFR with intensive BP control. Following the randomized study, all remaining subjects participated in a cohort study where the goal BP was set at 140/90 mm Hg. During the study, the goal BP was later changed to 130/80. For those with baseline proteinuria >0.22 g per day, there was a slower decline in GFR if they had been randomized to a MAP <92 mm Hg in the original study.[151] In contrast, the Ramipril Efficacy in Nephropathy 2 (REIN2) study randomized nondiabetic CKD patients with persistent proteinuria (1 to 3 g if the GFR <45 mL per minute, or >3 g if the GFR <70 mL per minute) to either standard BP control (diastolic BP <90 mm Hg) or intense BP control (<130/80 mm Hg). The study was halted at the first interim analysis because of similarities between BP groups in the outcomes of ESRD, proteinuria, and GFR decline despite the fact that systolic BP and diastolic BP were lower in the intensive BP group. These similarities persisted among the strata of baseline proteinuria.[152]

In summary, the following conclusions relevant to clinical practice emerge from these trials: (1) there is currently insufficient evidence from the cumulative trial data to demonstrate that, in patients with nondiabetic kidney disease, intensive BP goals (<130/80 mm Hg) slow the progression of CKD or reduce the incidence of ESRD and death, and (2) patients with proteinuria tend to have faster deterioration in renal function, but benefit the most from aggressive therapy. It is important to also acknowledge, based on studies in patients with diabetes, that renoprotection may not be synonymous with decreased overall cardiovascular risk reduction. The administration of combination therapy with perindopril and indipamide to participants with type 2 diabetes and varying levels of baseline renal disease (26% with microalbuminuria, 4% with macroalbuminuria, 19% with an estimated GFR <60 mL per minute) was associated with significantly reduced risk for the composite renal outcome of new onset microalbuminuria, new onset macroalbuminuria, new onset ESRD, or doubling of serum creatinine.[153] Achieving systolic BP <110 mm Hg offered the greatest renoprotection. Similarly, in post hoc analysis of the Irbesartan in Diabetic Nephropathy Trial (IDNT), the lowest quartiles of baseline and achieved systolic BP were associated with the lowest incidence of renal events.[154] However, the subgroup with systolic BP <120 mm Hg had a greater overall mortality than those with BP >120 mm Hg even after controlling for comorbidities. With systolic BP >120 mm Hg, cardiovascular mortality increased with each 10 mm Hg







increase, but also increased for each 10 mm Hg increment of diastolic BP lower than 85 mm Hg. Although these studies were inclusive of patients with diabetes and/or diabetic nephropathy and not completely generalizable to the whole CKD population, it is important to recognize potential limitations of overtreating BP in the context of outcomes other than renoprotection.

A large multicenter randomized clinical trial has been designed to address what the optimal BP target is for patients without diabetes mellitus in order to reduce the risk for cardiovascular events. The Systolic Blood Pressure Intervention Trial (SPRINT) will randomize almost 10,000 subjects to either an intensive BP goal (120 mm Hg) or a standard BP goal (140 mm Hg).[155] The inclusion criteria are age >55 years, hypertension, and the presence of a clinical or subclinical cardiovascular disease, excluding stroke. Inclusive in the definition is CKD with an estimated GFR of 25 to 59 mL per minute, but proteinuria >1 g will be one of the exclusion criteria. The primary outcome is the occurrence of the first major cardiovascular event, although a decline in renal function and the development of ESRD over a 6-year follow-up are some of the secondary end points. The large number of CKD patients expected to be enrolled in SPRINT will provide enough power to reach meaningful conclusions in this patient population. Given the exclusion criteria of diabetes and proteinuria >1 g per day, this study will be directly applicable to CKD patients considered at a lower risk for adverse events than some of the earlier mentioned studies.

Despite the existing debate for the ideal BP in a CKD patient, evidence shows that the majority of CKD patients fail to have BP adequately controlled.[5,10] Although most CKD patients will require more than one antihypertensive drug, all CKD patients should be prescribed a low sodium diet as the first step in managing BP. Dietary sodium intake will also affect the degree of proteinuria in CKD patients, such that increased dietary sodium intake abolishes the antiproteinuric effects of RAAS inhibition.[156] The current recommendations are to limit dietary sodium intake to less than 2.4 g per day.[147]

Inhibitors of the RAAS are the recommended first-line antihypertensive agents for most CKD patients, with the most commonly used agents being ACE inhibitors or ARBs. These agents should be titrated to the maximum recommended doses in order to achieve the greatest RAAS inhibition. Several randomized clinical trials have evaluated the efficacy of ACE inhibitors in CKD patients and, similar to the effects of implementing intensive BP lowering, show that the benefits are most appreciable in patients with higher baseline proteinuria. The African-American Study of Kidney Disease and Hypertension (AASK) and Ramipril Efficacy in Nephropathy (REIN) studies included randomization arms with different antihypertensive agents. In REIN, the ACE inhibitor ramipril decreased the risk of ESRD compared to placebo regardless of baseline proteinuria and slowed the decline of GFR in patients with nephrotic range proteinuria.[157,158] In AASK, subjects were randomized to the ACE inhibitor ramipril, the beta-blocker metoprolol, or the calcium channel blocker amlodipine. Ramipril caused a slower overall decline in GFR compared to metoprolol.[150] There was no difference in the overall decline in GFR between ramipril and amlodipine.[159] However, this was confounded by the acute increase in GFR with amlodipine because the chronic decline in GFR was slower with ramipril. Furthermore, for subjects with mild-to-moderate baseline proteinuria or renal impairment (GFR <40 mL per minute), there was a significantly slower reduction in GFR in the ramipril group. Ramipril also reduced the composite outcome of ESRD, the doubling of serum Cr, or death compared to metoprolol and amlodipine.[150,159]

The benefit of ACE inhibitors extends even to advanced nondiabetic cases of CKD. In a randomized clinical trial, patients with serum creatinine (Cr) between 3 and 5 mg per deciliter were randomized to either benazepril 10 mg twice daily or placebo, in addition to other antihypertensives.[160] Proteinuria >0.3 g per day was one of the inclusion criteria, and the mean baseline proteinuria was 1.6 and 1.7 g per day in the benazepril and placebo groups, respectively. The use of benazepril reduced the occurrence of the primary endpoint of the composite of doubling serum Cr, ESRD, or death. There was also a slower reduction in GFR and creatinine clearance over time, which was assessed as a secondary endpoint in the benazepril group. These findings occurred in the context of similar BP control between groups, and the average achieved systolic BP was <130 mm Hg in both groups.

The cumulative findings show that use of an ACE inhibitor offers benefits over other drugs even when a similar BP is achieved. In addition to these studies in nondiabetic kidney disease, there is robust evidence for BP control and RAAS inhibition in reducing renal endpoints in patients with diabetic kidney disease, specifically in the progression of overt nephropathy to composite clinical endpoints in type 1 and type 2 diabetes,[161–163] progression of microalbuminuria to macroalbuminuria in type 2 diabetes,[164] and the primary prevention of microalbuminuria in hypertensive patients with type 2 diabetes.[165,166] For CKD patients without diabetes, it should be emphasized that the benefits of RAAS inhibition are strongest in patients with the greatest risk for CKD progression. In fact, one meta-analysis confirmed that use of an ACE inhibitor was most beneficial in those with >500 mg per day of proteinuria.[167] The benefits of ACE inhibitors as first-line agents are less certain in those without proteinuria.

Additional agents are frequently required to control BP in CKD patients. Diuretic therapy addresses the impact of extracellular volume on BP and optimizes sodium balance. When GFR is significantly impaired, loop diuretics such as furosemide may be more effective than hydrochlorothiazide. It is important to dose loop diuretics at least twice daily and to consider increased doses in patients with significantly impaired GFR in order to optimize delivery of the drug to the site of action. Diuretics additionally offer the benefit of increasing renal potassium excretion in CKD patients who may be prone to hyperkalemia. Following the use of RAAS inhibitors and diuretics, the decision of which additional agents to

use will be dependent on other underlying comorbidities. Beta-blockers are recommended for patients with congestive heart failure, coronary artery disease, and arrhythmias.[147] Calcium channel blockers, vasodilators such as hydralazine and minoxodil, and clonidine may also be required if BP remains elevated. Although a post hoc analysis of the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial demonstrated that subjects with a GFR <45 mL per minute had decreased progression of CKD using the ACE inhibitor benazepril plus the calcium channel blocker amlodipine compared to benazepril plus hydrochlorothiazide,[168] it is unknown how the former combination compares to a regimen including an ACE inhibitor and a loop diuretic. A suggested approach to the selection of an antihypertensive regimen for CKD patients is provided in Figure 40.3.

Combination Renin-Angiotensin-Aldosterone System Inhibition

Because of the concerns of incomplete inhibition of the production or action of Ang II, combination therapy with both ACE inhibitors and ARB has been considered. This strategy has been shown to lower proteinuria in numerous studies of CKD patients, but it is uncertain how much of this effect is derived from additional BP lowering.[169] Because of the concerns of aldosterone escape and the non–ACE-related production of Ang II related to increased PRA in patients already receiving either an ACE inhibitor or ARB, add-on therapy using either a mineralocorticoid receptor blocker or a direct renin inhibitor has also been considered. None of these strategies is currently recommended for patients with CKD, but there is accumulating evidence of the effects of such regimens that is worth briefly discussing here.

Mineralocorticoid Receptor Blockers and Direct Renin Inhibitors. Most of the benefits of add-on therapy with a mineralocorticoid receptor antagonist (MRA) are related to a reduction in proteinuria as opposed to BP. In one clinical trial, patients with proteinuric CKD were randomized to ramipril plus dual placebo, ramipril plus spironolactone plus placebo, ramipril plus placebo plus irbesartan, or triple therapy with all three medications.[170] There were no differences in systolic BP during follow-up, but the groups receiving spironolactone as either dual or triple therapy had a clear benefit in proteinuria reduction compared to the group receiving only ramipril. Other studies involving MRA have been exclusively in patients with diabetic nephropathy and yielded similar results, suggestive of an antiproteinuric benefit from MRA,

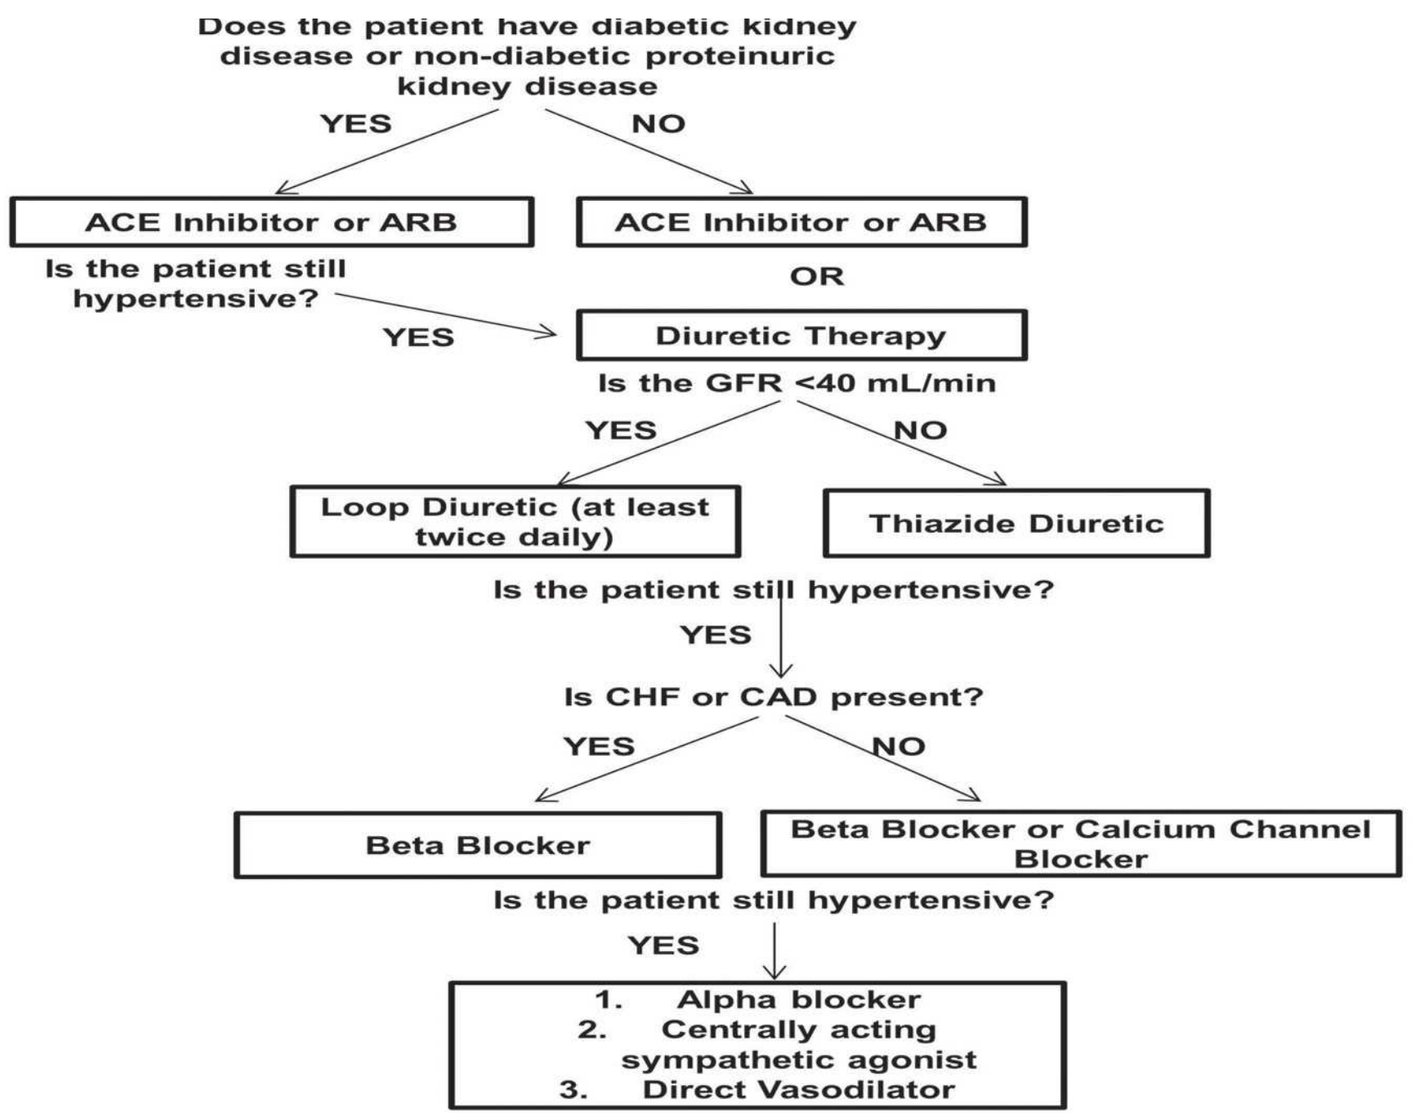


FIGURE 40.3 For chronic kidney disease (CKD) patients with diabetic kidney disease or nondiabetic proteinuric kidney disease, inhibition of the renin-angiotensin-aldosterone system (RAAS) system using either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) should be the first-line therapy. These drugs can also be used as first-line therapy in patients without proteinuria or diabetic kidney disease, but the evidence to support this decision is not as clear. Diuretics should be used to reduce extracellular volume. It is important to use a thiazide diuretic only if the glomerular filtration rate (GFR) is >40 mL per minute and to dose loop diuretics at least twice daily. For patients that remain hypertensive, those with coronary artery disease (CAD) or congestive heart failure (CHF) should receive an indicated beta-blocker, whereas for others, calcium channel blockers can be used. Finally, patients that are still hypertensive may be started on fourth- or fifth-line agents.

although BP differences have varied.[171–173] Clinical trials of the direct renin inhibitor aliskiren in CKD patients are mainly limited to diabetic nephropathy. Although the use of aliskiren as a single agent lowers BP and albuminuria,[174] the beneficial effects of combination therapy, including aliskiren compared to single agent RAAS inhibition, mainly stem from albuminuria reduction.[175,176]

End-Stage Renal Disease

The current recommendations for managing hypertension in ESRD patients is to target a pre-HD systolic BP <140 mm Hg and a post-HD systolic BP <130 mm Hg.[177] There is significant overlap in the etiology of hypertension in patients with ESRD and pre-ESRD CKD. There is increasing evidence of outcomes related to strategies aimed at targeting the underlying causes of hypertension in the HD population. Hemodialysis patients are even more vulnerable to the impact of volume overload than CKD patients because of the extremely limited ability to excrete sodium and water due to kidney failure. The mechanisms of increased vasoconstriction are also similar between ESRD and pre-ESRD CKD patients. Furthermore, the duration and timing of the weekly HD regimen may impact BP control in HD patients.

Identifying and achieving an HD patient's target dry weight are the initial steps that should be taken in managing BP. This process involves a careful clinical assessment of the patient's extracellular volume status, strict enforcement of dietary sodium restriction, and prudent application of ultrafiltration during the HD procedure. Current recommendations are to limit interdialytic sodium intake to 2 to 3 g per day in patients who appear volume overloaded.[177] In patients who remain hypertensive, there should be a consideration of a reduction in dry weight. A slow, progressive reduction in estimated dry weight over several weeks has been shown to reduce ambulatory BP in hypertensive HD patients.[48] Increasing the amount of time a patient spends on HD with either daily or nocturnal dialysis compared to thrice weekly sessions has also been shown to improve BP control. One RCT compared thrice weekly HD with a regimen consisting of six treatments per week.[178] The rates of death and a left ventricular (LV) mass were reduced after 12 months in the group randomized to more frequent HD. Pre-HD systolic BP and the number of antihypertensives required were also reduced in this group, although ambulatory BP was not measured. In an observational study, nocturnal HD has been associated with improved BP and LV mass.[179] One randomized study has demonstrated reductions in LV mass, pre-HD systolic BP, and the antihypertensive requirement in subjects converted to nocturnal HD.[180] Finally, another randomized study confirmed the improved BP with nocturnal HD, but failed to demonstrate improvement in the primary outcome of mortality and LV mass reduction.[181]

Despite the effects from dry weight reduction or more frequent HD treatments, pharmacologic treatment with antihypertensive agents is frequently required to further lower BP in HD patients. Overall, evidence from two meta-analyses supports the use of antihypertensive medications in HD patients to improve cardiovascular outcomes and mortality.[182,183] First-line recommended therapy for HD patients is the use of a RAAS-inhibiting drug.[177] In observational studies of HD patients, the use of ACE inhibitors was associated with reduced mortality.[184] However, this has not yet been confirmed in a randomized clinical trial. The Fosinopril in Dialysis (FOSIDIAL) trial randomized HD patients to either fosinopril or standard therapy and achieved a nonsignificant 8% reduction in the hazard ratio for mortality and cardiovascular death.[185] One small study that randomized hypertensive ESRD patients to one of several ARB (candesartan, losartan, valsartan) versus placebo demonstrated a reduction in both fatal and non-fatal cardiovascular events.[186] For patients that remain hypertensive after implementing a pharmacologic RAAS inhibition, other antihypertensive drugs should be prescribed based on existing comorbidities. The beta-blocker carvedilol has been shown to improve survival in patients with dilated cardiomyopathy,[187] and other beta-blockers may be used in the context of coronary artery disease. Additionally, the calcium channel blocker amlodipine has been shown to improve the composite outcome of mortality and nonfatal cardiovascular events in hypertensive HD patients already prescribed other agents, including ACE inhibitors and beta-blockers,[188] and should be considered as an add-on therapy. Fourth- and fifth-line agents, if necessary, include alpha-blockers, centrally acting sympathetic agonists (clonidine), and direct vasodilators. A suggested approach to the selection of an antihypertensive regimen for CKD patients is provided in Figure 40.4.

Despite the fact that peritoneal dialysis (PD) offers a more continuous treatment modality than intermittent HD for removing fluid and toxins, there is a high prevalence of hypertension in the PD population. In a multicenter Italian study of over 500 peritoneal dialysis patients, it was determined that the prevalence of hypertension was 88%.[189] Just as in HD patients, extracellular volume is an important determinant of BP, and both hypertensive status and the amount of sodium and fluid removal have been associated with increased mortality in PD patients.[190] Extracellular volume overload remains a primary concern in PD patients, and there is evidence using either an assessment of left atrial volume or bioimpedance analysis that PD patients are generally more volume overloaded than HD patients.[191,192] Further observational evidence, however, suggests that BP may not be as important of a predictor of the relative risk of death in the PD population.[193] Formal recommendations do not exist for the PD population as in HD patients, although attaining euvolemia in these patients remains an important goal.

CONCLUSION

Hypertension is a prevalent comorbidity associated with chronic kidney disease from the early stages to ESRD. Its existence in this population is related to multiple factors

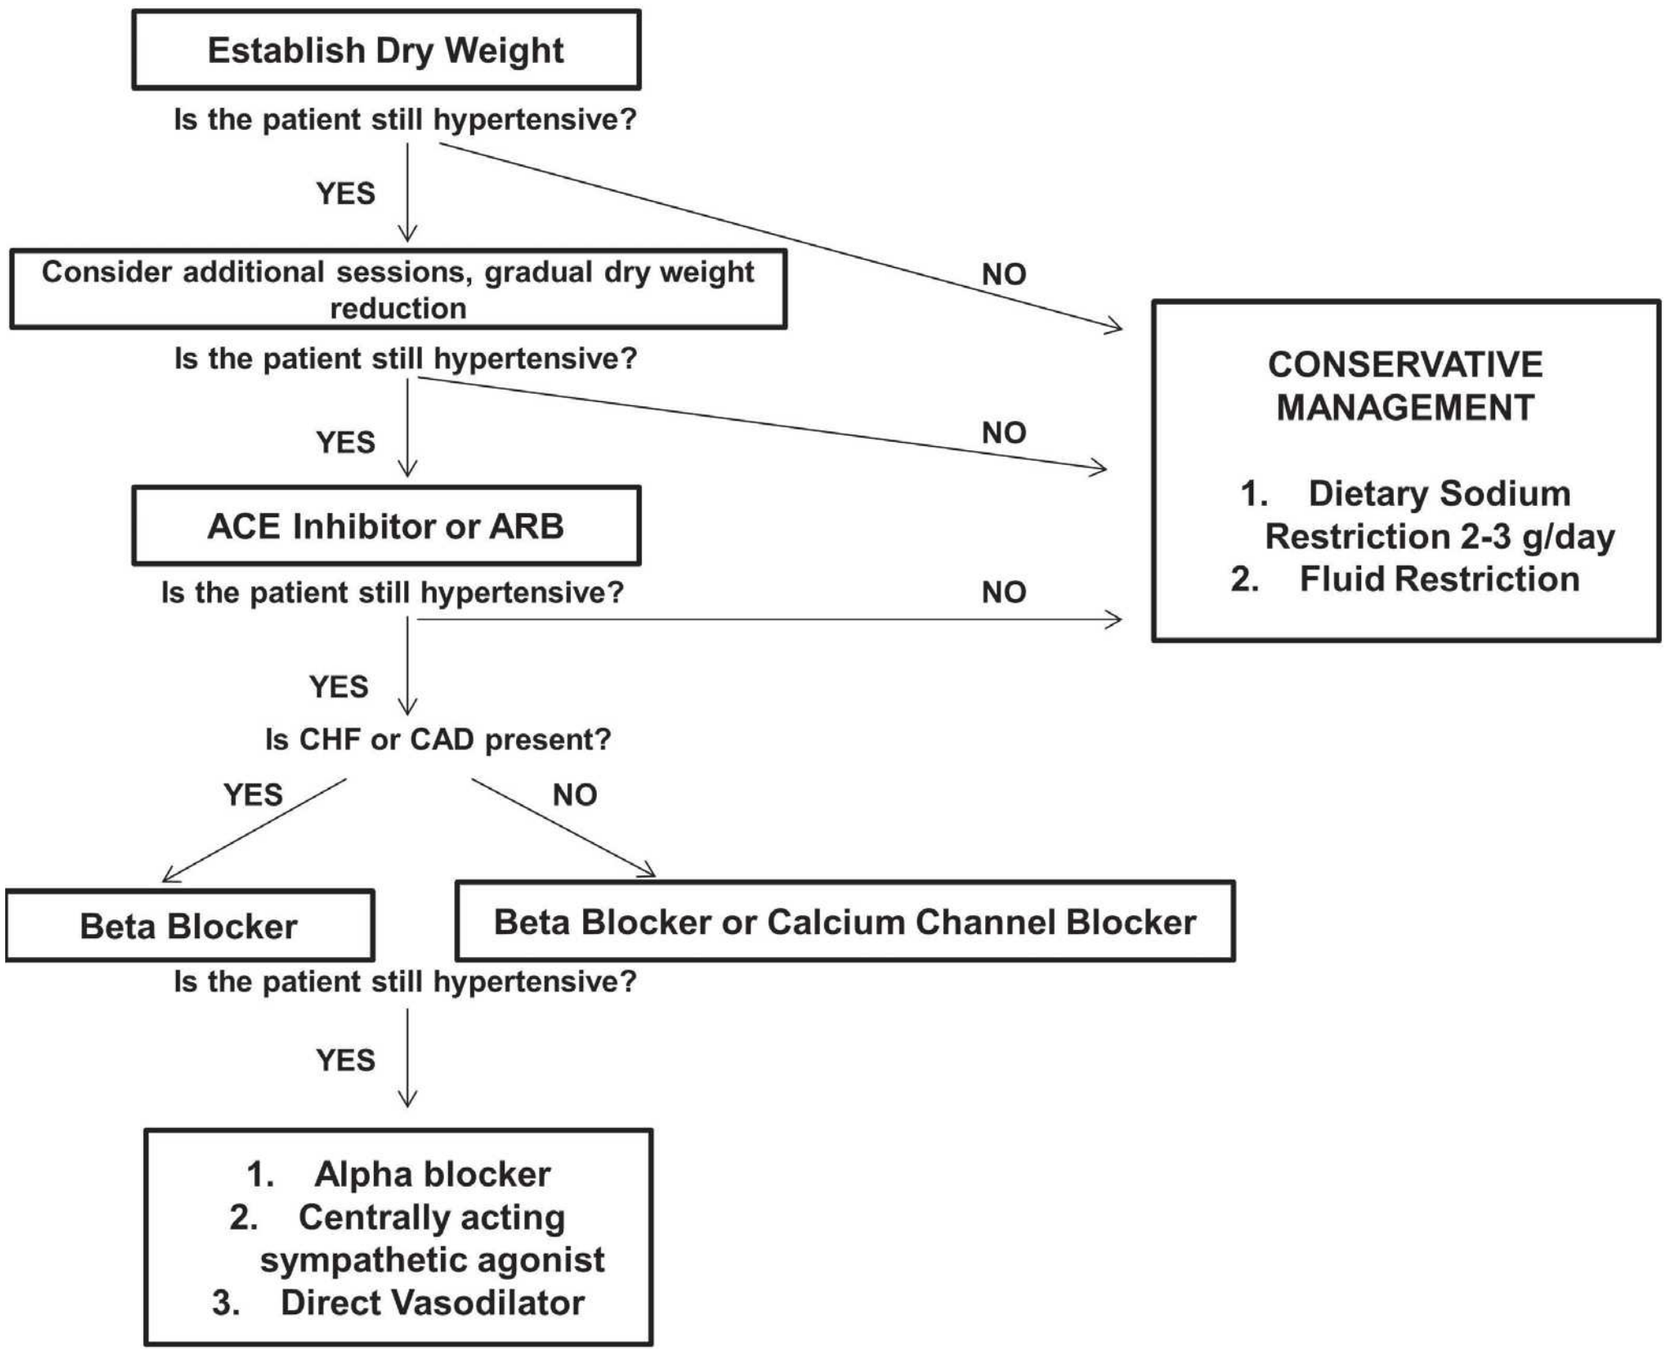

FIGURE 40.4 For hemodialysis (HD) patients, the first step in managing blood pressure (BP) should be to identify and achieve the accurate dry weight. Overtly volume overloaded patients may require additional HD treatments to achieve dry weight, and in others, a trial of gradual dry weight reduction may be possible. Inhibitors of the renin-angiotensin-aldosterone system (RAAS) (angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers) are first-line pharmacologic therapy in HD patients. As in pre–end-stage renal disease (ESRD) chronic kidney disease (CKD) patients, additional therapy may be dictated by underlying comorbidities reserving indicated beta-blockers for patients with congestive heart failure (CHF) or coronary artery disease (CAD). Calcium channel blockers can be added next for patients that remain hypertensive because there is evidence that they reduce cardiovascular end points compared to placebo in HD patients. Finally, patients that are still hypertensive may be started on fourth- or fifth-line agents (alpha-blockers, centrally acting sympathetic agonists, direct vasodilators). All HD patients should limit their interdialytic weight gain through dietary salt and water restriction to prevent extracellular volume overload.

including extracellular volume overload and increased vasoconstriction. Uncontrolled hypertension is associated with the progression of CKD to ESRD and with cardiovascular morbidity and mortality. Home and ambulatory BP measurements are currently the gold standard for predicting outcomes and assessing the overall BP burden. The target BP for CKD patients that optimally reduces the risk for both renal and cardiovascular outcomes remains unknown, but subjects with increased proteinuria derive more benefit from aggressive BP lowering. The optimal BP for patients on HD also remains unknown, but appropriate estimation and achievement of dry weight are paramount in controlling BP for most of these patients. Pharmacologic antihypertensive agents will be required for most CKD and ESRD patients, and inhibitors of the RAAS appear to be the most beneficial in CKD patients with proteinuria, with accumulating evidence that there may also be an advantage to these drugs in ESRD patients.

CHAPTER

41 Hypertension in End-Stage Renal Disease

Rajiv Agarwal

Hypertension among patients with end-stage renal disease (ESRD) is common. The diagnosis, pathophysiology, prognosis, and treatment of this condition are complex and subject of much controversy. The purpose of this review is to describe the epidemiology, pathophysiology, treatment, and control of hypertension among dialysis patients and point out controversies where they exist.

EPIDEMIOLOGY

The prevalence, treatment, and control of hypertension among people on hemodialysis have used varying definitions to diagnose hypertension. Most studies have been performed using blood pressure (BP) measurements obtained before and after dialysis and are discussed first. Studies using ambulatory BP recordings are discussed later.

Hemodialysis

Defined as a 1-week average predialysis systolic BP >150 mm Hg or diastolic BP >85 mm Hg or the use of antihypertensive medications in 2,535 clinically stable, adult hemodialysis patients participating in a multicenter trial, the prevalence of hypertension was found to be 86%.[1] Among hypertensive patients, 12% did not receive antihypertensive drugs, 58% were treated but not controlled, and only 30% were controlled. This is in line with other studies which have found the use of antihypertensive drugs to vary between 59% and 83%.[2–4] Furthermore, even among children on long-term hemodialysis similar findings have been reported.[5]

The determinants of hypertension in the general population (not on dialysis) are age, sex, and race. Among hemodialysis patients, sex and race are not found to be determinants of hypertension.[1] Thus, men and women, blacks and whites are equally at risk of having hypertension once they are on hemodialysis. In contrast to the general population, younger patients were more likely to be hypertensive. The independent determinants of hypertension are younger age, etiology of ESRD (either due to diabetes mellitus or hypertension), absence of obesity, and fewer years on dialysis. Thus, nondiabetic, obese, and older patients who have been on dialysis for several years are least likely to be hypertensive.

Treatment with antihypertensive drugs is independently associated with the following factors: younger age, diabetes mellitus, lack of obesity, and aspirin use. Control of hypertension is independently associated with the following: white race, absence of diabetes mellitus, longer years on hemodialysis, use of aspirin, and less antihypertensive drug use. Several studies have confirmed greater antihypertensive drug use to be associated with poorer control.[6,7] It appears that poor control of hypertension among hemodialysis patients is also associated with poor control of hypertension prior to reaching ESRD.[8]

The true prevalence of hypertension in people with ESRD on hemodialysis is difficult to ascertain. This is because among such patients, hypertension is difficult to diagnose. This uncertainty in making a firm diagnosis of hypertension is discussed later (see Diagnosis). Using 44-hour interdialytic ambulatory BP monitoring among 369 chronic hemodialysis patients, the prevalence, treatment, and control of hypertension has been ascertained.[7] The prevalence of hypertension, defined by either an interdialytic ambulatory BP of 135/85 mm Hg or more or the prescription of any antihypertensive agent, was 86%. Volume excess determined inferior vena cava diameter was an independent determinant of prevalent hypertension. Although hypertension was being treated with antihypertensive drugs in 89% of these patients, it was adequately controlled only in 38%. The independent determinants of poor control were the use of antihypertensive drugs and an expanded extracellular volume state. When antihypertensive medications were withdrawn nearly 80% of the participants became hypertensive. Poor control of hypertension was more likely when patients received multiple antihypertensive drugs. However, if patients had volume excess they were more likely to become hypertensive after withdrawing antihypertensive therapy.

The level of illness (comorbidities) among hemodialysis patients varies widely across the world. For example, the crude 1-year mortality rates show a wide range: 6.6% in Japan, 15.6% in Europe, and 21.7% in the United States.[9]

These differences in mortality are not fully accounted for by adjustment for observed comorbidities. Nonetheless, U.S. patients are the sickest. Similarly, there is substantial variation in the prevalence of hypertension among countries. These differences may be due to patient selection, demographic factors, and country-specific practices. As an example, in Tassin, France, patients are dialyzed using long hours of dialysis and administered a low sodium diet.[10–12] These patients have an astonishingly low prevalence of hypertension with <5% requiring antihypertensive therapy at 6 months after initiation of hemodialysis.[12] In contrast, as noted previously, the majority of patients in the United States require antihypertensive drugs.[1,7]

The epidemiology of hypertension has changed considerably since the introduction of hemodialysis. In the early years of dialysis, low sodium dialysate was prescribed, dietary sodium was restricted, and great attention paid to dry weight.[13] The prevalence of hypertension was then reported to be 10% to 15%.[13] The prevalence estimates of 85% to 90% currently reported may be due to several factors such as increased prevalence of diabetes mellitus but also because of change in dialysis practice over the years. For example, the introduction of higher sodium dialysate and less attention to dietary sodium and dry weight may have contributed to the epidemic of poorly controlled hypertension.

Peritoneal Dialysis

The epidemiology of hypertension in patients on long-term peritoneal dialysis (PD) has been less well studied.

Some studies suggest that hypertension control in patients on PD is superior compared to those on hemodialysis.[14,15] For example, among 1,202 patients participating in the 1995 Peritoneal Dialysis Core Indicators Study, the average blood pressure among peritoneal dialysis patients was 139/80 mm Hg.[16] This is in contrast to the predialysis BP of 152/82 mm Hg among 1,238 participants in the HEMO study.[3] Only 29% of PD patients had systolic blood pressure that exceeded 150 mm Hg and only 18% had a diastolic blood pressure greater than 90 mm Hg.[16] Putatively, these observations are explained by removal of vasopressors and sodium pump inhibitors by PD.[17] Nonetheless, high quality head-to-head studies are sparse and the epidemiology of hypertension may be similar to that seen among hemodialysis patients.[18]

Among 414 Italian PD patients, 24-hour ambulatory BP recordings were obtained.[19] The prevalence of hypertension was 88% based on office BP ≥140/90 mm Hg, and 69% based on BP load >30%. BP load is defined as number of BP recordings above a certain threshold. In another study, comparison of 22 hemodialysis patients with 24 patients on PD with 44-hour ambulatory BP monitoring showed no differences in daytime and nighttime BP.[20]

As seen among hemodialysis patients,[21] ambulatory BP among PD patients was related to left ventricular mass.[22,23] This was not the case for office BP.[22] The arterial distensibility of the common carotid artery was significantly related to systolic BP and concentric left ventricular hypertrophy (LVH).[22] On the other hand, overhydration, as assessed by tracer dilution, was common and was related to diastolic BP elevation and eccentric LVH.[22] Volume overload in PD patients may be affected by the peritoneal transport characteristics.[24] High transporters tend to have a higher BP; ultrafiltration may restore their BP to more normotensive levels.[24] In a small study, patients on continuous cyclic PD were reported to have a greater left ventricular mass compared to those on continuous ambulatory PD.[23] This was thought to be due to greater volume overload.[23]

Dipping Phenomenon in Dialysis

Among dialysis patients the physiologic decline in BP from day to night during sleep, known as nocturnal dipping, is nearly universally blunted.[25–29] This blunted nocturnal dipping, or nondipping, has been associated with left ventricular hypertrophy and mortality in some reports[30–33] but not all.[34,35] Although nondipping is said to be a manifestation of volume excess,[26] improving dry weight in a randomized trial did not restore dipping despite improving interdialytic ambulatory BP.[36] Whether nondipping is causally related to LVH and mortality remains unclear.

PATHOPHYSIOLOGY

Both cardiac output and systemic vascular resistance are directly related to BP. An increase in cardiac output without a concomitant reduction in systemic vascular resistance will therefore elevate BP. Conversely, if systemic vascular resistance is increased without a parallel reduction in cardiac output blood pressure would also increase. The pathophysiology of hypertension among dialysis patients is further analyzed using this hemodynamic construct.[37]

Increased Cardiac Output Due to Increased Sodium Load and Extracellular Fluid Volume Expansion

The kidneys are the primary regulators of sodium balance. In the absence of kidney function, sodium regulation is impaired. Sodium balance then has to be maintained by its removal by dialysis. Whereas it is not difficult to remove the interdialytic weight by ultrafiltration, subtle loss of lean body mass can lead to volume overload that is difficult to recognize. Typical clinical signs such as pedal edema are often not useful in detecting the presence of volume excess.[38] Volume excess evokes increase in cardiac output which over time provokes increase in systemic vascular resistance.[37,39] Increase in systemic vascular resistance manifests clinically as hypertension. The rise in blood pressure provokes natriuresis which normalizes BP. However, hemodialysis patients have markedly impaired ability to excrete sodium and therefore to reduce BP. Unless excess extracellular fluid volume is removed with ultrafiltration, a rise in vascular resistance sustains hypertension in these individuals. Thus, assessment

and treatment of volume excess is an important and modifiable target of therapy in patients with ESRD. Whereas both dialysate and dietary sodium restriction are important for achieving euvolemic state, unless dry weight is achieved, sodium restriction by itself is unlikely to produce euvolemia.[40]

Intercurrent illnesses such as catheter-related bacteremia, pneumonia, and diabetic foot infection may cause declines in BP and result in difficulties with ultrafiltration. If these illnesses are substantially severe and cause loss of lean body mass, then recovery from these inflammatory illnesses may be associated with volume overload if loss of lean body mass is not recognized. Thus, as a practical corollary, dry weight should be reassessed especially after a recent intercurrent illness even when BP may not be elevated.

In more than 90% of patients, mean arterial pressure with ultrafiltration dialysis falls. This decline in BP has been somewhat misleadingly called "volume-dependent hypertension."[41,42] In contrast to the fall in BP within hours, volume-dependent hypertension is characterized by a decline in BP in response to sodium and volume restriction that takes several weeks or months to manifest. For example, in patients with essential hypertension who are prescribed thiazide diuretics, an initial fall in extracellular fluid (ECF) volume is followed by a slower decline is systemic vascular resistance that finally evokes a reduction in BP.[43] Similarly, in patients with stage 3 and 4 chronic kidney disease (CKD) who are prescribed loop diuretics there is an initial fall in ECF volume associated with a rise in plasma renin activity; subsequently reduction in BP is seen.[44] In dialysis patients reduction in body weight with ultrafiltration, long-duration dialysis coupled with dietary sodium restriction leads to improvement in BP over several weeks.[36] In contrast to the intradialytic reduction in BP, it is the long-term changes in BP evoked by a reduction in ECF volume that are examples of volume-dependent hypertension.

Some investigators have described a delayed reduction of BP after dry weight is lowered. This is called the lag phenomenon. This phenomenon was described using observations on predialysis or postdialysis BP who had dry weight lowered when they were new to dialysis (incident patients).[45] The existence of the lag phenomenon in this population has been questioned by the findings of a trial among prevalent hemodialysis patients.[36] In this randomized trial, a prompt improvement in interdialytic ambulatory BP within 4 weeks was noted; no further reduction in BP at 8 weeks was found. Therefore, these findings question the existence of a lag phenomenon. Several other reports when patients are dialyzed more frequently have also found prompt improvements in BP.[46,47] In one such report, prompt reduction in BP was seen within 1 month, with no reduction in BP over 1 year.[47] It is also important to recognize fluid weight loss may need to reach a certain threshold before BP improves among hemodialysis patients. In other words, BP may not decline until a threshold of euvolemia is achieved. Once achieved, BP decline may be rapid and precipitous. Accordingly, among incident patients where dry weight is challenged gradually a lag phenomenon may appear to exist when in fact this may be simply a threshold effect of volume on BP.

Patients with ESRD may have salt craving and may therefore consume excess salt. Compared to 11 healthy volunteers, among 29 patients with CKD who underwent a taste test with sodium impregnated test strips dietary sodium intake was proportional to the taste threshold for sodium.[48] The taste threshold for sodium was blunted in patients with CKD; it was particularly blunted in patients on oral diuretics. Furthermore, zinc deficiency was associated with this latent taste dysfunction. These findings suggest that latent gustatory dysfunction and zinc deficiency may underlie excess sodium intake among patients with CKD. Although this study was limited to patients with earlier stages of CKD, similar mechanisms may mediate gustatory dysfunction among those with ESRD.

Emerging data suggest that sodium may have a more complex role in the pathogenesis of hypertension. For example, high-salt diet in rats provokes interstitial hypertonic sodium accumulation in skin—this evokes proliferation of the lymph capillary network. The mechanisms underlying these effects on lymphatics involve activation of tonicity-responsive enhancer binding protein (TonEBP) in macrophages that are present in the interstitial compartment of the skin. Activation of TonEBP causes vascular endothelial growth factor (VEGF)-C secretion by macrophages. This in turn increases the density of the lymph capillary network. Interrupting VEGF-C signaling augments interstitial hypertonic volume retention and elevates BP in response to a high-salt diet.[49] These data provide support to the notion that, besides external sodium balance, the redistribution of sodium between the skin and circulation provides extrarenal regulation of body fluid volume and BP control. The relevance of this finding to sodium balance in humans is not yet clear.

Increased Systemic Vascular Resistance

In has been long recognized that increased systemic vascular resistance may play an important role in maintaining hypertension among patients undergoing nephrectomy and hemodialysis.[50] However, there is no consistent hemodynamic pattern that distinguishes hypertensive from normotensive dialysis patients.[51] Mediators that may influence systemic vascular resistance are discussed in the following sections.

Renin-Angiotensin System

It has also been long recognized that among uremic patients with hypertension, although many patients may have plasma renin activity in the normal range, plasma renin activity may be inappropriately increased in relationship to exchangeable sodium.[52] That the renin-angiotensin system (RAS) is activated even in hemodialysis patients is illustrated by the following: (1) renin increases with ultrafiltration dialysis suggesting that kidneys with nearly no excretory function can still sense volume[53]; (2) blood pressure improves with

an infusion of saralasin, an angiotensin II antagonist[54]; and (3) patients treated with angiotensin-converting enzyme (ACE) inhibitors have a dose-dependent increase in plasma renin activity[55] and an improvement in blood pressure.[55,56]

Sympathetic Nervous System

Besides serving as an excretory organ for salt and toxin removal, the kidneys, even when dysfunctional as in ESRD, somewhat surprisingly, also serve as an afferent sensor for the activation of the sympathetic nervous system (SNS). Strong evidence has emerged that implicates enhanced sympathetic activity as a cause of hypertension in patients with ESRD.[57,58]

Initial studies provided indirect evidence of increased sympathetic nerve activity. For example, investigators reported diminished vascular response to norepinephrine in animals with chronic renal failure.[59] This was explained by a chronic increase in sympathetic nerve activity that downregulated adrenergic receptors. However, later studies provided more direct evidence of elevated sympathetic tone in patients with ESRD.[57] This was made possible by direct measurement of efferent sympathetic nerve activity.[60] That latter technique involves microneurography in which a fine tungsten electrode is placed in the sympathetic nerves that run along the peroneal nerve. Using this technique, sympathetic activity is noted to be markedly increased in those patients on chronic hemodialysis who still have their native kidneys. In contrast, patients with bilateral nephrectomy have reduced sympathetic activity, lower calf vascular resistance, and lower mean arterial pressure.[57] Thus, the kidney, although devoid of excretory function, serves as an afferent organ to signal the midbrain region to increase sympathetic activity. The central mechanisms of increased sympathetic activity may involve endogenous nitric oxide; endogenous nitric oxide may inhibit sympathetic activity in several brain nuclei involved in the neurogenic control of BP.[61] Dopaminergic neurons may be responsible. For example, experiments in hypertensive hemodialysis patients show that administration of the dopamine-releasing drug bromocriptine decreased plasma norepinephrine and other markers of sympathetic outflow, and lowered mean arterial pressure.[62] Baroreceptor desensitization has also long been recognized in hypertensive patients with ESRD and may contribute to elevated BP.[63]

Recent discovery of an enzyme that catabolizes catecholamines may be important in the pathogenesis of hypertension among dialysis patients. This enzyme called renalase is an amine oxidase which is secreted into the blood by the kidney.[64] Renalase is secreted as a proenzyme and degrades circulating catecholamines. This enzyme is activated by an increase in BP or brief surges in plasma catecholamines. Infusion of recombinant renalase lowers BP by reducing peripheral vascular resistance as well as cardiac output. Markedly reduced levels of circulating renalase are found among hemodialysis patients; renalase levels are inversely related with glomerular filtration rate (GFR). Renalase knockout in the mouse is associated with hypertension and these mice are sensitive to cardiac ischemia.

Nitric Oxide and Its Circulating Inhibitors

Endothelial derived nitric oxide plays a critical role in the maintenance and regulation of vascular tone and modulates key processes mediating vascular disease including leukocyte adhesion, platelet aggregation, and vascular smooth muscle proliferation.[65] Endothelial nitric oxide synthase enzymatically produces nitric oxide from the substrate L-arginine. L-arginine supplementation can partially reverse renal failure-associated endothelial dysfunction[66] and improve BP.[67] A circulating inhibitor of nitric oxide synthase, asymmetrical dimethyl arginine (ADMA), competes with L-arginine for nitric oxide synthase. In humans with salt-sensitive hypertension, administration of a high-salt diet increases plasma ADMA and BP.[68] Circulating ADMA is increased in subjects with CKD[69] and ESRD[70] and may contribute to endothelial dysfunction and increased BP. In patients with ESRD, ADMA is correlated with increased left ventricular (LV) thickness and reduced ejection fraction, consistent with its ability to increase systemic vascular resistance.[71] Furthermore, ADMA is highly correlated with norepinephrine in dialysis patients.[70] Both are strongly linked to mortality in cohort studies.[70] As discussed previously, nitric oxide may be important for the control of nuclei that control sympathetic activity.[61] This suggests a strong relationship between impaired NO availability and sympathetic activation in these patients.

In normal healthy subjects, approximately 300 μmol ADMA is generated per day, but only 50 μmol per day is excreted by the kidneys; the remaining is degraded enzymatically by dimethylarginine dimethylaminohydrolase (DDAH).[72] Pharmacologic inhibition of DDAH (with a small molecule, 4124W) causes accumulation of ADMA and generalized vasoconstriction. As may be expected, overexpression of DDAH in genetically engineered mice reduces ADMA, improves NO bioavailability, and reduces systolic BP. Oxidative stress impairs DDAH activity by oxidizing a sulfhydryl moiety critical to enzymatic activity; this leads to accumulation of ADMA and promotes endothelial dysfunction. Inflammation, increased homocysteine levels, reduced antioxidant defenses, and increased free radicals in ESRD may therefore provide an explanation for the relationship between oxidative stress, endothelial dysfunction, and the generation of hypertension. Cohort studies show an association between increased ADMA and cardiovascular events or death in hemodialysis patients.[70] However, lowering homocysteine does not prevent cardiovascular events.

Erythropoietin

Hypertension is a common but frequently overlooked adverse effect of erythropoietin therapy.[73–78] Hypertension can be missed because of variability in BP from predialysis to postdialysis and the lack of home or ambulatory BP measurements.[2] Studies that failed to detect increases in BP with erythropoietin therapy may have managed hypertension more aggressively through the prescription of antihypertensive drugs or closer attention to dry weight.[79,80]

Erythropoietin therapy was an independent predictor of hypertension diagnosed by ambulatory BP monitoring.[7] Some studies show association of erythropoietin use with nondipping.[81] Increase in BP with erythropoietin occurs more commonly in those people with preexisting hypertension[77,82] or those with a family history of hypertension.[82]

Although the exact mechanism by which erythropoietin increases BP is not known, it may be multifactorial such as increased vascular reactivity to norepinephrine,[83] increased generation of endothelin-1,[84–86] and vasoconstrictor prostaglandins.[84] In line with the generation of vasoconstrictor prostaglandins, use of antiplatelet therapy has been postulated to prevent the development of hypertension among patients treated with erythropoietin.[87] The critical importance of nitric oxide in erythropoietin-induced hypertension has been studied in a mouse model.[88] Transgenic mice overexpressing human erythropoietin were generated. Despite hematocrit levels of 80%, adult transgenic mice did not develop hypertension or thromboembolism because of a compensatory increase in endothelial nitric oxide (NO) synthase levels, NO-mediated endothelium-dependent relaxation, and circulating and vascular tissue NO levels. Administration of the NO synthase inhibitor N(G)-nitro-L-arginine methyl ester (L-NAME) led to vasoconstriction, an increase in vascular resistance, hypertension, and death of transgenic mice; the wild-type siblings developed hypertension but did not show increased mortality. L-NAME-treated polyglobulic mice revealed acute left ventricular dilatation and vascular engorgement associated with pulmonary congestion and hemorrhage. Thus, endothelial NO appears to be critical in maintaining normotension, preventing cardiovascular dysfunction, and survival in vivo when erythropoietin is used.

Erythropoietin levels were correlated with systemic vascular resistance and ambulatory BP among untreated patients with essential hypertension.[89] In carefully conducted studies to determine the mechanism of increase in BP with erythropoietin, it was observed that the systemic vascular resistance was uniformly increased with the administration of erythropoietin.[90] Furthermore, a good relationship was seen between exchangeable sodium and increase in BP. Somewhat surprisingly, aldosterone was also increased with this therapy. Accordingly, close attention should be paid to volume status and sodium balance while using this drug.[90] All patients prescribed this therapy should have careful BP monitoring.

Uncertainty exists regarding the determinants of hypertension among patients treated with erythropoietin. For example, some studies show that although increase in hemoglobin is dose-dependent, an increase in BP is not.[73,91] On the other hand, during the first 5 weeks of administration of erythropoietin, the change in hemoglobin concentration was directly related to increase in diastolic BP ($r = 0.42$, $P < .001$).[75] Interestingly, in animal experiments hypertension does not track with increase in hemoglobin.[92] If erythropoietin is administered to anemic animals with chronic renal failure, but hemoglobin is kept stable by feeding an iron deficient diet, hypertension still occurs. In blood vessels harvested from these animals treated with erythropoietin, vasodilatory responses to NO donors were impaired, but response to several vasoconstrictors was normal. Among patients on long-term hemodialysis, treatment with iron to increase hemoglobin was not associated with parallel increases in BP.[93]

Others

A variety of other substances have been described which can have vasoconstrictive properties. These are discussed in detail elsewhere in the book, but for the sake of completeness, they are summarized briefly here. For example, compounds that block the sodium pump, such as digoxin-like immunoreactive substance and ouabain-like compound, can lead to an increase in intracellular calcium that may elicit vascular small muscle contraction.[17] Plasma endothelin-1 levels are noted to be increased among hypertensive dialysis patients compared to normotensive dialysis controls.[94]

Parathyroid hormone (PTH) can increase intracellular calcium and aggravate hypertension[95] and parathyroidectomy may improve BP.[96] Not all investigations support this notion. For example, elevated PTH levels can reduce the pressor response to norepinephrine in animals with chronic renal failure[97] and parathyroidectomy may not correct hypertension.[98]

Loss of medullary prostaglandins and other renal-derived vasodilators may also be responsible for hypertension in this population. Plasma concentrations of the vasoconstrictive peptide endothelin are elevated in patients on hemodialysis[99,100] and much more so than in those patients requiring no dialysis.[100]

Use of illicit drugs such as cocaine or prescription drugs such as decongestants containing pseudoephedrine may also contribute to increased BP. Nonadherence with dialysis treatments may make hypertension difficult to control.[101] This may be related to both excess accumulation volume and toxins.

Unlike the general population in which obesity is associated with hypertension, absence of obesity is consistently associated with less prevalence of hypertension and better control. The mechanism of this relationship is not clear. It is possible that even subtle volume excess among lean patients leads to hypertension. Those with obesity may be able to buffer the excess volume without manifesting hypertension.[102]

Sleep apnea is very common in dialysis patients and is often associated with volume overload. Hypopneic spells during the night lead to nocturnal hypoxemia and provoke intense sympathetic arousal and an increase in nocturnal BP.[103]

Vascular Changes as a Basis of Systolic Hypertension

Systolic BP increases with age.[104] In contrast, there is an increase in diastolic BP until about age 55 years and then a fall. Accordingly, pulse pressure widens with age. Structural and functional changes in the arterial circulation that occur

with aging are accelerated with hypertension[105] and CKD.[106] Vascular aging is associated with increase in arterial stiffness. Arterial stiffness is strongly and directly related to systolic BP[107] and mortality in ESRD.[107] Arterial stiffness is also related to ventricular stiffness making intradialytic hypotension and interdialytic hypertension two faces of the same disease.[108] Diabetes mellitus, age, and smoking are some of the factors that also accelerate vascular aging. These are common among those with CKD. Factors peculiar to uremia that contribute to accelerated vascular stiffening include hyperparathyroidism, increased calcium × phosphorus product, increased circulating endothelin concentration,[109] sympathetic activation,[57] and vascular inflammation; increases in intravascular volume and inappropriately high angiotensin II further augment vascular stiffness.[110] Accordingly, it is not surprising that systolic hypertension is common in those with ESRD.

DIAGNOSIS

The diagnosis of hypertension among patients on hemodialysis is challenging and misdiagnosis may lead to overtreatment or undertreatment of hypertension.[111–114] Diagnosing hypertension is difficult because of several reasons.[115] BP in these patients is often measured without attention to technique.[116] BP declines during hemodialysis with ultrafiltration. This decline in BP can be variable and in part is related to the magnitude and intensity of ultrafiltration.[117] For example, those patients who have a large volume removed over a short period of time may have a large decline in BP. These patients may also gain the removed volume back over the interdialytic interval and have a large increase in BP.[118] Predialysis BP may therefore be hypertensive and postdialysis BP hypotensive. It therefore becomes unclear which BP to use to diagnose hypertension[119] and substantial errors can occur both in the detection of hypertension and assessing its severity.[120,121] Both predialysis and postdialysis BP measurements are highly variable from one visit to the next. The variability within patients (between visits) is so much that it approaches the variability in BP between patients.[122] Additionally, hemodialysis patients have significant seasonal variability in BP; BP is highest during winters and lowest during summers.[123] This may be related to temperature-induced vasodilatation. Although significant relationships exist between both predialysis and postdialysis BP and interdialytic ambulatory BP,[124] a meta-analysis has shown that predialysis and postdialysis BP measurements agree poorly with interdialytic ambulatory BP.[125] Accordingly, among hemodialysis patients, large errors are possible when using predialysis or postdialysis BP to judge the magnitude of elevation in interdialytic ambulatory BP.

The current National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines recommend that prehemodialysis and posthemodialysis BP should be <140/90 and <130/80 mm Hg, respectively.[126] Use of predialysis or postdialysis BP measurements to make management decisions in the interdialytic period can be problematic. For example, in a survey in the United Kingdom, centers that achieved better postdialysis BP targets had more intradialytic hypotension.[127] What is clear is that interdialytic weight gain increases predialysis BP[3,128–131] and provokes the use of antihypertensive therapy.[128,129] However, interdialytic weight gain does not correlate with interdialytic ambulatory BP.[132,133] Therefore, whether achieving these pre- or postdialysis BP targets would cause clinical harm (or benefit) remains unknown.

Using all BP measured during a midweek dialysis treatment may serve as a more useful tool to estimate interdialytic ambulatory BP.[134] Although the mean intradialytic BP serves as a useful tool to assess hypertension, the calculation of median intradialytic BP is computationally less intense. It may therefore be used as a bedside tool to predict interdialytic ambulatory BP. Midweek median intradialytic BP of 140/90 mm Hg or more has sensitivity and specificity that exceeds predialysis or postdialysis measurements and can serve as a rapid and convenient tool to assess hypertension in long-term hemodialysis patients.[134] However, this is the method of last resort because better methods are available to evaluate hypertension in hemodialysis patients. Why these distinctions are important is discussed later.

Home BP monitoring is a practical way to diagnose and manage hypertension in all patients with kidney disease.[135,136] Home BP monitoring is recommended by both the American Heart Association and the European Society of Hypertension for diagnosing and managing hypertension.[137,138] Home BP monitoring is especially valuable in diagnosing and managing hypertension for those on hemodialysis for the following reasons.[139] Home BP correlates more closely with ambulatory BP compared to predialysis or postdialysis BP recordings.[140] Home BP can track changes in BP evoked by reduction in dry weight.[141] Home BP, compared to predialysis or postdialysis BP recordings, is much more reproducible from one week to the next.[141] Home BP is superior to measurements made in the dialysis unit, even when the dialysis unit measurements are made using recommended techniques, in predicting the presence of target organ damage (echocardiographic LVH)[21,142] or long-term outcomes such as cardiovascular events [143] or mortality.[143–146] The association of BP and outcomes is discussed further in the section on Prognosis. A recent trial randomized stable hemodialysis patients to home BP-guided therapy or predialysis BP-guided therapy.[147] The primary endpoint was to assess change in interdialytic ambulatory BP at 6 months and change in echocardiographic LVH. There was no change in ambulatory BP at 6 months in the predialysis BP-guided therapy group. A significant fall was noted at 6 months in ambulatory BP. Between group differences were significant. Given the small number of patients and variability in timing of echocardiographic left ventricular mass measurements, no between groups differences in the latter measurement were seen. Another trial randomized 17 hemodialysis patients to usual care and 17 to home BP monitoring. Significant

improvement in average weekly systolic BP was seen in the home BP group only.[148] These data support the use of home BP measurement to manage patients on hemodialysis.

Among hemodialysis patients, the timing and frequency of home BP monitoring is of particular importance. Home BP increases on average at a rate of 4 mm Hg every 10 hours elapsed after dialysis.[149] Therefore, measurement soon after dialysis or just before dialysis will underestimate or overestimate the burden of hypertension. Therefore it is important to measure BP at various intervals following dialysis. Simply obtaining BP 20 minutes postdialysis may not yield the most representative interdialytic BP.[150] We recommend that measurements be made twice daily (on waking up in the morning and just before going to sleep) following a midweek dialysis for 4 days.[151] These measurements allow an adequate number for diagnosing and managing hypertension. For the long-term follow-up, monthly measurement should suffice in most patients. More frequent measurements may be needed in those who are clinically unstable.

Ambulatory BP monitoring, among hemodialysis patients, is held to be the gold standard for diagnosing hypertension.[119,152–154] Compared to peridialytic BP recordings, it correlates better with LVH,[21] and all-cause mortality.[155] Using a validated monitor,[156] we recommend measuring BP over the entire interdialytic interval (44 hours). We recommend recording BP every 20 minutes from 6 AM to 10 PM and every 30 minutes from 10 PM to 6 AM.[157] As in the case of home BP, interdialytic systolic BP increases but at a lower rate of 2.5 mm Hg every 10 hours.[158,159] Because, compared to home BP, typically a much greater number of measurements during the interdialytic interval are available, patterns of BP can be evaluated. Figure 41.1 illustrates the pattern of BP and heart rate over an interdialytic interval.

Evaluating the pattern of ambulatory BP offers insights into the volume state and arterial stiffness. A cohort of long-term hemodialysis patients underwent evaluation for arterial stiffness by aortic pulse wave velocity and interdialytic ambulatory BP monitoring.[159] In a cross-sectional analysis from 11,833 blood pressure measurements from 125 long-term hemodialysis patients, it was found that aortic pulse wave velocity and interdialytic weight gain had a substantial impact on interdialytic ambulatory BP level, trends, and rhythms (Fig. 41.2). Arterial stiffness was associated with an overall increase in the level (intercept) of systolic, diastolic, and pulse pressure. Interdialytic weight gain, on the other hand, was associated with interdialytic increase (linear trend) in BP. The circadian amplitude was blunted by increments in either arterial stiffness or interdialytic weight gain. These results suggest that arterial BP patterns may be of prognostic importance.

If there was a causal relationship between dry weight and patterns of BP it would follow that challenging dry weight will alter the pattern of BP. If dietary patterns were not clamped, but dry weight is challenged it is expected that

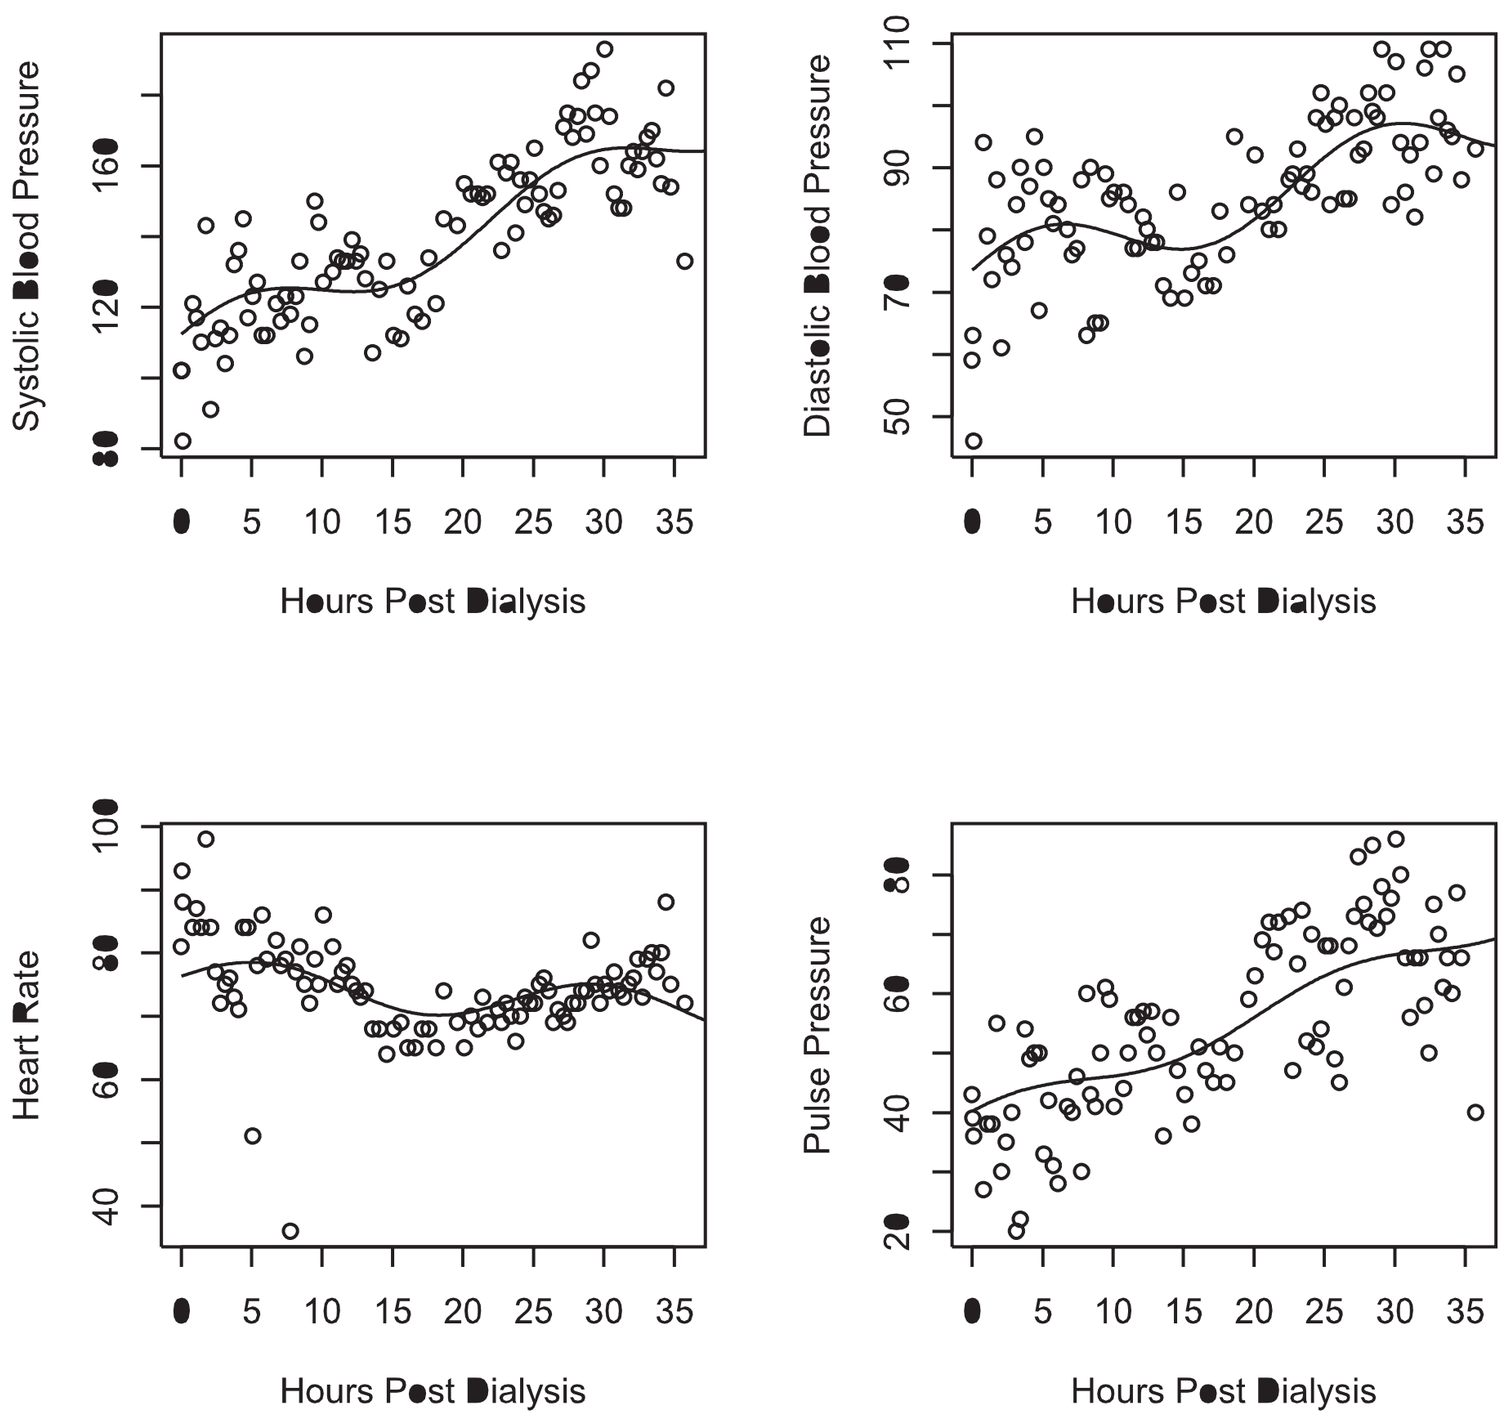

FIGURE 41.1 Modeled trended cosinor blood pressure and pulse rate in a hemodialysis patient. Notice the linear trend in systolic, diastolic, and pulse pressure but lack thereof in heart rate. (Reprinted from Kelley K, Light RP, Agarwal R. Trended cosinor change model for analyzing hemodynamic rhythm patterns in hemodialysis patients. *Hypertension*. 2007;50:143.)

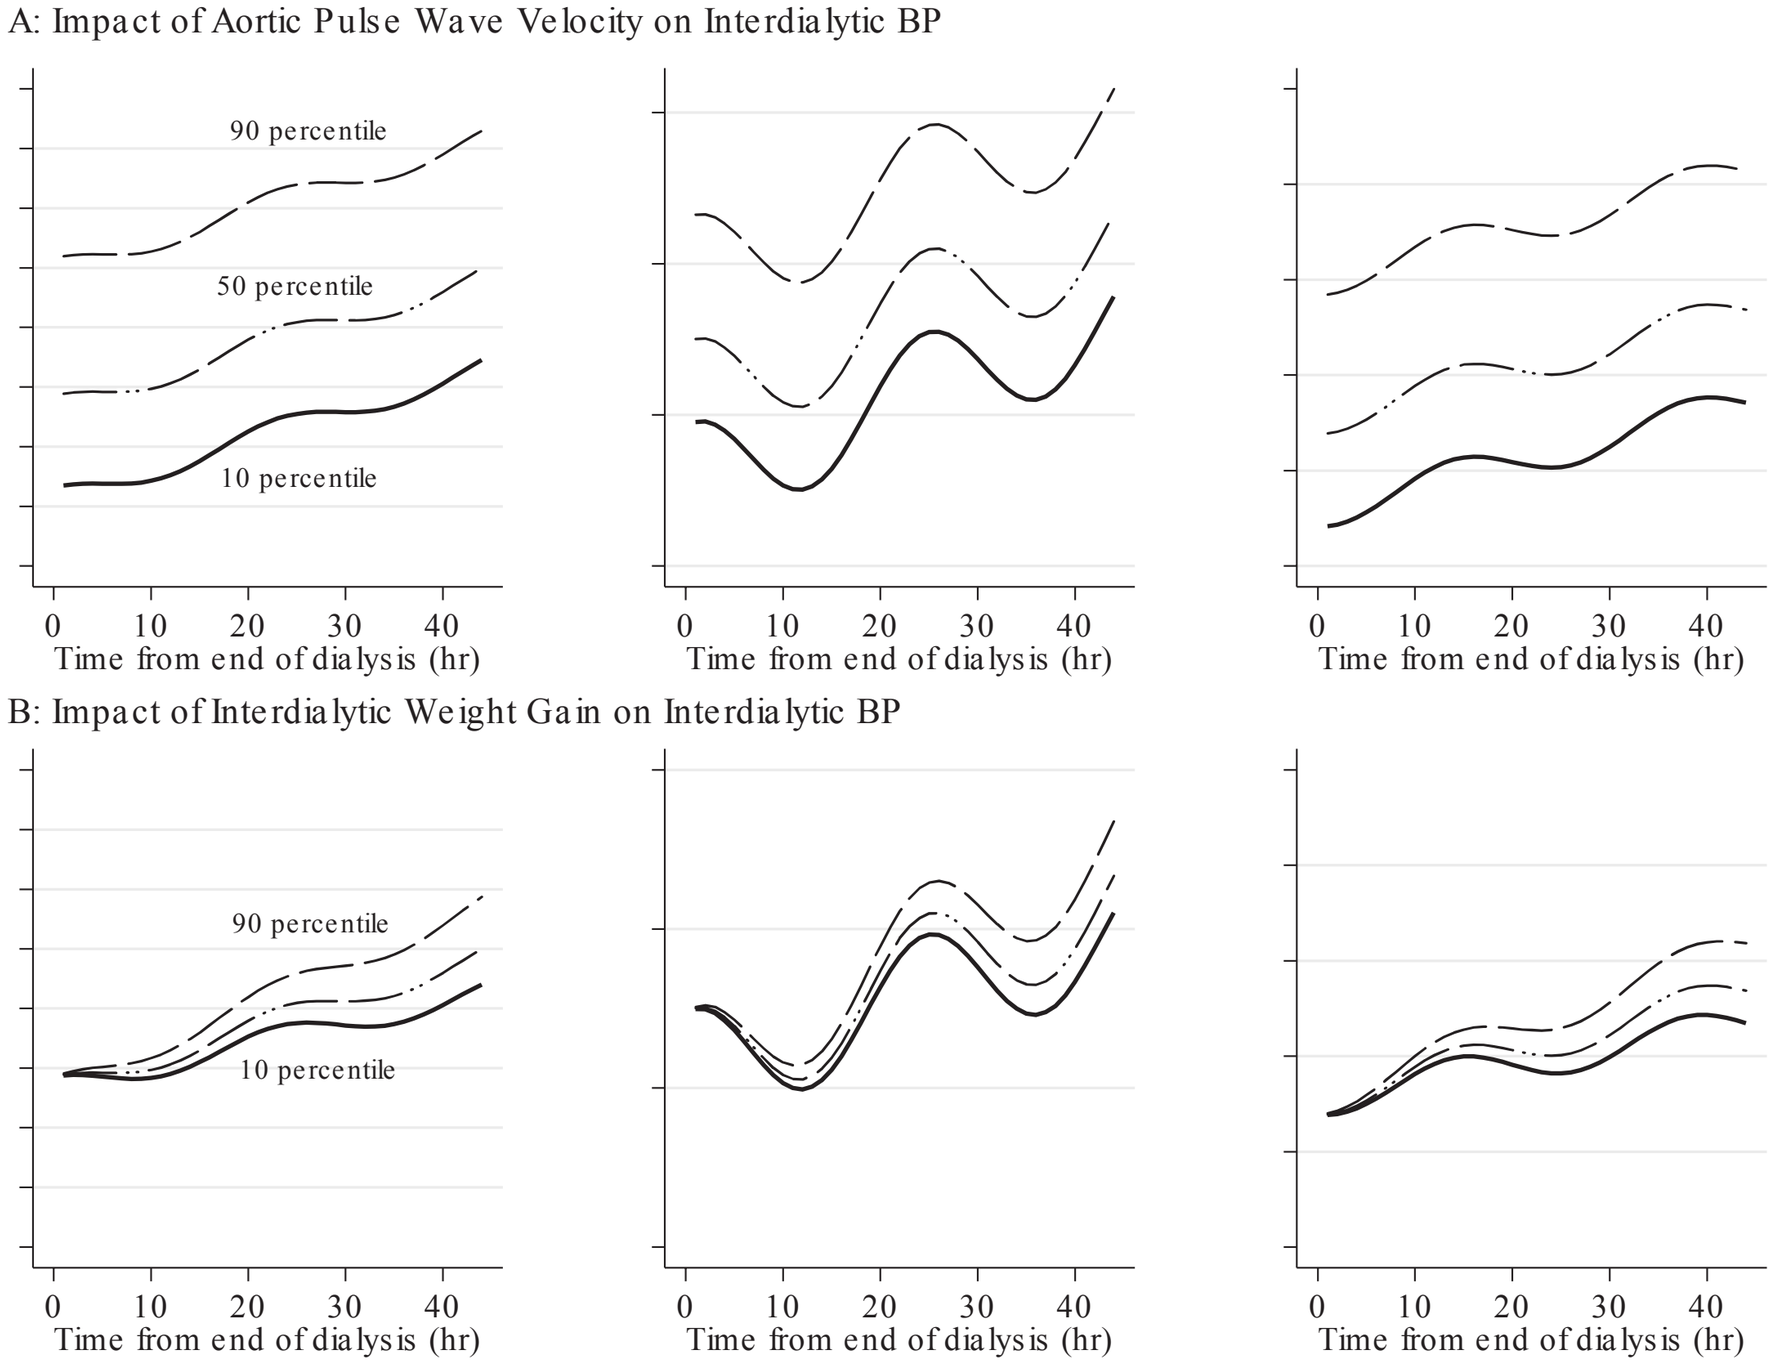

FIGURE 41.2 Impact of aortic pulse wave velocity and interdialytic weight gain on ambulatory blood pressure between two consecutive dialysis treatments. The top three graphs show the impact of increasing pulse wave velocity at 10th percentile (4.1 m/s, *solid line*, bottom), 50th percentile (6.00 m/s, *dashed and dotted line*, middle), and 90th percentile (10.6 m/s, *dashed line*, top) on blood pressures with interdialytic weight gain plotted at the median (2.4 kg). Only the intercept blood pressure changes. The bottom three graphs show the impact of increasing interdialytic weight gain at 10th percentile (0.9 kg, *solid line*, bottom), 50th percentile (2.4 kg, *dashed and dotted line*, middle), and 90th percentile (4.6 kg, *dashed line,* top) on blood pressures with aortic pulse wave velocity plotted at the mean (6.0 m/s). The slope of the line is influenced by interdialytic increase in blood pressure. (Reprinted from Agarwal R, Light RP. Arterial stiffness and interdialytic weight gain influence ambulatory blood pressure patterns in hemodialysis patients. *Am J Physiol Renal Physiol.* 2007;294:F303–F308.)

interdialytic ambulatory systolic BP will be lowered but interdialytic weight gain will increase. Compared to a control group, patients who had dry weight challenged experienced steepening of the interdialytic systolic BP slopes and lowering of intercept systolic BP (Fig. 41.3). Thus flat interdialytic BP slopes and high overall systolic BP may reflect volume overload.[118]

In approximately 10% to 15% of the patients, instead of decreasing, BP paradoxically increases during dialysis.[160] These patients have intradialytic hypertension. Intradialytic hypertension is defined in different ways. These definitions include the following: (1) a discrete change in BP from pre- to postdialysis in a certain proportion (typically >50%) of dialysis sessions; (2) regression of all intradialytic BP with slope >0; and (3) change from pre- to postdialysis of >0 mm Hg. Intradialytic hypertension is associated with greater short-term (6 month) mortality in hemodialysis patients.[161] In another cohort, increasing systolic BP by more than 10 mm Hg during hemodialysis occurred in about 10% of incident patients, and although increasing systolic BP during hemodialysis was associated with decreased 2-year survival, these findings were limited to patients with predialysis systolic BP less than 120 mm Hg.[162] Although the exact mechanism of this relationship is unclear,[163,164] a study shows that intradialytic hypertension in hemodialysis patients using definition 2 is associated with both volume excess and interdialytic hypertension.[165] Another study, using definition 1, confirmed the association between intradialytic hypertension and interdialytic hypertension.[166]

At least two studies suggest that lowering dry weight may improve interdialytic hypertension. Cirit et al. studied seven hypertensive patients on hemodialysis with marked cardiac dilatation who experienced paradoxical hypertension during dialysis.[167] After probing dry weight, both BP and postdialysis weight was reduced; BP reduction was 46/22 mm Hg and postdialysis weight was reduced by 6.7 kg. They concluded that BP may paradoxically rise with ultrafiltration when patients are volume overloaded. In

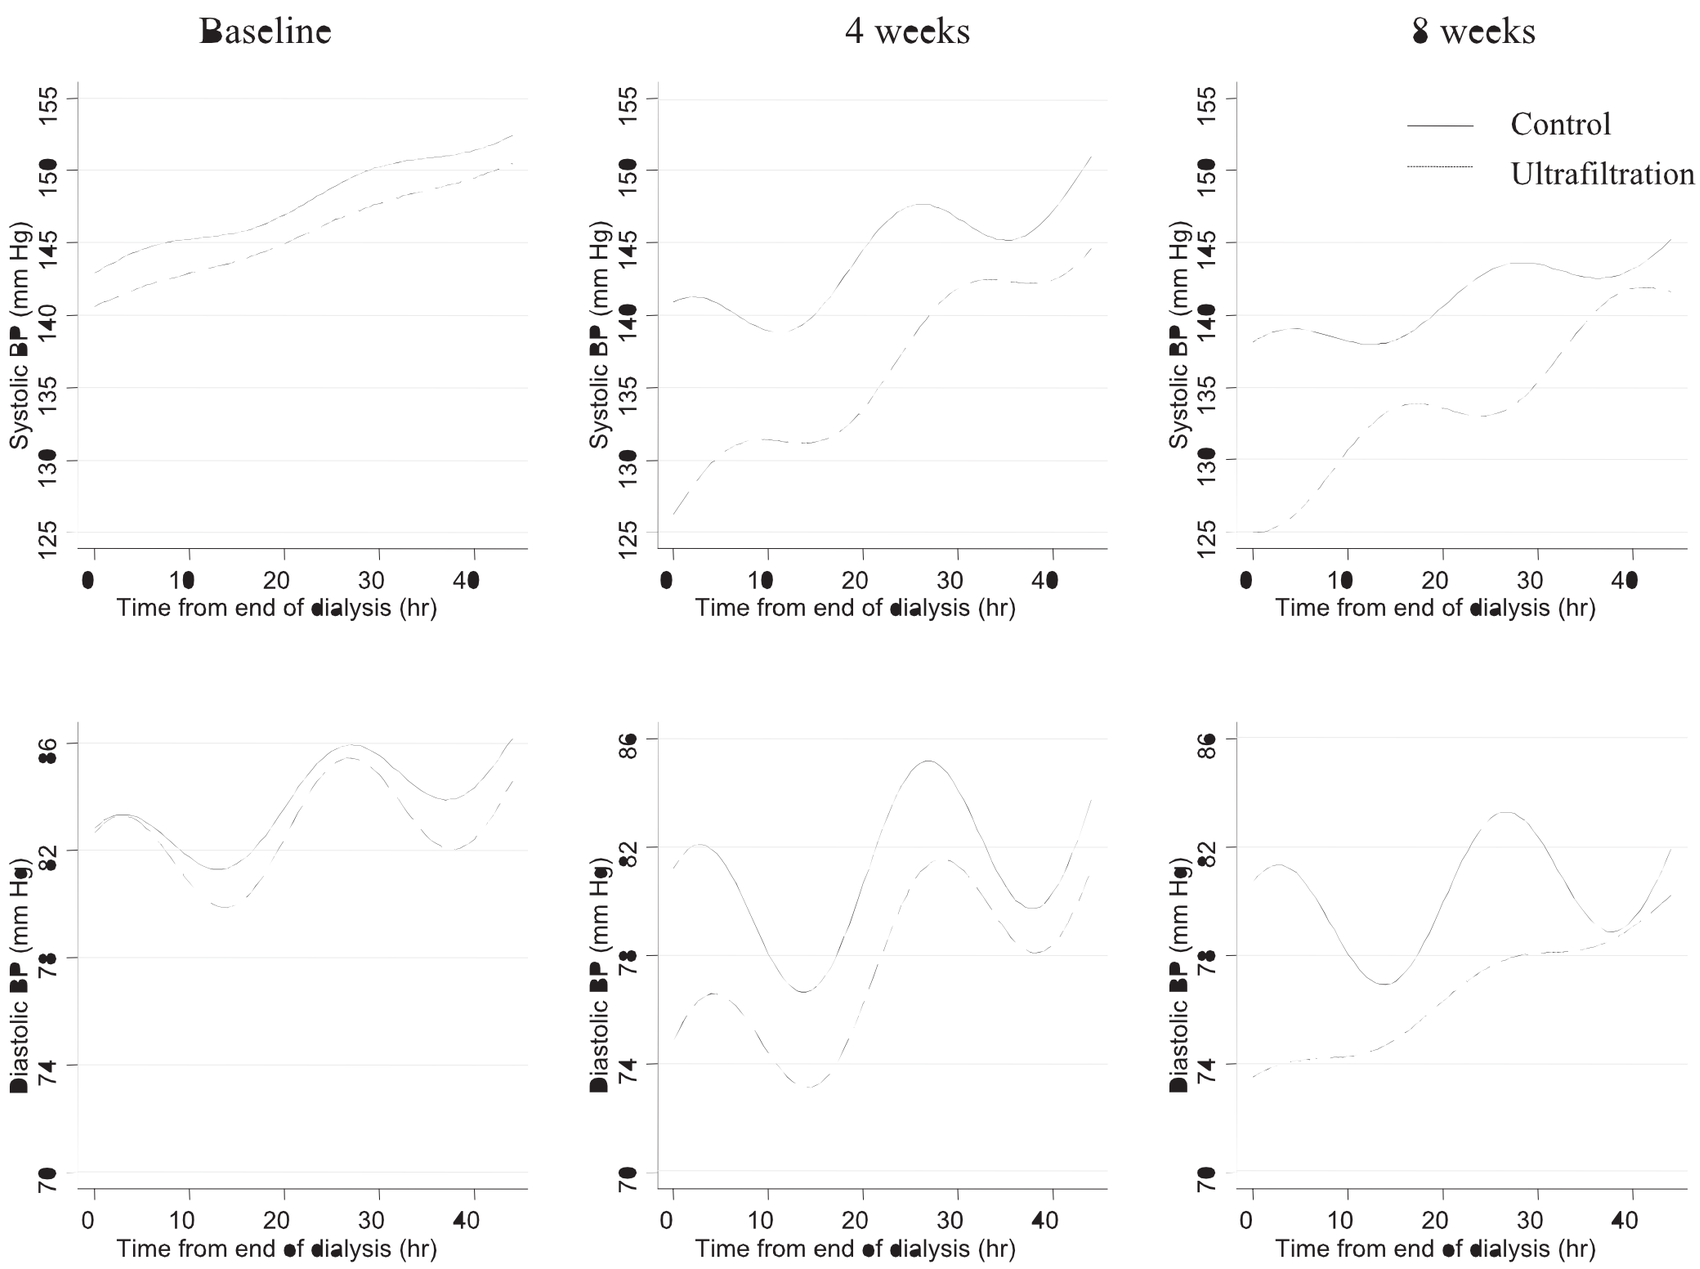

FIGURE 41.3 Patterns of systolic and diastolic blood pressure obtained using ambulatory blood pressure monitoring over 44 hours during an interdialytic period and analyzed using the trended cosinor change model. The *solid line* is the control group and *dotted line* the ultrafiltration (UF) group. The left panel represents recordings at baseline, the center panel measurements at 4 weeks, and the right panel 8 weeks following randomization. UF caused a reduction in intercept systolic and diastolic blood pressure but steepened the slope of change over time at 4 weeks and 8 weeks. The amplitude of variation increased in the control group compared to UF group at 4 weeks and 8 weeks in the case of diastolic but not systolic blood pressure. (Reprinted from Agarwal R. Volume-associated ambulatory blood pressure patterns in hemodialysis patients. *Hypertension*. 2009;54:241.)

another randomized trial (DRIP trial, discussed later), dry weight was reduced progressively.[36] Those patients who had intradialytic hypertension who had additional ultrafiltration and therefore reduction in dry weight had improvement in both intradialytic and interdialytic hypertension.[165] This suggests that an appropriate therapy for intradialytic hypertension would be to further lower dry weight.

A meeting report of the Kidney Disease Improving Global Outcomes (KDIGO) controversy conference concluded the following: "Although a worthy goal, neither measurement of ambulatory blood pressure monitoring nor self-measured home BP may be feasible for most patients throughout the world, leaving pre-hemodialysis and post-hemodialysis BP measurements to be used, but with caution and with the knowledge that these are inferior."[168] This discussion makes it clear that the opinions of the author differ from that of the work group. Home BP measurement is a practical way to measure and manage hypertension among hemodialysis patients. The targets of therapy using home BP monitoring will need to be defined in future trials. Guidelines of the American Heart Association define hypertension in the general population as home BP of at least 135/85 mm Hg; lowering BP in the interdialytic period to at least 140/90 mm Hg appears to be a reasonable goal.

NONPHARMACOLOGIC TREATMENT

Once an accurate diagnosis is made (see section on how to make an accurate diagnosis), the therapy of hypertension among hemodialysis patient rests on nonpharmacologic management. Although scarcely studied, one small study lasting 6 months showed a beneficial effect of exercise on BP and medication requirements.[169] Exercise consisted of using a stationary bicycle during dialysis.[169] Besides this promising strategy, the nonpharmacologic management of hypertension is based on four principles: dietary sodium restriction, individualizing dialysate sodium, the management of dry weight, and providing an adequate dialysis. These principles are discussed in the following sections.

Dietary Sodium Restriction

Dietary sodium restriction limits interdialytic weight gain and improves the feasibility of achieving dry weight.[170,171] Instead of restricting dietary sodium, patients on hemodialysis

are sometimes prescribed fluid-restricted diets. With the exception of treating hyponatremia, there is no scientific basis for prescribing a fluid-restricted diet in these patients.[172]

Recent guidelines suggest that the elderly and those with CKD are most likely to derive the greatest benefits of dietary sodium restriction.[173] These guidelines recommend restricting sodium intake even more than those advocated earlier (2 g per day). Dietary sodium restriction to no more than 1.5 g sodium (or about 65 mmol) per day is now recommended.

Although no randomized trials have been performed among patients with ESRD, observational studies among long-term hemodialysis patients suggest that restricting dietary sodium and achieving dry weight can improve LVH.[174]

Although dietary sodium intake remains a common cause of excess volume accumulation, an often overlooked source of sodium loading among hemodialysis patients is through the prescription of dialysate sodium.

Individualizing Dialysate Sodium

Short dialysis treatment sessions provokes hemodynamic instability; hypertonic dialysate was introduced into practice to provide better hemodynamic stability. However, this practice came at a cost. It has been recognized for a long time now that substantial increments in interdialytic weight gain and thirst can be provoked with the prescription of hypertonic dialysate.[175] Reducing interdialytic weight gain and thirst are now being recognized as important treatment targets.[176] The prescription of high Na dialysate triggers increased fluid volume removal, hemodynamic instability, and prescription of even a higher dialysate sodium.[177] In some patients, worsening of BP control may ensue.[178] The vicious cycle can be interrupted by individualizing dialysate sodium concentration[179] which may improve BP control.[180] In a pilot study of 16 patients, dialysate sodium at end dialysis was decreased in four phases from 137.8 mmol to 135.6 mmol.[181] As a result of this maneuver, the net sodium loss increased nearly 100 mmol from 383 to 480 mmol; this also reduced interdialytic weight gain and BP.[181] Thus, facilitating diffusive sodium losses in addition to convective loss can increase net sodium removal and therefore BP. Sodium ramping which is prescribed to offer intradialytic hemodynamic stability is associated with fewer hypotensive episodes on dialysis but greater interdialytic fatigue and thirst, greater interdialytic weight gain, and hypertension.[182] Interdialytic 24-hour ambulatory BP increased when time-averaged concentration of Na was extremely elevated at 147 mEq/dL.[183] Therefore, one sodium prescription may not fit all patients.

In a nonrandomized trial improvement in nocturnal mean arterial pressure was found among patients who were prescribed a low dialysate sodium.[40] However, if the low dialysate sodium was not accompanied by reduction in dry weight, BP did not change. Simply prescribing low dialysate sodium without altering dry weight may not improve BP control. On the other hand, BP increments provoked by higher sodium dialysate can be adequately controlled by adjustment of dry weight.[184]

Management of Dry Weight

The management of dry weight poses several challenges. First and foremost, there is not even a universally agreed upon definition of dry weight.

The concept of dry weight was proposed in the early years of dialysis.[185] In 1967, Thomson and colleagues defined dry weight as reduction of BP to hypotensive levels during ultrafiltration and unassociated with other obvious causes.[185] Then, in 1980, dry weight was defined by Henderson as the weight obtained at the conclusion of a regular dialysis treatment below which the patient more often than not will become symptomatic and go into shock. In 1996, dry weight was defined by Charra and colleagues as the body weight at the end of dialysis at which the patient can remain normotensive until the next dialysis despite the retention of saline and ideally without the use of antihypertensive medications.[186] In 2008, Raimann et al. proposed a definition of dry weight defined by continuous calf bioimpedance analysis during dialysis. They defined dry weight as a flattening of the baseline/instantaneous impedance ratio curve for at least 20 minutes in the presence of ongoing ultrafiltration. Finally in 2009, Sinha and Agarwal proposed a definition that combined subjective and objective measurements.[187] According to this definition, dry weight is defined as the lowest tolerated postdialysis weight achieved via gradual change in postdialysis weight at which there are minimal signs or symptoms of either hypovolemia or hypervolemia.

Assessment of Dry Weight

The physical examination is notoriously unreliable in excluding volume overload. For example, pedal edema does not correlate with dry weight very well. In a case control study, Agarwal et al. found that inferior vena cava diameter, blood volume monitoring, plasma volume markers, and inflammation markers were not determinants of edema.[38] In hemodialysis patients, pedal edema correlated with cardiovascular risk factors such as age, obesity, and left ventricular mass but not volume markers. For the most part, the assessment and achievement of dry weight is an iterative process that often provokes uncomfortable intradialytic symptoms such as hypotension, dizziness, cramps, nausea, and vomiting. These symptoms often lead to interventions such as cessation of ultrafiltration, administration of saline, the premature cessation of dialysis, or placing the patient in the head-down (Trendelenburg) position. Interestingly, placing the patient in the head-down position does little to protect the BP[188]; whereas raising the leg passively without lowering the head can be effective in raising ventricular filling pressure.[189] Often physicians will respond to these distressing symptoms by raising dry weight, which may result in the necessity of adding more antihypertensive medication. Paradoxically, this may make

subsequent achievement of dry weight even more difficult. However, there are strategies to gently reduce target weight by setting the ultrafiltration goal slightly above the interdialytic weight gain (by ~0.2 to 0.3 kg in an adult) optimally by prolonging the dialysis time to allow for slower ultrafiltration. Then dry weight can often be successfully achieved without troublesome symptoms (as discussed further later in this chapter).

Technologies to Assess Dry Weight

Although several technologies claim to assess dry weight none can be regarded as a reference standard. Some of these technologies are discussed further.

Relative plasma volume (RPV) monitoring utilizes photooptical technology to noninvasively measure absolute hematocrit through a transparent chamber affixed to the arterial end of the dialyzer. The assumption underlying this technology is that in the absence of blood loss and uniform mixing of blood, the rise in hematocrit is proportional to the amount of fluid withdrawn during the dialysis procedure. Accordingly, percent blood volume change during the dialysis procedure can be calculated in real time. RPV slope then is a function of ultrafiltration rate and the plasma refill rate. Patients who are "wet" have large interstitial fluid volumes and therefore a high plasma refill rate—their RPV slope will be flat. Patients with a low plasma refill rate will have steeper slopes and are more likely to be at their "dry weight" (Fig. 41.4). Prospective, randomized trials suggest that relative blood volume-controlled dialysis can improve the predialysis BP, reduce the frequency of intradialytic hypotension, as well as reduce the cardiothoracic ratio.[190]

In the Dry-weight Reduction In Hypertensive Hemodialysis Patients (DRIP) trial (discussed later in the chapter), RPV monitoring was performed in all patients at the beginning and end of the study.[191] RPV slopes were defined as flat when they were less than the median (1.33% per hour) at the baseline visit. The study found that flat RPV slopes may indicate a volume-overloaded state. This is because of the following four reasons: (1) probing dry weight in these patients leads to steeper slopes; (2) those with flatter slopes at baseline have greater weight loss; (3) both baseline RPV slopes and the intensity of weight loss are important for subsequent change in RPV slopes; and, most importantly, (4) RPV slopes predict the subsequent reduction in interdialytic ambulatory systolic BP—those with the flattest slopes have the greatest decline in BP on probing dry weight. Thus, RPV slope monitoring may be useful to assess dry weight among hypertensive hemodialysis patients. RPV monitoring, combined with clinical assessment of intradialytic hypovolemia, and postdialytic fatigue, can help assess patient dry weight and optimize volume status while reducing dialysis-associated morbidity.[192] Several studies in hypertensive pediatric hemodialysis patients have successfully utilized RPV monitoring to improve BP control.[193,194]

Certain echocardiographic parameters have been reported to assess volume among hemodialysis patients. Cheriex et al. in a small study of 18 hemodialysis patients first reported the usefulness of inferior vena cava (IVC)

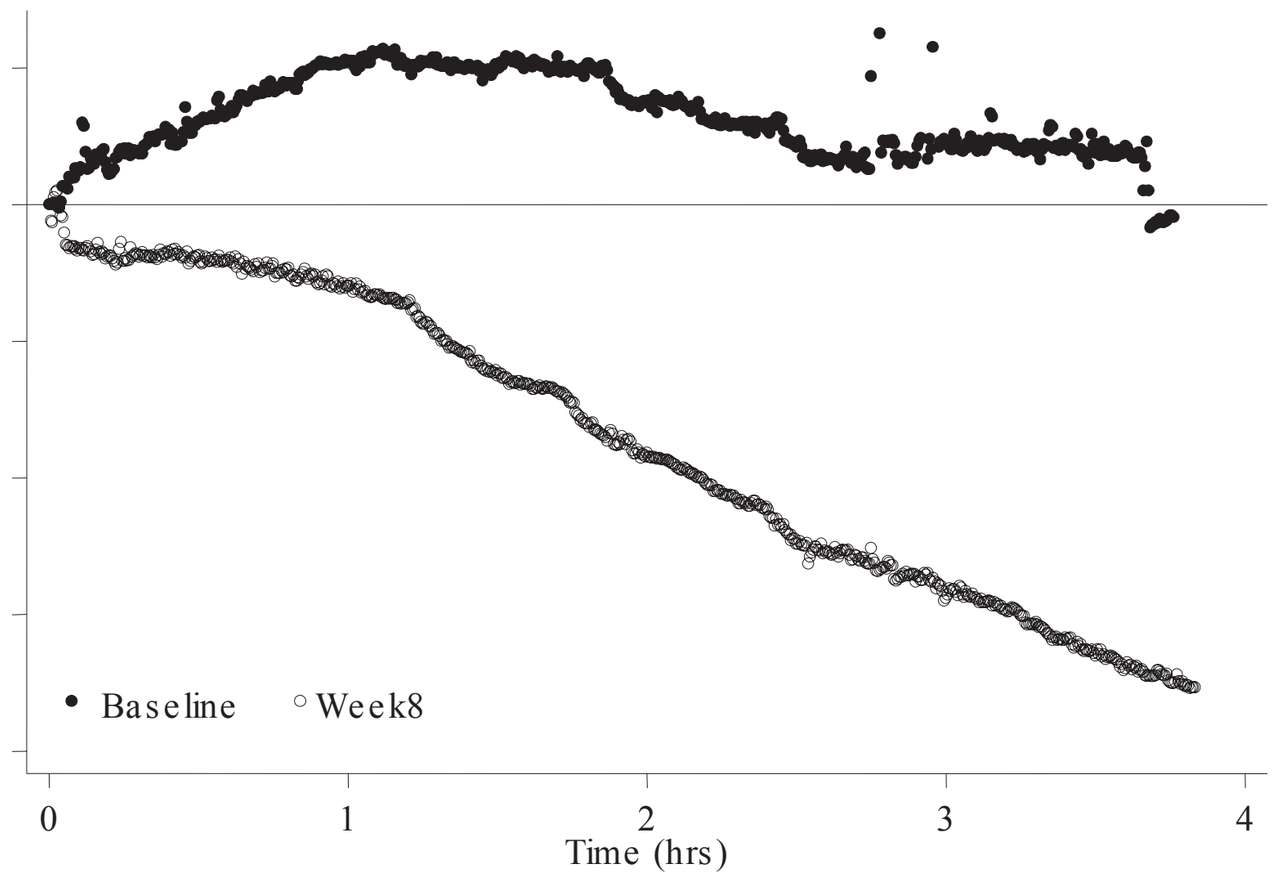

FIGURE 41.4 A 42-year-old black man with end-stage renal disease on chronic hemodialysis for 8 years treated with four antihypertensive medications consented to participate in the DRIP trial after he was noted to be hypertensive. Interdialytic ambulatory blood pressure monitoring revealed blood pressure of 149/89 mm Hg. At baseline, relative plasma volume monitoring demonstrated no change in relative plasma volume. Dry weight was probed in the subsequent 8 weeks. He lost 2.0 kg of postdialysis weight from 62.0 kg to 60.0 kg. At 8 weeks relative plasma volume monitoring revealed 3.15% reduction in relative plasma volume per hour. Interdialytic ambulatory blood pressure improved to 125/77 mm Hg. Relative plasma volume monitoring may be a useful tool to assess dry weight. (Reprinted from Agarwal R, Weir M. Dry-weight: A concept revisited in an effort to avoid medication-directed approaches for blood pressure control in hemodialysis patients. *Clin J Am Soc Neph*. 2010;5:1255.)

diameter and its collapse with inspiration as a marker of volume.[195] A good relationship was found both between IVC diameter and right atrial pressure and between collapse index and right atrial pressure; the right atrial pressure was measured invasively. However, the collapse index was found not to correlate with changes in blood volume. These results were confirmed by Agarwal et al. in the context of a larger randomized trial.[196] The end point was not right atrial pressure but the relationship of reduction in IVC diameter and interdialytic ambulatory BP.

Not all studies have given such encouraging results. For example, Katzarski et al. suggest that IVC diameter measured at the end of dialysis or shortly thereafter gives a misleading indication of volume overload in these patients.[197] Among children on chronic hemodialysis, IVC diameter also did not vary significantly after changing dry weight.[198] Another problem with the use of IVC diameter is that there is no uniform definition of the threshold used to classify patients into hypovolemic, euvolemic, or hypervolemic groups. For example, depending on the criterion used, before dialysis, hypovolemia was found in an astounding 39% to 47% of the patients.[199] An additional 21% to 25% were euvolemic before dialysis despite being above dry weight. Thus, further evaluation is needed before this test can be become mainstream in determining dry weight.

Left atrial diameter is a part of routine echocardiographic evaluation and is volume responsive.[196] Thus, this measurement can be easily used among patients who do not have other reasons to have left atrial enlargement such as mitral regurgitation. Furthermore, left atrial volume has been reported to be a correlate of fatal and nonfatal cardiovascular events among hemodialysis patients.[200] Hepatic vein Doppler evaluation can also assess right atrial pressure but has not been found to be of value to determine dry weight. One reason for this may be the technical difficulty associated with its measurement especially in the postdialysis state where the hepatic veins may be so collapsed that they are hard to visualize.

Another technique to assess dry weight is through body impedance analysis.[201–203] Wabel et al. measured body composition through body impedance analysis and predialysis systolic blood pressure among 500 patients from eight dialysis centers in Europe.[204] The joint consideration of volume state and BP may provide a useful tool to classify patients in terms of volume sensitive and volume resistant hypertension. One third of the patients had normal BP and normal fluid status by the definitions used by the authors. Hypertension and volume expansion was found in 15%, hypertension without volume expansion in 13%, and normotension with volume expansion in 10%. The remaining patients had reasonably controlled BP and volume state. Volume expansion in follow-up of a cohort of 269 patients found expanded extracellular fluid volume to be associated with increased mortality.[205]

Mass spectrometers, through determination of distribution phase of orally administered deuterated water, can provide an accurate estimate of total body water. Absolute measurements of total body water may become more feasible with the use of portable mass spectrometers. Chan et al. reported on the use of a flowing afterglow mass spectrometer following ingestion of heavy water immediately after dialysis among 12 hemodialysis patients.[206] Measurements of total body water immediately after hemodialysis and immediately preceding the following dialysis showed excellent agreement between the two measurements after accounting for insensible losses and urine output. The coefficient of variation in total body water between the two measurements was 2.6%. This proof of principle study demonstrated that absolute total body water can be determined among hemodialysis patients. Further work is required before this study can be used for day-to-day decision making about volume management.

Other strategies to assess dry weight such as through measurement of natriuretic peptides[207] are still being evaluated for the management of hypertension in dialysis patients.

In summary, there is no established gold-standard test or marker of dry weight in dialysis patients. The technologies available can assist the detection of volume excess, but clinical judgment provides the ultimate guidance on what the most appropriate postdialysis weight of a patient should be.

Benefits of Probing Dry Weight

Probing dry weight may be defined as a gradual change in postdialysis weight at which there are minimal signs or symptoms of either hypovolemia or hypervolemia. Probing is the current gold standard by which dry weight is defined. Briefly, dry weight is the lowest tolerated postdialysis weight achieved via gradual change in postdialysis weight at which there are minimal signs or symptoms of either hypovolemia or hypervolemia.

To test the hypothesis that hypertension among hemodialysis patients who do not manifest overt signs of volume overload is mediated by excess volume, dry weight was probed without changing the dialysis time in a randomized controlled trial of hypertensive hemodialysis patients.[36] Notably, in this study, patients with obvious volume overload were excluded. Interdialytic ambulatory BP monitoring was performed at baseline, 4 weeks, and 8 weeks in 50 patients randomized to a control group and 100 patients randomized to the ultrafiltration group. In the intervention group, ambulatory BP was reduced within 4 weeks by 11/6 mm Hg.[36] This level of BP reduction was achieved despite stable concurrent use of 2.7 antihypertensive drugs. The magnitude of reduction in BP is therefore much larger than what would be expected by adding an additional antihypertensive agent. Because the control group had a placebo effect, a correction for this effect is needed. Even after the correction for the placebo effect, ambulatory BP reduction was significant at 7/3 mm Hg. This antihypertensive effect was sustained for 8 weeks of observation. Despite provoking occasional uncomfortable intradialytic symptoms, the quality of life was not impaired. Even in this randomized trial, the presence or absence of edema, which is often taken to be a reliable sign of volume overload, had no predictive value in separating

the responders from nonresponders. Furthermore, 10% of the patients in the control group developed accelerated hypertension defined as BP ≥175/105 mm Hg by interdialytic ambulatory monitoring. This study provides strong support to the hypothesis that among hemodialysis patients, probing dry weight is an effective strategy for reducing BP.

Observational studies also support the practice of probing dry weight. In 1969, Vertes et al. reported that 35 of 40 patients became normotensive by achieving dry weight.[13] In a report from Turkey, Kayikcioglu et al. compared the benefit of nonpharmacologic to pharmacologic therapy for control of left ventricular mass among hemodialysis patients.[208] In a case-control study patients who had been treated at one center with salt restriction and dry weight reduction were compared to patients at another center where antihypertensive-based therapy was the primary method for management of hypertension. The center using dry weight and salt restriction as a primary strategy had the following benefits: lower antihypertensive drug use (7% vs. 42%); lower interdialytic weight gain; lower left ventricular mass; better diastolic and systolic left ventricular function; and fewer episodes of intradialytic hypotension. These observations are important and of clinical relevance; they suggest that probing for dry weight as opposed to adding more antihypertensive drugs perhaps diminishes the risk for cardiac remodeling and mitigates LVH and preserves systolic and diastolic left ventricular function. Although a case-control study cannot assert causation, the results of this study support the use of nonpharmacologic therapies in the management of patients with ESRD.

Dry Weight and Outcomes

Studies among hemodialysis patients in both adults and children suggest that managing intradialytic RPV may reduce the number of hospital admissions due to fluid overload,[192,209] improve BP control, and decrease hypotension-associated dialysis symptoms.[210] It is possible that the latter benefit is, in part, related to diminished use of antihypertensive medication. Accordingly, monthly monitoring of RPV and home BP may offer an attractive way to assess the adequacy of volume control among hemodialysis patients.

To study the effect of volume status on mortality, Wizeman et al. followed 269 prevalent hemodialysis patients for several years.[211] They measured hydration state using a body composition analyzer. If there was greater than 15% excess of extracellular water (2.5 L volume excess), they classified such patients as volume overloaded; 25% of the patients had excess extracellular fluid (ECF) volume. In a multivariate adjusted analysis, they found that excess volume was associated with high mortality. Compared to those without excess ECF volume, the hazard ratio of mortality with excess fluid volume was 2.1 (P = .003). Although the study did not examine reduction in ECF volume on subsequent outcomes, such studies need to be performed in the future.

Inrig et al. compared the change in pulse pressure during dialysis as a risk factor for hospitalization and mortality among prevalent hemodialysis patients participating in a randomized controlled trial.[212] They found that patients who had the least change in pulse pressure from before to after dialysis had clinical characteristics indicating volume overload. Among these patients, lowering of the pulse pressure from before to after dialysis was associated with lower hospitalization and mortality outcomes. Because pulse pressure is largely driven by systolic BP, it is likely that lowering of pulse pressure with dialysis reflects more volume loss, a lower ECF volume state, and may provide better cardiovascular outcomes, perhaps through less pressure/volume stress on the heart. Further research is needed to establish a cause and effect relationship.

Potential Hazards of Probing Dry Weight

There are potential hazards related to probing dry weight, none of which have been adequately examined. These include the following: (1) increased risk of clotted angioaccess; (2) increased rate of attrition in residual renal function; and (3) complications related to interdialytic hypotension. Intradialytic hypotension, besides requiring more nursing interventions, can be complicated by cerebral hypoperfusion, seizures, myocardial dysfunction, and mesenteric ischemia. Furthermore, it has been associated with mortality.[213] The relative risks and benefits of probing dry weight need to be examined in long-term randomized trials.

Providing Adequate Dialysis

The European Best Practice Guidelines recommend that dialysis should be delivered at least three times a week and the total duration should be at least 12 hours per week, unless substantial residual renal function is present.[214] An increase in treatment time and or frequency should be considered in patients who experience hemodynamic instability or remain hypertensive despite maximal possible fluid removal.

In the United States, a recent study reported that the average duration of dialysis among 32,065 participants in the ESRD Clinical Performance Measures Project was 217 minutes.[215] The interquartile range was 195 to 240 minutes. This means that one fourth of the patients were receiving <3 hours and 15 minutes of dialysis and only one fourth of the patients were receiving >4 hours of dialysis.

Although the adequacy of dialysis is still debated, it is clear that patients who shorten treatment have hypertension that is more difficult to control.[101] Patients that are dialyzed 8 hours three times a week have excellent BP control, minimal requirement for antihypertensive drugs, and excellent long-term survival.[11,133] In a randomized cross-over trial of 38 patients, the effects of 4 hours dialysis to 5 hours dialysis were evaluated.[216] Hemodynamic stability and hypotensive episodes were fewer with longer dialysis, especially among older patients (>65 years of age). However, these data are difficult to generalize since treatment was evaluated only over 2 weeks and those requiring >4 L ultrafiltration were excluded. Longer or more frequent dialysis sessions, in general, are associated with less hemodynamic instability, better

achievement of target postdialysis weight, better control of blood pressure, and the reduced need for antihypertensive drugs. These are discussed further in the next section.

Frequent Dialysis and Its Effect on Blood Pressure

Observational studies suggest that conversion of patients from three times a week conventional dialysis to nocturnal dialysis may improve BP and left ventricular mass.[217] In a cumulative analysis of 72 patients from nine centers it was noted that predialysis systolic and diastolic BP falls within 1 month of dialysis by 13/7 mm Hg from 163/94 mm Hg.[47] This reduction was accompanied by 1% decline in postdialysis weight. Although BP did not change after 1 month, the number of antihypertensive agents declined significantly. At baseline, 54% were not taking antihypertensive drugs whereas at 12 months after switching to daily dialysis, 75% were not taking antihypertensive agents.

Several observations have suggested improvements in BP and left ventricular mass among patients undergoing more frequent dialysis. For example, Chan reported an improvement in both systolic and diastolic BP, reduction in antihypertensive drugs and doses, and reduction in left ventricular mass in patients undergoing nocturnal dialysis.[217] This group has also reported an improvement in pharyngeal size among nocturnally dialyzed patients.[218] This may improve sleep apnea and, consequently, ambulatory BP. Another mechanism of BP reduction is suggested to be an increase in arterial compliance and consequently improvement in baroreflex sensitivity.[219] Others may be better volume and toxin removal.[220] In another small study, both systolic and diastolic BP improved with six times per week compared to thrice weekly dialysis, whether they were recorded predialysis or postdialysis improved. The number of medications and predialysis and postdialysis weight remained unchanged. Intradialytic symptoms commonly attributed to volume shifts also improved. A randomized two-period crossover study compared the effect of short daily hemodialysis versus standard hemodialysis on BP and left ventricular mass index among 12 hypertensive patients with ESRD.[221] At the end of 6 months of standard hemodialysis and 6 months of daily dialysis, 24-hour ambulatory BP monitoring, echocardiography, and bioimpedance were performed. Interdialytic ambulatory BP declined by 20/6 mm Hg with daily dialysis. The decrease in BP was accompanied by the withdrawal of antihypertensive therapy in seven of eight patients during daily dialysis. Left ventricular mass index decreased by 28.6 g per m^2 from 148.7 g per m^2. Extracellular water content decreased 5.1% from 52.7% and correlated with 24-hour improvements in left ventricular mass index and systolic BP.

A randomized controlled trial assigned 52 hemodialysis patients to either frequent dialysis, six nights per week, or conventional three times a week treatment. In the frequent dialysis group, improvement was seen in cardiac magnetic resonance imaged left ventricular mass and reduction in the need for BP medications.[222] The Frequent Hemodialysis Network (FHN) study randomized hemodialysis patients to either conventional three times weekly dialysis or more frequent in-center dialysis; the primary endpoint was an improvement in both LVH and physical health composite. The primary endpoint was met but perhaps the most notable finding was an improvement in systolic BP, reduction in antihypertensive drug use, and improvement in left ventricular mass.[223] These findings suggest better achievement of dry weight in these patients.[224] Increasing the treatment duration may improve hemodynamic stability of dialysis and make the procedure more tolerable but is not a requirement for improvement in left ventricular mass. Shortening the procedure to tailor dialysis to a minimum Kt/V may provoke intradialytic symptoms, postdialysis fatigue, and nonadherence to therapy—thus, this is not recommended.[225] Normotension can be achieved independently of the duration of dialysis if the control of volume is adequate.[226] In fact, left ventricular mass index was also improved to a comparable degree in the DRIP trial participants where the duration of dialysis was not altered but the dry weight was aggressively challenged.[227]

PHARMACOLOGIC TREATMENT

All classes of antihypertensive drugs, except diuretics, are useful for managing hypertension in hemodialysis patients.[228] Diuretics are generally ineffective at very low GFR. There is no role for loop diuretics even when given in high doses, as high as 250 mg intravenously of furosemide, among anuric hemodialysis patients.[229] Measurements using tissue Doppler echo images found that central cardiac hemodynamics were unaltered when anuric hemodialysis patients were given even such high doses of loop diuretics. Given the ototoxicity associated with high doses of loop diuretics, their use, especially in high doses, is not recommended.

Both angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are useful for lowering BP[55,230–232] and some recommend their use in all patients.[233] But not all agree with this recommendation.[234] Consideration of pharmacokinetics is important when prescribing these drugs.[235] For example, lisinopril is renally removed and can be administered just three times a week after dialysis.[55] Ramipril may also accumulate with repeated dosing.[236] The pharmacokinetics of losartan have been carefully examined and remain unaltered in hemodialysis patients.[237] Unique among antihypertensive drugs, the use of ACE inhibitors or ARBs can reduce angiotensin II which can worsen anemia.[238] Whether ACE inhibitors attenuate response to erythropoietin among dialysis patients is debated.[239–241] Also unique among antihypertensive drug classes, the use of ACE inhibitors can trigger anaphylactoid reactions when used concomitantly with AN69 membranes; this adverse reaction appears less frequent with ARBs.[242] A multicenter, open label, 6-month study was performed in 406 patients to test the tolerability and efficacy of losartan in patients on hemodialysis.[242] Fifteen patients discontinued the study

due to adverse reactions related to losartan, and in seven of them the adverse reaction was hypotension. In two patients a possible anaphylactoid reaction was reported after dialysis with an AN69 membrane, necessitating premature termination of dialysis and losartan in one patient. In contrast, nine patients with a history of previous anaphylactoid reaction with an ACE inhibitor and AN69 did not show this complication with losartan and AN69. Thus, losartan appears to have a lower incidence of anaphylactoid reactions than those detected with ACE inhibitors and AN69. Taste disturbances may occur with captopril.[230] Although one small cohort study found reduction in mortality with the use of ACE inhibitors,[243] a larger cohort did not reveal any improvement in survival.[244] In a randomized controlled trial, fosinopril, an ACE inhibitor, was not associated with reduced mortality.[245] Another small study failed to show improvement in myocardial mass or diastolic function with ACE inhibitor therapy.[246]

Beta-blockers can lower BP among hemodialysis patients.[247,248] Atenolol is completely removed by the kidney and is not metabolized in the body. Accordingly, some have suggested that this is a contraindication for using atenolol in patients with CKD. However, we have taken the reverse approach and used it liberally among hemodialysis patients. Even when administered three times a week after dialysis it effectively lowers BP and retains its effect over the entire interdialytic interval.[249,250] Several other β-blockers such as propranolol[251–254] and carvedilol[255,256] have been successfully used. Compared to other classes of drugs, the use of β-blockers has been associated with 16% improvement in all-cause mortality among patients with ESRD.[244]

Calcium channel blockers are commonly prescribed to patients with ESRD. They can effectively lower BP even in the volume expanded state.[257,258] Their use has been associated with improved aortic pulse wave velocity[258] and reduced mortality[259] but other studies dispute mortality claims.[260] For example, no one class of antihypertensive drugs was associated with improved survival in one study.[260] Furthermore, use of both amlodipine and valsartan has been associated with reduced oxidative stress.[261] The pharmacokinetics of amlodipine are unaltered among dialysis patients and the drug is not dialyzable.[262] Therefore, the dose of amlodipine does not need to be modified among dialysis patients.

Vasodilators such as minoxidil and hydralazine are sometimes used as drugs of last resort to control BP. These drugs are powerful vasodilators and provoke reflex tachycardia, the control of which may require the administration of β-blockers.[263] The duration of action of hydralazine is short and its use may result in large variation (spikes and valleys) in BP control. In contrast, the duration of minoxidil is long and likely results in smoother BP control.[264] Minoxidil use can produce vexing side effects such as pedal edema and hirsutism. A serious adverse drug reaction associated with minoxidil is pericardial effusion and is not rare.[265] Hydralazine use can result in a lupuslike illness.

Centrally acting agents such as clonidine can effectively lower BP by reducing autonomic activation.[266,267] Clonidine clearance is GFR dependent[268,269] but the drug is not removed much by dialysis.[269] Because clonidine can be delivered through a transdermal delivery system that lasts 1 week, its use may be associated with lesser nonadherence.[270] However, dry mouth, dizziness, and somnolence are troublesome side effects of this drug. In contrast, guanfacine, another centrally acting agent, is associated with less somnolence and dry mouth.

Alpha-blockers, in our experience, are associated with orthostatic hypotension and intradialytic hypotension events. Among 22 hypertensive hemodialysis patients treated with the α-blocker prazosin, 11 patients described transient dizziness in the first month of therapy and one patient had recurrent syncope requiring termination of therapy.[271] Accordingly, α-blockers should be used cautiously among hemodialysis patients.

There is a renewed interest in spironolactone as a therapy to improve hypertension and left ventricular hypertrophy. Small trials suggest improvement in predialysis BP without the occurrence of hyperkalemia.[272]

In observational studies, the use of antihypertensive drugs has been associated with improvement in all-cause mortality.[273–275] An interventional study used antihypertensive drugs in addition to both the correction of anemia and management of dry weight to evaluate multiple outcomes.[276] It reported that the multitargeted intervention was associated with reduced LVH, reduced cardiovascular mortality, and reduced all-cause mortality. Substantial variation in the use of antihypertensive drug class between countries has been noted.[277] Lopes et al. analyzed the variable use of antihypertensive drug classes among hemodialysis patients and subsequent mortality.[277] Most often, use of antihypertensive drugs was associated with improved outcomes. For example, facilities that treated 10% more patients with ARBs had on average 7% lower all-cause mortality independent of patient characteristics and prescription patterns of other antihypertensive medications. At the patient level, benefits were seen with the prescription of β-blockers (RR = 0.88, $P < .0001$), peripheral α-blockers (RR = 0.89, P = .02), and long-acting dihydropyridine calcium channel blockers (RR = 0.92, P = .003). On the other hand, the use of short-acting dihydropyridine calcium channel blockers was associated with all-cause mortality (RR = 1.67, $P < .0001$). Cardiovascular mortality at the patient level was reduced with the use of β-blockers, ARB, and α-blockers but increased with short-acting dihydropyridine calcium channel blockers. At the facility level, improvement in cardiovascular mortality was seen only with angiotensin receptor blockers; mortality was increased with the use of central antagonists and long-acting dihydropyridine calcium channel blockers. Because these data are observational in nature, causality cannot be implied; randomized trials are needed to test the safety and efficacy of antihypertensive agent use among hypertensive hemodialysis patients.

Regrettably, the reduction in all-cause mortality with antihypertensive drug therapy has not been realized with

adequately powered randomized controlled trials. This may be due to multiple reasons including the low numbers of patients. Nonetheless, meta-analyses of these trials show improvement in the cardiovascular event rate.[278,279] These benefits are especially seen among those who have hypertension.[279]

Nephrectomy for Resistant Hypertension

Nephrectomy has been reported as therapy for resistant hypertension as early as 1967. Of the 40 patients reported, 35 had BP controlled with dry weight reduction; the remaining five required nephrectomy.[13] A case series of 10 patients who underwent bilateral nephrectomy for drug-resistant hypertension reportedly had no antihypertensive drug requirement after the procedure and had a good quality of life.[280]

PROGNOSIS

Among hemodialysis patients, the relationship of BP with outcomes is a subject of much controversy.[274,281–286] Some studies confirm the association of high BP with strokes,[287,288] cerebral atrophy,[289] cardiovascular events,[290] complex cardiac arrhythmias,[291] the development of congestive heart failure,[284] and all-cause mortality[292] as is noted in the general population. Other studies suggest that the relationship of BP and outcomes is the reverse of that seen in the general population. These studies show that low BP measured either predialysis or postdialysis is associated with increased mortality.[273,274,293,294] This association of low BP and mortality is magnified further when BP is considered as a time-dependent covariate.[273] High BP measured either predialysis or postdialysis is either not associated or minimally associated with increased mortality. This phenomenon has been labeled as reverse epidemiology of hypertension. This has raised concerns regarding lowering of BP among hypertensive hemodialysis patients.[295,296] Other studies, however, have demonstrated a direct relationship between BP and mortality.[10,11,144,292] Consideration of the patient characteristics, dialysis practices, and BP measurement techniques are useful when evaluating these outcomes and addressing these controversies.

Patient characteristics differ which is reflected in long-term outcomes that also differ markedly around the world. The lowest crude mortality rate of about 50/1,000 patient years has been reported from centers in Tassin, France, and Okinawa, Japan.[10,11,297,298] Intermediate mortality rates of about 100/1,000 patient years are reported from some centers in Europe and South America.[8,283,299] The highest mortality rates of about 160 to 180/1,000 patient years are those reported from the United States.[275]

In the population of patients who have a lower crude mortality rate and those who have been followed for several years, hypertension is a risk factor for poor outcomes.[282,292,300] In contrast, in the population of patients who have a higher crude mortality rate and those who have been followed for a year or less low BP is a risk factor for poor outcomes and high BP is either protective or has no ill consequence.[276] Some insights can be derived from examining the cohorts with intermediate risks. One such cohort demonstrated that deaths within 2 years (early deaths) were related to deaths due to cancer and withdrawal from dialysis whereas deaths after 2 years (late deaths) were related to cardiovascular and noncardiovascular causes.[283]

Consideration of the level of illness and considering the vintage of the patient are also instructive to ascertain the value of hypertension as a risk factor among hemodialysis patients. Examining the outcomes of 2,770 patients on peritoneal dialysis provides such insights.[18] These patients were studied between 1997 and 2004 and had been on peritoneal dialysis for at least 180 days in England and Wales. In fully adjusted analyses, greater systolic, diastolic, mean arterial, and pulse pressure were associated with decreased mortality among patients who had been on dialysis for less than 1 year. However, greater systolic pressure and pulse pressure (but not mean arterial pressure and diastolic BP) were associated with increased mortality among patients who had been on peritoneal dialysis for 6 or more years. A subgroup of patients was placed on the transplant wait list within 6 months of starting renal replacement therapy and was presumably healthier. Among these patients, greater systolic, diastolic, mean arterial, or pulse pressure were not associated with decreased mortality in the first year. Similarly, among 16,959 dialysis patients in the United States, low systolic BP (<120 mm Hg) was associated with increased mortality in years 1 and 2.[301] However, high systolic BP (150 mm Hg or more) was associated with increased mortality among patients who survived at least 3 years.[301]

Regional differences in mortality are unlikely to be due to patient specific characteristics alone. For example, in France the center in Tassin reports a mortality rate of 45/1,000 patient years. In contrast, Degoulet et al., also from France, have reported a mortality rate of 96/1,000 patient years.[299] Differences in outcomes may be due to center-specific practices. For example, patients reported by Charra et al. in Tassin are dialyzed long hours with low sodium dialysate and given low sodium bread from the dialysis unit. The vast majority of these patients become normotensive without needing antihypertensive drugs. In these patients, the conventional epidemiology of hypertension holds. In fact, normotension has been advocated as a criterion for adequacy of dialysis. This is not unreasonable given that sodium is a ubiquitous uremic toxin and its excess is critically important for the pathogenesis of hypertension among hemodialysis patients.

Difference in techniques used for BP measurement is also quite likely to contribute to variation in the observed relationship between BP and outcomes. For example, Amar et al. were the first to discover the strong relationship between ambulatory BP and mortality.[144] These authors reported that nocturnal systolic BP was directly related to mortality. We have used ambulatory BP to detect its

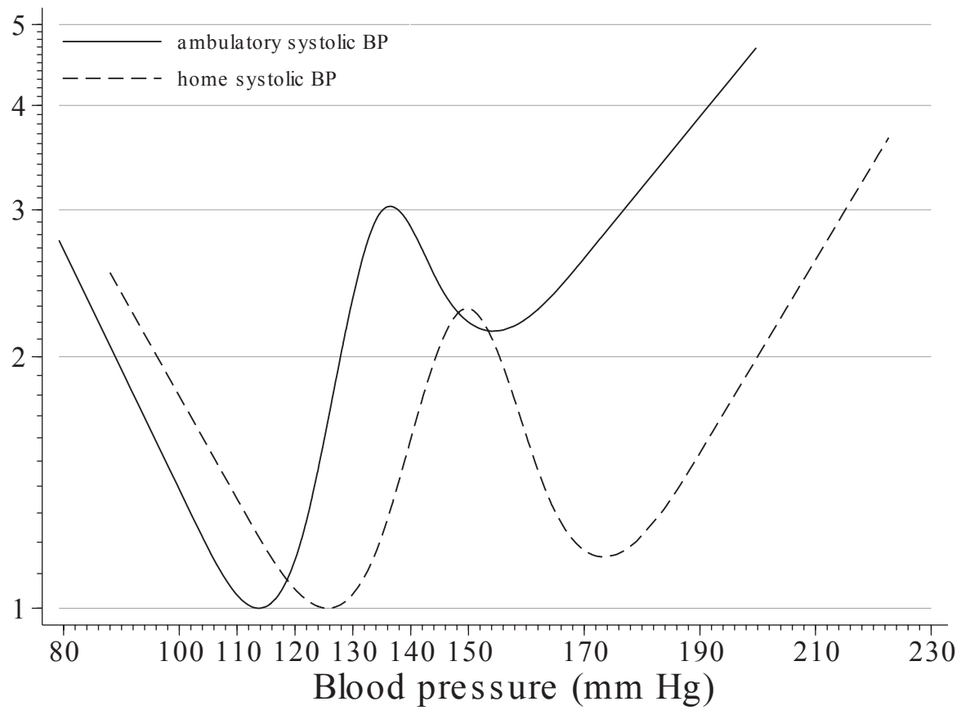

FIGURE 41.5 Nonlinear relationship of systolic blood pressure obtained outside the dialysis unit and subsequent mortality over up to 6 years. The best outcome was seen when ambulatory systolic blood pressure was between 110 and 120 mm Hg and home systolic blood pressure was between 120 and 130 mm Hg. The splines are calculated at the average age of this cohort which was 55 years. (Reprinted from Agarwal R. Blood pressure and mortality among hemodialysis patients. *Hypertension*. 2010;55:762.)

relationship with mortality. In a cohort of approximately 150 patients we found a direct and statistically significant relationship of both home (self-measured) and ambulatory (automatically measured) BP with mortality.[145] No such relationship was detectable using pre- and postdialysis BP recordings. In a larger cohort followed for a longer time we found a W-shaped relationship between both ambulatory BP and home BP with all-cause mortality (Fig. 41.5).[302] At extremes of BP, mortality was noted to be high. Compared to ambulatory BP, the optimal BP ranges for home BP were about 10 mm Hg higher.

CONCLUSION

Hypertension is common, difficult to diagnose, and poorly controlled among patients with ESRD. Although there is controversy surrounding its diagnosis and treatment, evidence suggests that home BP monitoring may help make a more accurate diagnosis of hypertension. Goal home BP of <140/90 mm Hg is 5 mm Hg more than the goal suggested by the American Heart Association to be a reasonable target for dialysis patients. The primary strategies to control BP are dietary and dialysate sodium reduction, an adequate prescription of dialysis, and achievement of dry weight. Pharmacologic therapy should be second line. Use of antihypertensive drugs may improve cardiovascular outcomes. Frequent dialysis is effective in improving BP control and increasing treatment times among hypertensive patients may be a reasonable way to both afford hemodynamic stability and improve BP control.

CHAPTER

42 Renal Artery Stenosis, Renovascular Hypertension, and Ischemic Nephropathy

Stephen C. Textor

The identification and management of renovascular disease presents a clinical challenge that is directly relevant to nephrologists, and also one that relates to many other medical specialties, including cardiovascular specialists, internal medicine physicians, vascular surgeons, and interventional clinicians. How best to manage renovascular disease remains controversial, in part because of the near simultaneous development of far more effective diagnostic tools, medical therapy, and revascularization techniques over the past decade that has ever been available before. It behooves clinicians caring for patients with renal disease to have a solid understanding of these concepts as part of their clinical responsibility to prevent an irreversible loss of kidney function and adverse effects of arterial hypertension.

Few conditions are more rewarding to treat than new onset severe hypertension and/or progressive renal insufficiency that reverses after the successful restoration of renal blood flow. Occlusive lesions of the main renal arteries can now be detected readily with any of a variety of imaging tools. Determining when to pursue renovascular lesions in clinical hypertension, renal insufficiency, or circulatory congestion; establishing their pathophysiologic role; and whether the hazards associated with revascularization are warranted are pressing concerns regularly faced by nephrologists. Although recent trial data fail to provide compelling evidence in favor of endovascular stenting for all patients with atherosclerotic disease, the validity of prospective clinical trials in this disorder has been fiercely challenged.[1,2] Experienced clinicians understand that renal revascularization in these disorders sometimes should be undertaken both to improve hypertension and to salvage renal function.

Recognition that reduced renal perfusion activates pressor systems that raise systemic blood pressure remains one of the seminal observations and most widely studied mechanisms in cardiovascular physiology. Reversal of renovascular hypertension can provide major benefits to patients with accelerating hypertension (e.g., allowing effective blood pressure control and reduction of long-term drug therapy). Selecting patients and determining optimal timing for vascular intervention at a reasonable risk is rarely simple, however.

These issues are complicated further by the rapid expansion of endovascular procedures over the past two decades. Although restoring lumen patency in partially occluded vessels intuitively may seem beneficial, recent trials indicate that revascularization procedures carry both substantial costs and some risks, whereas the clinical benefits remain ambiguous.[3,4] This is a remarkable turn of events, insofar as renovascular hypertension traditionally has been considered a prototype for "curable" secondary hypertension. Most diseases of the renal arteries are progressive, and the clinical manifestations develop gradually over time, either because the vascular compromise worsens or because adaptive mechanisms to offset hemodynamic effects become overwhelmed. Because advances in medical therapy have allowed more effective antihypertensive drug treatment than ever before, more patients are appearing clinically at later stages in their disorder with a manifest loss of kidney function and/or circulatory disorders.[5] It may be argued that such patients face more severe consequences of renovascular compromise and may have less of a likelihood of benefit from restoring the renal circulation. Hence, it behooves nephrologists to recognize the importance of a close follow-up of vascular disease in the kidney, as with many other vascular conditions. Before moving forward with renal revascularization, both affected patients and physicians should consider carefully the potential benefits and risks. Understanding the pathophysiologic basis for the clinical syndromes associated with renal artery stenosis is an important first step in this process. This chapter will review the background and basis for much of the clinical information related to these disorders.

The basic clinical syndromes to be discussed are outlined in Figure 42.1. Many renal artery stenoses produce little hemodynamic effect and represent "incidental" disease. Such lesions sometimes may be found in asymptomatic, normotensive individuals. Because many renal arterial lesions are detected in patients with preexisting hypertension, the role of renovascular disease itself may be obscured. Renovascular hypertension denotes the syndrome of rising arterial pressures specifically caused by impaired renal perfusion that leads to the activation of pressure pathways. When the severity and duration of reduced blood flow threatens the viability of kidney tissue, many authors

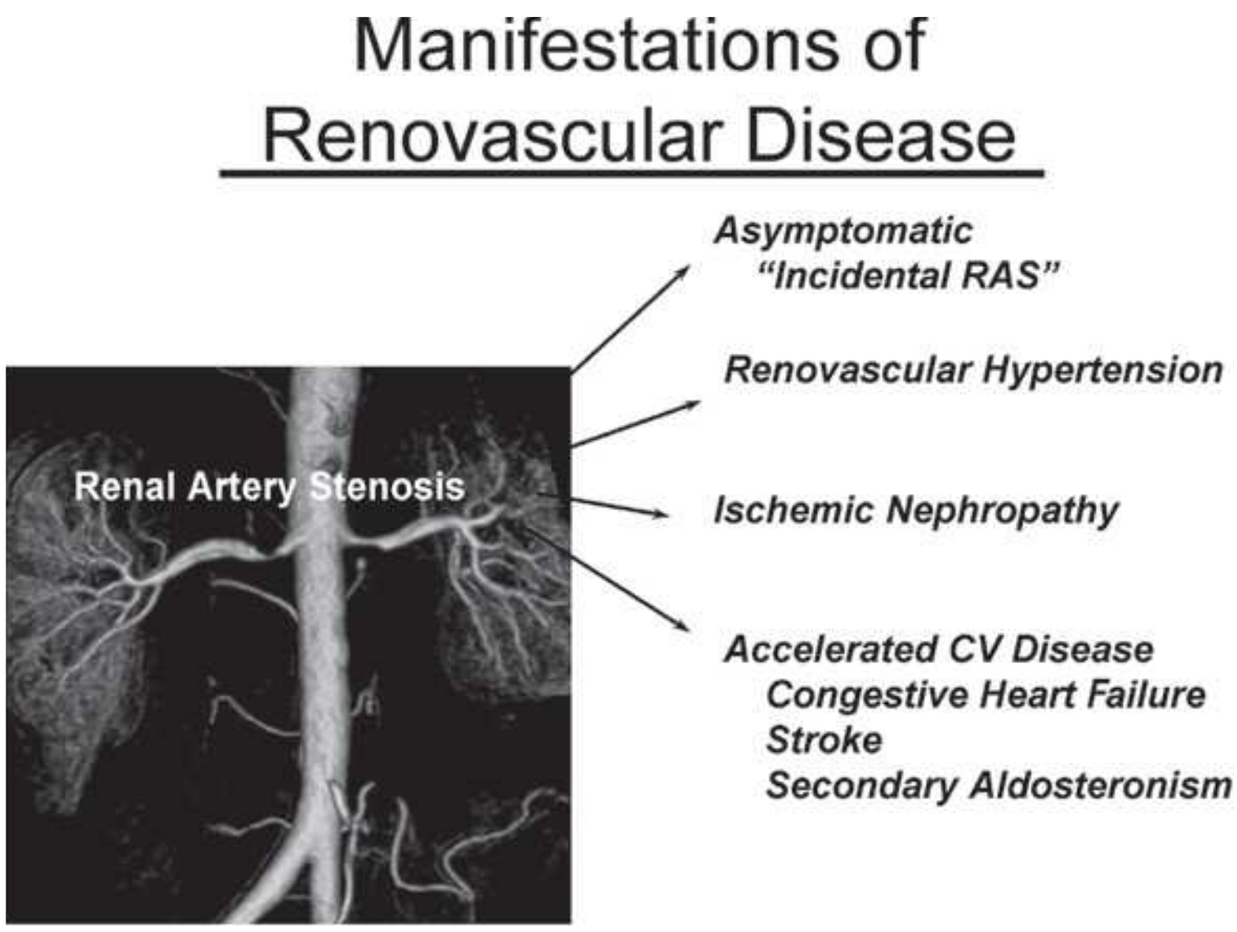

FIGURE 42.1 Clinical manifestations of renal artery stenosis range across a broad spectrum. Many, perhaps most, represent incidental lesions with minimal hemodynamic effects. Some reach levels wherein the activation of pressor mechanisms produces a rise in blood pressure, identified as renovascular hypertension, and at some point, threaten kidney function sufficiently to warrant the term ischemic nephropathy (see text). Particularly when the entire renal mass is affected, impaired kidney function and solute excretion from renovascular disease can accelerate cardiovascular morbidity, sometimes identified as one of the cardiorenal syndromes, with worsening congestive heart failure. The task facing the clinician is to identify where along this spectrum an individual patient lies. *CV,* cardiovascular; *RAS,* renal artery stenosis.

have designated this condition as ischemic nephropathy, which some believe is a major cause for some patients reaching end-stage renal disease (ESRD).[6,7] More recently, attention has been focused on the role of renovascular disease in impairing cardiac function, both by reducing the systemic excretion of sodium and volume and by producing abrupt rises in arterial afterload that magnify cardiac dysfunction. The primary task of the clinician is to elucidate the role of renal arterial stenosis in a given patient and to direct therapy accordingly.

HISTORICAL PERSPECTIVE

Observations in the 1800s regarding blood pressure measurements revealed important connections between fluid volume, arterial pressure, and vascular resistance. How these observations ultimately led to the elucidation of the renin-angiotensin-aldosterone system has been reviewed.[8] In 1898, Tigerstedt and Bergman established that extracts of the kidney had pressor effects in the whole animal, and these authors are credited with the identification of renin. The identification of each component of the renin-angiotensin system represents a remarkable series of research ventures spanning a half century and several investigators in many countries. Goldblatt and others provided seminal experiments with the development of an animal model in which reduced renal perfusion produced hypertension, published between 1932 and 1934. Numerous investigators thereafter identified the peptide nature of angiotensin, the role of renin substrate or angiotensinogen, the role of nephrectomy in sensitizing the animal to the pressor effects of angiotensin, and the sequential phases of renovascular hypertension. Hence, the renin-angiotensin system owes its initial discovery and nomenclature primarily to early studies related to the regulation of blood pressure by the kidney. Only recently have the multiple additional effects of angiotensin become evident regarding vascular remodeling, the modulation of inflammatory pathways, and interactions with fibrogenic mechanisms. Understanding that reduced renal blood flow produces sustained elevations in arterial pressure led to a broad study of the mechanisms underlying many forms of hypertension. Experimental models of two-kidney and one-kidney renal clips (two-kidney and one-kidney Goldblatt hypertension) represent some of the most extensively studies models of blood pressure and cardiovascular regulation.

Extension of these studies into clinical medicine followed soon thereafter. A time line highlighting these developments is illustrated in Figure 42.2.[9] Some patients presented with malignant forms of hypertension during the late 1930s and 1940s, so designated due to remarkably poor survival if the patient's blood pressure could not be lowered successfully. Few antihypertensive agents were known until the 1950s, and intervention consisted mainly of extremely low sodium intake diets and/or lumbar sympathectomy.

Recognition that some forms of severe hypertension were secondary to occlusive renovascular disease led surgeons to undertake unilateral nephrectomies for small kidneys in 1937.[10] The fact that some of these were indeed pressor kidneys and blood pressure fell to normal levels provided proof of concept and led to more widespread use of nephrectomies. Unfortunately, achieving a cure of hypertension after the nephrectomy was rare, and Homer Smith reviewed the poor results overall in a 1956 paper discouraging this practice.[10]

The 1960s marked the introduction of methods of vascular surgery to restore renal blood flow. These procedures carried substantial morbidity associated with aortic surgery, but offered an opportunity to improve the renal circulation and to potentially reverse renovascular hypertension. One result of this development was a series of studies aiming to characterize the functional role of each vascular lesion in producing hypertension, thereby allowing a prediction of the outcomes of vascular surgery.[10] A large, cooperative study of renovascular hypertension[81] included major vascular centers and reported on the results of more than 500 surgical procedures. These results provided limited support for vascular repair,

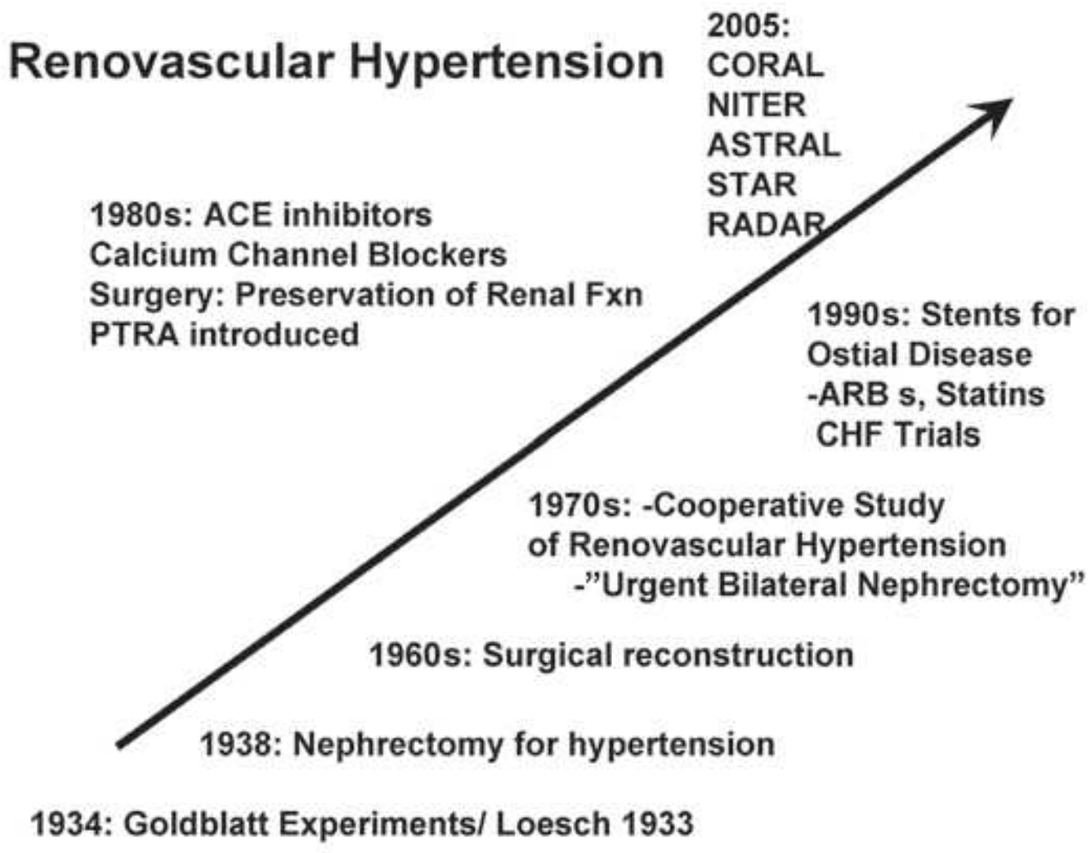

FIGURE 42.2 A time line with major events in the understanding of renovascular hypertension. Goldblatt and Loesch are identified as the original investigators in the 1930s who linked reduced kidney perfusion to the development of sustained hypertension. Surgical revascularization only became technically feasible in the 1960s, with the emergence of effective medical therapy and endovascular procedures in the 1980s and 1990s. The application of effective medical therapy, including statins, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin-receptor blockers (ARBs), have led to clinical equipoise that is the basis for prospective, randomized trials comparing optimal medical treatments with or without revascularization, beginning around 2005. *PTRA*, percutaneous transluminal renal angioplasty; *CORAL*, cardiovascular outcomes for renal atherosclerotic lesions; *NITER*, nephrotherapy ischemic therapy; *ASTRAL*, angioplasty and stent for renal artery lesions; *STAR*, stent placement in patients with atherosclerotic renal artery stenosis and impaired renal function; *RADAR*, randomized, multicenter, prospective study comparing best medical treatment versus best medical trearment plus stenting in patients with hemodynamically relevant atherosclerotic renal artery stenosis; *CHF*, congestive heart failure.

but identified relatively high associated morbidities and mortalities, particularly in patients with atherosclerotic disease.

In the 1980s and 1990s, further developments led to both improved medications and the introduction of endovascular procedures, including percutaneous angioplasty and stents. These both broadened the options for treating patients with vascular disease and raised new issues regarding timing and overall goals of intervention. Recent developments highlighted the need for intensive cardiovascular risk factor reduction and more stringent standards of blood pressure control. Antihypertensive medications have improved dramatically, both with regard to efficacy and tolerability. As emphasized in the following, the broad application of angiotensin-converting enzyme inhibitors and angiotensin-receptor antagonists for reasons other than hypertension alone changed the clinical presentation of disorders associated with renal artery stenosis.

Uncontrollable hypertension is now less commonly the reason to intervene in renovascular disease. Often, the main objective is the long-term preservation of renal function. In recent years, endovascular techniques make possible renal revascularization with relatively low morbidity in many patients previously considered unacceptable surgical candidates. The challenge for clinicians is how and when to apply these tools most effectively in the management of individual patients.[11]

DEFINITIONS AND CLASSIFICATION

The syndrome of renovascular hypertension (RVH) refers to hypertension primarily mediated by the reduction of renal artery perfusion pressure. The prevalence of renovascular hypertension is not known with precision, but available data suggest that it occurs in 0.5% to 5.0% of the general hypertensive population.[12] RVH can develop with a variety of arterial lesions, including arterial dissection, extrinsic compression, embolic infarction, or thrombosis (Table 42.1).

42.1 Lesions Producing Renovascular Hypertension and Ischemic Nephropathy

Causes of Renal Artery Stenosis
Atherosclerotic renal artery disease
Fibromuscular dysplasias
Medial fibroplasia
Perimedial fibroplasia
Intimal fibroplasia
Medial hyperplasia
Endovascular aortic stent graft crossing the renal artery
Acute arterial embolism/thrombosis (e.g., antiphospholipid syndrome)
Arterial trauma
Aortic dissection
Neurofibromatosis
Arterial aneurysm
Arteriovenous malformation/fistulae
Cholesterol emboli
Systemic necrotizing vasculitis
Polyarteritis nodosa

Atherosclerotic renal artery disease is the most common cause of renal artery stenosis, accounting for about 80% of renal arterial lesions. Fibrous renal artery diseases, as a group, account for less than 20% of renal arterial lesions. Reports of resistant hypertension suggest that when renovascular disease is a factor, more than 84% is atherosclerotic renal artery disease and 16% is fibromuscular renal artery disease.[13] Fibrous renal artery disease has been reported in 2% to 6% of potential renal transplant donors (usually normotensive individuals).[14,15] The vast majority of incidental renal artery lesions in angiographic series are atherosclerotic.

In addition to atherosclerotic and fibrous renal artery disease, a number of less common clinical entities can produce renovascular hypertension. These include acute arterial thrombosis or embolism, cholesterol emboli, aortic dissection, renal arterial trauma, arterial aneurysm, arteriovenous malformation of the renal artery, neurofibromatosis, polyarteritis nodosa, and Takayasu arteritis. Recent expansion of the use of endovascular aortic stent grafts, sometimes with structural impingement of the main renal arteries, is a new addition to the list of iatrogenic causes of renovascular hypertension.[4,16,17] Renal artery thrombosis occurring as a complication of umbilical artery catheterization has been recognized as causing renovascular hypertension in infants.[18] Transplant renal artery atherosclerosis, intimal hyperplasia, or vascular kinking may contribute to renal transplant renovascular hypertension (see Chapter 82).

Table 42.2 presents a classification of atherosclerotic and fibrous renal artery diseases with a description of their morphology and histology. These types of renal artery occlusive diseases represent a heterogeneous group of diseases, occurring in different age groups and behaving differently with regard to their individual natural history. An appreciation of these differences may be important for therapeutic decision making in patients with renal artery occlusive disease.

Fibromuscular Dysplasias

Fibromuscular dysplasia (FMD) lesions produce distortions of the luminal diameter of large- and medium-sized arteries due to nonatherosclerotic arteriopathies. The lesions usually involve the mid to distal vessel beyond the first 1 to 2 cm from the aorta (Fig. 42.3). The prevalence of clinically apparent renovascular FMD is estimated at 4 out of 1,000, with lower prevalence of cerebrovascular involvement (1 out of 1,000). Observations from screening angiographies in normotensive potential kidney donors indicate that some degree of FMDs can be observed in 3% to 6% of otherwise healthy, normotensive individuals.[15] Clinically apparent FMDs are most common among young females between the ages of 15 and 50 years. It may be familial in 10% of cases and tends to involve both renal arteries. It has been associated with subclinical carotid fibromuscular disease in first-degree relatives, which, in some cases, is consistent with an autosomal dominant inheritance. Renal arteries are involved with FMDs in 65% to 70% of cases, whereas 25% to 30% involve cerebral vessels. Both sites are involved in approximately 15% of patients. FMDs may develop in association with hereditary disorders of the connective tissue, such as Ehlers-Danlos and Marfan syndromes.

The lesions of FMD develop as disruptions of vascular wall components with abnormal deposition of collagen

42.2 Histologic Classifications of Fibromuscular Dysplasia and Angiographic Appearance

Type	Frequency	Histology	Angiographic Appearance
Medial		Alternating ridges of collagen/ loss of elastic membrane	String of beads Medial: bead diameter is larger than lumen diameter Perimedial: bead diameter is smaller than lumen diameter Medial hyperplasia: smooth stenosis without beads
Medial fibroplasia	85%–100% most common		
Perimedial fibroplasia	Rarer (10%–15%)	True smooth muscle hyperplasia: no fibrosis	
Medial hyperplasia	Rarest		
Intimal	<10%	Circumferential deposition of collagen in intima: fragmented or duplicated internal elastic lamina	Concentric smooth stenosis: long, smooth vessel narrowing
Adventitial	<1%	Dense collagen replaces fibrous tissue in adventitia and surrounding tissue	Smooth stenosis or diffuse attenuation of vessel lumen

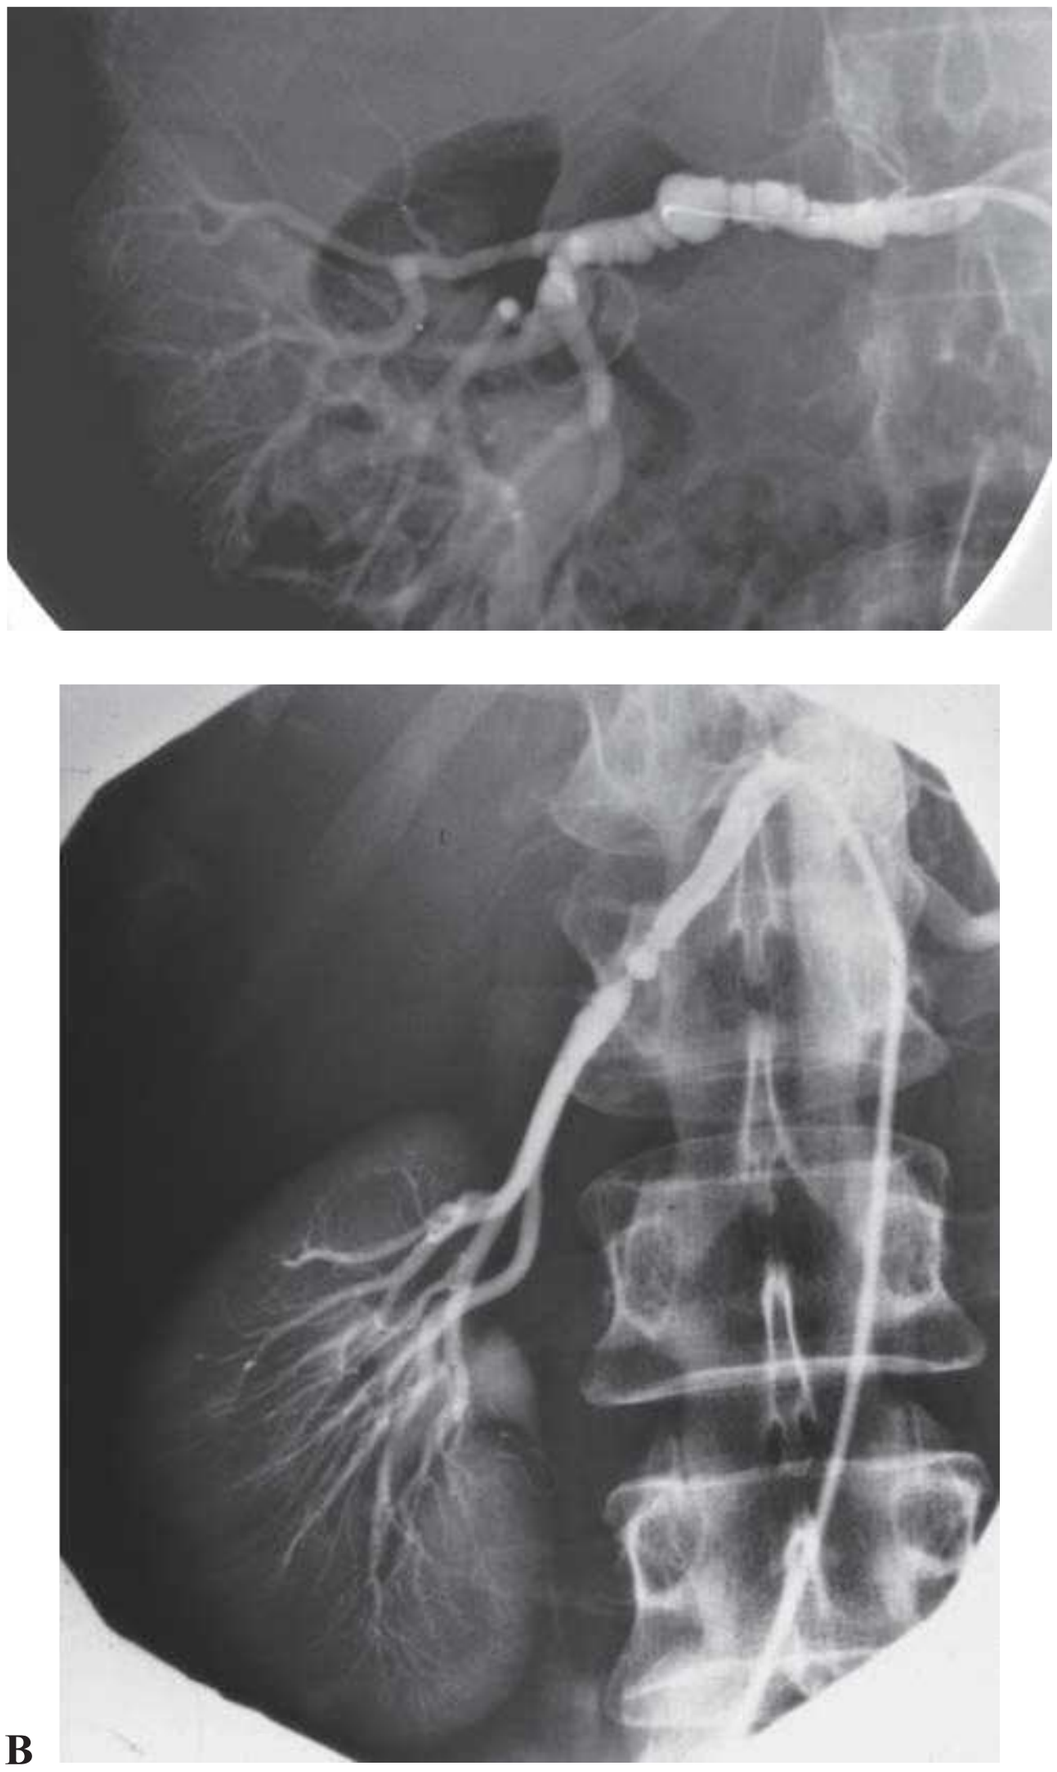

FIGURE 42.3 Examples of fibromuscular disease of the renal artery. **A:** An image of the string of beads appearance that is typical of medial fibroplasia with aneurysmal bulging beyond the artery. **B:** An image of a tight, focal lesion that is typical of intimal hyperplasia in a young male.

in bands, sometimes with disruption of the vascular elastic membrane. The molecular basis for these disruptions is unknown, although several candidate genes have been proposed. The primary subtypes of FMDs are designated as medial fibroplasia, intimal fibroplasia, and periadventitial fibroplasia, defined initially on the basis of histologic analysis of surgically resected vessels. Medial fibroplasia is the most common phenotype, and often manifests as a string-of-beads appearance with alternating stenoses with apparent luminal dilations, as summarized in Table 42.2. The other phenotypes appear as focal or elongated vascular occlusions. Medial fibroplasia affects the distal half of the main renal artery, frequently extends into the major branches, is often bilateral, and angiographically gives the appearance of multiple aneurysms wherein the diameters of the aneurysms are wider than the apparently unaffected portion of the main renal artery (Fig. 42.3A). Most cases of medial fibroplasia are diagnosed in women between the ages of 30 and 50 years. Although medial fibroplasia progresses to higher degrees of stenosis in about one-third of patients, complete arterial occlusion and/or ischemic atrophy of the kidney ipsilateral to the renal artery stenosis are rare. The stenotic lesions in medial fibroplasia are secondary to thickened fibromuscular ridges replacing the normal structure of the intima and the media of the artery. These thickened ridges alternate with thinned areas that may not have an internal elastic membrane, thereby becoming aneurysmal.

Perimedial fibroplasia (subadventitial fibroplasia) accounts for approximately 15% of fibrous renal artery lesions. This lesion also occurs predominantly in women, typically between the ages of 15 and 30 years. Angiographically, it is often characterized by a small string-of-beads appearance, with the beads being of similar or of smaller diameter compared to the diameter of the apparently unaffected portion of the renal artery. This lesion typically affects the distal half of the main renal artery, is frequently bilateral and highly stenotic, and may progress to total arterial occlusion. Collateral blood vessels and renal atrophy on the involved side are commonly observed.[19,20]

Medial hyperplasia and intimal fibroplasia account for only 5% to 10% of fibrous renal artery lesions. Intimal fibroplasia occurs primarily in children and teenagers and angiographically appears as a localized, highly stenotic, and smooth lesion with poststenotic dilation. It may occur in the proximal portion of the renal artery and when it does, it can resemble atheroma. Intimal fibroplasia is progressive and is occasionally associated with dissection or renal infarction and renal atrophy (Fig. 42.4C). Medial hyperplasia, also rare, is found predominantly in teenagers, and angiographically also appears as a smooth, linear stenosis, sometimes appearing as though a ligature were tied around the renal artery. There is considerable difficulty in distinguishing between intimal fibroplasia and medial hyperplasia by angiography alone, and these two types of fibrous artery disease are sometimes grouped together in the literature.[21]

Renal artery aneurysms can develop in up to 50% of these lesions, which sometimes produce local dissection and/or occlusion (Fig. 42.4C). Arteriovenous fistulae and thrombosis can also occur.

Rates of progression differ between histologic subtypes and are poorly understood. Many lesions remain below hemodynamic thresholds and have minimal clinical importance. Others progress to produce hypertension and occasional thrombosis, particularly in women, although this happens far more commonly with atherosclerotic lesions. Smoking appears to be the major risk factor for progressive disease in young women.

Takayasu arteritis is a variant form of systemic vasculitis that affects large arteries such as the aorta and its main branches, including the renal arteries. It mainly affects young women. It can cause discrete stenosis of the aorta

FIGURE 42.4 **(A)** and **(B)** Illustrate the ability of percutaneous transluminal renal angioplasty (PTRA) to open otherwise tight fibrous bands and successfully reverse renovascular hypertension in a young athlete. **C:** Fibromuscular disease complicated by a renal artery aneurysm that produced a segmental infarction and renovascular hypertension not amenable to renal revascularization.

and its main branches, including the common carotid, and the subclavian and the renal arteries.[22] Renal artery involvement is not uncommon in Asian and African patients and is a major cause of renovascular hypertension in these countries.[23] Koide[24] reported renovascular hypertension in 278 (18.8%) of 1,475 patients in a Japanese nationwide survey of Takayasu arteritis. Takayasu arteritis is a common cause of renovascular hypertension in Southeast Asia, including India and China, and accounts for between 20% and 60% of RVH cases.[23,25]

A recent expansion in the use of endovascular procedures for aortic aneurysm repair (EVAR) has produced a new clinical source of renal artery occlusion (Fig. 42.5A). Many of these stent grafts are placed in close proximity to the origins of the renal arteries. Occlusion of the renal arteries is observed in up to 6% of these procedures, sometimes related to migration or inadvertent coverage of the vessels.[4,26] Some grafts are designed for deliberate extension of uncovered struts above the renal arteries for anatomic reasons. Remarkably, the frequency of renal artery compromise is modest, and current endovascular procedures can restore luminal patency if promptly recognized.[27] Identifying and treating vascular occlusion due to aortic stent grafts is important, because failure to achieve patency is associated with a clinically important loss of kidney function in up to 20% of subjects.[28]

Acute and chronic renal artery occlusion secondary to renal artery emboli, aortic or renal artery dissection, neurofibromatosis, arterial trauma, arteriovenous malformations, and polyarteritis nodosa are discussed elsewhere in this book.

Atherosclerotic Renal Artery Stenosis

Atherosclerotic renal artery stenosis (ARAS) most often develops in older patients (> 50 years of age) and is associated with systemic atherosclerosis. ARAS is the most common

FIGURE 42.5 Examples of atherosclerotic renal artery stenosis. **A:** An aortic aneurysm repair using an endovascular stent graft with an extension to cover portions of the renal arteries, which represents a new form of treatment-associated renovascular compromise. (See Color Plate.) **B:** High-grade bilateral renal arterial stenoses from ostial lesions and **(C)** a total renal occlusion to the right kidney and high-grade stenosis to a solitary functioning kidney. Such lesions are becoming more common because effective antihypertensive drug therapy may be delaying the identification of ARAS until later stages with deteriorating kidney function and blood pressure control.

C

cause of RVH and can contribute to a loss of renal function leading to ESRD (Fig. 42.5B,C). Atherosclerotic plaque often arises in the first 1 to 2 cm of the renal artery or may extend directly from the aorta into the renal ostium. Aortic and renal vascular calcification is often present. Some 75% to 80% of patients with renal artery atherosclerosis and renovascular hypertension have ostial atherosclerotic lesions, and 25% to 30% of lesions are in the nonostial location. ARAS is a manifestation of systemic atherosclerotic disease and is associated with coronary, cerebrovascular, peripheral vascular, and aortic disease.[29,30] The prevalence of ARAS appears to be increasing. This probably reflects the fact that more people are living long enough for atherosclerotic vascular disease in the visceral abdominal vessels to reach critical levels, thus aggravating hypertension when the kidney is affected. In a recent systematic analysis of patients undergoing an angiography of the peripheral or coronary circulations, ARAS was found in 11% to 42% of cases.[30] Predictors of ARAS include a history of hypertension, the presence of renal functional impairment, coexisting vascular or coronary artery disease, the presence of abdominal bruits, and a history of smoking. Renal artery lesions are bilateral in 20% to 40% of such patients. Estimates of the prevalence of ARAS depend on the population screened. One population-based study of a cohort of 870 patients older than 65 years screened with renal artery duplex sonography found a 6.8% prevalence of ARAS, defined as greater than 60% stenosis. No differences in prevalence were detected between African Americans and Caucasians,[31] although reported rates for surgically corrected renovascular hypertension are lower for African Americans.[32] Men are affected more often than women, but this gender difference declines with advancing age. Recent series indicate a distinct shift toward women in series referred for revascularization.[33,34] Several studies suggest that atherosclerotic renal vascular disease is associated with adverse coronary events[33,35] and increased mortality. Autopsy series report an overall prevalence of 4% to 20%, with progressively higher rates for those older than 60 years (25% to 30%) and 75 years (40% to 60%). These studies suggest that ARAS leading to renal artery stenosis is the single most common cause of secondary hypertension in patients older than 50 years.[36] It also commonly leads to systolic hypertension with wide pulse pressures. Furthermore, renal artery stenosis has been reported to contribute

to the decline in renal function in 15% to 22% of patients reaching ESRD.[37,38]

Adaptation and Progressive Vascular Occlusion in Atherosclerotic Renal Artery Stenosis

With improved antihypertensive drug therapy and the recognized potential for advanced ARAS to lead to reduced kidney function, clinicians need to consider the potential for progressive renovascular occlusion during medical therapy. This has been a controversial subject. Initial retrospective studies of serial angiograms suggested that progressive occlusion could develop in 40% to 50% of subjects[37] with 15% progressing to total occlusion over periods between 3 to 5 years.[39] A series of studies in the 1990s with ARAS followed prospectively with high-resolution Doppler ultrasound indicated that measurable hemodynamic progression occurred in nearly 50% of subjects over 5 years,[40] although the rates of clinical progression defined by changes in kidney size (24%), loss of GFR, and/or progression to total occlusion were much lower.[41] The 3-year cumulative incidence of renal artery disease progression for 295 renal arteries initially classified as normal, less than 60% stenosis, and greater than or equal to 60% stenosis, was 18%, 28%, and 49%, respectively. In this prospective series, the early progression to total occlusion occurred only in nine arteries (3%), all of which had a baseline reduction in lumen diameter greater than 60% (Fig. 42.6). The cumulative incidence of progression to total occlusion in patients with baseline stenosis of 60% or more was 4% at 1 year, 4% at 2 years, and 7% at 3 years. Factors associated with the risk of renal artery disease progression during the time of monitoring included systolic blood pressure (BP) greater than or equal to 160 mm Hg, diabetes mellitus, and high-grade stenosis (more than 60%) in either the ipsilateral or contralateral renal artery.[37] One of the prospective treatment trials from Europe suggested that 16% of subjects treated without revascularization developed total occlusion, based on renography.[39] Recent prospective treatment trials indicate far lower rates of disease progression. BP control and statin therapy in these trials have been more effective and more widely applied than before, with crossover rates from medical therapy to renal revascularization below 10% over reporting periods between 3 and 5 years.[42] It should be emphasized that the epidemiologic and clinical hazard of progressive stenotic disease is closely related to the level of initial stenosis. For lesions that are more than 75% occluded, further progression is not only far more likely to occur, but the consequence regarding tissue ischemia and loss of functioning tissue is more severe (see Pathophysiology, which follows).

PATHOPHYSIOLOGY OF CLINICAL SYNDROMES WITH RENOVASCULAR DISEASE

Renovascular Hypertension

Renovascular occlusive disease from any cause that reaches a "critical" level can activate pressor mechanisms that tend to raise systemic arterial pressure and restore renal artery

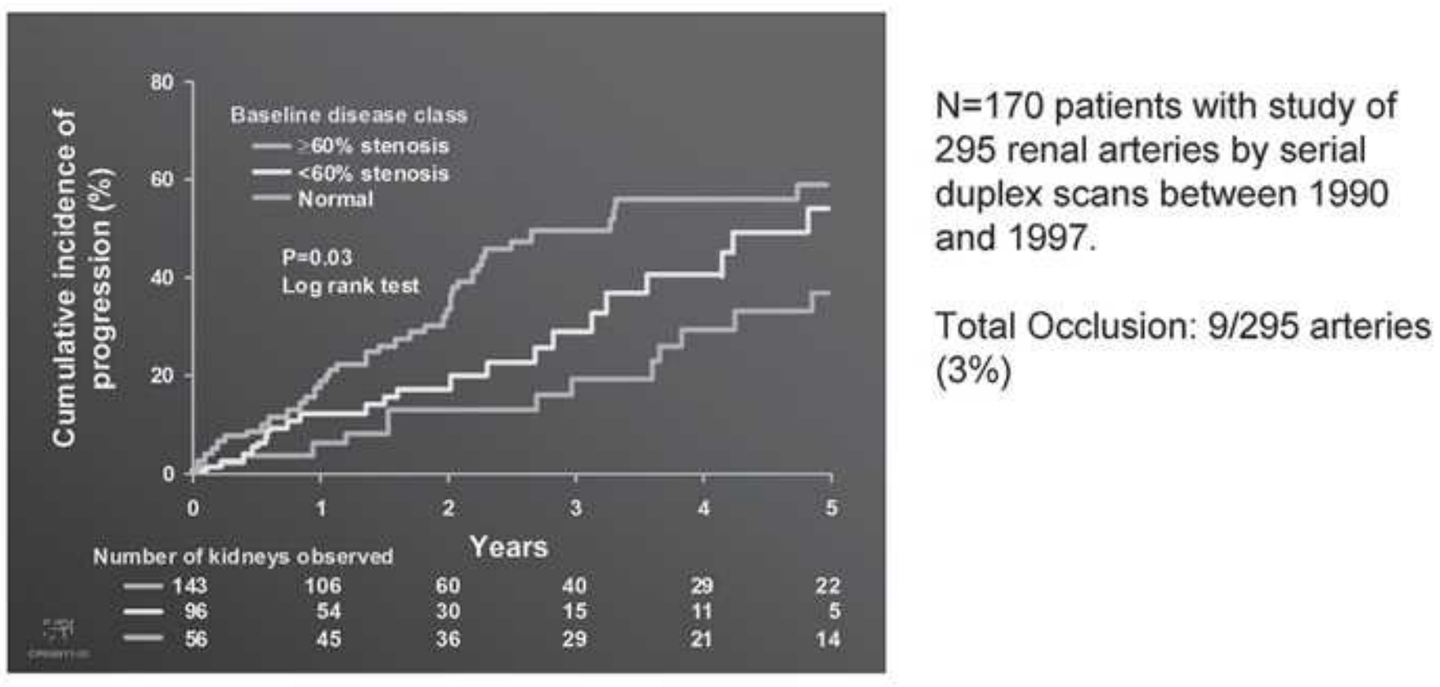

FIGURE 42.6 The progression of atherosclerotic renal artery stenosis (ARAS) of varying severity during a serial follow-up by Doppler ultrasound. There were 295 arteries that were followed sequentially at 6-month intervals for 5 years. Measurable hemodynamic progression (defined as an increase in peak systolic velocity of at least 100 cm per second) was identified in 31% by 3 years, and more than 50% of the group with more than 60% at baseline. Importantly, clinical progression was uncommon (defined by a change in serum creatinine, loss of kidney size, or total occlusion). Predictors of progression included systolic blood pressure, age, and diabetes. (Adapted from Caps MT, Perissinotto C, Zierler RE, et al. Prospective study of atherosclerotic disease progression in the renal artery. *Circulation*. 1998;98:2866–2872.) (See Color Plate.)

perfusion pressures. Luminal occlusion of less than 60% (cross-sectional area) rarely produces any measurable gradient for either pressure or flow. Hence, a fall in renal perfusion pressure sufficient to initiate RVH occurs only when luminal occlusion is relatively severe, usually in the 70% to 80% cross-sectional occlusion range (Fig. 42.7). When critical stenosis develops and reduces renal perfusion pressure, multiple mechanisms are activated in the kidney to restore renal blood flow. Foremost among these pathways is the release of renin from the juxtaglomerular apparatus, leading to the activation of the renin-angiotensin-aldosterone system (RAAS). Release of plasma renin occurs only after poststenotic pressures fall by at least 10% to 20% compared with aortic pressures.[43] This is mediated in part by the stimulation of neuronal nitric oxide synthase and cyclooxygenase 2 in the macula densa. Blockade of the RAAS at the time an experimental renal artery lesion is created prevents the development of hypertension. Animals genetically modified to lack the angiotensin (Ang 1) receptor fail to develop two-kidney one-clip hypertension.[44] Experiments using kidney transplantation from AT1 receptor knockout mice indicate that both systemic and renal angiotensin receptors participate in additive fashion to blood pressure regulation.[45]

In the presence of an intact RAAS, systemic arterial pressures increase until renal perfusion is restored. Studies in both experimental models and humans indicate that additional mechanisms add to long-term elevation of blood pressure in the presence of renal artery stenosis, including activation of the sympathetic nervous system, impairment of nitric oxide generation, and release of endothelin as well as hypertensive microvascular injury to the nonstenotic kidney.

Although there are differences among species (rat, dog, rabbit) in experimental renovascular hypertension, two basic models of Goldblatt hypertension are recognized: the two-kidney, one-clip (2K-1C) model (in which one renal artery is constricted and the contralateral renal artery and kidney are left intact) and the one-kidney, one-clip (1K-1C) model (in which one renal artery is constricted and the contralateral kidney is removed). These two experimental models of renovascular hypertension are diagrammed in Fig. 42.8A,B. Mechanisms responsible for sustained RVH differ according to whether one or both kidneys are affected. Both of these models depend initially on impaired renal perfusion and activation of the RAAS with sodium retention. However, the presence of a normal contralateral kidney allows pressure natriuresis to occur, by which the elevated perfusion pressure produces sodium excretion in the nonstenotic kidney. Because the nonstenotic kidney eliminates excess sodium and volume, the level of perfusion pressure to the stenotic side remains reduced, leading to the ongoing activation of the renal artery underperfusion and RAAS stimulation. This sequence of events producing angiotensin II (Ang II)–dependent hypertension and secondary aldosterone excess with hypokalemia is summarized in Fig. 42.8A.

By contrast, 1K-1C hypertension represents a model in which the entire renal mass is exposed to reduced pressures

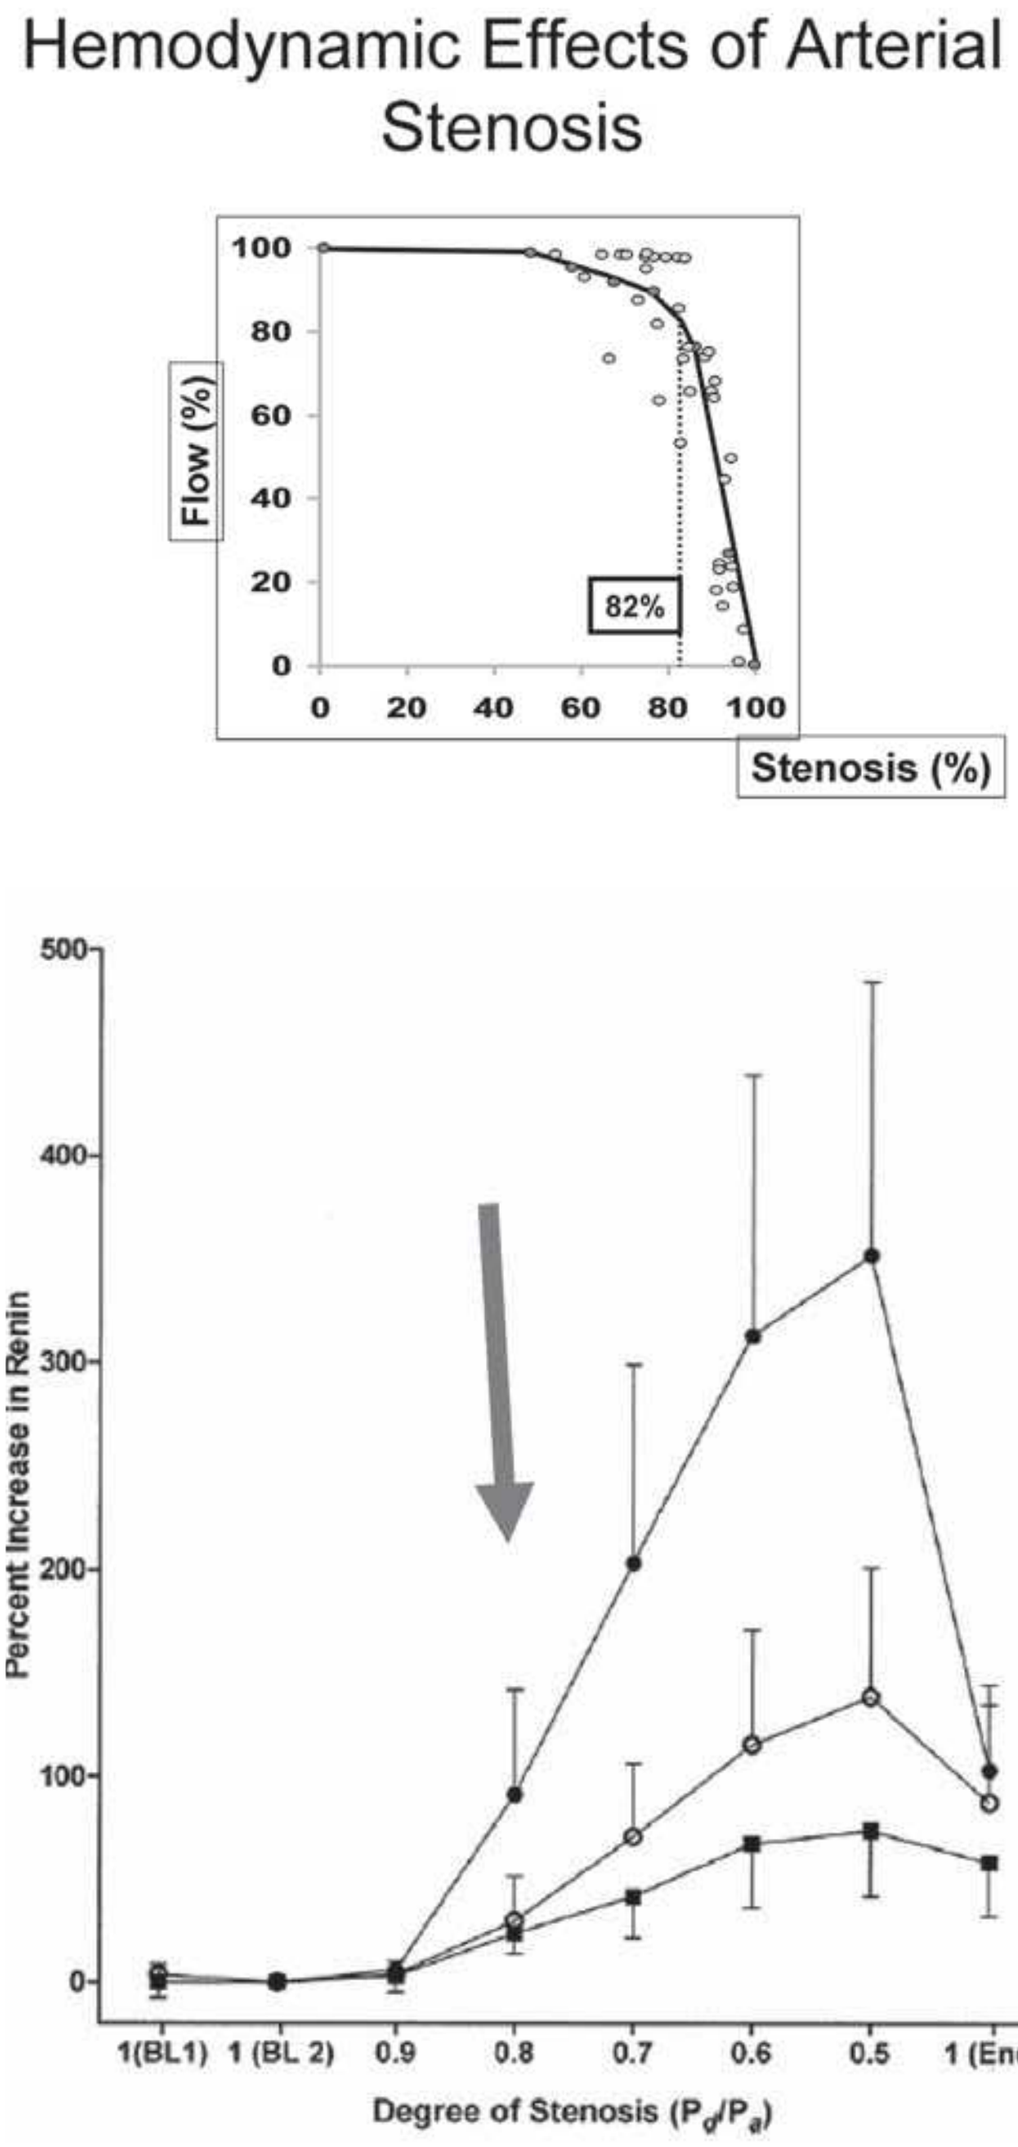

FIGURE 42.7 **A:** Arterial pressure depicted as a function of degree of luminal occlusion. These data highlight the fact that no change in postlesion pressure or flow can be identified until cross-sectional occlusion is severe, usually more than 70% to 80%. These experimental data in dogs are consistent with measurements in human subjects **(B),** wherein renal vein renin release was not detected during balloon occlusion until translesional gradients between the aorta and renal artery of at least 10% to 20% were produced. MAP, mean arterial pressure. (Data from May et al.[229] and De Bruyne et al.[43])

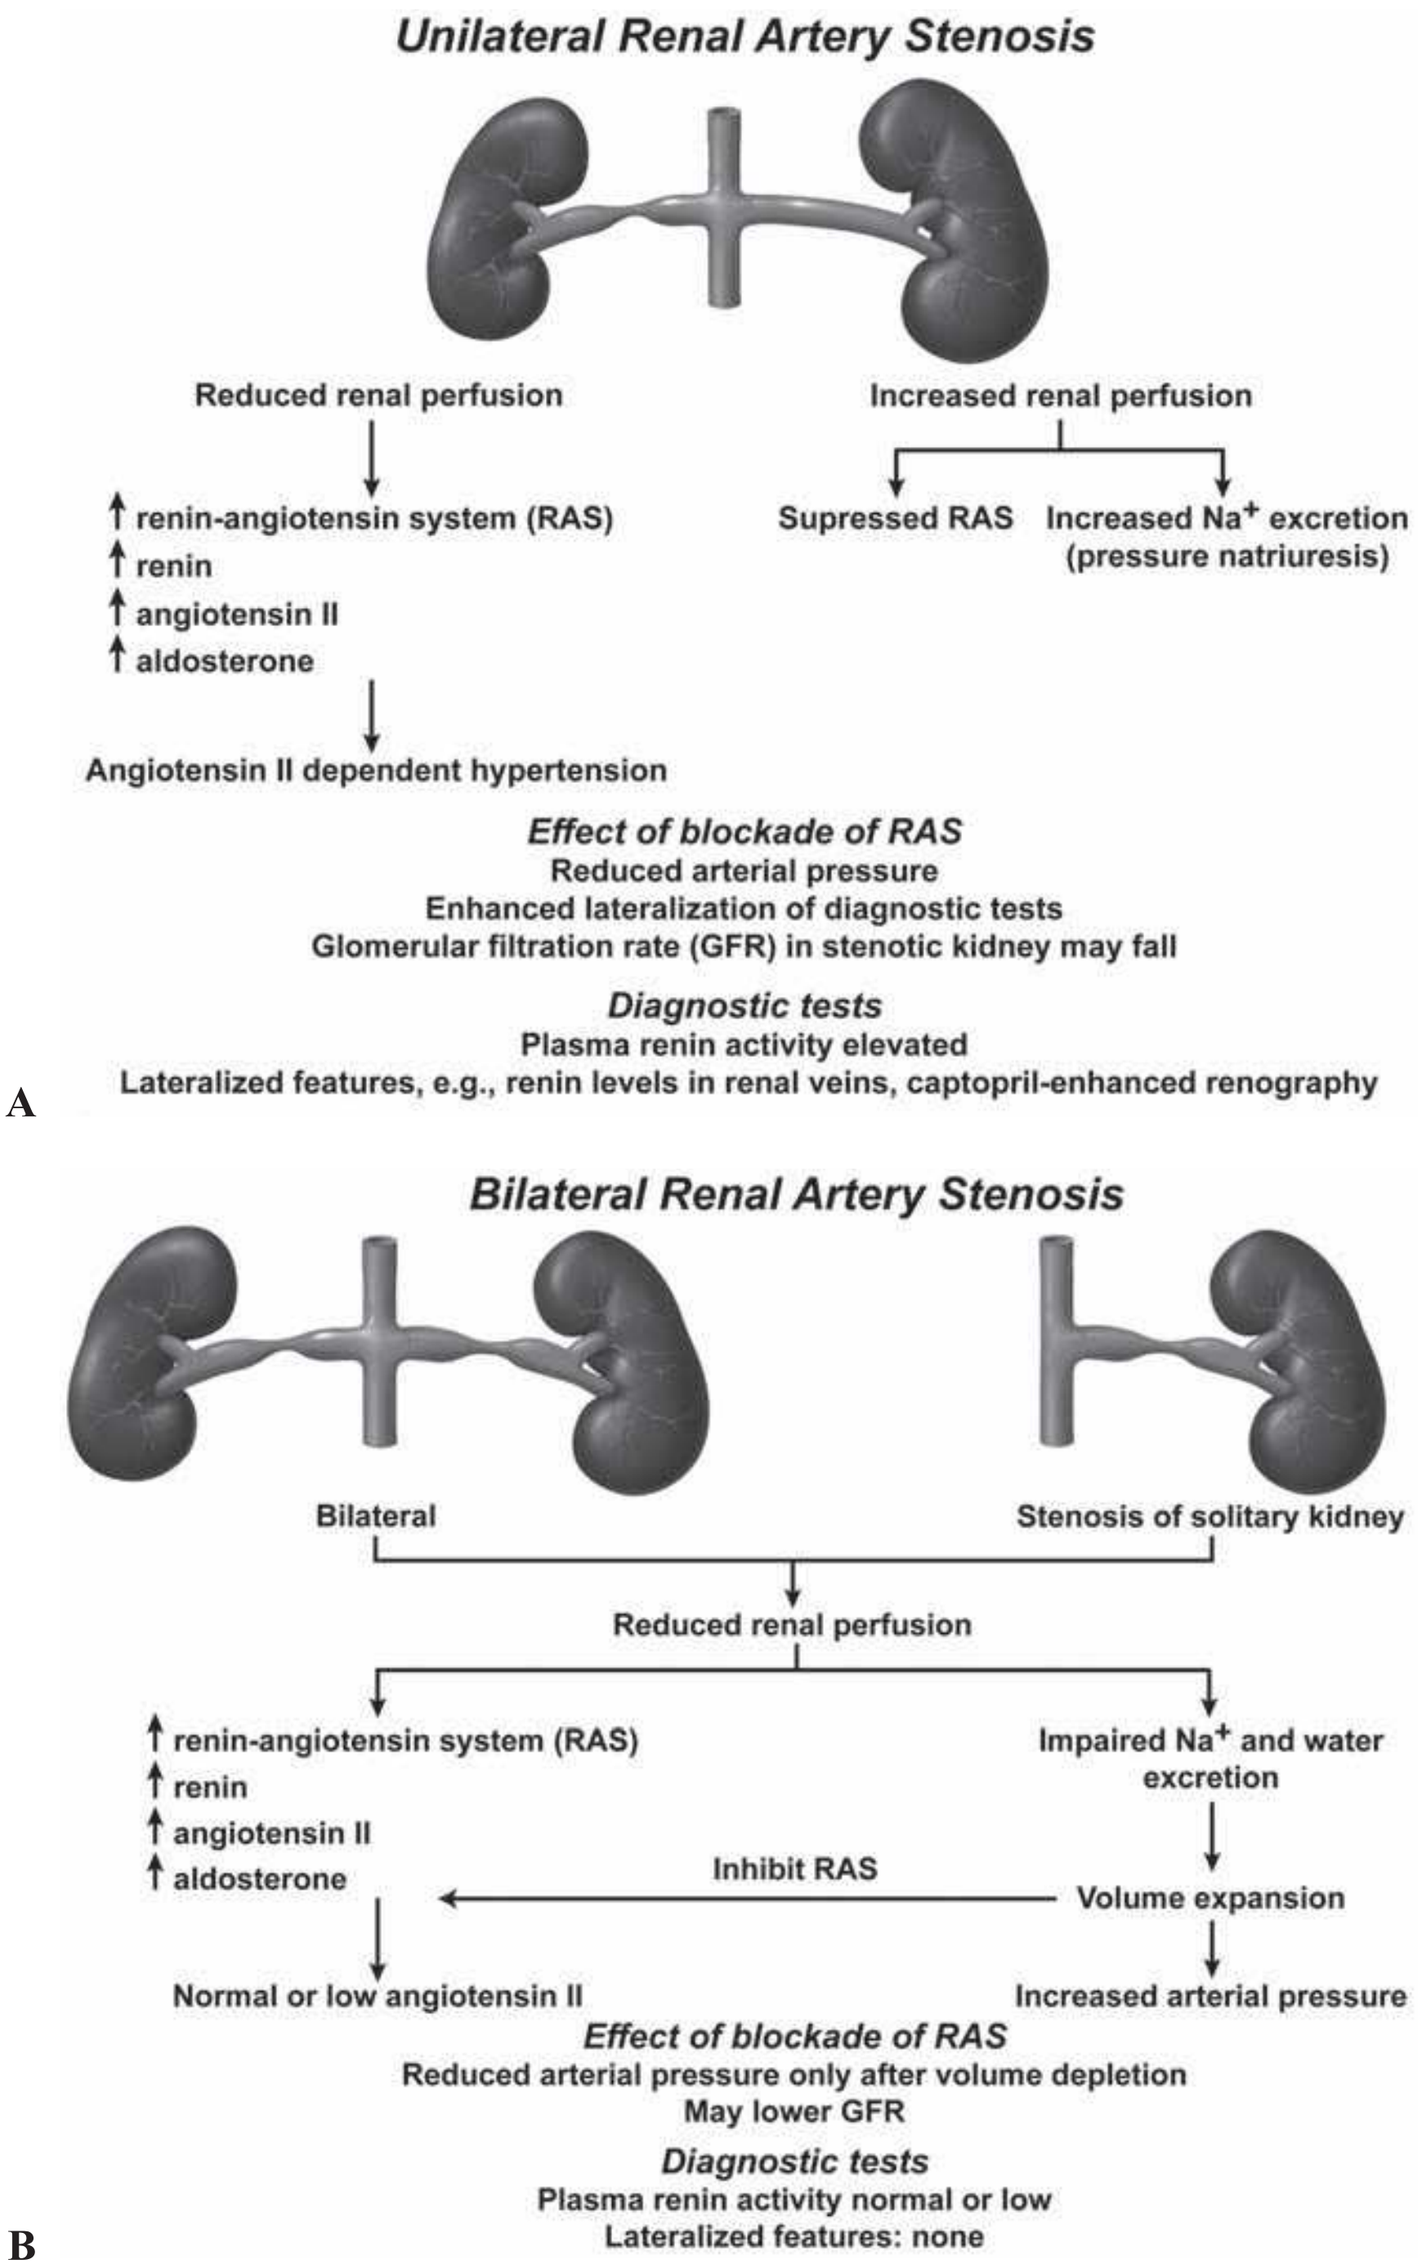

FIGURE 42.8 A: A schematic illustration of hormonal and hemodynamic effects of unilateral renal artery stenosis to produce renovascular hypertension. Unilateral disease is identified as 1-clip-2-kidney Goldblatt hypertension and manifests with the activation of the renin-angiotensin system so long as the contralateral kidney continues to undergo pressure natriuresis (see text). (Adapted from Safian and Textor[91].) Panel **(B)** illustrates the sequence of events with 1-clip-1-kidney Goldblatt hypertension, wherein no normal contralateral kidney is available to excrete sodium and volume in response to rising arterial pressures. In this model, the initial activation of the renin-angiotensin system is temporary due to volume expansion.

beyond a stenosis. There is no normal or nonstenotic kidney to counteract increased systemic pressures. As a result, sodium is retained and the blood volume is expanded, which eventually feeds back to inhibit the renin-angiotensin system (RAS) (Fig. 42.8B). Therefore, 1K-1C hypertension is typically not angiotensin dependent unless the removal of volume is achieved that reduces renal perfusion pressure and again activates the RAAS.

Most renovascular disease in humans is asymmetric and is thought most often to resemble 2K-1C renovascular models. The mechanistic differences between these forms of RVH have clinical implications regarding diagnosis and treatment. Many diagnostic studies classically used to evaluate the functional significance of renal artery lesions depend on comparisons of the different physiologic response of the two kidneys, which may not be evident if both kidneys are affected or if only one kid ney is present. Furthermore, diagnostic tests that depend on differences in responses to alterations in sodium status (such as the measurement of renal vein renin levels after sodium depletion or individual

kidney sodium reabsorption) may be problematic, because high levels of Ang II and aldosterone stimulate sodium reabsorption in both the stenotic and nonstenotic kidney.

The Phases of Renovascular Hypertension

Many of the primary physiologic drivers, such as activation of the RAAS, underlying renovascular hypertension manifest differently at various points in time. These changing manifestations complicate defining primary pathogenic mechanisms and establishing whether renovascular lesions are actually causal in hypertension. Rarely is it known exactly when critical levels of stenosis are attained. In experimental models, these observations have been summarized by separating two-kidney renovascular hypertension into sequential phases.[46] In phase 1, renal ischemia and activation of the RAS are central and the BP elevation is renin dependent. The acute administration of Ang II antagonists or angiotensin-converting enzyme (ACE) inhibitors, removal of the renal artery stenosis (i.e., removal of the clip), or removal of the stenotic kidney normalizes the BP. In the absence of these maneuvers, a transition phase (phase 2) subsequently develops, bridging the acute (phase 1) and chronic (phase 3) phases of experimental renovascular hypertension. This transition phase variably lasts from a few days to several weeks depending on the experimental model and animal species. During this transition phase, plasma renin levels gradually fall, but the BP remains elevated. Salt and water retention are observed as a consequence of the effects of hypoperfusion of the stenotic kidney, augmented proximal renal tubular reabsorption of sodium and water, and secondary aldosteronism.[47,48] In addition, the high levels of Ang II stimulate thirst, further contributing to an expansion of the extracellular fluid volume. The expanded extracellular fluid volume results in suppression of peripheral plasma renin activity (PRA). During this transition phase, the hypertension is still responsive to removal of the unilateral renal artery stenosis, to Ang II blockade, or to unilateral nephrectomy, although these maneuvers do not normalize the BP as promptly and consistently as in the acute phase. These changes may depend on the recruitment of additional mechanisms of Ang II action, including the generation of reactive oxygen species,[49,50] the quenching of nitric oxide,[51] and the generation of endothelium-derived substances such as endothelin[52,53] and thromboxanes.[54] Some of these mechanisms depend on slowly developing effects of Ang II at levels that do not reverse rapidly with direct Ang II blockade.[55] Additional mechanisms recruited over time that sustain BP elevation and induce tissue injury are summarized in Table 42.3.

After several days or weeks, a chronic phase (phase 3) evolves, wherein the removal of the stenosis by unclipping the renal artery in the experimental animal or nephrectomy of the stenotic kidney fails to reduce the BP to baseline levels. The mechanism maintaining elevated arterial pressure—that is, the failure of "unclipping" to lower the BP in this chronic phase of 2K-1C hypertension—is multifactorial but is thought to reflect widespread arteriolar damage in the contralateral kidney consequent to elevated systemic pressure and the initial high levels of Ang II. The BP remains elevated even though the PRA has returned to a normal level. The pressure natriuresis of the contralateral kidney blunts the extracellular fluid volume expansion initially generated by the stenotic kidney (Fig. 42.8A), but because the contralateral kidney suffers vascular damage from prolonged exposure to the increased BP, its excretory function diminishes and

42.3 Interactive Mechanisms Underlying Hypertension and Kidney Injury in Atherosclerotic Renal Artery Stenosis

Tissue Underperfusion	Recurrent Local Ischemia
Activation of the renin-angiotensin system	ATP depletion
Altered endothelial function: (endothelin, NO, prostaglandins)	Tubulointerstitial injury
Sympathoadrenergic activation	Microvascular damage
■ Increased reactive oxygen species	Immune activation
■ Cytokine release/inflammation (NF-κB, TNF, TGF-β, PAI-1, IL-1)	Vascular remodeling
■ Impaired tubular transport functions	Interstitial fibrosis
Apoptosis/necrosis	Activation of the renin-angiotensin aldosterone system
	Sympatho-adrenergic activation
	Endothelin
	Disturbances of "oxidative stress" Oxidized-LDL

NO, nitric oxide; NF-κB, nuclear factor kappa B; TNF, tumor necrosis factor; TGF-β, transforming growth factor-beta; PAI-1,plasminogen activating factor inhibitor; IL-1, interleukin 1; ATP, adenosine triphospate; LDL, low-density lipoprotein. From Textor SC. Atherosclerotic renal artery stenosis: overtreated, but underrated? J Am Soc Nephrol. 2008;19:656–659, with permission.

extracellular fluid volume expansion persists. In phase 3 of 2K-1C hypertension, acute blockade of the RAS fails to lower the BP. Sodium depletion may ameliorate the hypertension, but does not normalize it.

Exactly how and whether this sequence of events applies directly to humans is not known. All of these features obscure the diagnosis of true renovascular hypertension and limit predictability of the BP response to revascularization. Not surprisingly, a documented history of a brief duration of hypertension suggests a more favorable response to revascularization procedures.[56]

There are additional important clinical correlates of this process. First, many of the diagnostic studies that depend on the lateralization of effects have only modest predictive value when results are negative. As a general rule, these tests are most useful when results are positive, meaning that high-grade lateralization of renin release, differences in renal function, and changes in the glomerular filtration rate (GFR) after the administration of an ACE inhibitor most accurately predict improvement after revascularization when results are markedly positive. A negative test result, however, may also be associated with a beneficial outcome. Second, coexistent intrarenal disease, such as arteriolosclerosis with glomerulosclerosis, is usually associated with persistent hypertension despite the correction of renal artery stenosis, particularly for patients with ARAS.[57] In such patients, a long duration of hypertension favors the development of arteriosclerotic lesions and renal injury in the contralateral kidney. Thus, older age and a long duration of hypertension for more than 3 to 5 years predict a poorer clinical BP outcome after renal revascularization. Most older patients with ARAS also have impaired renal function that itself predisposes one to long-term hypertension.[11]

The Pathogenesis of Ischemic Nephropathy

The activation of pressor mechanisms producing RVH often occurs with a minor loss of renal size or function, particularly with fibromuscular disease.[58–60] Conversely, improved BP control after revascularization sometimes may be achieved without an appreciable improvement in kidney function. However, the more common clinical scenario with ARAS involves both increasing severity of hypertension and deteriorating renal function, often with a loss of renal size. Hence, the decision to consider renal revascularization commonly combines consideration of both the likelihood of salvage or the preservation of function, in addition to possible benefits regarding BP control.

Basal energy requirements for the kidney are met with less than 10% of blood flow, consistent with its filtration function. The term ischemic renal disease should be used with caution in this context.[61] Under normal conditions, cortical blood flow provides vastly more oxygenated blood than is needed for tissue metabolism. Postglomerular vasa recta deliver a portion of kidney blood flow to the medulla. The major metabolic workload of the kidney takes place in medullary segments as a function of solute transport, leaving the medulla normally with substantial oxygen desaturation.[62] The balance between regional oxygen saturation within the cortex and the medulla is carefully maintained over a variety of conditions.[63] Remarkably, blood flow to the kidney can be reduced gradually to levels sufficient to reduce kidney volume, activate pressor mechanisms including the RAAS, and lower GFR without measurably disturbing cortical or medullary oxygenation.[64] Lowered GFR is associated with a reduced filtered load of solutes and thereby reduced requirements for solute reabsorption.[63] Venous oxygen levels from poststenotic kidneys therefore can be higher than those from normally functioning kidneys due to reduced metabolic oxygen consumption.[64] Measurements of cortical and medullary deoxyhemoglobin by use of blood oxygen level–dependent magnetic resonance in human subjects confirm that both cortical and medullary oxygen saturation can be well preserved over a wide range of renovascular occlusion.[65] These observations may explain the relative stability of kidney function observed in recent prospective treatment trials for ARAS for many years, despite an obvious reduction in renal blood flow beyond the stenotic lesion.

There are limits to the renal capacity for adaptation, however. When vascular occlusion is sufficiently severe, cortical blood flow and oxygenation falls.[66] This in turn overwhelms the adaptive capacity of the medulla, with expanding hypoxia and activation of fibrogenic and inflammatory pathways.

Mechanisms underlying parenchymal renal damage differ from those responsible for generating hypertension. Remarkably, parenchymal fibrosis rarely develops in patients with fibromuscular disease with the exception of those experiencing renal infarction. This suggests that the activation of remodeling mechanisms in the poststenotic kidney partly is related to the atherosclerotic milieu itself, which produces microvascular proliferation and abnormal endothelial function within the kidneys.[67] Recent experimental studies underscore the development of magnified renal microvascular changes distal to a stenosis in the renal artery in the context of atherosclerosis.[68,69] An example of microvascular proliferation induced by cholesterol feeding (a surrogate for early atherosclerosis) and the subsequent rarefaction of renal small vessels beyond a main renal artery lesion is illustrated in Fig. 42.9. Numerous signaling pathways lead to the upregulation of cytokines and inflammatory mediators, including transforming growth factor (TGF)-β, within the poststenotic kidney.[70,71] Over time, rarefaction of the distal arterioles develops and is associated with fibrogenesis and a loss of viable function.[72,73] The sequence of events underlying the transition from a reversible loss of function beyond a vascular lesion to irreversible tissue fibrosis is not well understood. Atherosclerotic and inflammatory pathways can produce disturbances in endothelial function in small vessels that parallel tissue injury and accelerate cytokine signaling pathways.[74,75] At some phase, microvascular rarefaction occurs that accompanies a fall in tissue oxygenation and activation of fibrogenesis.[75] An irreversible loss of viable

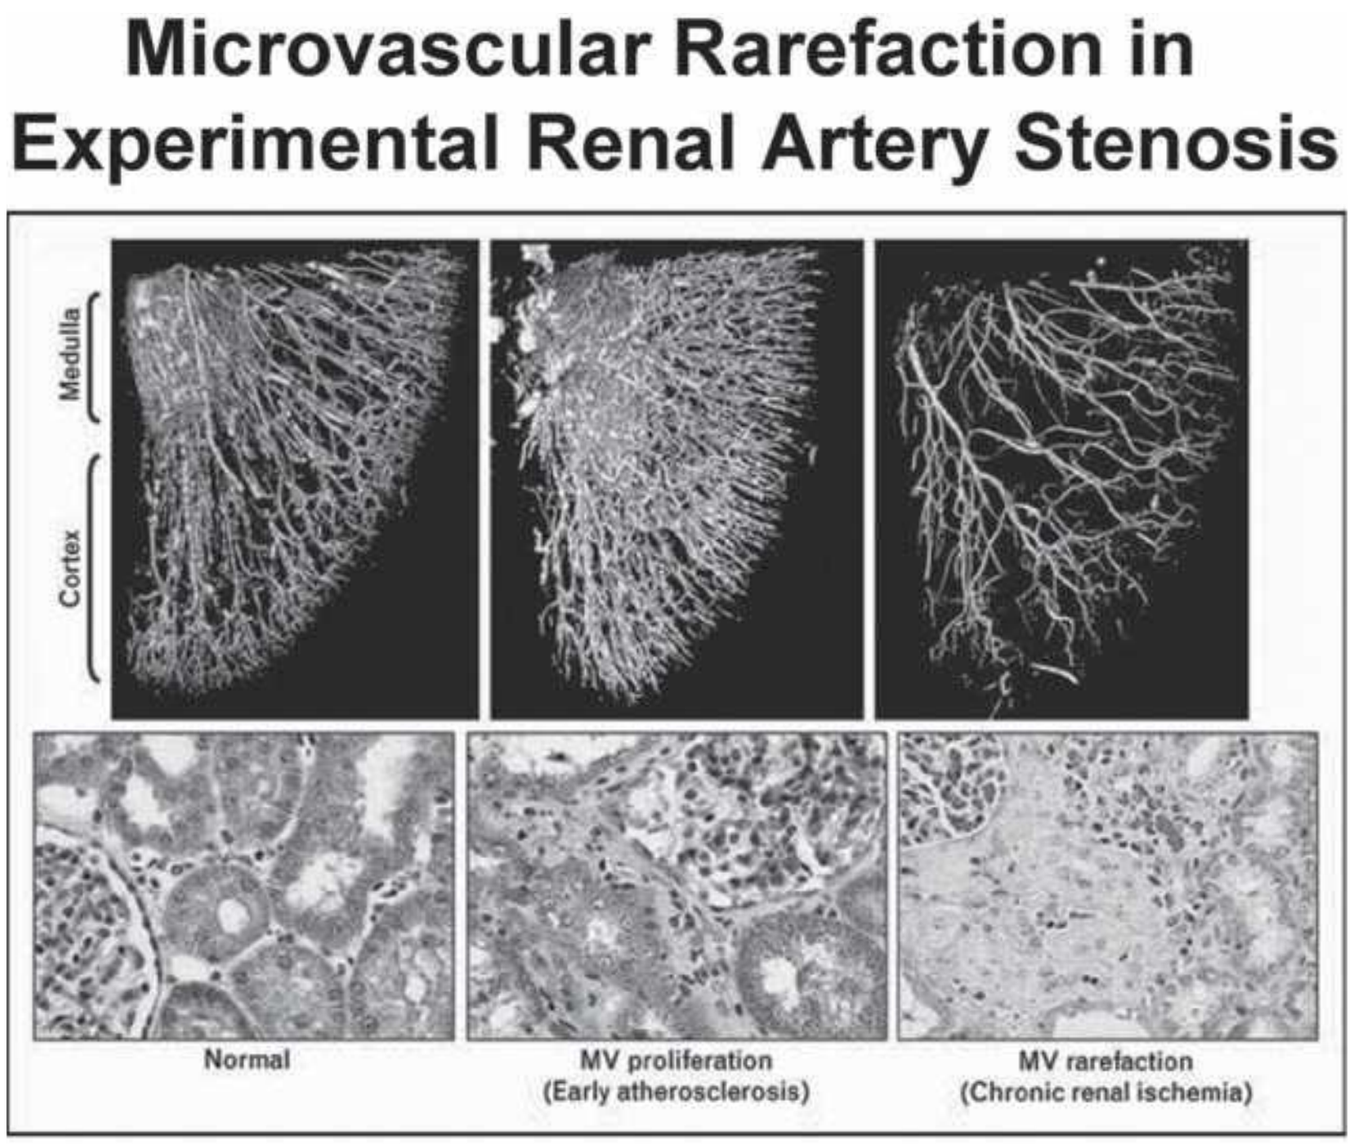

FIGURE 42.9 Reconstructions of the vascular structures using micro-computed tomography (CT) imaging in experimental renal artery stenosis. The atherosclerotic milieu produced by cholesterol feeding leads to microvascular (MV) proliferation and renders the animal especially susceptible to rarefication and obliteration of microvessels in the setting of high-grade renal artery stenosis. These changes eventually lead to interstitial fibrosis and a loss of kidney function. (From Lerman LO, Chade AR. Atherosclerotic process, renovascular disease and outcomes from bench to bedside. *Curr Opin Nephrol Hyper.* 2006;15:583–587, with permission.)

microcirculation may explain some of the limitations observed after the restoration of large-vessel patency (e.g., with renal revascularization). Occasionally, renovascular disease is associated with nephrotic range proteinuria that can regress after renal revascularization.[76] The mechanism of enhanced glomerular permeability in this context is unknown.

Circulatory Congestion and Flash Pulmonary Edema

Among other clinical manifestations, ARAS increasingly has been implicated in episodes of congestive heart failure and has been described as one of the cardiorenal syndromes.[47] Several mechanisms contribute to this disturbance, including (1) Impaired sodium excretion due to reduced renal perfusion pressure and activation of the RAAS that affects both stenotic and contralateral kidneys and (2) sustained, and sometimes rapid, increases in systolic arterial pressure can abruptly add to pressure overload of the left ventricle (Fig. 42.10).[77] Normally, the left ventricle compensates for changes in afterload with increased end-diastolic volume. This mechanism may be impaired, however, in patients with stiffened left ventricles due to left ventricular hypertrophy, precipitating in abrupt rises in end-diastolic pressure, left atrial, and pulmonary venous pressures. It is this abrupt rise in ventricular pressures that leads to sudden decompensation, often termed flash pulmonary edema, that was originally described by Pickering et al.[78] In addition, the activation of sympathetic nervous pathways magnifies these effects and alters the transcapillary capacities for gas exchange. Reports from several case series suggest that renal revascularization can interrupt this cycle and reduce reoccurrences.[79,80] In less dramatic cases, the presence of bilateral ARAS with reduced GFR may limit the effectiveness of diuretics and render congestive heart failure refractory to fluid removal short of external ultrafiltration.

Clinical Features of Renal Artery Stenosis

Renovascular Hypertension

In the 1970s, a cooperative study of RVH compared clinical characteristics of patients with surgically proven RVH with those of patients with primary hypertension. In this study, the average age of onset for fibrous renal artery disease as the cause of renovascular hypertension was 33 years, and 16% of these patients were younger than 20 years. For atherosclerotic renal artery disease as the cause of renovascular hypertension, the average age at onset was 46 years, and 39% of these patients were older than 50 years.[81] For these reasons, many argue that the clearly defined onset of hypertension below the age of 30 or above the age of 55 warrants the consideration of renovascular hypertension. Some features, such as the presence of an abdominal bruit, hypokalemia, and the absence of a family history of hypertension, were statistically more prevalent in RVH, but had little clinical predictive value. Recent studies suggest that for any level of office BP, patients with RVH may have higher nocturnal pressures and therefore higher overall pressure load as "non-dippers."[82] As a result, target organ manifestations are more severe, including left ventricular hypertrophy (Fig. 42.11). A series of patients with treatment-resistant hypertension indicate that elevated cholesterol, impaired renal function, lower body mass index (BMI), and smoking provide positive clues. In practical terms, none of these features is sufficiently sensitive or specific to offer diagnostic precision. As noted previously, RVH rarely may be associated with nephrotic-range

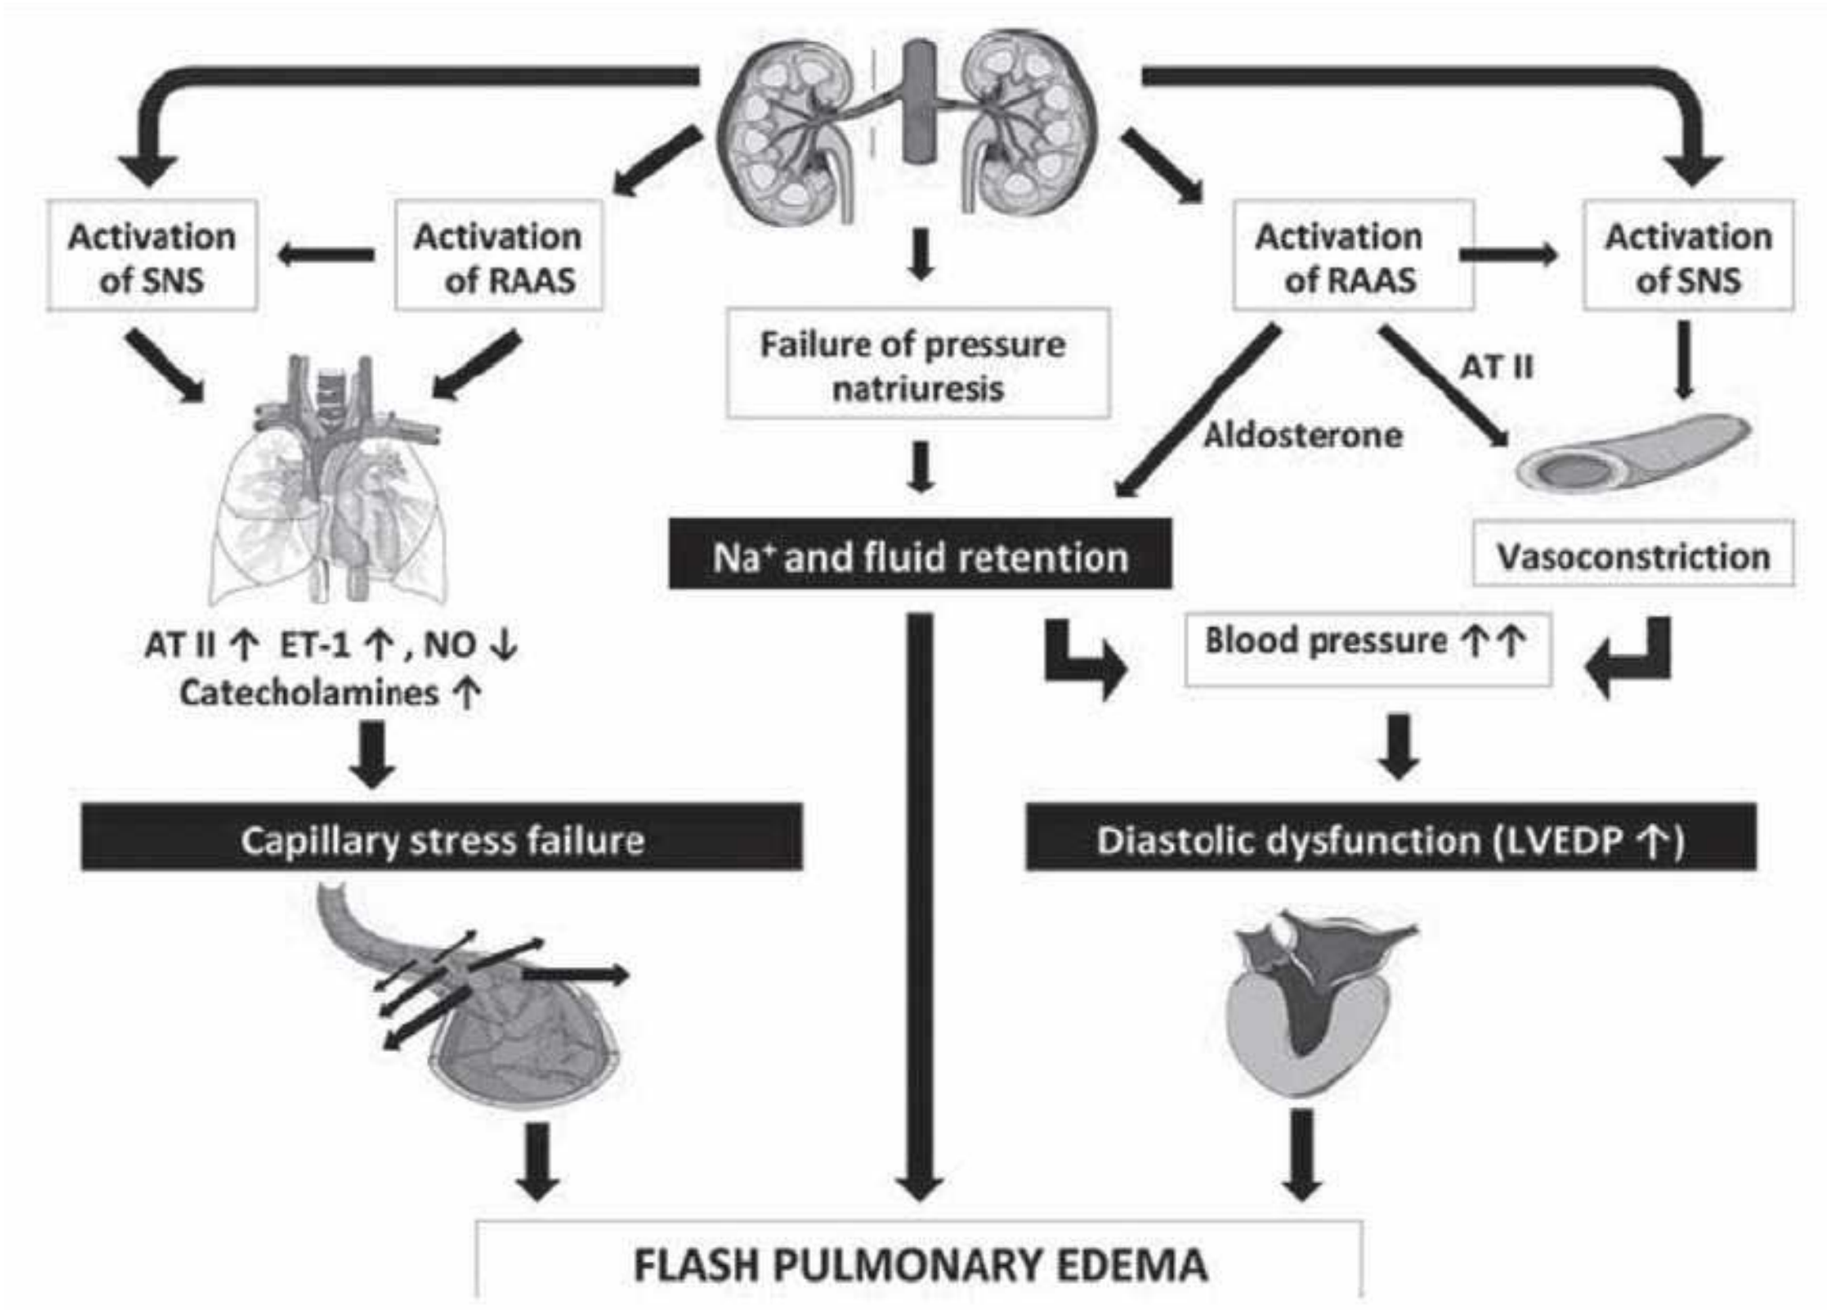

FIGURE 42.10 A schematic depicting the interplay of mechanisms leading to rapidly developing symptoms of left ventricular heart failure sometimes observed with renal artery stenosis. These include impaired volume excretion with bilateral atherosclerotic renal artery stenosis (ARAS), a rise in afterload and impaired left ventricular pump function, as well as disturbed capillary function within the pulmonary vasculature in part related to the activation of neurogenic and hormonal pathways. *SNS,* sympathetic nervous system; *RAAS*, renin-angiotensin-aldosterone system; *ATII*, angiotensin II; *ET-1*, endothelin 1; *NO*, nitric oxide; *LVEDP*, left ventricular end-diastolic pressure. (From Messerli FH, Bangalore S, Makani H, et al. Flash pulmonary oedema and bilateral renal artery stenosis: the Pickering syndrome. *Eur Heart J.* 2011;32(18):2231–2237, with permission.)

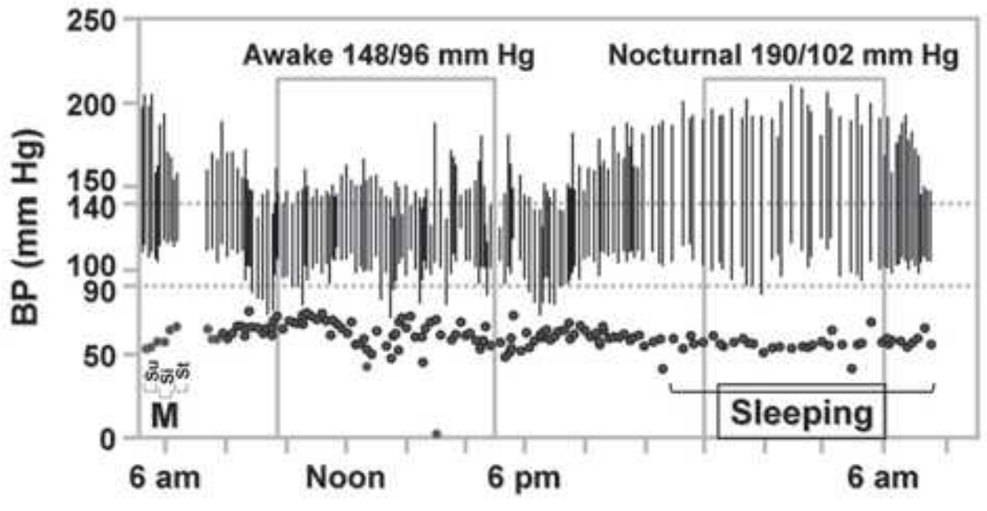

FIGURE 42.11 Ambulatory blood pressure (BP) monitoring in patients with renovascular hypertension commonly reveals a loss of nocturnal pressure fall, or in some cases, a complete reversal of the day–night pattern as shown here. This may be one of the features by which target-organ injury such as left ventricular hypertrophy is exaggerated as compared to patients with similar daytime blood pressure levels.[232]

proteinuria, which can regress with the correction of the vascular lesions.

BP elevations from RVH vary widely, often as a function of the rapidity of onset. Acute renal artery occlusion may only gradually produce an increase in pressure or it may produce a rapid increase in hypertension that may precipitate a hypertensive urgency or emergency. Before the current era of antihypertensive agents, 30% of Caucasian patients appearing in an emergency department with hypertensive urgency (defined as grade 3 or 4 hypertensive retinopathy) were ultimately found to have RVH. Hence, patients presenting with accelerated forms of hypertension should be considered candidates for renovascular hypertension (Table 42.4). Syndromes of polydipsia and accelerated hypertension with hyponatremia and hypokalemia, sometimes attributed to the dipsogenic actions of Ang II, also have been observed. Current antihypertensive medications have changed the clinical presentation of RVH, thus making them less severe.

Recent consensus documents regarding hypertension emphasize the need for effective populationwide BP control while limiting the number and expense of diagnostic studies.

42.4 Clinical Features Suggestive of Renovascular Disease

Clinical Clues

- Age at onset of hypertension (< 30 or > 55 years)
- Abrupt onset of hypertension
- Acceleration of previously well-controlled hypertension
- Hypertension refractory to an appropriate three-drug regimen
- Accelerated retinopathy
- Malignant hypertension/occasionally with hyponatremia
- Systolic–diastolic abdominal bruit
- Flash pulmonary edema
- Evidence of generalized atherosclerosis obliterans
- Acute renal failure with angiotensin-converting enzyme (ACE) inhibitor treatment

Laboratory Features of Renovascular Hypertension

- Early activation of renin-angiotensin-aldosterone system (RAAS)
- Paroxysmal symptoms: sympathetic nervous system activation
- Abnormal circadian rhythm: loss of nocturnal pressure fall
- Accelerated target organ damage
  - Left ventricular hypertrophy
  - Microvascular disease
  - Renal injury: fibrosis

Modified from Textor SC, Greco BA. Renovascular hypertension and ischemic renal disease. In: Floege J, Johnson RJ, eds. Comprehensive Clinical Nephrology. St. Louis, MO: Saunders/Elsevier; 2010: 451–468, with permission.

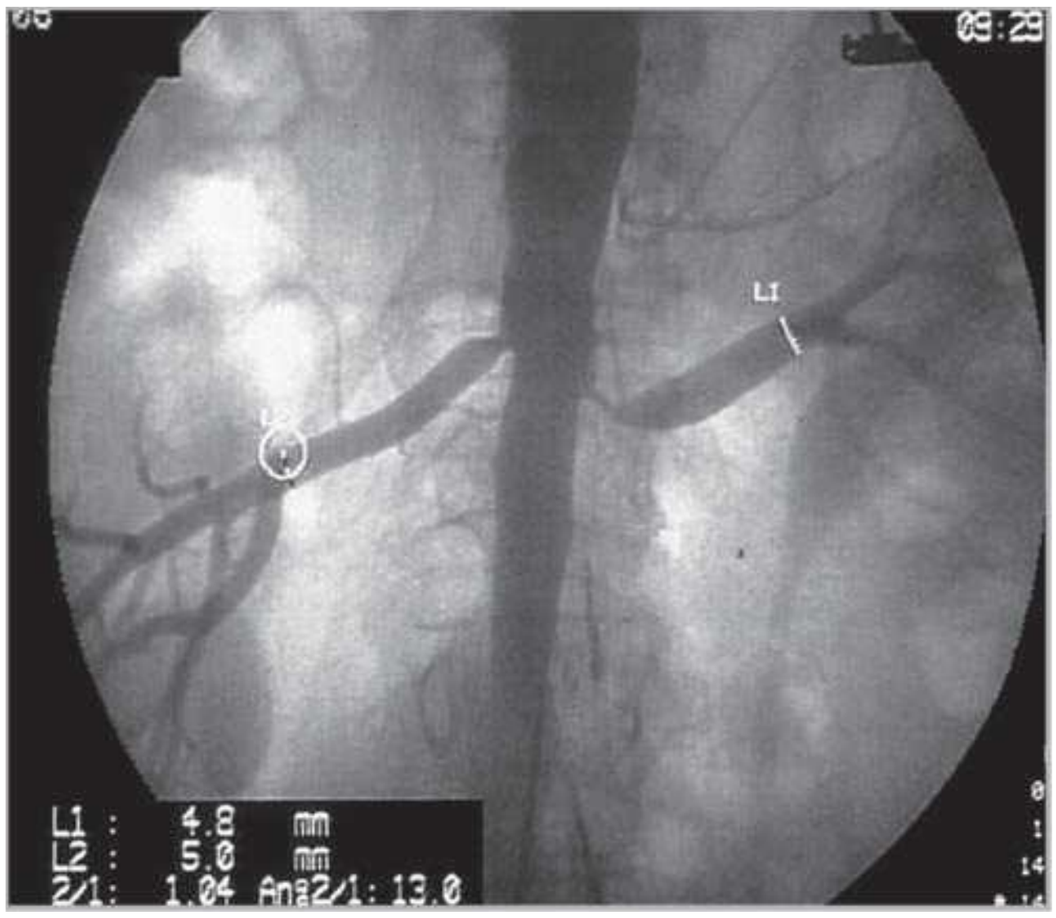

FIGURE 42.12 An aortogram revealing bilateral renal arterial disease performed during a coronary angiography. This individual was treated with antihypertensive drug therapy with excellent blood pressure (BP) control and normal kidney function and was identified only because imaging was included with coronary studies. Numerous series indicate that many such patients are otherwise never identified, but can be managed with medical therapy only. The number that progress to more advanced disease and/or loss of kidney function with current medical therapy may be less than 10% (see text).

When combined with the ambiguous results of prospective treatment trials in which medically treated individuals with ARAS fared as well as those treated with renal revascularization, some would argue that there is little evidence to support extensive diagnostic studies to identify all cases of renovascular hypertension. As a result, most patients with hypertension simply are treated and subjected to few laboratory investigations. For those who reach acceptable BP control without adverse effects, no further studies are performed. Hence, many if not most cases of true RVH are not detected (Fig. 42.12) unless hypertension becomes more difficult to treat or if renal dysfunction ensues. One important reason that RVH is less frequently detected is the availability of orally active antihypertensive agents that block the RAAS. Early studies beginning with captopril indicated that satisfactory BP control can be achieved in more than 86% of patients with RVH compared with less than 50% with previously available drugs. In recent years, the widespread application of ACE inhibitors and angiotensin receptor blockers (ARBs) for indications other than hypertension (e.g., congestive cardiac failure, diabetic nephropathy, and other proteinuric renal disease) increases the exposure of individuals with undetected renal artery stenosis to these drugs.

One result of these changes has been the emergence of distinctive clinical syndromes that merit a further evaluation in patients at risk for ARAS. These are summarized in Figure 42.1. As a result, patients who typically undergo a diagnostic evaluation and renal revascularization are a subset of the population of patients with RVH.

Deterioration of Renal Function During Antihypertensive Drug Therapy

The availability of effective and tolerable drugs for hypertension has meant that many patients are primarily treated with medical management (see the following). Because some patients with renovascular disease are functioning near the lower end of autoregulation, further pressure reduction may curtail blood flow further. Some authors argue that a rise in serum creatinine more than 30% above pretreatment levels should prompt the exclusion of large vessel ARAS.[83] The rapid deterioration of renal function following BP reduction with conventional antihypertensive agents or particularly following BP reduction with ACE inhibitors suggests the

presence of bilateral renal artery stenosis, or stenosis in a solitary functioning kidney.[84–88] In one series, more than half of patients demonstrating an acute elevation in the plasma creatinine concentration that was either unexplained or occurred shortly after the institution of therapy with an ACE inhibitor had main renal artery disease, whereas the remainder presumably had a disease of the intrarenal vessels due to nephrosclerosis.[88] Remarkably, most patients with renal artery stenosis tolerate ACE inhibition or ARB Rx with few adverse effects.[89]

Diagnostic Testing for Renovascular Hypertension and Ischemic Nephropathy

Goals of Evaluation

Given the array of diagnostic studies available and the need to focus the evaluation on patients most likely to benefit, it behooves clinicians to consider carefully the objectives of initiating expensive and sometimes ambiguous studies beforehand. As with all tests, the reliability and value of diagnostic studies depend heavily on the pretest probability of disease.[90] Furthermore, it is helpful to consider from the outset exactly what objective is to be achieved. Is the major goal to exclude high-grade renal artery disease? Is it to exclude bilateral (as opposed to unilateral) disease? Is it to identify stenosis and estimate the potential for clinical benefit from renal revascularization? Is it to evaluate the role of renovascular disease in explaining deteriorating renal function? The specific diagnostic studies may differ depending on which of these is the predominant clinical objective (Table 42.5).

Noninvasive diagnostic tests for renovascular hypertension and ischemic nephropathy remain imperfect. For the purposes of this discussion, diagnostic tests fall into the following general categories (Table 42.6): (1) physiologic and functional studies to evaluate the role of stenotic lesions particularly related to activation of the RAS, (2) perfusion and imaging studies to identify the presence and degree of vascular stenosis, and (3) studies to predict the likelihood of benefit from invasive maneuvers, including renal revascularization.

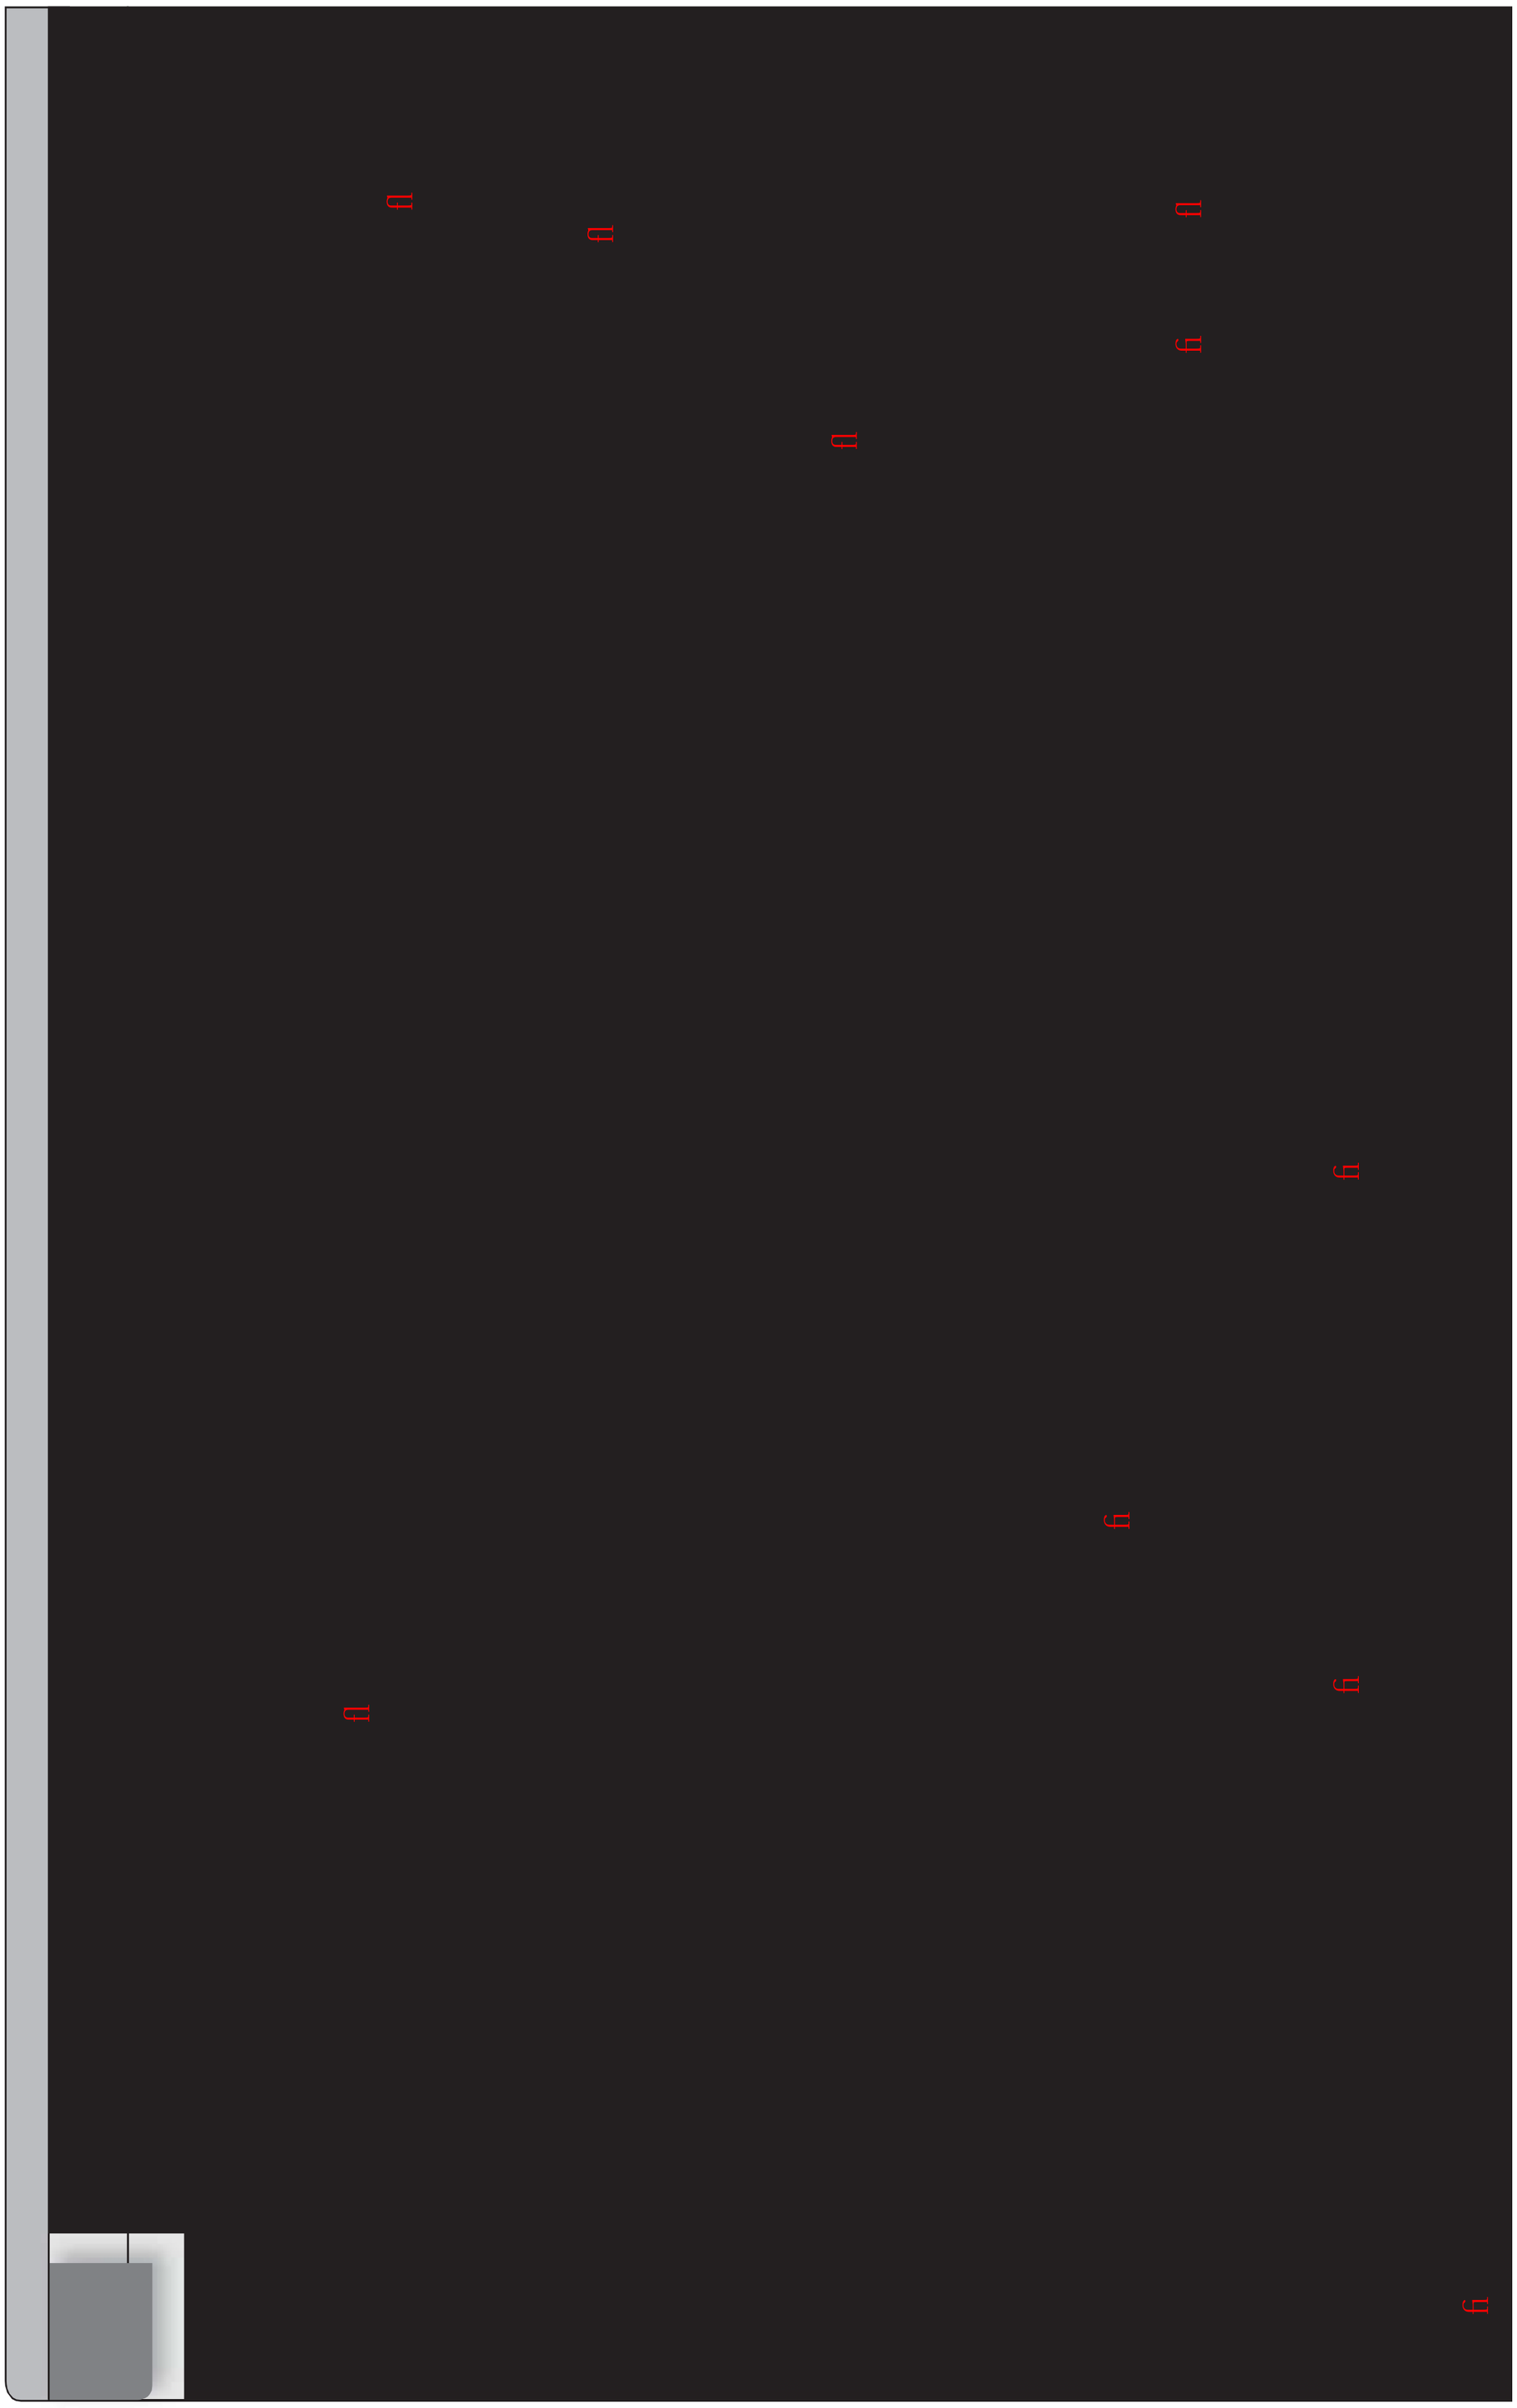
Physiologic and Functional Studies of the Renin-Angiotensin System

Efforts have been made for many years to link the measurement of activation of the RAS as a marker of underlying renovascular hypertension. Although these studies are promising when studied in patients with known renovascular hypertension, they have lower performance results as diagnostic tests when applied to wider populations, as we and others have reviewed.[91–93] PRA is modified by changes of sodium intake, volume status, renal function, and many medications. The sensitivity and specificity of measuring PRA are heavily dependent upon the a priori probability of renovascular hypertension. Although unilateral hypersecretion of renin is an expected finding in hemodynamically significant renal artery stenosis when renovascular hypertension is eventually proved, baseline PRA is elevated in only 50% of patients with renovascular hypertension.[92] Tabulation of the number of patients whose hypertension was cured or improved by surgical renal revascularization indicates that probably no more than 50% of patients with renovascular hypertension have elevated PRA.[94,95] In practice, the major utility of these studies often depends on their negative predictive value, specifically the certainty with which one can exclude significant renovascular disease if the test is negative. Because negative predictive value rarely exceeds 60% to 70%, these tests offer limited value in clinical decision making.

There are several reasons for the relatively low specificity and sensitivity of peripheral PRA in the diagnosis of renovascular hypertension. Most high-renin hypertension is not renovascular in origin; increased renin substrate can

42.5 Goals of Diagnostic and Therapeutic Intervention in Renovascular Hypertension and Ischemic Nephropathy

Goals of Diagnostic Evaluation
Establish presence of renal artery stenosis: location and type of lesion Establish whether unilateral or bilateral stenosis (or stenosis to a solitary kidney) is present Establish presence and function of stenotic and nonstenotic kidneys Establish hemodynamic severity of renal arterial disease Plan vascular intervention: degree and location of atherosclerotic disease
Goals of Therapy
I. Improved Blood Pressure Control Prevent morbidity and mortality of high blood pressure Improve blood pressure control and reduce medication requirement
II. Preservation of Renal Function Reduce risk of renal adverse perfusion from use of antihypertensive agents Reduce episodes of circulatory congestion ("flash" pulmonary edema) Reduce risk of progressive vascular occlusion causing loss of renal function: "preservation of renal function" Salvage renal function (i.e., recover glomerular filtration rate)



be due to estrogen intake, pregnancy, cortisol excess, intrarenal microvascular ischemia (parenchymal disease), or accelerated or malignant hypertension, and the 15% to 20% of patients with primary (essential) hypertension and high renin levels constitute the majority of high-renin hypertensives. Renin secretion fluctuates widely and is influenced by sodium intake, posture and sympathetic tone,[96] a variety of drugs, age, sex, and race.[97] The utility of peripheral PRA is reportedly enhanced when measured in the morning with the patient in the seated position and when indexed against urinary sodium excretion; when measured under these exacting circumstances, a high peripheral PRA is found in 75% to 80% of patients with proven renovascular hypertension.[98] Other investigators, measuring peripheral PRA under similar circumstances, failed to demonstrate significantly increased sensitivity of the peripheral PRA in predicting either the presence of ARAS and the response to therapy.[92,99,100]

The measurement of renal vein renin levels is a means to determine the role of a specific pressor kidney and has been widely applied in planning surgical revascularization for hypertension. Because surgical revascularization entails greater risks than those associated with current endovascular procedures, a substantial effort in the 1970s was directed to identify patients most likely to benefit.[101] These measurements are obtained by sampling renal vein blood and inferior vena cava blood individually. The level of the inferior vena cava is comparable to the arterial levels into each kidney and allows for the estimation of the contribution of each kidney to total circulating levels of plasma renin activity. Lateralization is defined usually as a ratio exceeding 1.5 to 2.0 between the renin activity of the stenotic kidney and the nonstenotic kidney. Some authors propose a detailed examination not only of the relative ratio between kidneys, but also the degree of suppression of renin release from the nonstenotic or contralateral kidney.[101] In general, the greater the degree of lateralization, the more probable that clinical BP reductions would follow after surgical revascularization. Results from many studies support the observation that large differences between kidneys identify high-grade renal artery stenosis. In 1976, Marks et al.[102] reviewed 21 published series encompassing 468 patients with unilateral renovascular disease who had been subjected to a broad spectrum of renin-stimulating maneuvers (e.g., sodium depletion, upright posture). They concluded that a lateralizing renal vein renin ratio predicted surgical cure or substantial improvement in the BP in 93% of patients. Remarkably, 57% of patients with a nonlateralizing renal vein renin ratio (less than 1.5 ipsilateral to contralateral) also benefited from surgery.[102] This later expanded to a review of 58 studies that suggested a ratio of 1.5 or more (stenotic kidney to contralateral kidney) as the diagnostic criterion predicting renovascular hypertension had a sensitivity of 80% and a specificity of 62%.[103] These observations have been extended recently through studies of renal vein measurements prior to considering a nephrectomy for refractory hypertension and advanced renovascular occlusive disease.[104] As with many tests of hormonal activation, study conditions are crucial and can change the interpretation of these tests. Strong and colleagues[105] demonstrated that nonlateralization can be changed to strongly lateralizing measurements by the administration of diuretics between sequential studies. A number of measures to enhance renin release and magnify differences between kidneys have been proposed, including sodium depletion with diuretic administration, hydralazine, tilt-table stimulation, or captopril.[106,107] Volume expansion with intravenous saline poses particular limitations due to the near universal application of this maneuver to limit nephrotoxicity associated with contrast imaging, which is usually performed with renal vein sampling.[108] Because of this variability with different testing conditions, recent series[109,110] concluded that the overall sensitivity of renal vein renin measurements was no better than 65% and that positive predictive value was 18.5%. For these and other reasons, renal vein assays are performed less commonly than before. A major additional factor is that the goals of renal revascularization have shifted substantially and are often directed toward the preservation of renal function, rather than BP control, per se. Nonetheless, the sum of cumulative data regarding renal vein renin determinations indicate that the renal vein renin ratio has a strong positive predictive value in forecasting favorable blood pressure responses to renal revascularization. On the other hand, many patients (at least 50%) demonstrating a nonlateralizing renal vein renin ratio have a marked improvement or cure of their hypertension following an intervention for the renal artery stenosis.

Many more patients are seen with bilateral renal arterial lesions in which both are suspected of participating in a loss of renal function. The most marked asymmetry is seen in patients who have complete occlusion of one renal artery, wherein renal vein renin levels from the side of the occluded artery may represent a combination of low flow through the kidney in addition to hypersecretion of renin.[111] In cases for which it is important to establish the degree of pressor effect of a specific kidney or site, such as before considering a nephrectomy of a pressor kidney, measurement of renal vein renin levels can provide strong supportive evidence. It may be argued that recent trials that suggest limited benefits from renal revascularization may prompt more extensive testing, including formal measurements of individual renin secretion before moving to interventional procedures.

Studies of Individual Renal Function

Serum creatinine, iothalamate clearance, and other estimates of total GFR are measures of overall renal excretory function and do not address differences between separate kidneys. A large body of literature addresses the potential for individual split renal function studies to establish the functional importance of each kidney in renovascular disease.

Split renal function studies classically utilized separate ureteral catheters to allow individual urine collection for the measurement of separate GFR, renal blood flow, sodium excretion, concentrating ability, and the response to blockade of

Ang II.[112] These studies demonstrate that the hemodynamic effects of renal artery lesions in fact do translate into functional changes, such as avid sodium retention, before major changes in blood flow occur. They emphasize that the autoregulation of blood flow and GFR can occur over a wide range of pressures in humans and may be affected in both stenotic and contralateral kidneys by the effects of Ang II. These studies require urinary tract instrumentation and provide only indirect information regarding the probability of benefit from revascularization. They are now rarely performed.

Separate renal functional measurements can be obtained less invasively with radionuclide techniques. These methods use a variety of radioisotopes (e.g., 99mTc-mercaptoacetyltriglycine [99mTc-MAG3] or 99Tc-diethlyene triamine penta-acetic acid [DTPA]) to estimate fractional blood flow and filtration to each kidney. The administration of captopril beforehand magnifies differences between kidneys, primarily by delaying excretion of the filtered isotope due to the removal of the efferent arteriolar effects of Ang II. Some authors advocate such measurements to follow progressive renal artery disease and its effect on unilateral kidney function as a guide to consider revascularization.[113] Serial measurements of individual renal function by radionuclide studies may allow a more precise identification of progressive ischemic injury to the affected kidney in unilateral renal artery disease than can be determined from the overall GFR. Recent studies indicate that single kidney GFR measurements by this method accurately reflect changes in three-dimensional volume parameters measured by magnetic resonance imaging (MRI).[114] These authors argue that demonstrating well-preserved parenchymal volume with a disproportionate reduction in single kidney GFR supports the concept of "hibernating" kidney parenchyma and might provide a predictive parameter for the recovery of kidney function after revascularization.[114]

Imaging of the Renal Vasculature

Advances in Doppler ultrasound, radionuclide imaging, magnetic resonance arteriography (MRA), and computed tomography (CT) angiography continue to improve the field of renovascular imaging. The details of these methods are beyond the scope of this discussion. They are addressed more fully elsewhere. What follows is a discussion of some of the specific merits and limitations of each modality as they apply to renovascular hypertension and ischemic nephropathy.[90]

Current practice favors limiting invasive arteriography to the occasion of endovascular intervention (e.g., stenting and/or angioplasty). Although for many, angiography remains the gold standard for evaluating the renal vasculature, its invasive nature, potential hazards, and cost make it most suitable for those in whom intervention is planned, often during the same procedure. As a result, most clinicians favor preliminary noninvasive studies. When noninvasive studies are equivocal, arterial angiography may be warranted to establish the presence of transstenotic pressure gradients, as recommended for treatment trials.[115,116]

Noninvasive Imaging

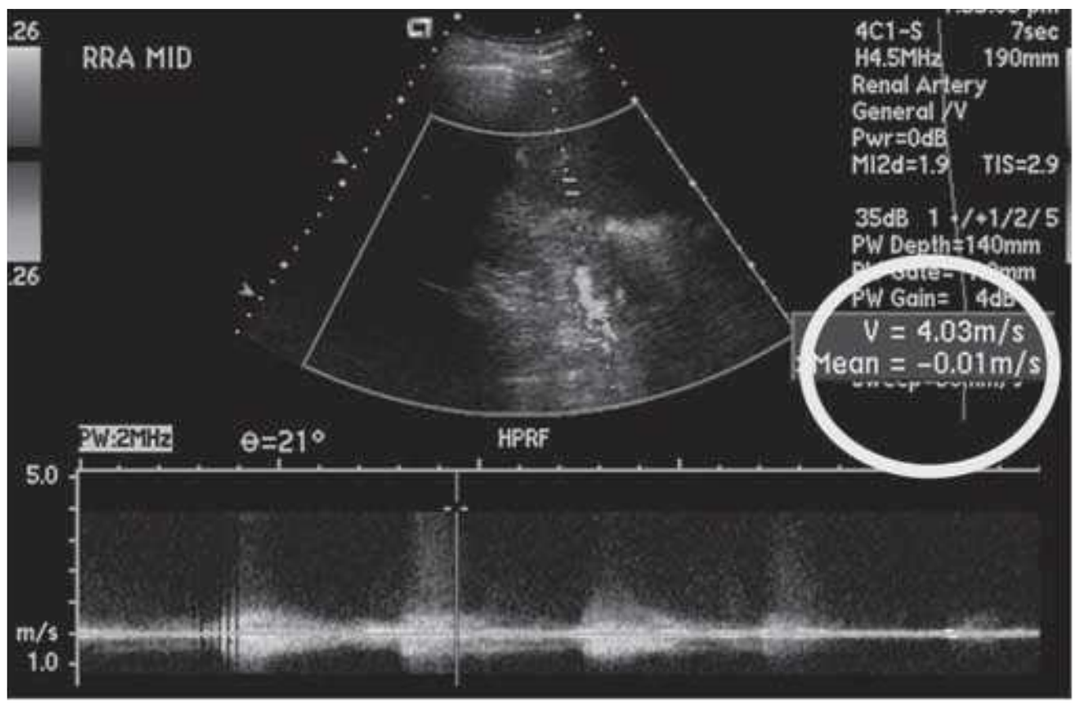
Doppler Ultrasound of the Renal Arteries

Duplex interrogation of the renal arteries provides measurements of localized velocities of blood flow. This technique is available in most institutions and provides an inexpensive means for measuring vascular occlusive disease at sequential time points, both to establish the diagnosis of renal artery stenosis and to monitor its progression. After renal revascularization, Doppler studies are commonly used to detect restenosis and target vessel patency (Fig. 42.13A, B).[117,118] Its main drawbacks relate to the technical difficulties of obtaining adequate studies in obese patients and in those with complex vessels. The usefulness and reliability of Doppler ultrasound depend partly on the specific operator and the time allotted for optimal studies. These factors vary considerably between institutions. In our experience, results are most useful when positive (i.e., when a high grade renal artery velocity can be documented). Failure to identify a velocity increase (i.e., a negative duplex study) sometimes reflects an incomplete localization of the renal vessels.

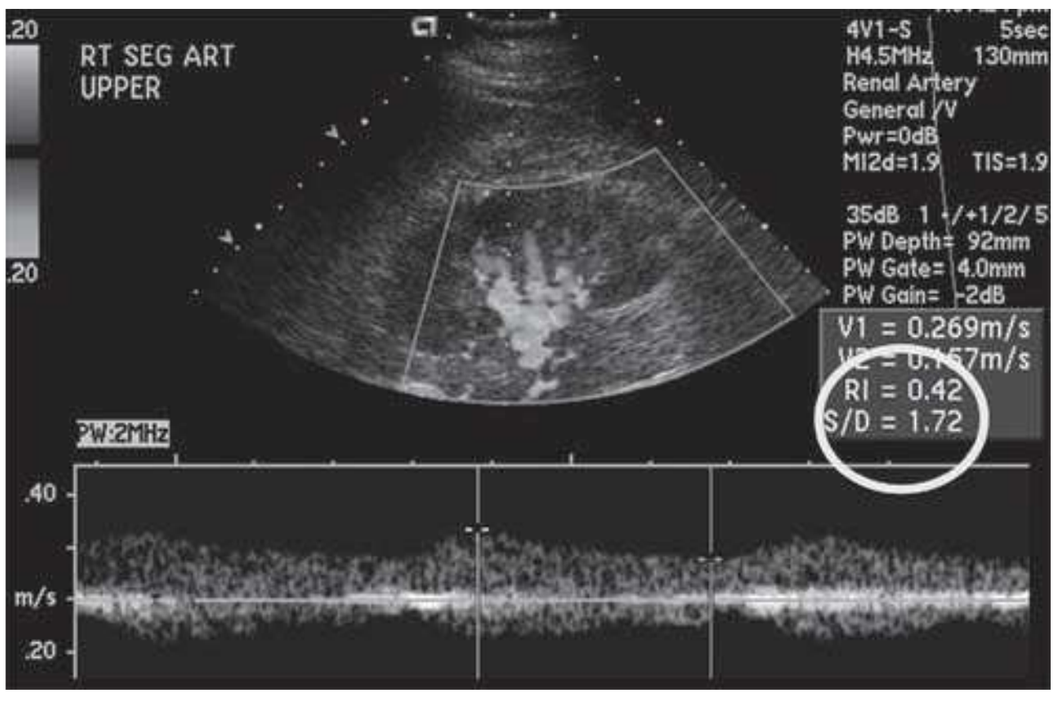
Traditional primary thresholds for renal artery studies are a peak systolic velocity above 180 cm per second and/or a relative velocity above 3.5 as compared to the adjacent aortic flow.[119] Using these criteria, sensitivity and specificity with angiographic estimates of lesions exceeding 60% can surpass 90% and 96%, respectively, although not universally.[120] Increasing the threshold for peak systolic velocities reduces the rate of false positive estimates of stenosis. When main vessel velocities cannot be determined reliably, segmental waveforms within the arcuate vessels in the renal hilum can provide additional information. Damping of these waveforms, labeled as parvus and tardus, have been proposed as indirect signs of upstream vascular occlusive phenomena.[121] Recent studies challenge the use of angiographic estimates of stenosis as representing a gold standard altogether.[122] These authors argue that Doppler velocities correlate highly ($R = 0.97$) with a truer estimate of vascular occlusion, specifically stenosis, as determined by intravascular ultrasound.

Positive Doppler velocities in an artery clearly identified as the renal artery are rarely proven to be negative later. False negative studies are more common. In subjects with accessible vessels, Doppler ultrasound provides the most practical means of following vessel characteristics sequentially over time. A drawback of renal artery Doppler studies includes frequent failure to identify accessory vessels. Because the correlation between velocity and the degree of stenosis is only approximate, clinical trials such as Cardiovascular Outcomes for Renal Atherosclerotic Lesions (CORAL) have raised the diagnostic threshold for peak systolic velocity to 300 cm per second. This seems warranted, particularly when the risk of overdiagnosis of renal arterial lesions is high, as in the Stenting for Atherosclerotic Renal artery stenosis (STAR) trial, in which 18 out of 64 patients assigned to stenting were not treated because of insignificant renovascular disease at the time of angiography despite noninvasive estimates to

A



B



C

FIGURE 42.13 A and B: High-grade renal artery stenosis in a normal-sized kidney characterized by high peak systolic velocity (4.03 m per second) at the origin of the main vessel. **C:** Doppler velocity measured in the distal renal artery segments of the same kidney, illustrating delayed arrival with a blunted pulse wave (parvus and tardus) appearance characteristic of proximal stenosis. The sustained flow during diastole in this instance is expressed as low resistive index (RI) suggestive of favorable intrarenal hemodynamics (see text). (See Color Plate.)

the contrary.[123] A recent report suggests that a correlation with quantitative estimates of renal artery occlusion above 60% correlate best with velocities above 300 cm per second for native vessel disease and somewhat higher (395 cm per second) for in-stent restenosis.[124]

An additional feature of Doppler ultrasound allows for the characterization of small vessel flow characteristics within the kidney. The resistive index (RI) provides an estimate of the relative flow velocities in diastole and systole. In a study of 138 patients with renal artery stenosis, a RI above 80 provided a predictive tool for the identification of parenchymal renal disease that did not respond to renal revascularization (Fig. 42.14).[125] A sizable portion of the group with an elevated RI eventually progressed to renal failure. An RI less than 80 was associated with a more than 90% favorable BP response and stable or improved renal function. The authors emphasize that accurate predictive power depended on using the highest RI observed, even when present in the nonstenotic kidney. A subsequent study of 215 subjects with mean preintervention serum creatinine levels of 1.51 mg per deciliter failed to confirm the predictive value of RI measurements. Of 99 subjects with improved renal function after 1 year, 18% had an RI above 0.8 before intervention, whereas 15% of 92 subjects with no improvement had an index above 0.8 (not significant). In this series, the preintervention level of serum creatinine itself was the strongest predictor of improved renal function.[126] Additional studies indicate an overlap between levels of RI in those with and without clinical improvement after stenting. Nonetheless, low RI remained a predictor of clinical BP benefit after adjusting for age, sex, duration of hypertension, and other conditions.[127] In a series of 106 patients with ARAS undergoing revascularization, 70% of patients with an RI below 80 had a clinical benefit, as compared with only 20% of those with an RI above 80. Most clinicians agree that detecting a low RI indicates well-preserved vasculature within the kidney.[128]

Captopril Renography

Imaging the kidneys before and after the administration of an ACE inhibitor (e.g., captopril) provides a functional assessment of the change in blood flow and GFR to the kidney, related both to changes in arterial pressure and the removal of the efferent arteriolar effects of Ang II. The most commonly used radiopharmaceuticals are 99mTc, DTPA, and MAG3. The latter agent has clearance characteristics similar to Hippuran and is often taken as reflecting renal

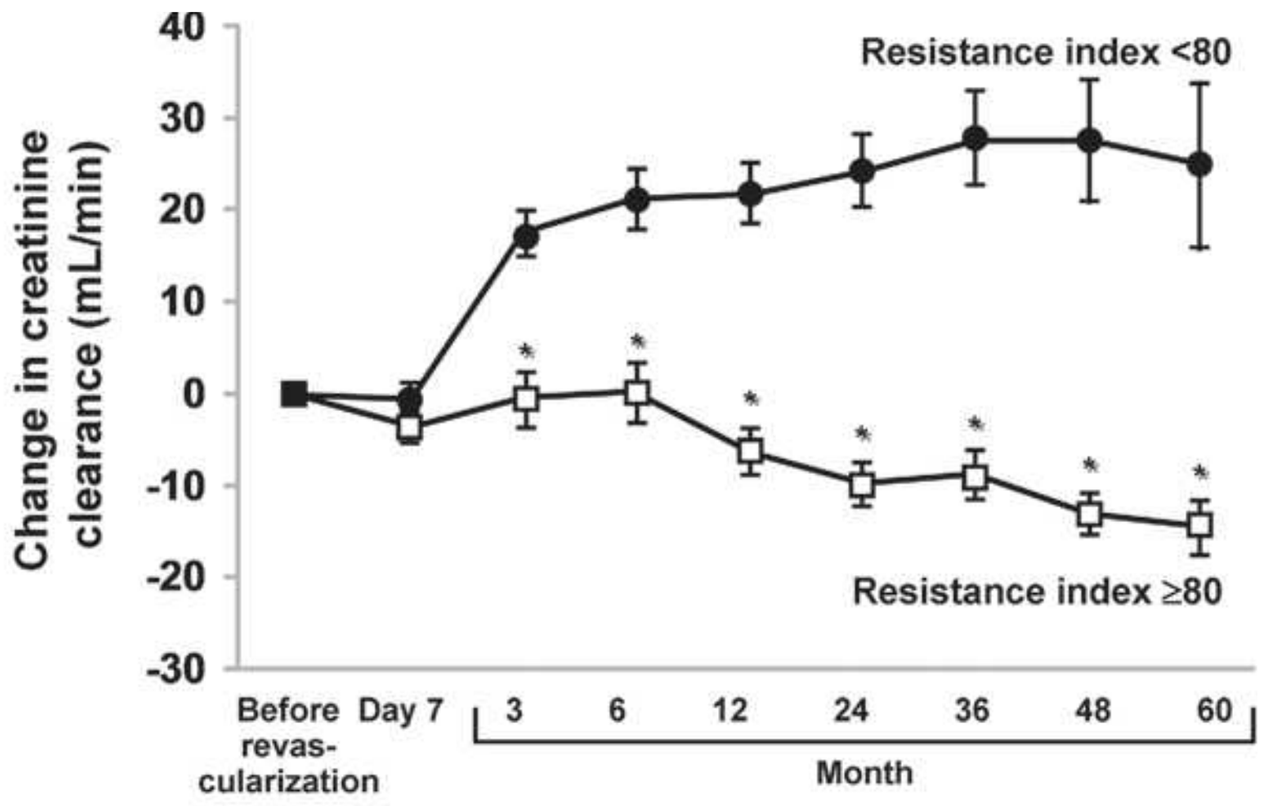


FIGURE 42.14 A resistive index (RI) obtained from 131 subjects undergoing renal revascularization. Those with relatively low resistive indexes (< 80) were more likely to have higher glomerular filtration rates (GFRs) during follow-up and were more likely to have a favorable blood pressure response than those with higher levels (> 80). These data suggest that preserved diastolic flow, which is the main determinant of RI, is a favorable sign for kidney recovery. (Adapted from Radermacher J, Chavan A, Bleck J, et al. Use of Doppler ultrasonography to predict the outcome of therapy for renal-artery stenosis. *N Engl J Med*. 2001;344:410–417, with permission.)

plasma flow. Both can be used, although specific interpretive criteria differ.[129] Both provide information regarding the size and filtration of both kidneys and the change in these characteristics after the inhibition of ACE allows inferences regarding the dependence of glomerular filtration on Ang II. Patient groups with the prevalence of renovascular disease rates between 35% and 64% of subjects suggest that sensitivity and specificity range between 65% and 96% and 62% and 100%, respectively.[129] Because of its high specificity, captopril renography can be applied to populations at low pretest probability with an expectation that a normal study will exclude significant renovascular hypertension in more than 96% of cases.[95] Some series report 100% accurate negative predictive values.[130]

These studies are less sensitive and specific for renovascular disease in the presence of renal insufficiency (usually defined as creatinine > 2.0 mg per deciliter). These performance characteristics deteriorate for patients who cannot be prepared carefully (i.e. withdrawal of diuretics and ACE inhibitors 4 to 14 days before the study).[129] It should be emphasized that renography provides functional information but no direct anatomic information (i.e., the location of renal arterial disease, the number of renal arteries, or associated aortic and/or ostial disease) (Fig. 42.15A,B). Some authors

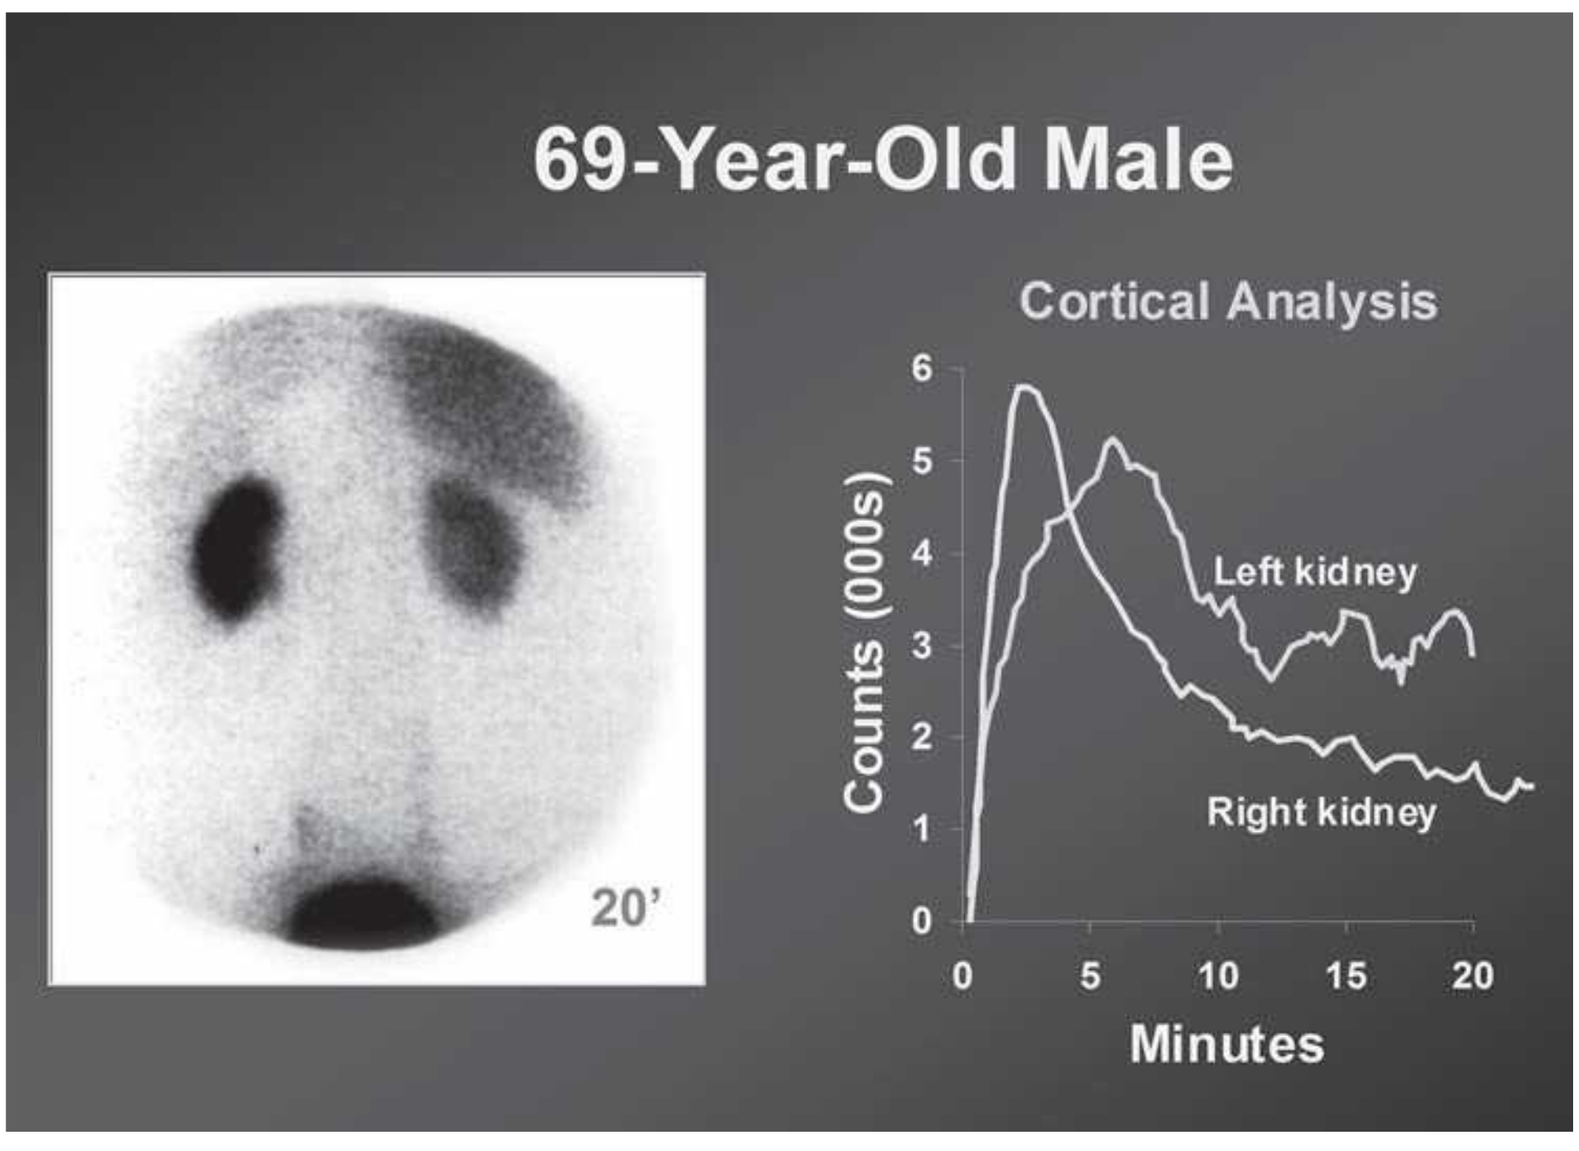

FIGURE 42.15 A radionuclide renogram illustrating asymmetry of flow and function between two kidneys in a patient with high-grade renovascular disease.

argue that renographic screening of patients using this technique is among the most cost-effective methods of identifying candidates for further diagnostic studies and superior to functional studies of the RAS. On the other hand, prospective studies of renovascular disease from the Netherlands did observe changes in the renogram during follow-up, but did not find captopril renography predictive of angiographic findings or outcomes.[39] A prospective study of 74 patients undergoing both renography and Doppler ultrasound evaluation before renal revascularization could identify only a limited predictive value of scintigraphy (sensitivity 58% and specificity of 57%) regarding BP outcomes.[131]

Under carefully controlled conditions, some authors argue that changes in renographic appearance correlate with changes in BP to be expected after revascularization. Changes in split renal function indicate that stenotic kidneys regain GFR after revascularization, sometimes with a decrement in contralateral GFR, thereby leaving overall kidney function unchanged.[132]

Computed Tomography Angiography

CT angiography using helical and/or multiple detector scanners and intravenous contrast can provide excellent images of both kidneys and the vascular tree. Resolution and reconstruction techniques render this modality capable of identifying smaller vessels, vascular lesions, and parenchymal characteristics, including malignancy and stones (Fig. 42.16A,B).[133] When used for the detection of renal artery stenosis, CT angiography agrees well with conventional arteriography (correlation 95%) and sensitivity may reach 98% and specificity may reach 94%.[134,135] Recent studies indicate that CT provides excellent accuracy regarding the evaluation of in-stent restenosis[136] and the evolving quantitative three-dimensional image analysis may improve on intra-arterial methods.[134] Although this technique offers a noninvasive examination of the vascular tree suitable for kidney donors with normal GFR, for example, it has the drawback of iodinated-contrast requirement. As a result, it is less than perfect for the evaluation of renovascular hypertension and/or ischemic nephropathy for patients with an impaired renal function. Concerns regarding toxicity associated with MRA contrast nonetheless encourage the wider use of multidetector CT as a diagnostic imaging test for patients suspected of renovascular disease. There are limitations, including the reduced visibility of vessel lumens in the presence of substantial calcium deposition. A single study comparing both CT angiography and MRA with intra-arterial studies in 402 subjects indicated substantially worse performance for the detection of lesions $>$ 50% stenosis.[137] In this particular study, CT angiography had a sensitivity of 64% and a specificity of 92%, whereas MRA had a sensitivity of 62% and a specificity of 84%. This was an unusual population with only 20% of the screened population having stenotic lesions, nearly half of which were FMD. The results of such studies reinforce the importance of careful patient selection for study and establishing in advance why imaging is being undertaken.[138]

FIGURE 42.16 A and B: Computed tomography (CT) angiographic images with reconstruction can identify important elements of vascular anatomy and parenchymal function. **A:** A right renal artery stent with normal kidney parenchyma as compared with advanced renal artery stenosis affecting the left kidney, with evident loss of kidney size, perfusion, and function. **B:** A high-grade left renal artery stenotic lesion is evident with a moderate reduction in perfusion to the kidney as shown by its reduced size and the intensity of the nephrogram. (See Color Plate.)

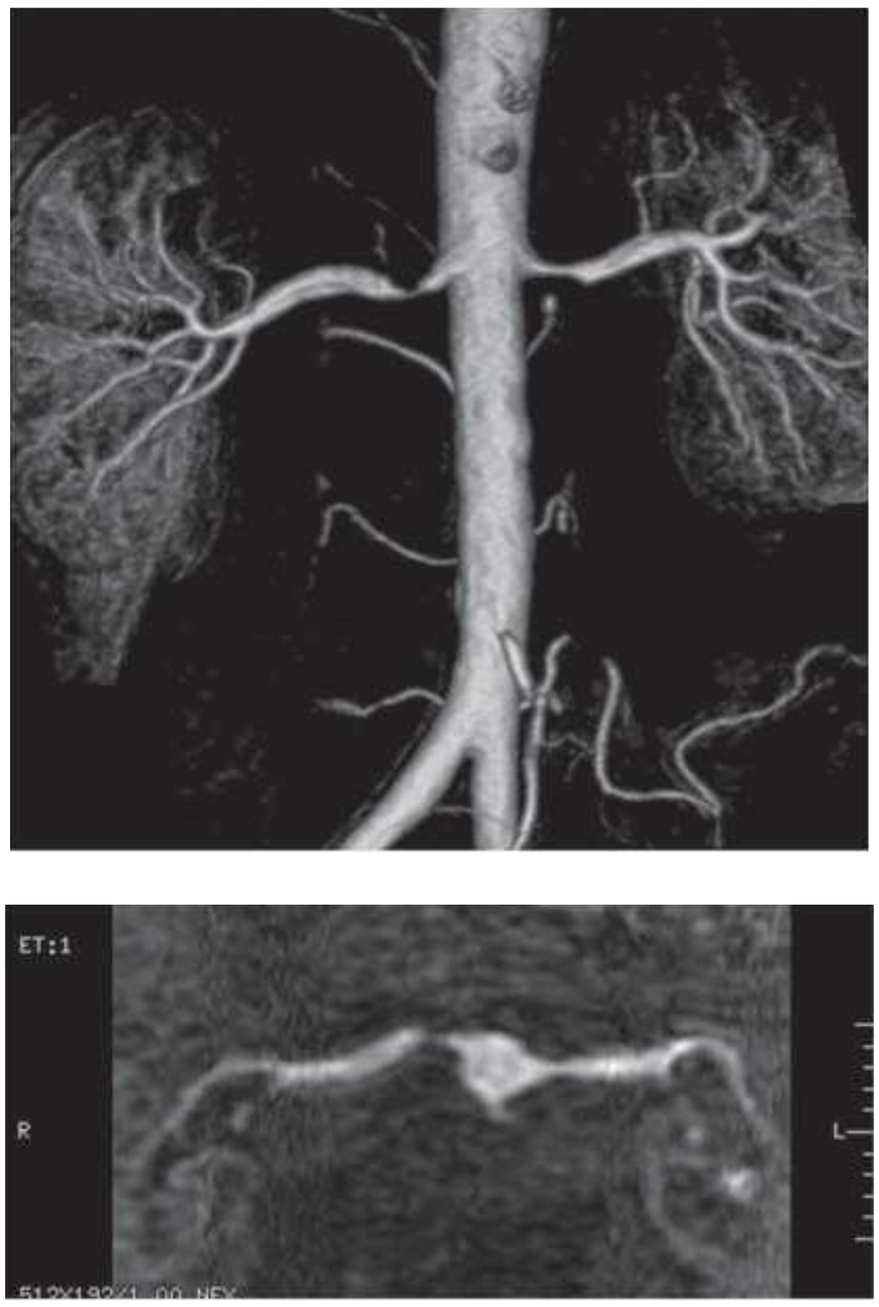
Magnetic Resonance Angiography

Gadolinium-enhanced images of the abdominal and renal vasculature have been a mainstay of evaluating renovascular disease in many institutions.[133,139] Comparative studies indicate that sensitivity ranges from 83% to 100% and specificity ranges from 92% to 97% in renal artery stenosis.[140,141] Meta-analyses of published literature[142] including 998 subjects support more than 97% sensitivity using gadolinium-enhanced imaging. The nephrogram obtained from gadolinium filtration provides an estimate of relative function and filtration, as well as parenchymal volume. The quantitative measurement of parenchymal volume determined by MRI appears to correlate closely with isotopically determined single kidney GFR in some institutions.[114] However, since 2006, concerns about the potential for gadolinium-based contrast to produce nephrogenic systemic fibrosis effectively have drastically reduced contrast-enhanced MR for patients with impaired kidney function in the United States.[143]

Technologic advances allow increasingly high-resolution vascular MRI without contrast in many patients. An example of MRA without contrast is shown in Fig. 42.17B. Drawbacks include the expense and the tendency to overestimate the severity of lesions, which in fact appear as a signal void.[144] The limits of resolution with current instrumentation make the detection of small accessory vessels limited, and quantitating fibromuscular lesions is difficult with current technology. Both of these are improving with newer generations of scanners. High spatial resolution three-dimensional contrast-enhanced MR scanners provide up to 97% sensitivity and 92% specificity for renal artery stenotic lesions.[145] Signal degradation in the presence of metallic stents renders MRA unsuitable for follow-up studies after endovascular procedures in which stents are used.

Functional Magnetic Resonance Imaging: Blood Oxygen Level–Dependent Magnetic Resonance

Blood oxygen level–dependent (BOLD) MR utilizes the properties of deoxygenated hemoglobin as a paramagnetic material that affects the local rates of magnetic polarization within tissues after a radiofrequency pulse (estimated as R2*).[146] These tools allow a real-time, noninvasive estimate of local oxygenation, which differs between the highly blood-perfused cortex and the much less perfused deeper medullary segments within the kidney.[147,148] Despite sufficient renal artery occlusion to reduce blood flow and GFR within the affected kidney by 30%, recent studies[61,64] indicate that overall cortical and medullary oxygenation in subjects treated with ACE inhibitors or ARBs maintain normal intrarenal patterns of oxygenation. In patients with more severe and/or long-standing reductions in blood flow, cortical oxygenation begins to deteriorate, reflecting overt hypoxia within the kidney associated with intrarenal fibrosis and inflammatory changes (Fig. 42.18).[66,149] Future studies hold the promise that such functional imaging may better identify those kidneys (1) at actual risk of ischemic injury and (2) that may benefit from restoring blood flow to recover function.[9]

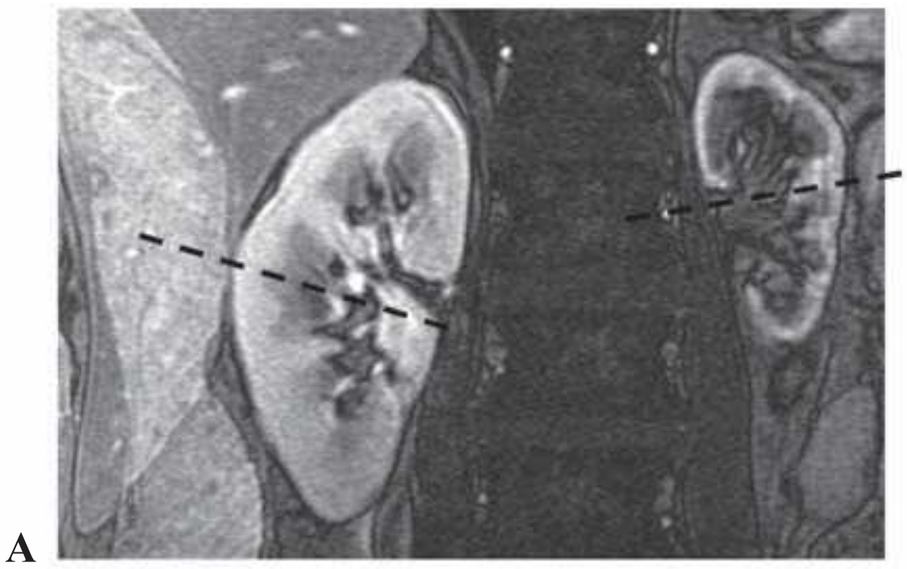


A **B**

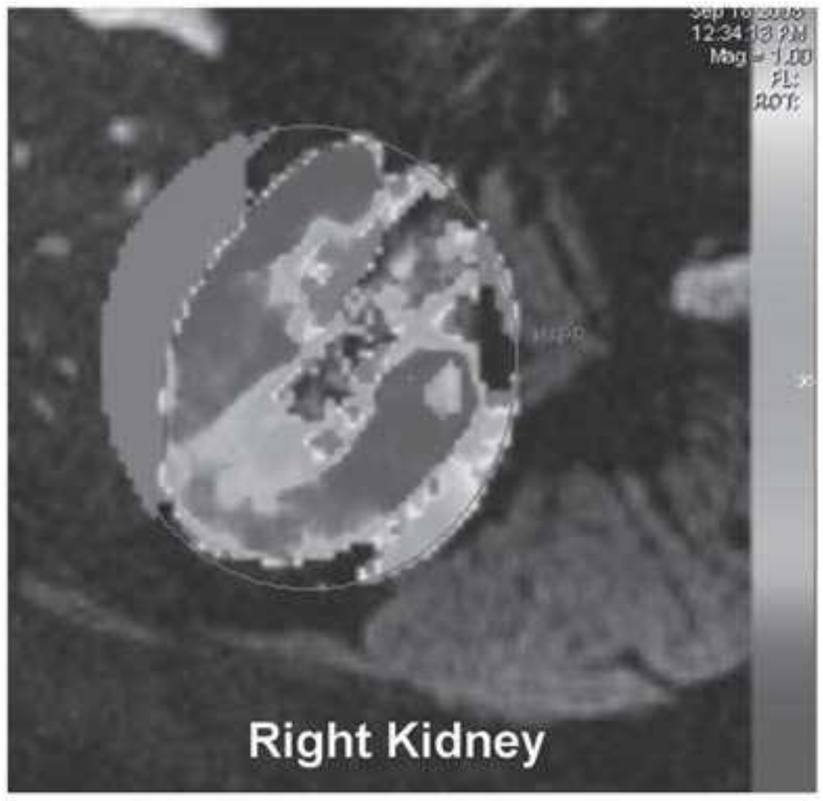
FIGURE 42.17 Examples of magnetic resonance angiograms (MRAs) with **(A)** vascular reconstruction using gadolinium contrast. Continually improving MR imaging allows for the definition of smaller vessels with improved resolution and the definition of parenchyma without ionizing radiation. Use of gadolinium-based contrast agents has declined after concerns about nephrogenic systemic fibrosis (NSF) in patients with impaired glomerular filtration rates (GFRs). **B:** Time-of-flight imaging without contrast in the axial plane also can provide excellent definition of vascular occlusion, even at oblique angles from the aorta.

Invasive Imaging

Intra-arterial angiography currently remains the gold standard for the definition of vascular anatomy and stenotic lesions in the kidney. Often, it is completed at the time of a planned intervention, such as endovascular angioplasty and/or stenting. What is the current role of including angiography of the renal arteries during imaging of other vascular beds, such as drive-by angiography during coronary artery imaging? Several studies confirm that the prevalence of renal artery lesions exceeding a 50% lumen occlusion in patients with hypertension and coronary artery disease is high, usually between 18% and 24%.[150] Some individuals (7% to 10%) will have high-grade stenoses above a 70% occlusion



A



B

C

FIGURE 42.18 A, B, and C: Functional magnetic resonance (MR) using blood oxygen level–dependent (BOLD) imaging provides a measurement of tissue deoxyhemoglobin levels (expressed as R2* (sec^{-1})) illustrated in axial sections of a normal kidney **(B)** and the severely stenotic **(C)** kidney shown here. Maps of R2* in the normal kidney demonstrate abundant oxygenation in the kidney cortex (low R2* levels associated with blue-green regions) with a gradient to hypoxic regions in the medulla (higher R2* levels associated with orange-red). When blood flow is reduced sufficiently, cortical flow falls and the tissue becomes overtly hypoxic in the cortex and the zone of medullary hypoxia widens **(C)**. (Adapted from Reference (66) with permission.) BOLD MR represents one potential tool to identify vascular insufficiency leading to tissue hypoxia and may allow improved selection of patients for renal revascularization. (See Color Plate.)

and some will be bilateral. Accepting the fact that an arterial puncture and catheterization of the aorta and coronary vessels produces some risk, the added risk from including an aortography of the renal vessels appears to be small/almost negligible. Follow-up studies[12,151] of individuals with identified incidental renal artery lesions suggest that the presence of these lesions does provide an additive predictive risk for mortality. No data to this point suggest that combining screening angiography with renal revascularization changes that risk. Hence, endovascular procedures for such lesions should be confined to individuals with strong indications for renal revascularization, as even the most ardent advocates of catheter-based intervention have suggested.[150] Remarkably, studies of patients with identified ARAS during the preoperative screening indicate no increased risk for acute kidney injury (AKI) during or after cardiovascular surgery as compared to those without ARAS.[152]

Contrast toxicity remains an issue with conventional iodinated agents.[153] Intravascular ultrasound procedures have been undertaken using papaverine to evaluate flow reserve beyond stenotic lesions.[154] Various reports indicate that either a reduction or preserved flow reserve may identify a poststenotic kidney that may improve function after successful revascularization.[154,155] Previous studies of pressure gradients measured across stenotic lesions have failed to predict the clinical response to renal revascularization. Measurements using currently available low profile wire probes do, however, indicate a relationship between pressure gradients and the activation of the RAS.[43] Outcomes of patients with translesional pressure gradients measured after vasodilation suggest that a measurement of hyperemic systolic gradient above 21 mm Hg most accurately predicts high-grade stenosis (average 78% by intravascular ultrasound) and a beneficial response of BP after stenting.[156] The latter observation and the increasing reliability of technical measurements underscore the value of measuring gradients to establish a hemodynamic role for vascular lesions of marginal severity.

Management of Renal Artery Stenosis and Ischemic Nephropathy

Overview

Considering the variety of potential treatments and major differences in individual patient comorbid diseases and risks, clinicians need to formulate a clear set of therapeutic goals for each patient. Each treatment, ranging from medical therapy alone to surgical revascularization, carries both benefits and risks. The clinician's task is to weigh the role of each of these within the context of each patient's response and likely long-term outcome. Rarely is it obvious how best to proceed. In most cases, the long-term management of the patient with renovascular disease requires an integrated pharmacologic management of BP, treating cardiovascular risk factors, and the careful timing of renal revascularization. The objective of this section is to provide a framework by which to plan a balanced approach to the patient with unilateral or bilateral renal artery stenosis. It should be emphasized that the consideration of renal artery disease takes place in the broad context of managing other cardiovascular risk factors, including withdrawing tobacco use, reducing cholesterol levels, and treating diabetes and obesity.

Medical Therapy of Renovascular Disease

The overall goals of therapy are summarized in Table 42.5. Foremost among these is the statement by the Joint National Committee (JNC) of the National High Blood Pressure Education Program (NHBPEP): "The goal of treating patients with hypertension is to prevent morbidity and mortality associated with high blood pressure."[157] This task may include the effort to simplify or potentially eliminate long-term antihypertensive drug therapy. Several scenarios should be considered in the care of patients with renal artery stenosis and hypertension: (1) true renovascular hypertension, in which atherosclerotic or fibrous renal artery disease is the sole cause of the hypertension; (2) pure essential hypertension, in which atherosclerotic or fibrous renal artery disease is present but does not contribute to the hypertension at all; (3) essential hypertension with superimposed renal artery stenosis producing a renovascular contribution to the underlying essential hypertension; and (4) the hypertension of renal parenchymal disease, that is, chronic renal insufficiency with superimposed renal artery stenosis contributing to the hypertension (Fig. 42.19). Accordingly, the medical management of patients with presumed renovascular hypertension and renovascular disease is primarily an effort to control the BP. As will be summarized in the following, rarely does any specific revascularization procedure lead to the withdrawal of all antihypertensive therapy or to a true cure for hypertension. Hence, medical therapy at some level is a primary component of treatment for nearly all patients with renovascular disease. A second corollary is that a trial of medical therapy often becomes a practical test of the need for expanded diagnostic studies. Regarding this, some of the major criteria recommended by an American Heart Association writing group are summarized in Table 42.7.

A further goal is to prevent a loss of kidney function related to impaired renal blood flow. In some instances, renal revascularization is undertaken to allow for the improved management of salt and water balance in the process of managing patients with congestive cardiac failure. This may allow safer use of diuretic agents and ACE inhibitor/ARB classes of medication in patients with critical renal artery lesions to the entire renal mass. Because prospective, randomized trial information is limited and ambiguous for renovascular disease, each patient must be considered individually. What cannot be assumed is that renal revascularization prolongs

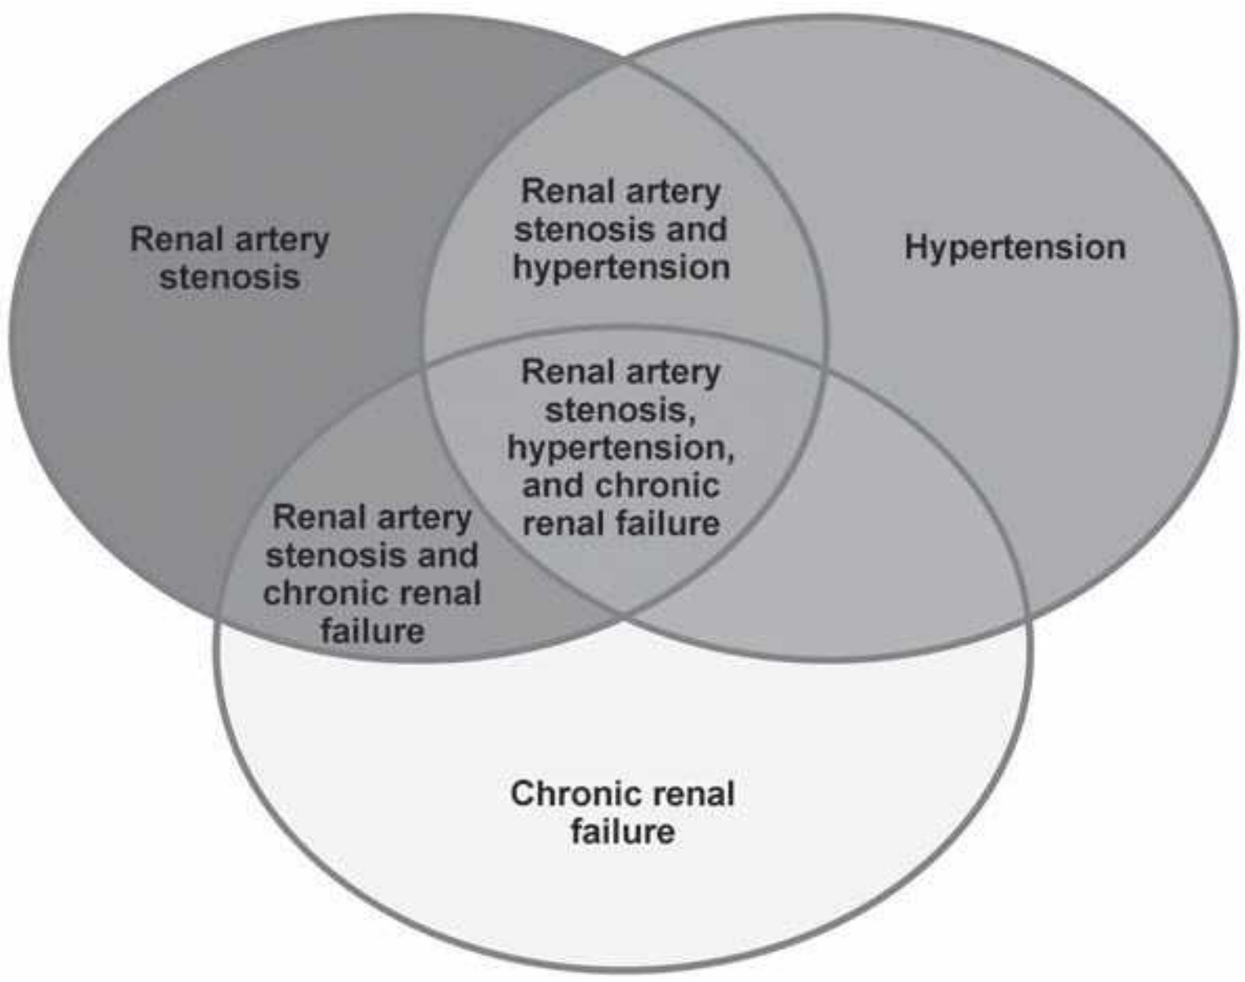


FIGURE 42.19 A Venn diagram illustrating the relationships between renal artery stenosis, hypertension, and chronic renal failure. The challenge to clinicians is to evaluate the relationship between these circles for an individual patient. Because all three are common and increase with age, it is no surprise that identifying patients with truly causal interconnections is difficult. In many respects, elucidating the role of renal artery stenosis remains a clinical judgment based on time, duration, and severity, in addition to the practical difficulties in managing both blood pressure and kidney function. (From Safian RD, Textor SC. Medical progress: renal artery stenosis. *N Engl J Med*. 2001;344:431–442, with permission.)

42.7 Classification and Therapies for Renal Artery Stenosis

A. Functional Classification for Atherosclerotic Renal Artery Stenosis

Grade I: Renal artery stenosis present, but no clinical manifestations (normal blood pressure and normal renal function)
Grade II: Renal artery stenosis present, but patients have medically controlled hypertension and normal renal function
Grade III: Renal artery stenosis present and patients have evidence of abnormal renal function, medically refractory hypertension, or evidence of volume overload

B. Factors Favoring Specific Therapies for Renal Artery Stenosis

Factors favoring **medical therapy and revascularization** for renal artery stenosis
- Progressive decline in GFR during treatment of hypertension
- Failure to achieve adequate blood pressure control with optimal medical therapy
- Rapid or recurrent decline in the GFR in association with a reduction in systemic pressure
- Decline in GFR during therapy with ACE inhibitors or ARBs
- Recurrent congestive heart failure in a patient in whom the adequacy of left ventricular function does not explain the cause

Factors favoring **medical therapy and surveillance** of renal artery disease
- Controlled blood pressure with stable renal function
- Stable renal artery stenosis without progression on surveillance studies (e.g., serial duplex ultrasound)
- Advanced age and/or limited life expectancy
- Extensive comorbidities that make revascularization too risky
- High risk or previous experience with atheroembolic disease
- Other concomitant renal parenchymal diseases that cause progressive renal dysfunction (e.g., diabetic nephropathy)

GFR, glomerular filtration rate; ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker. Adapted from the writing group for Atherosclerotic Peripheral Vascular Disease Symposium.[5,234]

life or regularly prevents ESRD.[11,158] The Centers for Medicare and Medicaid Services (CMS) commissioned a formal review of strategies for managing atherosclerotic renal artery disease. The results were published in 2006 and concluded that "data were insufficient to conclude substantial benefit regarding blood pressure control, kidney function or mortality for atherosclerotic renal artery disease" in favor of either specific management strategy.[159] Since that review, several prospective randomized trials have been reported or remain in progress, albeit with limitations (see the following). None have provided compelling evidence supporting a major benefit for renal revascularization for all patients, although a subgroup of patients in each of these studies has benefited. As noted previously, the burden of atherosclerotic disease associated with renal artery stenosis is often widespread and the causes of death include a broad array of cardiovascular events. Both endovascular and surgical intervention in the aorta and renal vasculatures carry substantial risks that may accelerate morbidity and the loss of renal function. As a result, these measures must be considered within the entire context of patient management over time.

There is little question that the more severe the hypertension, the greater the likelihood that it has a renovascular component and the more one has to gain by successful revascularization to facilitate BP control. Furthermore, younger patients with fibromuscular renal artery diseases have less risk of procedural complications and may respond well to revascularization with either angioplasty or surgery. However, the results of renal revascularization in patients with atherosclerotic renal artery disease are less favorable, because many of these patients are older and almost certainly have coexisting primary or essential hypertension.[56]

Unilateral Versus Bilateral Renal Artery Stenosis

Consideration of these disorders differs in some respects. In this context, bilateral refers to the circumstances when the entire functional renal mass is affected by vascular occlusion. This may be associated either with bilateral stenoses or stenosis to a solitary functioning kidney. Not only are the putative mechanisms related to BP and volume control different in the presence of a nonstenosed, functioning contralateral kidney with unilateral disease (as outlined under pathophysiology, previously), but also the potential hazards of intervention and/or medical therapy differ. Patient survival is reduced in patients with bilateral disease or stenosis to a solitary functioning kidney. Progressive arterial disease in this group also poses the most immediate hazard of declining renal function. Patient survival depends on the extent of vascular involvement[160] regardless of whether renal revascularization is undertaken.

Management of Unilateral Renal Artery Stenosis. Most patients with atherosclerotic renal artery disease have preexisting hypertension. As a result, most are exposed to antihypertensive therapy before the lesion has been identified and may be treated successfully with only moderate medication use.[34,161] Such patients commonly come to clinical attention when recognizable clinical progression occurs or when imaging is undertaken for other reasons. Occasionally, clinical decision making is influenced strongly by concerns about the hazards of medical therapy and failing to achieve both BP control and failing to maintain adequate blood flow soon enough. Examination of the results of medical therapy alone is important before evaluating the role of vascular reconstruction or dilation.

Since the introduction of agents blocking the RAS, most patients (86% to 92%) with unilateral renal artery disease can achieve blood pressure levels < 140/90 mm Hg with medical regimens based on these agents. Recent treatment trials[162–165] for ARAS confirm that target BP levels often can be achieved with optimized medical therapy with or without renal revascularization. It must be understood that widespread application of these agents to patients with many forms of cardiovascular disease already ensures that many subcritical cases of renovascular disease are treated medically unbeknownst to the clinician. Several clinical reviews, including large administrative databases, suggest that treating renal artery stenosis with ACE inhibitors or ARBs is associated with a more favorable patient outcome than that observed with other antihypertensive regimens.[89,166,167] Comparing 1,857 (53%) patients given either ACE inhibitors or ARBs out of 3,570 patients treated for renovascular disease, Hackam and colleagues[166] reported lower rates of overall mortality, congestive heart failure, and chronic dialysis in the group treated with RAAS blockers. There were, however, slightly higher rates of hospitalization for acute renal failure (1.2 versus 0.6 events per 100 patient years).[166] An example of a patient with complex aortic disease and high-grade unilateral ARAS managed for many years with ACE inhibitor therapy and diuretics is illustrated in Fig. 42.20A.

Do the risks of treating unidentified renal artery stenoses with antihypertensive drug therapy pose a hazard to patients? This issue is at the crux of many clinical debates

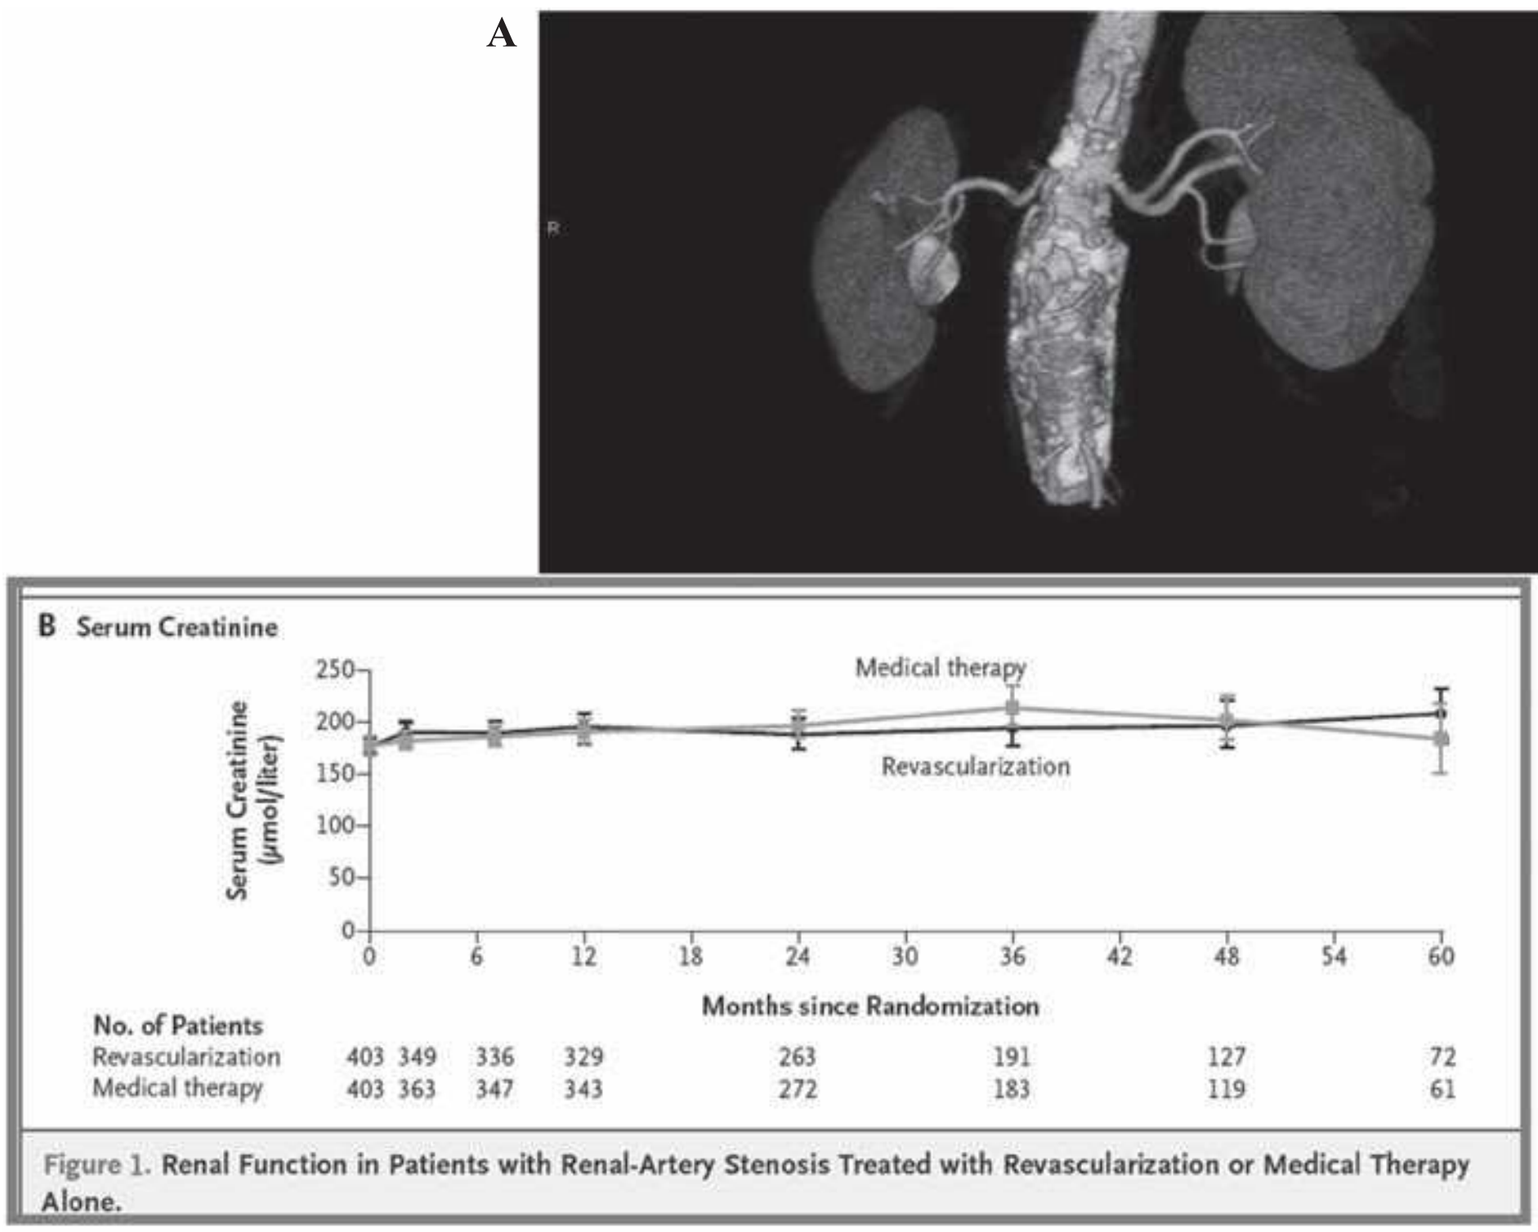

Figure 1. **Renal Function in Patients with Renal-Artery Stenosis Treated with Revascularization or Medical Therapy Alone.**

FIGURE 42.20 A and B: A computed tomography (CT) angiogram **(A)** obtained from a patient with high-grade renal artery stenosis leading to loss of parenchymal volume on the right kidney, but evidently normal blood flow and function on the left kidney. The aortic anatomy is complicated by an aneurysm formation and intramural thrombus that increases the hazards of endovascular stenting. This individual with unilateral renal arterial disease has been managed for years with stable renal function and blood pressure control with only modest antihypertensive drug requirements. Panel **B** reproduces the levels of serum creatinine for more than 400 patients in each group assigned to medical therapy with or without renal artery stenting in the ASTRAL trial. Patients assigned to this trial had moderate renal dysfunction that remained remarkably stable for the group as a whole during the follow-up approaching 5 years. Rates of progression to a renal endpoint were 16% to 20% in both groups. (From The ASTRAL Investigators. Revascularization versus medical therapy for renal-artery stenosis. *N Engl J Med.* 2009;361:1953–1962, with permission.)

(and prospective, randomized clinical trials) regarding the management of patients with renovascular hypertension. Early studies with experimental clip hypertension emphasized renal fibrosis and scarring, which occur in the stenotic kidney in animals treated with ACE inhibitors. It is well recognized that the removal of the efferent arteriolar effects of Ang II pose the possibility of a loss of glomerular filtration in a kidney with reduced renal perfusion. Experimental studies in 2K-1C rats indicate that the loss of kidney function is sometimes irreversible, although survival is improved in ACE inhibitor–treated animals as compared to minoxidil-treated ones.[168] The unique role of ACE inhibitors and ARBs must be understood in this regard. Any drug capable of reducing systemic arterial pressure has the potential to lower renal pressures beyond a critical stenosis. As a result, successful antihypertensive therapy in renovascular disease has the theoretical result of reducing blood flow to the poststenotic kidney sufficient to induce vascular thrombosis. The unique feature of agents that block the RAS is the reduction of efferent arteriolar resistance sufficient to lower transcapillary filtration pressures, despite preserved blood flow to the glomerulus. This property is central to the benefits of this class of agents in hyperfiltration states thought to accelerate renal damage in other settings. In the presence of renovascular disease, the fall in glomerular filtration beyond a stenotic lesion can be observed despite relatively preserved plasma flows. The fall in GFR heralds an approaching degree of critical vascular compromise before blood flow itself is reduced.[169] Studies[170] in renovascular hypertensive animals confirm that despite a reduction in filtration, renal structural integrity can be preserved and recovered after the removal of the clip and/or the removal of the ACE inhibitor. Hence, it is unlikely that ACE inhibitors or ARBs themselves pose a unique hazard beyond that attributable to a reduction in renal blood flow.

Recent studies of patients with ARAS treated with ACE or ARBs indicate that even with up to 30% reductions of renal blood flow beyond ARAS, actual tissue oxygenation can be remarkably well preserved. Gloviczki and colleagues[64] studied subjects under standardized conditions to measure regional blood flows within both stenotic and contralateral kidneys, as well as tissue oxygenation estimated by BOLD MR. Despite demonstrating high-grade stenosis with lateralizing renin activity and reduced blood flow in unilateral ARAS, both cortical and medullary levels of tissue oxygenation (as reflected by levels of deoxyhemoglobin) did not differ from either the contralateral kidney or from patients with essential hypertension under the same conditions. These authors argued that many such patients do not suffer true kidney hypoxia any more than essential hypertension or normal kidneys. Such observations support the relative safety of medical therapy and may partly explain the stability of kidney function during medical therapy over many years, as reported in recent trials such as Angioplasty and Stenting for Renal Atherosclerotic Lesions (ASTRAL) (Fig. 42.20B).[42] It should be emphasized that the same study format indicates that such an adaptation for oxygen delivery in a poststenotic kidney has limits. When the degree of vascular occlusion becomes sufficiently severe, cortical perfusion falls and overt hypoxia can appear in both the cortex and the medulla.[171]

It is important to recognize that the contralateral kidney supports total glomerular filtration despite reduced filtration in the stenotic kidney. Hence, changes in overall GFR may be small or undetectable. This may be interpreted in several ways. Some authors argue in favor of using split renal function measurements, such as radionuclide renal scans, to detect a loss of individual kidney function as a means of timing revascularization.[91] Depending on the circumstances, a loss of function in one kidney may be an acceptable price if one can assure the patient that the remaining kidney has adequate function and blood supply. The fall in GFR from a loss of one kidney represents a loss of GFR analogous to that of donating a kidney for renal transplantation or nephrectomy for malignancy. In such instances, the long-term hazard to the remaining kidney is small, although not negligible.[172,173] As the age and comorbid burden of the population at risk rises, the loss of one kidney may pose little additional hazard if overall glomerular filtration is adequate. The experience with ACE inhibition in trials of congestive cardiac failure is reassuring in this regard. Thousands of patients with marginal arterial pressures and clinical heart failure have been treated over many years with a variety of ACE inhibitors, and more recently, ARBs. These patients are at a high risk for undetected renal artery lesions as part of the atherosclerotic burden associated with coronary disease. Although a minor change in creatinine is observed in 8% to 10% of these individuals, a rise sufficient to lead to withdrawal of these agents under trial monitoring conditions occurs in only 1% to 2%.[169,174] Data from patients with a high risk of cardiovascular disease treated with ramipril included patients with creatinine levels up to 2.3 mg per deciliter. Those with creatinine levels between 1.4 and 2.3 mg per deciliter were at a higher risk for cardiovascular mortality and had a major survival benefit from ACE inhibition. A close follow-up of kidney function indicated that the withdrawal of ACE inhibition due to a deterioration of renal function was less than 5% and no greater than placebo.[175]

Should patients be evaluated for ARAS before major surgery, such as coronary artery bypass grafting (CABG)? Some raise concerns that these patients may be at a higher risk for AKI. A report[176] of 798 patients undergoing CABG surgery after having a diagnostic aortogram to detect renal artery stenosis indicated no increase in AKI related to the presence of ARAS.

Progressive Renal Artery Stenosis in Medically Treated Patients. The potential for vascular occlusive disease to worsen is central to the management of patients with renovascular disease. It may be argued that failure to revascularize the kidneys exposes the individual to the hazard of undetected, progressive occlusion, potentially leading to

total blood flow and/or an irreversible loss of renal function. A firm understanding of the data regarding progressive atherosclerotic disease of the kidney is important for planning both endovascular and surgical revascularization.

Atherosclerosis is a variably progressive disorder. Managing disorders of the carotid, coronary, aortic, and peripheral vasculatures all recognize the potential for progression, which occurs at widely different rates between individuals. Medical therapy of all of these disorders should incorporate measures aimed at an intensive reduction of risk factors, of which smoking cessation, BP control, and correction of dyslipidemias are paramount. Treatment of these risk factors reduces mortality rates related to cardiovascular disease.[177]

How does progressive renal artery occlusive disease affect the management of renovascular hypertension? Moderate anatomic progression alone does not reliably predict functional changes in terms of deteriorating BP control or renal function. In serial reports[41] of Duplex ultrasound studies from Seattle, a decrement in measured renal size by 1 cm (renal atrophy) developed in 5.5% of those with normal initial vessels and in 20.8% of those with baseline stenosis > 60% during a follow-up interval of 33 months. Changes in serum creatinine were infrequent but did occur in a subset of patients, particularly those with bilateral renal artery stenosis. These are in general agreement with early studies during medical therapy of renovascular hypertension in which 35% had a detectable fall in measured renal length, but only 8 out of 41 (19%) had a significant rise in creatinine levels during a follow-up of 33 months. The follow-up of the medical treatment arms during short-term studies fails to show major changes in kidney function, although the occasional loss of renal perfusion by radionuclide scan is observed.[39]

How often does the management of renal artery stenosis without revascularization lead to clinical progression, either in terms of refractory hypertension or advancing renal insufficiency? A follow-up of patients with incidentally identified renal artery stenosis is helpful in this regard. Review of peripheral aortograms identified 69 patients with high-grade renal arterial stenoses (> 70%) who were followed without revascularization for more than 6 months. Their long-term follow-up identified generally satisfactory BP control, although some required more intensive antihypertensive therapy during an average of 36 months follow-up.[178] Four patients eventually underwent renal revascularization for refractory hypertension and/or renal dysfunction. Five developed ESRD, of which only one was thought to be related to RAS directly. Overall, serum creatinine levels rose from 1.4 mg per deciliter to 2.0 mg per deciliter. These data indicate that many such patients can be managed without revascularization for years and that clinical progression leading to urgent revascularization develops in 10% to 14% of such individuals. Expansion of this data set to 160 individuals allowed for a comparison of different antihypertensive regimens. The rates of progression did not appear related to the introduction of ACE inhibitors, although the level of BP control improved in later years.[179] These observations are supported by a report of 126 patients with incidental renal artery stenosis compared to 397 patients matched for age. Measured serum creatinine levels were higher, and calculated (Cockcroft-Gault) GFR was lower in patients with RAS who were followed for 8 to 10 years. However, none of the patients progressed to ESRD.[180]

What Can We Learn From Prospective Randomized Trials of Medical Therapy in Renovascular Disease? As noted previously, advances in both medical therapy for hypertension and revascularization procedures have shifted the balance for therapy enormously. No fewer than six prospective, randomized trials conducted in several countries have attempted to address the relative advantages of medical therapy as compared to revascularization for ARAS, either with endovascular or surgical methods. Most of these trials have been small with short-duration follow-ups and inconclusive. Results of two recent trials have appeared in the general medical literature, including the largest single trial of 806 patients from the United Kingdom in ASTRAL.[42,123] The major results of these trials are summarized in Table 42.8. Although the number of antihypertensive drugs were slightly lower in revascularized groups, BP levels often did not differ. Kidney function was unchanged overall in these trials. Procedural complications, although not common, were occasionally severe. Overall, these data fail to demonstrate clinically important benefits to renal revascularization in the patients enrolled during follow-ups between 2 and 5 years. The U.S. trial addressing overall cardiovascular outcomes, CORAL, which completed enrollment at the beginning of 2010, is the largest and is the most stringent regarding entry criteria. Data from CORAL are not expected until late in 2012 at the earliest.

Negative conclusions from these trials have been unsatisfying and widely criticized.[1,2,181] Recruitment for randomized controlled trials (RCTs) has been difficult, in part due to intense preconceptions of practicing clinicians. Many of the patients enrolled in these trials were found to have mild—sometimes trivial—vascular disease, clearly reducing the power of the study. In the STAR trial, for example, nearly a quarter of patients assigned to renal revascularization did not have the procedure performed because of a lack of clinically evident vascular stenosis at the time of angiography.[123] It is clear that many patients with high-grade disease, sometimes to a solitary functioning kidney, were not included in these trials out of a conviction on the part of the clinician that revascularization should or should not be considered. The largest trial to date, ASTRAL, excluded those "that required surgery" or were "likely to need" revascularization within 6 months. No contemporary registry of exclusions is available, nor is there any defined criteria for requiring intervention. Some authors have argued that atherosclerotic renal artery stenosis, in particular, is confounded so heavily with other individualized patient factors and comorbid disease risks that it cannot be addressed responsibly in a prospective trial format.[182]

Some observations from these trials warrant comment, however. The size (Table 42.8) and power estimates on

EMMA, Essai Multicentrique Medicaments vs Angioplastie, France 1998; SNRASCG: Scottish and Newcastle Renal Artery Stenosis Collaborative Group, UK, 1998; DRASTIC: Dutch Renal Artery Stenosis Intervention Cooperative study group, Netherlands, 2000; ASTRAL: Angioplasty and Stenting for Renal Artery Lesions, UK, Australia, New Zealand, 2009; STAR: Stenting for Atherosclerotic Renal artery lesions, Netherlands, 2009; NITER: Italy, presented in abstract form; HTN, hypertension; CKD, chronic kidney disease; Pts, patients; F/U, follow-up; BP, blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure; PTRA, percutaneous transluminal renal angioplasty.
These authors concluded that, taken together, blood pressure reductions with modest reductions in medication requirements were evident in revascularized patients. They could not identify differences in kidney function, cardiovascular events, or mortality in these trials between groups treated medically with or without revascularization. It should be emphasized that these trials were short in duration, mostly quite small and heterogeneous in their characteristics, and many patients were not treated as assigned (see text).

the part of planners reflect vastly different expected rates of progression and clinical events. The STAR trial reported results from 140 subjects, whereas the goal for CORAL based on overall cardiovascular outcomes was more than 1,000 subjects.[183] As often occurs in randomized trials, the event rates were lower than expected. Although average estimates for the severity of renovascular disease in ASTRAL exceeded 70% occlusion, the trial cohort included 40% of subjects between 50% and 70% occlusion, many of whom had only a minor disease. This was confirmed at the time of angiography, at which point 68 of 403 (17%) assigned to stenting failed to be treated, because many of them had only trivial vascular disease. Importantly, many patients in these trials achieved acceptable BP levels during medical therapy. Renal function was remarkably stable in both arms in ASTRAL over years of follow-up, thus reaffirming the observation that many patients can be managed for years. Crossover rates from medical to revascularization arms were between 6% and 24%, primarily due to treatment failures.

These observations extend and confirm results of prospective trials of medical versus surgical intervention started in the 1980s and extended into the 1990s.[184] No differences in patient survival or renal function could be identified. Taken together, all of these studies indicate that rates of progression of renovascular disease are moderate and occur at widely varying rates. Often, such patients can be managed without revascularization for many years. The clinical issue in a specific patient frequently hinges on whether or not the risks of revascularization are truly less than the risks of progression.

Although these reports are informative, they leave many questions unanswered (Table 42.9). How often does suboptimal BP control in renovascular hypertension accelerate cardiovascular morbidity and mortality? Does one lose the opportunity to reverse hypertension successfully by delaying renal revascularization? How often will the expense and morbidity associated with complex drug regimens lead to inadequate treatment and/or adverse outcomes compared to restoring blood flow? These issues will depend on more selective, long-term prospective studies. It is equally clear that for many patients with progressive disease, optimal long-term stability of kidney function and BP control can be achieved by successful surgical or endovascular restoration of the renal blood supply.

42.9 Limitations of Clinical Trials in Atherosclerotic Renal Artery Stenosis

1. Patient selection
   a. Most severe cases not considered for randomization
   b. Most severe hypertension and progressive renal disease not included
   c. Limited selection of antihypertensive drug therapy
      i. Role of renin-angiotensin system blockade
      ii. Nonstandardized measurement of outcomes: BP levels
   d. Nonstandardized therapy for dyslipidemia/comorbid disease
2. Outcome measurement
   a. Widely variable definitions of BP goals, achieved levels
   b. Variable measurement of renal function
   c. Circulatory congestion/volume control/drug selection
   d. Crossovers from medical to interventional arms: 20%–44%
   e. Short duration of follow-up
3. Confounders limiting interpretation
   a. Roles and magnitude of comorbid disease: diabetes, preexisting cardiovascular disease
   b. Age/timing of intervention/timing of detection of disease
   c. Intermixing degree of renal involvement/tissue at risk: roles of unilateral and bilateral disease unevenly addressed
   d. Rates of development of disease, including renal dysfunction/BP changes
   e. Definition of treatment resistance

BP, blood pressure.
From Textor SC, McKusick MA, Misra S, Glockner J. Timing and selection for renal revascularization in an era of negative trials: what to do? Prog Cardiovasc Dis. 2009;52:220–228, with permission.

ENDOVASCULAR RENAL ANGIOPLASTY AND STENTING

The ability to restore vessel patency in high-risk patients with renovascular hypertension and ischemic nephropathy using endovascular methods undoubtedly represents a major advance in this disorder. Stenting allows the reversal of major degrees of vascular occlusion in more than 98% of cases, as illustrated in Fig. 42.21A,B. The restoration of blood flow to the kidney beyond a stenotic lesion seems to provide an obvious means to improve renovascular hypertension and to halt progressive vascular occlusive injury. For clinicians experienced in the field of renovascular hypertension, these developments represented a major breakthrough that hardly required testing in a controlled trial. As one author[185] argued in 2005, "A recent report on the use of parachutes to prevent death and major injury after jumping out of airplanes emphasized the fact that the parachute has never been subjected to a randomized controlled trial, even though numerous reports of survival after jumping without a parachute have been published."

The past 2 decades have been characterized by a major shift from surgical reconstruction toward preference for endovascular procedures. The total volume of renal revascularization procedures registered for the U.S. Medicare population above age 65 rose 62% from 13,380 to 21,600 between 1996 and 2000. This change reflects an increase in endovascular procedures by 2.4-fold, whereas surgical renovascular procedures fell by 45%. The trend continued with an estimate of 35,000 endovascular procedures in 2005 (Fig. 42.21C).[9,186] The transition to endovascular procedures also has enlarged and reconfigured the physician pool engaged in making decisions about renovascular hypertension. Interventional cardiologists increased their activity in this field nearly fourfold during this interval.

Revascularization of the kidney carries both benefits and risks, however. With older patients developing renal artery stenosis in the context of preexisting hypertension in the present era, the likelihood of a cure for hypertension is small, particularly in atherosclerotic disease. The true risks and benefits of these procedures are sometimes difficult to ascertain from published literature. They may vary between institutions depending on the technical expertise available. As noted in the following, methods of reporting results regarding clinical outcomes are inconsistent. Although complications are not common, they can be catastrophic, including atheroembolic disease and aortic dissection. Wide variability in the experience with peripheral endovascular procedures is reflected by the observation that their use, combining renal and lower extremity vascular stents, varies more than 14-fold between regions in the United States.[187] The probability of renal angioplasty within 30 days of cardiac catheterization has been fourfold higher when cardiologists perform the procedure than when interventional radiologists are responsible. Knowing when to pursue renal revascularization is central to the dilemma of managing renovascular disease.

Angioplasty for Fibromuscular Disease

Most lesions of medial fibroplasia are located at a distance away from the renal artery ostium. Many of these have multiple webs within the vessel, which can be successfully traversed and opened by balloon angioplasty. Experience in the 1980s indicated more than 94% technical success rates.[188] Some of these lesions (approximately 10%) develop restenosis for which repeat procedures have been used.[189] Clinical benefit regarding BP control has been reported in observational outcome studies in 65% to 75% of patients, although the rates of cure are less secure.[190] Cure of

FIGURE 42.21 An angiogram obtained before **(A)** and after **(B)** renal artery stenting in an individual developing rapidly progressing renovascular hypertension. The ability to restore vascular patency using endovascular procedures has allowed many more patients to be treated than would have been considered for renovascular surgery. Development of these methods led to the striking expansion of renal artery stenting procedures, as reflected by the rise in Medicare claims submitted between 1996 and 2005 (see text) **(C).** *RAS*, renin-angiotensin system.

hypertension, defined as sustained BP levels less than 140/90 mm Hg with no antihypertensive medications, may be obtained in 35% to 50% of patients. Predictors of cure (normal arterial pressures without medication at 6 months and beyond after angioplasty) include lower systolic BP, younger age, and a shorter duration of hypertension.[191] A systematic analysis of treatment reports for fibromuscular dysplasia evaluated evidence from 47 series treated with angioplasty (1,616 patients) and 23 surgical series (1,014 patients).[192] Methods of evaluating BP outcomes and definitions of cure varied considerably in these reports. However, by selecting the criterion of BP $<$ 140/90 mm Hg after withdrawing antihypertensive drug therapy as a cure in contemporary terms, these authors found that only 36% of percutaneous transluminal renal angioplasty (PTRA)-treated patients and 54% of surgical patients achieved that response. Predictors of a favorable response included younger age and earlier date of publication. Major complications were lower with PTRA versus surgery (7% versus 15%). Hence, these authors concluded that renal revascularization even for FMD offers "moderate benefit."[192]

A large majority of patients with FMD are female. The age of detecting hypertension is usually younger than the series with atherosclerotic disease.[190] In general, such patients have relatively less aortic disease and are at less risk for major complications of angioplasty. Because the risk for major procedural complications is low and the potential antihypertensive drug treatment requirement is so long, most clinicians favor an early intervention for hypertensive patients with FMD with the hope of reduced antihypertensive medication requirements after successful angioplasty.

Angioplasty and Stenting for Atherosclerotic Renal Artery Stenosis

During the introduction of PTRA, it was soon evident that ostial lesions commonly failed to respond, in part because of extensive recoil of the plaque, which extended into the main portion of the aorta.[193] These lesions develop restenosis rapidly even after early success. Endovascular stents were introduced for ostial lesions in the late 1980s and early 1990s.[194]

The technical advantage of stents to achieve and maintain vessel patency is indisputable. An example of successful renal artery stenting is shown in Fig. 42.21. A prospective comparison between angioplasty alone versus angioplasty with stents indicates intermediate (6 to 12 months) vessel patency was 29% and 75%, respectively. Restenosis fell from 48% to 14% in stented patients.[193] As technical success

continues to improve, many reports suggest nearly 100% technical success in early vessel patency, although rates of restenosis continue to reach 14% to 25%.[150,195]

The introduction of endovascular stents has expanded the practice of renal revascularization, in part because of the improved technical patency that is possible with ostial atherosclerotic lesions as compared to angioplasty alone. It should be emphasized that much of the shift to endovascular procedures relates to their applicability in elderly patients and the widespread availability of interventional radiology.

What are the reported outcomes of patients undergoing renal artery stenting? These are commonly considered in terms of (1) BP control and (2) the preservation or salvage of renal function in ischemic nephropathy. Results from observational cohort BP studies after stenting face the same limitations as observed with angioplasty alone. Results during the follow-up from 1 to 4 years are summarized for representative series in Table 42.10. These have been reviewed elsewhere.[196] Typically, a fall in BP levels are in the range of 25 to 30 mm Hg systolic, the best predictor of which was the initial systolic BP.[197] Some authors report a 42% improvement in BP with fewer medications needed, although cures were rare and renal function was unchanged.[198] A careful attention to the degree of residual patency led to more than 91% patency at 1 year and 79% at 5 years in 210 patients with stents.[118] BPs were cured or improved in more than 80% of cases. In some cases, angina and recurrent congestive cardiac failure subsides.[199,200] As noted under the trials summarized previously, prospective randomized controlled trials have been less impressive regarding the benefits of angioplasty. The ambiguity of BP responses in these studies has produced widely different recommendations. These range from "we are left with whether renal angioplasty should be considered at all"[201] to a general conviction expressed within the interventional community that "open renal arteries are better than closed renal arteries" and that nearly all renal artery lesions should be opened (and probably stented).[150]

What results regarding the recovery of renal function can be expected after endovascular revascularization? Table 42.10 summarizes some of the recent series. In general, changes in renal function for atherosclerotic renal artery stenosis, as reflected by serum creatinine levels, have been small.[158] Remarkably, the changes in renal function in azotemic patients after surgical reconstruction are similar.[202,203] As we and others have observed, overall group changes in kidney function can be misleading. A careful evaluation of the literature indicates that three distinctly different clinical outcomes are routinely observed for patients with reduced GFR. In some instances (approximately 27%), revascularization produces meaningful improvements in kidney function. For this group, the mean serum creatinine level may fall from a mean value of 4.5 mg per deciliter to an average of 2.2 mg per deciliter. There can be no doubt that such patients benefit from the procedure and can avoid major morbidity (and probably mortality) associated with advanced renal failure. The bulk of patients (approximately 52%), however, have no measurable change in renal function. Whether such patients benefit much depends on the true clinical likelihood of progressive renal injury if the stenotic lesions were managed without revascularization, as discussed previously. Those without much risk of progression gain little. The most significant concern, however, is the group of patients whose renal function deteriorates further after a revascularization procedure. In most reports, this ranges from 19% to 25%.[158,204] In some instances,

42.10 Observational Outcomes of Renal Artery Stent Placement: Hypertension[118,193,194,198,204,206,236–240]

	Cured	Improved	No change
14 series n = 678 patients 98% technical success	Weighted mean: 17% Range: 3–68	Weighted mean: 47% Range: 5–61	Weighted mean: 36% Range: 0–61
Renovascular hypertension n = 472	12%	73%	15%
Renal Artery Stents: Effect on Renal Function in Azotemic Patients			
	Improved	**Stabilized**	**Worse**
14 series reporting "impaired renal function" n = 496 patients	Weighted mean: 30% Range: 10%–41%	Weighted mean: 42% Range: 32%–71%	Weighted mean: 29% Range: 19%–34%
Ischemic nephropathy n = 469	41%	37% no change	22%

this represents atheroembolic disease, or a variety of complications including vessel dissection with thrombosis.[205] Although less common with improved techniques, some of the complications associated with renal artery stenting can be clinically significant, as identified in Table 42.11. Hence, nearly 20% of azotemic patients face a relatively rapid progression of renal insufficiency and the potential for requiring renal replacement therapy, including dialysis and/or renal transplantation.[203,206,207] Possible mechanisms for deterioration include atheroembolic injury, which may be nearly universal after any vascular intervention[208] and acceleration of oxidative stress producing interstitial fibrosis.[209] Whether improving techniques, including the application of distal protection devices for endovascular catheters, will reduce these complications is not yet certain.

Several studies suggest that the progression of renal failure attributed to ischemic nephropathy may be reduced by endovascular procedures.[204,210] Harden et al.[204] presented reciprocal creatinine plots in 23 (of 32 patients), suggesting that the slope of loss of the GFR could be favorably changed after renal artery stenting. It should be emphasized that 69% "improved or stabilized," indicating that 31% worsened; these results were consistent with other series. These reports and a guideline document from the American Heart Association promote the use of breakpoint analysis to analyze and report the results of renovascular procedures. Caution must be applied regarding the use of breakpoints using reciprocal creatinine plots in this disorder, however. This concern was underscored by a report attempting to use estimated GFR (eGFR) changes compared to measured iothalamate GFR values to follow sequential changes in kidney function in atherosclerotic disease. Madder and colleagues[211] found that the staging of kidney disease—and even the direction of change, whether improving or deteriorating—in 254 patients was discordant between 28% and 40% of cases. Vascular disease does not affect both kidneys symmetrically, nor is it likely to follow a constant course of progression, in contrast to diabetic nephropathy, for example. As a result, a gradual loss of renal function with subsequent stabilization can be observed equally with unilateral disease, leading to total occlusion as well as successful revascularization. Perhaps the most convincing group data in this regard derive from serial renal functional measurements in 33 patients with high-grade (> 70%) stenosis to the entire affected renal mass (bilateral disease or stenosis to a solitary functioning kidney) with creatinine levels between 1.5 and 4.0 mg per deciliter. Follow-ups over a mean of 20 months indicate that the slope of GFR loss converted from negative (−0.0079 dL/mg/mo) to positive (0.0043 dL/mg/mo).[210] These studies agree with other observations that long-term survival is reduced in bilateral disease, and that the potential for renal dysfunction and accelerated cardiovascular disease risk is highest in such patients (see previous).

42.11 Complications After PTRA and Stenting of the Renal Arteries[205,206,227]

Minor: (most frequently reported)
- Groin hematoma
- Puncture site trauma

Major: (Reported in 71/799 treated arteries (9%)[227]
- Hemorrhage requiring transfusion
- Femoral artery pseudoaneurysm needing repair
- Brachial artery traumatic injury needing repair
- Renal artery perforation leading to surgical intervention
- Stent thrombosis: surgical or antithrombotic intervention
- Distal renal artery embolus
- Iliac artery dissection
- Segmental renal infarction
- Cholesterol embolism: renal
- Peripheral atheroemboli
- Aortic dissection[205]

Restenosis: 16% (Range: 0%–39%)

Deterioration of renal function: 26% (range: 0%–45%)

Mortality attributed to procedure: 0.5%

Procedure-related complications: 51/379 patients in 10 series: 13.5% (206)

Surgical Treatment of Renovascular Hypertension and Ischemic Nephropathy

Early experience with vascular disease of the kidney was based entirely on surgical intervention, either nephrectomy or vascular reconstruction, with the objective of surgical curability.[10] For that reason, much of the original data regarding split renal function measurements were geared toward identifying functionally significant lesions as a guide by which patients should be selected for a major surgical procedure. Surgical intervention is less commonly performed in the current era, in part because age and comorbid risks of patients with atherosclerotic disease commonly favor endovascular procedures when feasible.

Methods of surgical intervention have changed over the decades. A review in 1982 emphasized the role for ablative techniques, including the partial nephrectomy. Use of ablative operative means was guided by the difficulty of controlling BP during this period. They are less common since the expansion of tolerable medication regimens, as noted previously. The recent introduction of laparoscopic techniques, including the hand-assisted nephrectomy, may return attention to nephrectomies as a means to reduce medication requirements with low morbidity in high-risk patients.

Surgical series from the 1960s and early 1970s indicated that the cure of hypertension was present only in 30% to 40% of subjects, despite attempts at preselection. The survival of groups chosen for surgery appeared to be better than those chosen for medical management. This likely reflected the heavy disease burden and preoperative risks identified in those for whom surgery was excluded. The Cooperative Study of Renovascular Disease in the 1960s and 1970s examined many of the clinical characteristics of renovascular hypertension. These studies identified some of the limitations and hazards of surgical intervention and reported mortality rates of 6.8%, even in excellent institutions. The mean age in this series was 50.5 years. Definitions of operative mortality included events as late as 375 days after the procedure and may have overestimated the hazard. Had the authors considered only deaths within the first week, for example, the immediate perioperative mortality was 1.7%.[107]

The subsequent development of improved techniques for patient selection, including screening for coronary and carotid disease, for renal artery bypass, and endarterectomy, and for combined aortic and renal artery repair, represent major elements in the history of vascular surgery.[10] Several of the options developed for renal artery reconstruction are listed in Table 42.12. Most of these methods focus on reconstruction of the vascular supply for the preservation of nephron mass. A transaortic endarterectomy can effectively restore circulation to both kidneys. It requires aortic cross-clamping and may be undertaken as part of a combined procedure with aortic replacement. The identification and treatment of carotid and coronary disease led to reductions in surgical morbidity and mortality. By addressing associated cardiovascular risk before surgery, early surgical mortality falls below 2% for patients without other major diseases.

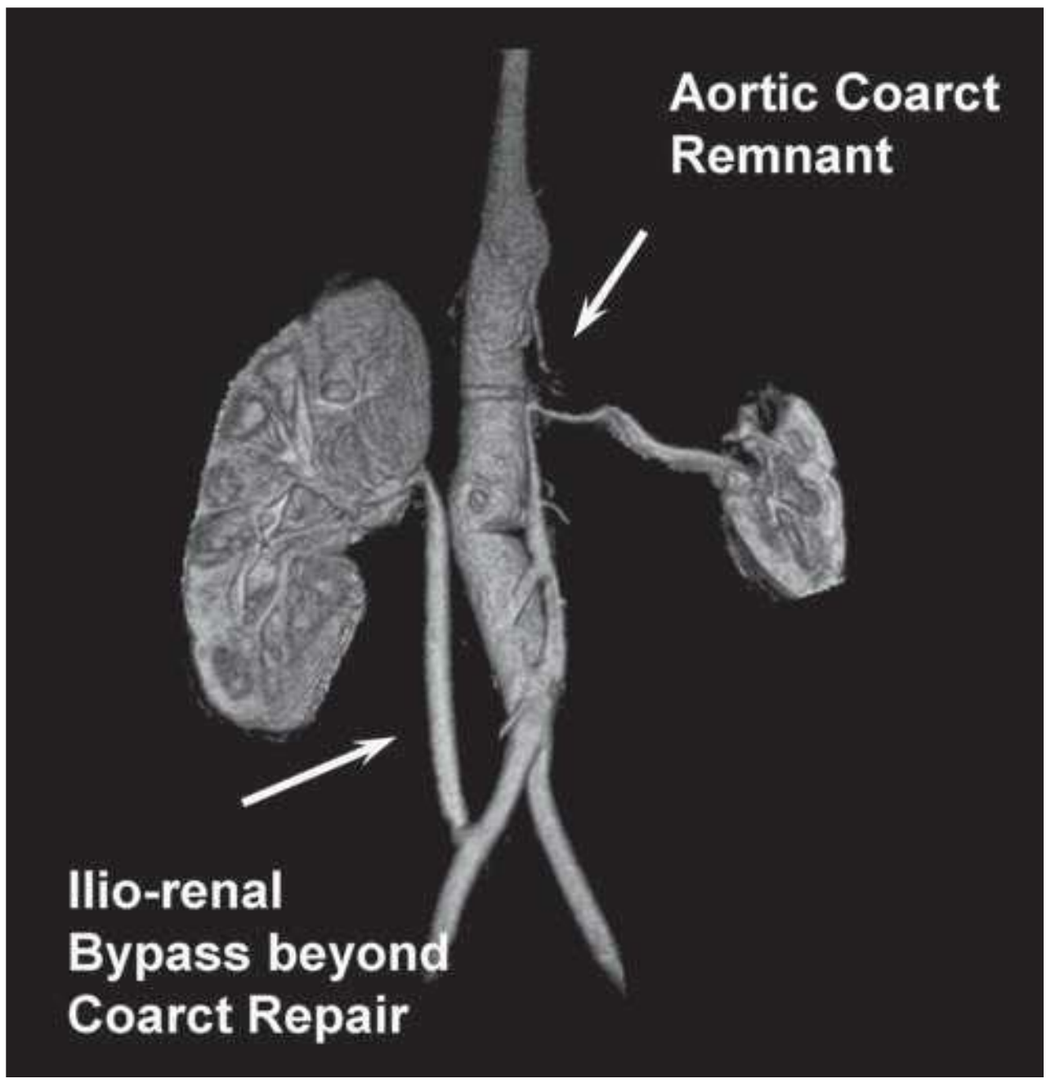

FIGURE 42.22 The surgical correction of renovascular disease. This is an example of late renal artery compromise after the correction of aortic coarctation in childhood. The tenuous status of renal circulation was corrected by construction of an ilio-renal bypass. These operative procedures now are reserved mainly for complex cases and repeated failures of endovascular stenting.

42.12 Surgical Procedures Applied to Reconstruction of the Renal Artery and/or Reversal of Renovascular Hypertension

Ablative Surgery: removal of a pressor kidney
- Nephrectomy: direct or laparoscopic
- Partial nephrectomy

Renal artery reconstruction (require aortic approach)
- Renal endarterectomy
- Transaortic endarterectomy
- Resection and reanastomosis: suitable for focal lesions
- Aortorenal bypass graft

Extra-anatomic procedures: (may avoid direct manipulation of the aorta)
- Require adequate alternate circulation without stenosis at celiac origin
- Splenorenal bypass graft
- Hepatorenal bypass graft
- Gastroduodenal, superior mesenteric, iliac-to-renal bypass grafts

Autotransplantation with ex vivo reconstruction

Modified from Libertino JA, Zinman L. Surgery for renovascular hypertension. In: Breslin DL, Swinton NW, Libertino JA, Zinman L, eds. Renovascular Hypertension. Baltimore, MD: Williams and Wilkins; 1982: 166–212.

Surgical reconstruction of the renal blood supply usually requires access to the aorta. A variety of alternative surgical procedures have been designed to avoid manipulation of the badly diseased aorta, including those for which previous surgical procedures make access difficult (Fig. 42.22). These include extra-anatomic repair of the renal artery using hepatorenal or splenorenal conduits, which avoid the requirement of manipulation of badly diseased aorta.[212] It should be emphasized that success with extrarenal conduits depends on the integrity of the alternative blood supply. Hence, a careful preoperative assessment of stenotic orifices of the celiac axis is undertaken before using either the hepatic or splenic arteries. The results of these procedures have been good, both in short-term and during long-term follow-up studies.[213] An analysis of 222 patients treated more than 10 years earlier indicated that these procedures were

performed with 2.2% mortality and low rates of restenosis (7.3%) and good long-term survival. The predictors of late mortality were age above 60 years, coronary disease, and previous vascular surgery.

The durability of surgical vascular reconstruction is well established. Follow-up studies after 5 and 10 years for all forms of renal artery bypass procedures indicate excellent long-term patency (above 90%) both for renal artery procedures alone and when combined with aortic reconstruction.[214] Results of surgery have been good despite increasing age in the reported series. Patient selection has been important in all of these reports. Although long-term outcome data are established for surgery, limited information is available for endovascular stent procedures, which are more prone to restenosis and technical failure. This proven record of surgical reconstruction leads some clinicians to favor this approach for younger individuals with longer life expectancies.

Some studies have compared endovascular intervention (PTRA without stents) and surgical repair. A single study of nonostial, unilateral atherosclerotic disease in which patients were randomly assigned to surgery or PTRA indicate that although surgical success rates were higher and PTRA was needed on a repeat basis in several cases, the 2-year patency rates were 90% for PTRA and 97% for surgery.[215] A prospective comparison of endovascular stents compared to open surgical renal revascularization argued that patency over 4 years was better with open surgical repair, but that otherwise, the outcome of the two procedures did not differ.[216]

In many institutions, surgical reconstruction of the renal arteries is most often undertaken as part of aortic surgery. Those with impaired renal function at the Mayo Clinic (creatinine ≥ 2.0 mg per deciliter) underwent simultaneous aortic and renal procedures in 75% of cases.[202] Recent experience indicates that combining renal revascularization with aortic repair does not increase the risk of the aortic operation. As with endovascular techniques, the results regarding changes in renal function include improvement in 22% to 26%, no change (some consider this stabilization) in 46% to 52%, and progressive deterioration in 18% to 22% (Fig. 42.23). Using intraoperative color flow Doppler ultrasound allows for the immediate correction of suboptimal results and improved long-term patency.[217] Despite good results, open operations for renal artery revascularization continue to decline. A review of the National Inpatient Sample indicates relatively high mortality rates (approximately 10%) overall, leading the authors to support lower risk endovascular methods where possible or a referral to high volume surgical centers.[218] For experienced centers using current techniques, operative risk is below 4% in good risk candidates.[219,220] Factors for higher risk include advanced age,

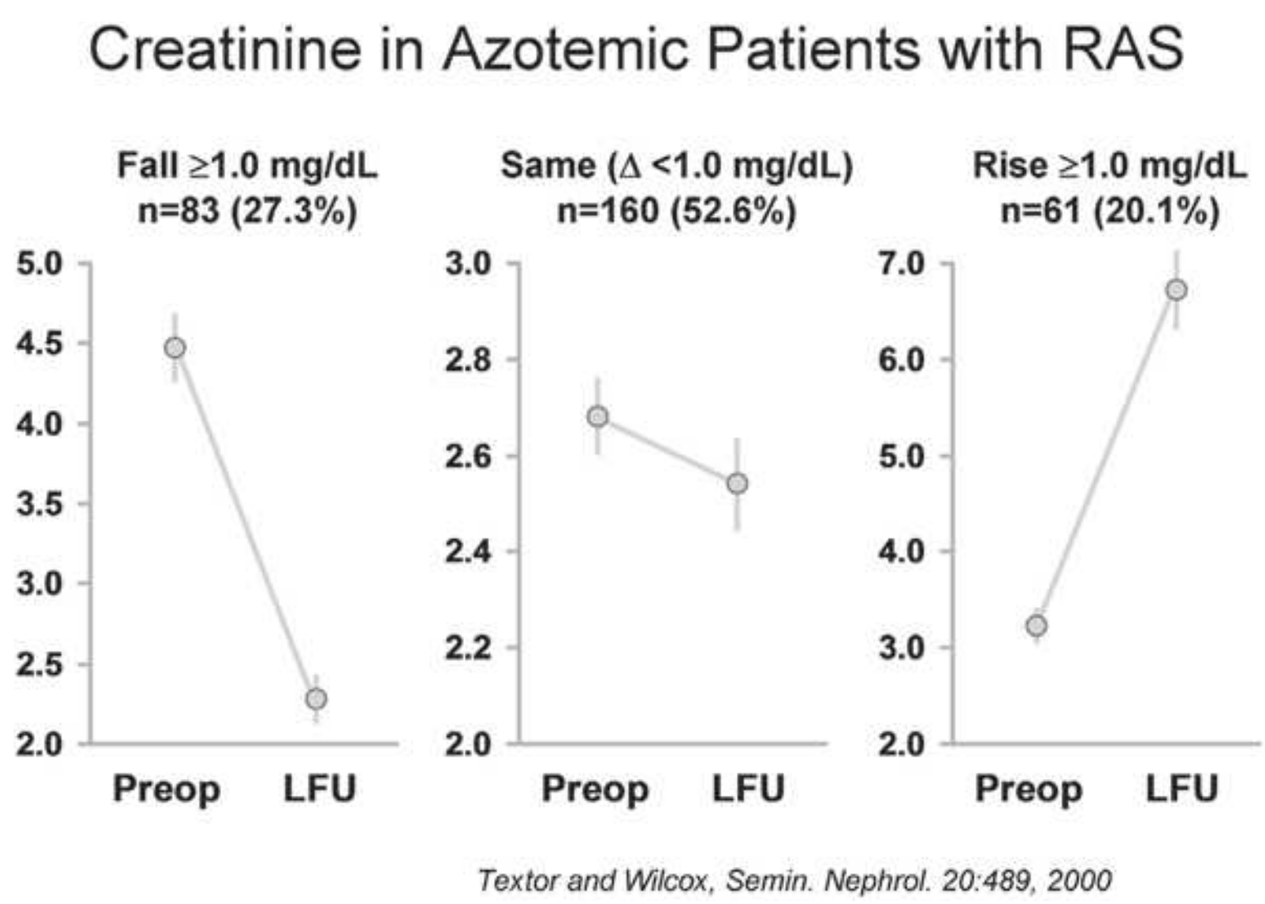

FIGURE 42.23 Renal functional outcomes following surgical revascularization of more than 300 patients with serum creatinine above 2.0 mg per deciliter. Although mean values for the entire group were unchanged, these figures obscured the fact that meaningful clinical improvement (defined as a fall in creatinine ≥ 1.0 mg per deciliter) was evident in 27.3%, and creatinine remained stable in 52.6% (thereby avoiding progression). These outcomes were counterbalanced in this cohort by 20.1% experiencing a distinct worsening of kidney function (defined as a rise in creatinine of more than 1 mg per deciliter). These outcomes have been remarkably reproducible in azotemic patients regardless of the method of revascularization and have been attributed to a variety of effects, including atheroembolic complications.[158] The identification of subjects likely to benefit from revascularization remains a primary challenge in this disorder. RAS, renal artery sclerosis; LFU, last follow-up. (From Textor SC, Wilcox CS. Renal artery stenosis: a common, treatable cause of renal failure? *Annu Rev Med.* 2001;52:421–442, with permission.)

elevated creatinine (above 2.7 to 3.0 mg per deciliter) and associated aortic or other vascular diseases. In some cases, nephrectomy of a totally infarcted kidney provides major improvement in BP control at low operative risk. The introduction of laparoscopic surgical techniques makes nephrectomy technically easier in some patients for whom vascular reconstruction is not an option. These series reflect widely variable methods of determining BP benefits, as discussed in the following.

Studies in patients with bilateral renal artery lesions or vascular occlusions to the entire renal mass indicate that the restoration of blood flow can lead to preservation of renal function in some cases.[221] Most often, this has been undertaken when a clue of preserved blood supply, sometimes from capsular vessels, is evident by renography. Occasionally, revascularization can lead to functional recovery that is sufficient to eliminate the need for dialysis.

Predictors of Likely Benefit Regarding Renal Revascularization

Identifying patients who are most likely to improve their BP and/or renal function after renal revascularization remains an elusive task. As noted previously, functional tests of renin release, such as the measurement of renal vein renin levels, have not performed universally well. Many of these studies are most useful when positive (e.g., the likelihood of benefit improves with more evident lateralization), but have relatively poor negative predictive value; that is, when such studies are negative, outcomes of vessel repair may still be beneficial. As a clinical matter, the recent progression of hypertension remains among the most consistent predictors of improved BP after intervention.

Predicting favorable renal functional outcomes is also difficult. Either surgical or endovascular procedures are least likely to benefit those with advanced renal insufficiency, which is usually characterized by serum creatinine levels above 3.0 mg per deciliter. Nonetheless, occasionally, patients with recent progression to far advanced renal dysfunction can recover GFR with durable improvement over many years. Small kidneys, as identified by a length less than 8 cm, are less likely to recover function, particularly when little function can be identified on radionuclide renography.[222] Reports of the renal resistance index as measured by Doppler ultrasound in 5,950 patients indicated that the identification of lower resistance was a favorable marker for both an improvement in GFR and BP, whereas an elevated resistance index was an independent marker of poor outcomes (Fig. 42.14).[125] None of these is absolute, and recent studies identify favorable outcomes in some patients with adverse predictors.[223] Some authors suggest that detecting abnormalities in fractional flow reserve, as measured by translesional flows and gradients after dilation with papaverine, may predict benefits of revascularization.[156,224] Recent deterioration of kidney function or hypertension portends a more likely improvement with revascularization.

Complications of Renal Artery Angioplasty and Stenting

Atherosclerotic plaque is commonly composed of multiple layers with calcified, fibrotic, and inflammatory components. The physical expansion of such a lesion applies considerable force to the wall of the artery and may lead to cracking and the release of small particulate debris into the bloodstream. Effective balloon angioplasty and stenting requires applying optimal techniques for limiting the damage to blood vessels during the procedure. A review[206] of 10 published series with 416 stented vessels indicated that significant complications arise in 13% of cases, not counting those that led to the need for dialysis. These include several of the events listed in Table 42.11, including hematomas and retroperitoneal bleeding requiring transfusion. Renal function deteriorated in these series on average 26% of the time and 50% of subjects (7 out of 14) with preprocedure creatinine levels above 400 mc/mol progressed to advanced renal failure requiring dialysis.[206] Most complications are minor, including local hematomas and false aneurysms at the insertion site. Occasional severe complications develop, including aortic dissection,[205] stent migration, and vessel occlusion with thrombosis.[225] Local renal dissections can be managed by the judicious application of additional stents. Mortality related directly to this procedure is small, but has been reported in 0.5% to 1.5% of patients.[206,223]

Restenosis remains a significant clinical limitation. Rates vary widely between 13% and 30%, most often developing within the first 6 to 12 months.[206,226–228] The most recent series reported 13% to 16% restenosis, sometimes leading to repeat procedures.

SUMMARY

Renovascular disease is common, particularly in older subjects with other atherosclerotic disease. It can produce a wide array of clinical effects, ranging from asymptomatic incidentally discovered disease to accelerated hypertension and progressive renal failure. With improved imaging and older patients, significant renal artery disease is detected more often than ever before. It is incumbent upon the clinician to evaluate both the role of renal artery disease in the individual patient and the potential risk/benefit ratio for renal revascularization. An algorithm to guide treatment and reevaluation of patients with atherosclerotic renal artery stenosis is presented in Fig. 42.24. The application of this strategy relies heavily on considering comorbid risks and the evolution of both BP control and kidney function over a period of time. Managing cardiovascular risks and hypertension are the primary objectives of medical therapy. For most patients, the realistic goals of renal revascularization are to reduce medication requirements and to stabilize renal function over time. Patients with bilateral disease or stenosis to a solitary functioning kidney may have a lower risk of circulatory congestion (flash pulmonary edema or its equivalent) and

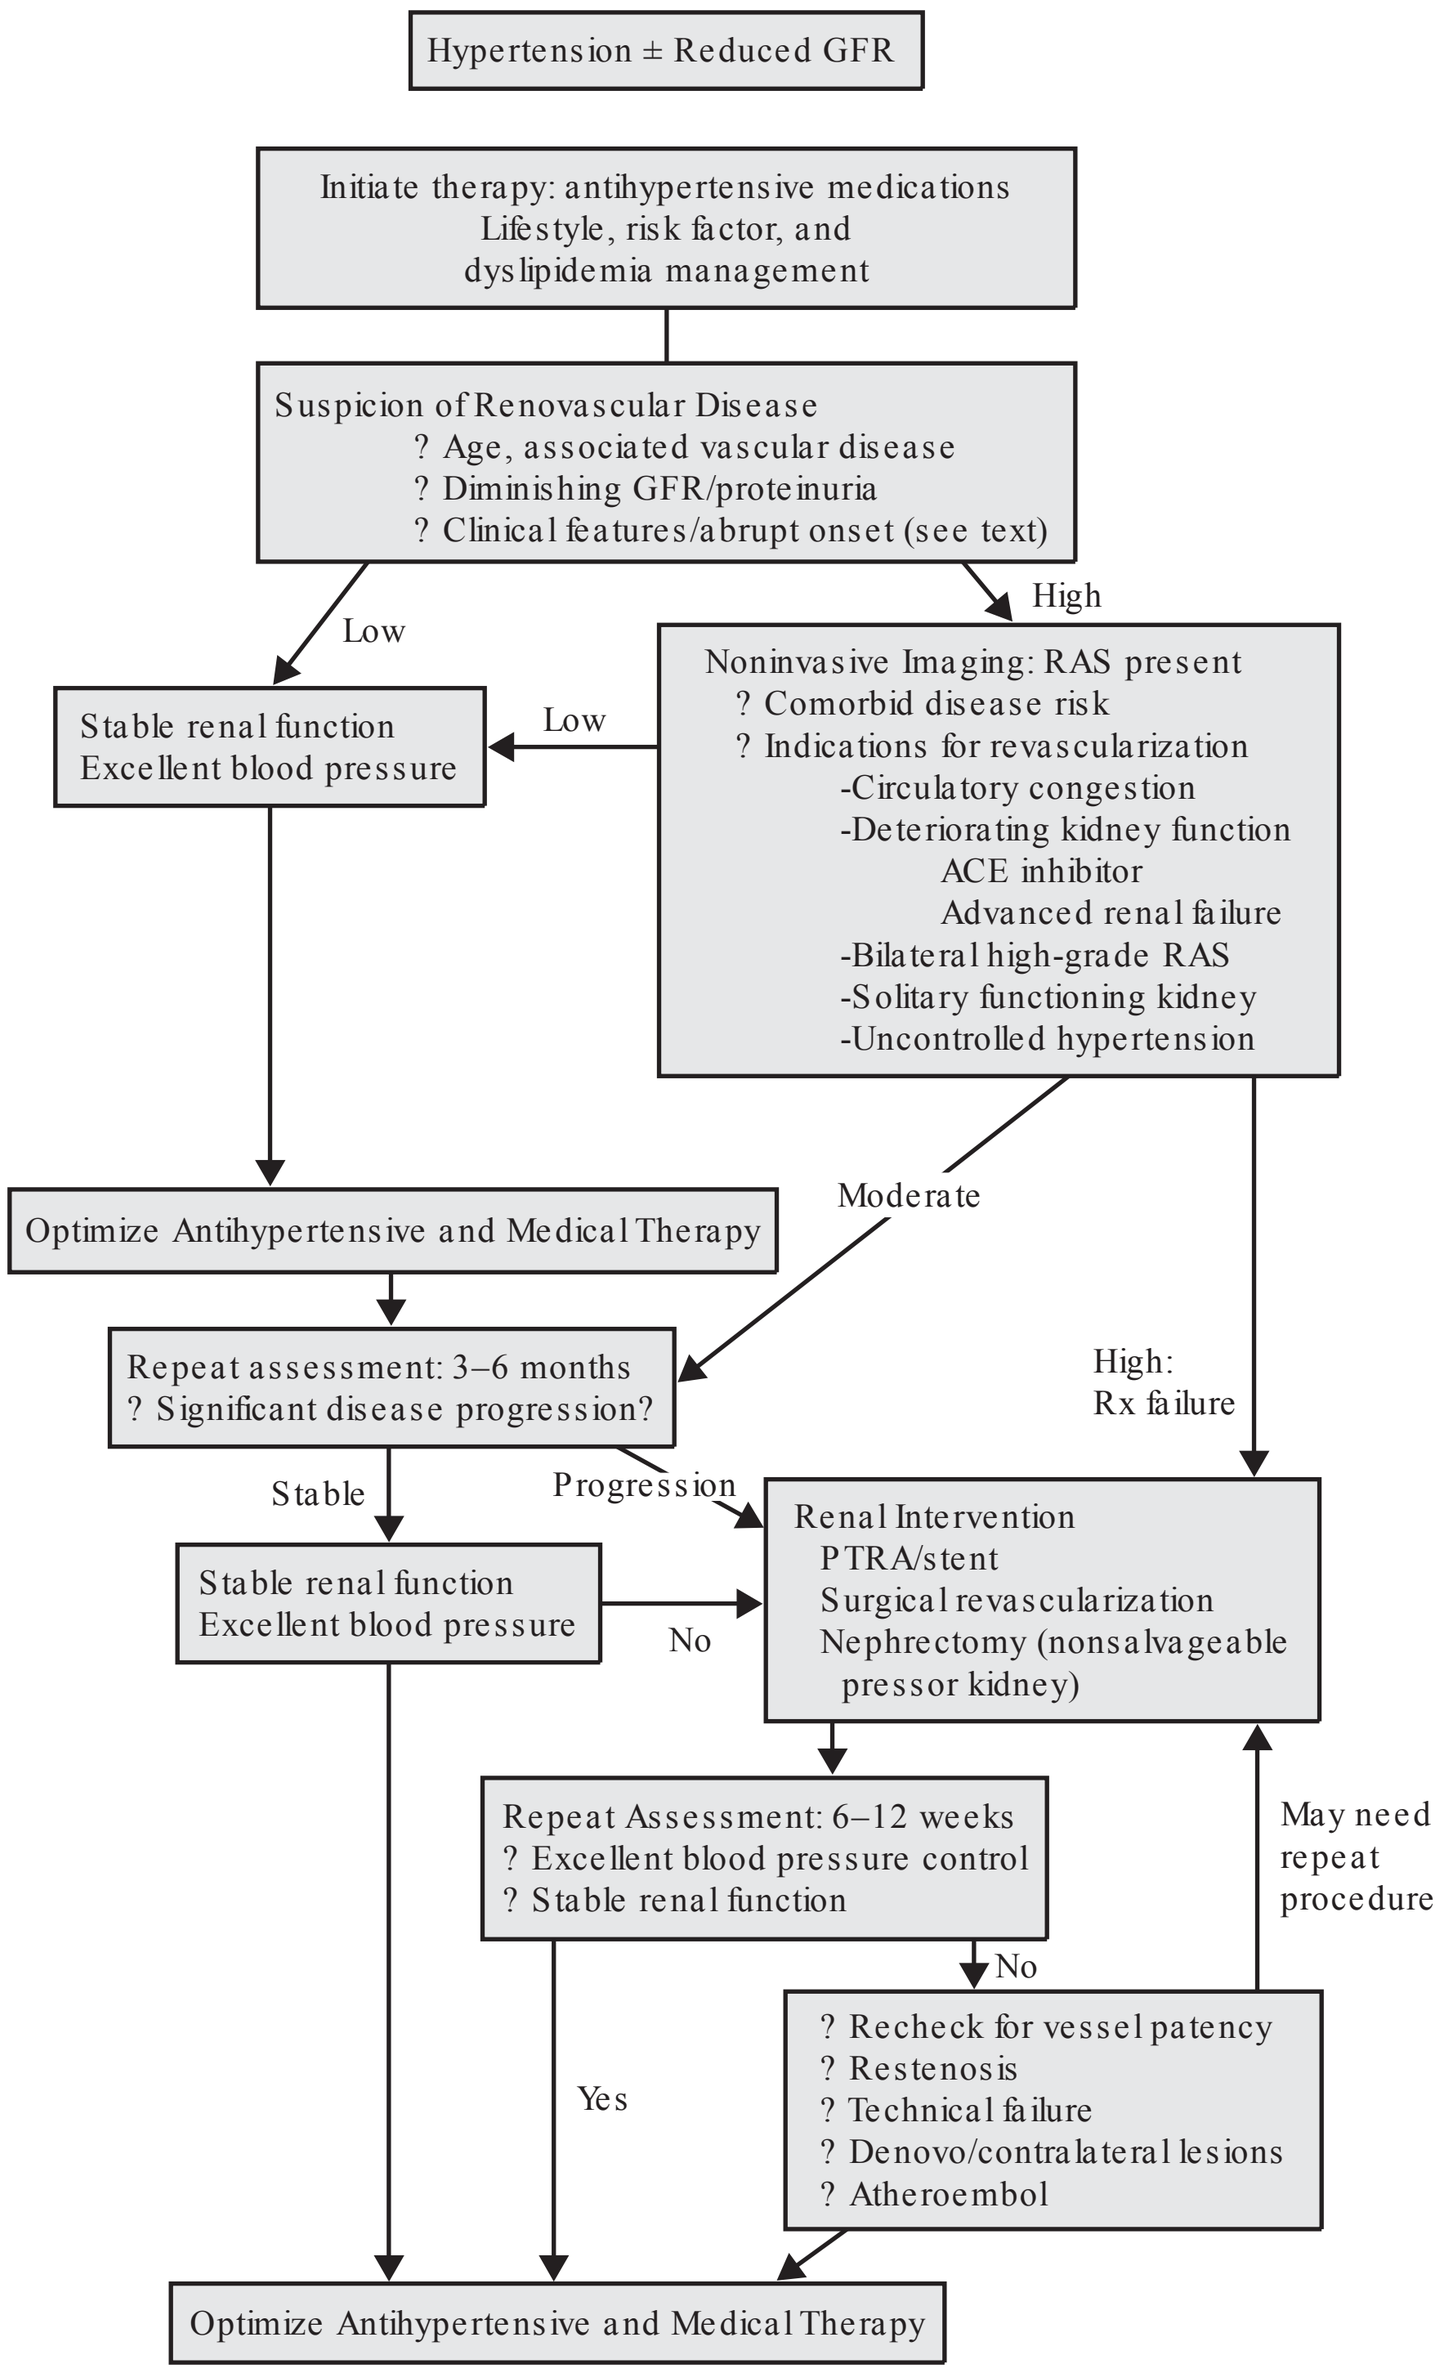

FIGURE 42.24 An algorithm proposed for the identification and management of renovascular disease and ischemic nephropathy. In general, antihypertensive drug therapy is a primary mode of therapy. If kidney function and blood pressure are stable and controlled with a tolerable regimen, there may be little to gain from an extensive evaluation for renovascular disease. If there is high suspicion for developing renovascular disease and/or a commitment to intervene, then more extensive imaging is appropriate. Indications for renal revascularization should be clearly defined before this process proceeds. If kidney function, blood pressure control, or circulatory congestion is inadequate and the individual is prepared to accept the hazards of revascularization, this may be appropriate. As with any vascular disease, periodic follow-up for disease progression and/or recurrence is warranted (see text). GFR, glomerular filtration rate; RAS, renal artery sclerosis; ACE, angiotensin-converting enzyme; PTRA, percutaneous transluminal renal angioplasty. (From Textor SC. Renovascular hypertension and ischemic nephropathy. In: Brenner BM, ed. *Brenner and Rector's: The Kidney*. Philadelphia, PA: Saunders; 2008: 1528–1566, with permission.)

a lower risk for advancing renal failure after revascularizing the kidney. It is essential to appreciate the risks inherent in either surgical or endovascular manipulation of the diseased aorta. These include a hazard of atheroembolic complications and the potential deterioration of renal function related to the procedure itself (estimated at 20% for patients with preexisting kidney dysfunction). Hence, the decision to undertake these procedures should include consideration of whether the potential gain warrants such risks. In many cases, improved BP and the recovery of renal function justify the costs and hazards completely. A follow-up of both BP and renal function is important, particularly because of the

potential for restenosis and/or recurrent disease. Optimal selection and timing for medical management and revascularization depend largely on the comorbid conditions for each patient.

CHAPTER

43 Hypertension due to Primary Aldosteronism and Related Disorders

Emmanuel L. Bravo • Muhammed A. Rafey • Surafel F. Gebreselassie

INTRODUCTION

Distinct hypertensive syndromes related clearly to mineralocorticoid overproduction are increasingly being recognized. Primary aldosteronism (PA), first described by Conn in 1955,[1] is characterized by hypertension, hypokalemia, suppressed plasma renin activity (PRA), and increased aldosterone production. Reversal of the clinical manifestations by the surgical removal of a right adrenal adenoma established the relationship among aldosterone overproduction, hypokalemia, and hypertension for the first time.

Three heritable forms of aldosteronism are known today. FH-1 is a glucocorticoid-remediable form of aldosteronism (GRA). Two glucocorticoid-resistant forms have been described: FH-II, the familial occurrence of aldosterone-producing adenoma (APA), or bilateral adrenal hyperplasia and FH-III, the familial occurrence of massive bilateral adrenal hyperplasia.

Excessive production of deoxycorticosterone (DOC) results from (1) disorders of steroid production (congenital adrenal hyperplasia), (2) generalized glucocorticoid resistance, and (3) DOC-producing adrenocortical tumors.

A group of disorders simulating PA but with a low production of aldosterone or other mineralocorticoids has also been described. These disorders occur as a result of increased activation of mineralocorticoid receptors (MR). The list includes (1) apparent mineralocorticoid excess (AME), (2) cortisol excess, (3) gain-of-function mutation of ENaC of distal renal tubules (Liddle syndrome), and (4) hypertension exacerbated by pregnancy due to a mutation of mineralocorticoid receptors.

PRIMARY ALDOSTERONISM

PA is the most common and important cause of secondary hypertension. The urgency in identifying PA early and treating it is heightened by data from studies demonstrating that persistent elevation of aldosterone levels can result in end organ damage. In addition, findings from animal studies indicate that cardiovascular and renal injury occur independently of blood pressure levels.[2] Cross-sectional studies in humans demonstrate early subclinical end organ damage that includes an increase in carotid intima media thickness and worsening in pulse wave velocity, both gold standard measures of arterial wall stiffness. Further, these studies have shown reduced endothelial function when compared to matched controls with essential hypertension. Several studies have also demonstrated clear evidence of increased left ventricular hypertrophy, diastolic dysfunction, myocardial fibrosis, and albumin excretion rate when compared to those with primary hypertension.[3–10] It appears that these deleterious end organ effects could potentially be ameliorated with early and appropriate medical and surgical intervention.[11]

Pathophysiology of Mineralocorticoid-Induced Hypertension

Aldosterone, a major mineralocorticoid hormone, has potent effects on unidirectional transepithelial sodium transport. Inappropriately elevated aldosterone levels drive sodium and water retention, which increases circulatory volume and cardiac output; the latter, in turn, is reflexively normalized by vasoconstriction, resulting in hypertension. It is reasoned that the increase in total peripheral resistance to maintain the elevated arterial blood pressure occurs later, following vascular autoregulation.[12] However, hypervolemia is not a universal finding in patients with PA.[13] Many patients have either low or normal intravascular volume and there is no correlation between arterial blood pressure and plasma or total blood volume in either men or women with untreated PA. The potent effects of aldosterone on salt and water retention reasonably suggest that hypervolemia might have had a role in initiating the pressure rise and then may have been superseded or even partially reversed by other mechanisms. One could speculate that a secondary rise of resistance after an initial increase in cardiac output would establish new levels of equilibrium. The accumulated evidence favors the conclusion that aldosterone, by producing functional changes in the arterial wall, is responsible for the

initial vasoconstrictive response and the sustained and progressive hypertensive state that follows. Most experimental evidence from intact animal studies suggests that mineralocorticoids both increase membrane permeability to sodium and elevate intracellular sodium concentration, which in turn decreases calcium efflux.[14] By partially depolarizing the muscle cell membrane, the abnormalities of cation turnover lead to vasoconstriction and elevated vascular resistance. Such changes also increase metabolic activity and provide an early signal for vascular smooth hypertrophy, which when combined with rising blood pressure, could lead to thickening of the media and so raise the wall-to-lumen ratio. This structural adaptation implying enhanced reactivity could be crucial for both potentiating and maintaining the hypertensive process.[15] The study suggests that an increase in systemic vascular resistance leading to hypertension could occur independent of changes in intravascular volume.

Prevalence

The prevalence of PA has remained debatable as studies have been fraught with several limitations, which include bias in patient selection and reliance on tests that are not regarded as confirmatory for the diagnosis of PA.[16] A large prospective clinical trial, the PAPY (PA Prevalence in Hypertensives) Study, demonstrated that PA involves at least 11.2% of consecutive patients with newly diagnosed hypertension. Although the patients underwent a thorough workup that allowed the investigators to definitively establish the presence or absence of PA, this may still be an overestimation of PA prevalence in patients with hypertension as study participants were enrolled from specialized hypertension clinics.[17] Gordon and coworkers[18] reported the incidence of 12% of PA in 199 patients referred to their clinic for hypertension. The clue that a much lower prevalence of PA exists in patients with hypertension is provided by another study by Douma et al.[19] that evaluated patients with resistant hypertension, which showed that 11.3% of patients in this group had PA based on the confirmatory salt suppression test. Based on the prevalence of PA in patients with resistant hypertension in the general hypertensive population and the lower prevalence of PA in milder forms of hypertension, we could assume that the prevalence of PA in the general unselected hypertensive population is much lower than currently thought. Therefore, the actual prevalence of PA among unselected hypertensives is still unknown, but can be estimated from the data of Mosso et al.,[20] considering the relative proportion of the different grades of hypertension in the general population is around 4%.

Case Detection of Primary Aldosteronism

A high index of suspicion for PA must be entertained in patients who develop (1) spontaneous or unprovoked hypokalemia; (2) severe hypokalemia (<3 mEq per liter), which does not normalize even with potassium replacement or addition of potassium-sparing diuretics; (3) potassium levels that do not normalize even after discontinuation of diuretics for 4 weeks; (4) resistant hypertension with no other evidence of secondary cause; (5) hypertension with adrenal adenoma; (6) and those who have a family history of PA, early onset hypertension, or cerebrovascular accident at a young age (<40 years).

Serum Potassium

Traditionally, spontaneous hypokalemia (serum K <3.5 mEq per liter) has been regarded as the most effective screening test to diagnosis PA. But data from our studies and others have shown that a substantial number of patients with PA do not present with hypokalemia.[13] The reported prevalence of normokalemia in PA is variable. Conn reported a 7.6% prevalence of normokalemia in his series of 145 patients.[21] In the PAPY study, only 9.6% of patients with PA were found to have spontaneous hypokalemia.[17] In a study by Douma et al.,[19] 45.6% of patients with PA demonstrated hypokalemia. Others have shown a normal serum potassium concentration in 7% to 38% of reported cases.[21,22] In addition, 10% to 12% of patients with proven adrenocortical tumors may not develop hypokalemia during short-term salt loading. A normal serum potassium does not rule out PA; however, spontaneous hypokalemia associated with renal potassium wasting (UkV≥30 mEq per liter) has a high sensitivity and specificity in the diagnosis of PA.

Plasma Aldosterone Concentration:Plasma Renin Activity Ratio (ARR)

The plasma aldosterone concentration (PAC):plasma renin activity (PRA) ratio is considered the best screening test for PA. This technique is highly sensitive but has a high false-positive rate (about 30% to 50%) because PRA, the denominator, can be very low (as low as 0.1 ng per milliliter per hour) in some laboratories. Accordingly, a minimum PRA of 0.65 ng per milliliter per hour is recommended in calculating the ratio.[23] In published studies, the screening cutoff values vary from 7.2 to 100 ng per deciliter per nanogram per milliliter per hour; consequently, there is wide variation in the sensitivity (64% to 100%) and specificity (87% to 100%) of the test.[24] Reported ratios are all laboratory dependent. In a large, multicenter, prospective trial the accuracy of ARR for pinpointing patients with aldosterone-producing adenomas (APA) was close to 80%.[25] In addition, study results demonstrated a highly significant within-patient correlation ($r=0.69$; $P< .0001$) and reproducibility (coefficient of determination: 0.47). Better diagnostic accuracy is obtained if the absolute PAC is included as a second criterion in combination with the ARR. In a retrospective study,[26] the combination of a PAC:PRA ratio >30 and a PAC value >20 ng per deciliter had a sensitivity of 90% and a specificity of 91% for APA.[26] At the Mayo Clinic, a PAC:PRA ratio of ≥20 and a PAC >15 ng per deciliter were found in more than 90% of patients with surgically confirmed APA.[27]

Several factors such as time of day, diet, posture, method of blood collection, and plasma potassium level may affect

ARR sensitivity and specificity. Other factors that may affect ARR sensitivity and specificity include age, gender, race, diabetes mellitus, and use of oral contraceptive agents. Most elderly and diabetic patients have low levels of PRA. About 40% of essential hypertensive patients have low PRA and about 27% of untreated patients with PA may have nonsuppressed PRA.[13] Pizzolo and coworkers[28] reported that oral contraceptive administration may increase ARR, contributing to the diagnostic inaccuracy in women. Only 36.9% of women with positive ARR had confirmed PA by intravenously administered salt.

Blood samples are best obtained in the morning in an ambulatory seated patient. Ideally, all antihypertensive medications should be discontinued 2 to 3 weeks before ARR testing, but in many patients, this is not feasible. Although some drugs may alter the accuracy of the PAC:PRA ratio, they are not usually an issue in patients with PA. Thiazide diuretics, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers can actually improve the diagnostic discriminatory power of the PAC:PRA ratio, whereas beta-adrenergic blockers and central alpha-2 agonists suppress PRA and may give false-positive results,[29] especially if the absolute PAC cutoff is not used. If blood pressure control is an issue, alpha-1-adrenoreceptor blockers and/or a nondihydropyridine calcium channel blocker (such as verapamil) may be used. Furthermore, specific aldosterone antagonists may stimulate plasma renin activity, giving rise to false-negative results.

Confirmatory Test(s)

The diagnosis of PA can often be established with relative ease. In the hypertensive patient receiving no treatment who demonstrates significant hypokalemia ($<$3 mEq per liter) with renal potassium wasting (24-hour urinary potassium $>$30 mEq), PRA below 1 ng per milliliter per hour, and elevated plasma or urinary aldosterone values, the diagnosis of PA is unequivocal and may not undergo salt suppression testing. Often, however, the diagnosis is not obvious because of equivocal values. In such cases, multiple measurements are needed during salt loading. Cleveland Clinic patients ingest a normal diet with additional salt added (1 tsp table salt) to food each day for 5 consecutive days. On the 5th day of increased dietary salt, 24-hour urine is collected for sodium, potassium, aldosterone, and creatinine. On the morning of the 6th day, blood is drawn for basic metabolic panel, aldosterone, and renin activity. A 24-hour urinary aldosterone $\geq$14 μg per day (mean +2 standard deviations above values obtained in essential hypertensives) is definitive evidence of a nonsuppressible aldosterone production as long as the 24-hour urinary sodium is $\geq$200 mEq. The development of hypokalemia (serum K $<$3.5 mEq per liter) with renal potassium wasting (UkV $\geq$30 mEq per liter) provides additional evidence of inappropriate aldosterone production. An aldosterone excretion greater than 14 μg per 24 hours following salt loading distinguishes most patients with PA from those with primary hypertension; only 7% of patients with PA have aldosterone excretion values that fall within the range obtained in primary hypertension.[13]

Because most classes of antihypertensive medications affect plasma aldosterone levels and PRA values, antihypertensive treatment should be modified 4 to 6 weeks before the salt loading test. Long-acting calcium channel blockers and the alpha-adrenoreceptor antagonist doxazosin may be used during this period to control blood pressure when required.

Other aldosterone suppression testing has been described.[30] These include intravenous sodium chloride loading, captopril stimulation, or fludrocortisone suppression with the measurement of PAC. The captopril stimulation test operates on the principle that ACE inhibition is without effect when PRA is suppressed and plasma aldosterone is elevated while PRA increases and plasma aldosterone decreases in patients with secondary aldosteronism. However, the specificity of the test is markedly compromised by the large number of hypertensive patients with suppressed PRA (i.e., in low renin essential hypertension, the elderly, diabetics, and African Americans).

Differentiation of Subtypes

The two major causes of PA are bilateral adrenal hyperplasia (BAH), accounting for 65% to 70% of PA patients and aldosterone-producing adenoma (APA) accounting for 30% to 35% of PA. Unilateral hyperplasia and familial hyperaldosteronism accounts for 3% to 4% of patients with PA.[31] It is important to differentiate those with APA because this is a potentially curable condition with surgical intervention.

Biochemical. Adenomas are likely to be present in a patient with spontaneous hypokalemia ($<$3 mEq per liter) and plasma 18-hydroxycorticosterone levels greater than 100 ng per deciliter. In addition, hyperaldosteronism resulting from a unilateral adrenal abnormality is exquisitely responsive to adrenocorticotropic hormone (ACTH) and not to angiotensin II infusions.[32] A plasma 18-hydroxycorticosterone level $<$100 ng per deciliter or a postural increase in plasma aldosterone, or both, are usually associated with adrenal hyperplasia but do not completely rule out the presence of an adenoma.[13] However, a postural decrease in PAC has a high positive predictive value for the diagnosis of APA because a postural decrease in PAC does not occur in hyperplasia.

Localization of Aldosterone Hypersecreting Adrenal Gland.

Adrenal Computed Tomography Scan. All patients diagnosed with PA should undergo an adrenal computed tomography (CT) scan as the initial study in subtype differentiation.[33] A high resolution CT scan with contrast with fine cuts (2.5 to 3 mm) is the imaging technique that displays the best sensitivity and specificity; it is generally more available and less costly than magnetic resonance imaging (MRI). Adrenal

FIGURE 43.1 A 1.5 cm left adrenal adenoma (*arrow*) in the noncontrast enhanced computed tomography examination. The mass has an attenuation value <10 H and a calculated washout rate >50%. These are radiologic features consistent with an adenoma. Adrenal venous sampling (results shown in Table 43.1) provided evidence of a unilateral, left aldosterone-producing tumor.

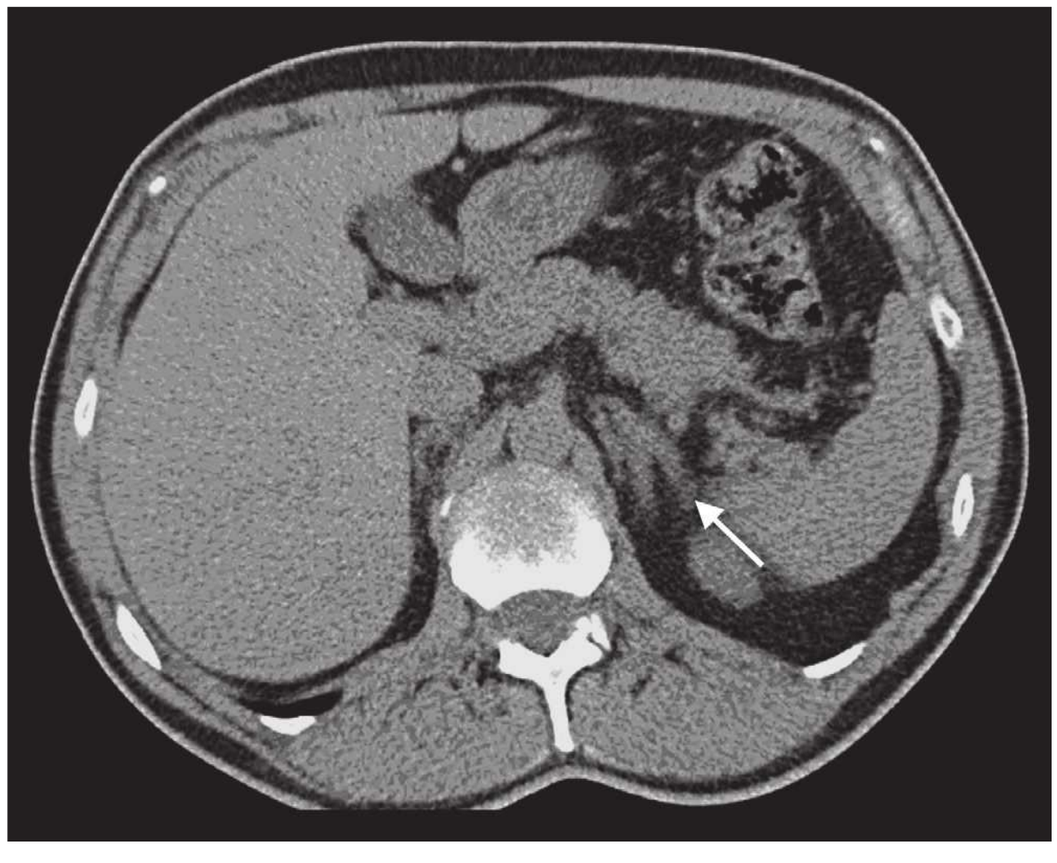

FIGURE 43.2 A noncontrast enhanced adrenal computed tomography scan of a patient with clinical characteristics suggestive of primary aldosteronism. There is marked thickening of both limbs of the left adrenal gland without discrete nodules. The right adrenal gland was reported as normal. Adrenal venous sampling (results shown in Table 43.2) showed bilateral secretion of aldosterone, indicating bilateral adrenal hyperplasia.

cortical adenomas typically have low X-ray attenuation (≤10 HU) in the noncontrast enhanced CT examination (Fig. 43.1). By adding a CT examination approximately 15 minutes after the start of the intravenous contrast enhancement, the washout rate of the iodine contrast medium from the tumor is typically faster (40%) in benign cortical adenomas compared to nonadenomas. Adenomas that are 1.5 cm or larger in diameter can accurately be detected with this procedure. Only 60% of adenomas that measure 1.0 to 1.4 cm are detected, whereas nodules that are less than 1 cm in size are more likely to be missed by a CT scan. Reported sensitivity rates of localizing adenomas by CT scans are between 75% and 80%.[34]

Adrenal Vein Sampling for Aldosterone. The Endocrine Society Guidelines[33] recommend that all patients for whom treatment is practicable and desired should undergo adrenal vein sampling (AVS). There are exceptions to this recommendation. A patient <40 years of age with spontaneous hypokalemia, PAC 15 to 20 ng per deciliter, PRA <1 ng per milliliter, with a solitary adrenocortical macroadenoma (>1 cm) that is discrete, uniform, of low attenuation (HU ≤10), has a contrast washout >40%, and a morphologically normal contralateral adrenal gland needs no further evaluation and should be referred for surgery. Older patients with PA with CT findings demonstrating bilateral morphologically normal or abnormal glands or unilateral microadenoma should be sent for AVS (Fig. 43.2). There is debate as to whether older patients with PA with adrenal CT characteristics identical to the 40-year-old patient described previously should undergo AVS for subtype characterization.

AVS is technically difficult and requires skill and expertise. Even allowing for publication bias from large centers of excellence, success rates are variable ranging from 42%[35] to 75%[36] to 98%[37] for successful bilateral cannulation. During AVS, continuous Cosyntropin is employed to increase adrenal blood flow and to augment aldosterone secretion from an APA. Blood samples are collected from the adrenal veins and the inferior vena cava (IVC) (peripheral sample) for the determination of cortisol and aldosterone concentrations. An adrenal vein:peripheral vein cortisol ratio of at least 3:1 indicates successful adrenal vein catheterization with 100% reproducibility. An aldosterone/cortisol (A/C) adrenal vein over an A/C contralateral adrenal vein of at least 4, plus an A/C contralateral adrenal vein/A/C IVC less than 1, indicates lateralization.[38] Recent data from an Italian center of excellence on a cohort of 44 cases where the diagnosis of APA was not in doubt and using an optimal lateralization ratio (as previously) demonstrated sensitivity and specificity rates of 80% and 75%, respectively (Tables 43.1 and 43.2).[38] A diagnostic approach to patients at risk for PA is shown in Figure 43.3.

11C-Metomidate Positron Emission Tomography/Computed Tomography Scan. Another imaging modality that targets the adrenal cortex is positron emission tomography (PET) using the tracer 11C-metomidate (MTO).[39] MTO binds to the 11β-hydroxylase enzyme in the adrenal cortex and is not taken up in noncortical tumors. The use of MTO-PET for imaging and the characterization of adrenocortical tumors has demonstrated high sensitivity and

43.1 Results of Adrenal Vein Sampling for Plasma Aldosterone and Cortisol Concentrations in the Patient with a Left Adrenal Nodule (Shown in Figure 43.1)

Site	Aldosterone (ng/dL)	Cortisol (μg/dL)	A/C ratio
Right	426	615	0.69
Left	15,230	545	27.94
IVC (peripheral)	65	17	3.82

Adrenal vein sampling was performed with constant infusion of Cosyntropin (50 μg/hr). The adrenal vein:IVC cortisol ratios exceed 3:1 indicating successful cannulation of both adrenal veins. Lateralization to the left is evidenced by an A/C ratio from the left that is ≥4 times greater than that from the right. Suppression of aldosterone secretion from the right adrenal gland is shown by the A/C ratio from the right/A/C ratio in IVC of <1.0 (0.18). A/C, aldosterone/cortisol; IVC, inferior vena cava.

specificity in differentiating adrenocortical from nonadrenocortical tumors.[40,41] Hennings and coworkers[41] evaluated 212 MTO-PET examinations in 173 patients in correlation with 75 histopathologic examinations in 73 patients. Sensitivity was 89% and specificity was 96% for MTO-PET in proving adrenocortical origin of the lesions. Pheochromocytomas, metastases to the adrenal gland, and nonadrenal masses were all MTO negative. A high 11C-MTO tumor uptake, quantified as the standard uptake values (SUV) 15 to 45 minutes after tracer administration, indicated an adrenocortical adenoma with hormonal overproduction. The SUV ratio between the tumor and the contralateral gland was significantly higher in all hormonally secreting adenomas. Burton and coworkers[42] tested the accuracy of 11C-MTO PET-CT scans in 15 patients with an adenoma and successful AVS study. They found that MTO qualitatively distinguished small tumors (>5 mm) from normal adrenal in all patients. They concluded that MTO offers a noninvasive technique to visualize subcentimeter adrenal adenomas and differentiate functional from nonfunctional adrenal tumors.

However, the technique is complicated and the tracer is very expensive to synthesize. The 20-minute half-life of 11C-MTO makes transportation of the tracer to other centers impossible. However, given an easier, cheaper, and more stable labeling procedure, MTO-PET could be an alternative to AVS for subtype differentiation in PA.

43.2 Results of Adrenal Vein Sampling for Plasma Aldosterone and Cortisol Concentration in the Patient with Left Adrenal Gland Hyperplasia (Shown in Figure 43.2)

Site	Aldosterone (ng/dL)	Cortisol (μg/dL)	A/C ratio
Right	3,007	1,257	2.39
Left	6,814	1,253	5.44
IVC (peripheral)	55	31	1.79

Adrenal vein sampling was performed with constant infusion of Cosyntropin (50 μg/hr). The adrenal vein:IVC cortisol ratios exceed 3:1 indicating successful cannulation of both adrenal veins. The A/C ratio from the left/A/C ratio from the right is <4 (2.28) indicating no lateralization. In addition, the A/C ratio from the right/A/C ratio in peripheral vein is >1.0 (1.34), indicating nonsuppression of aldosterone secretion from the right adrenal gland. A/C, aldosterone/cortisol; IVC, inferior vena cava.

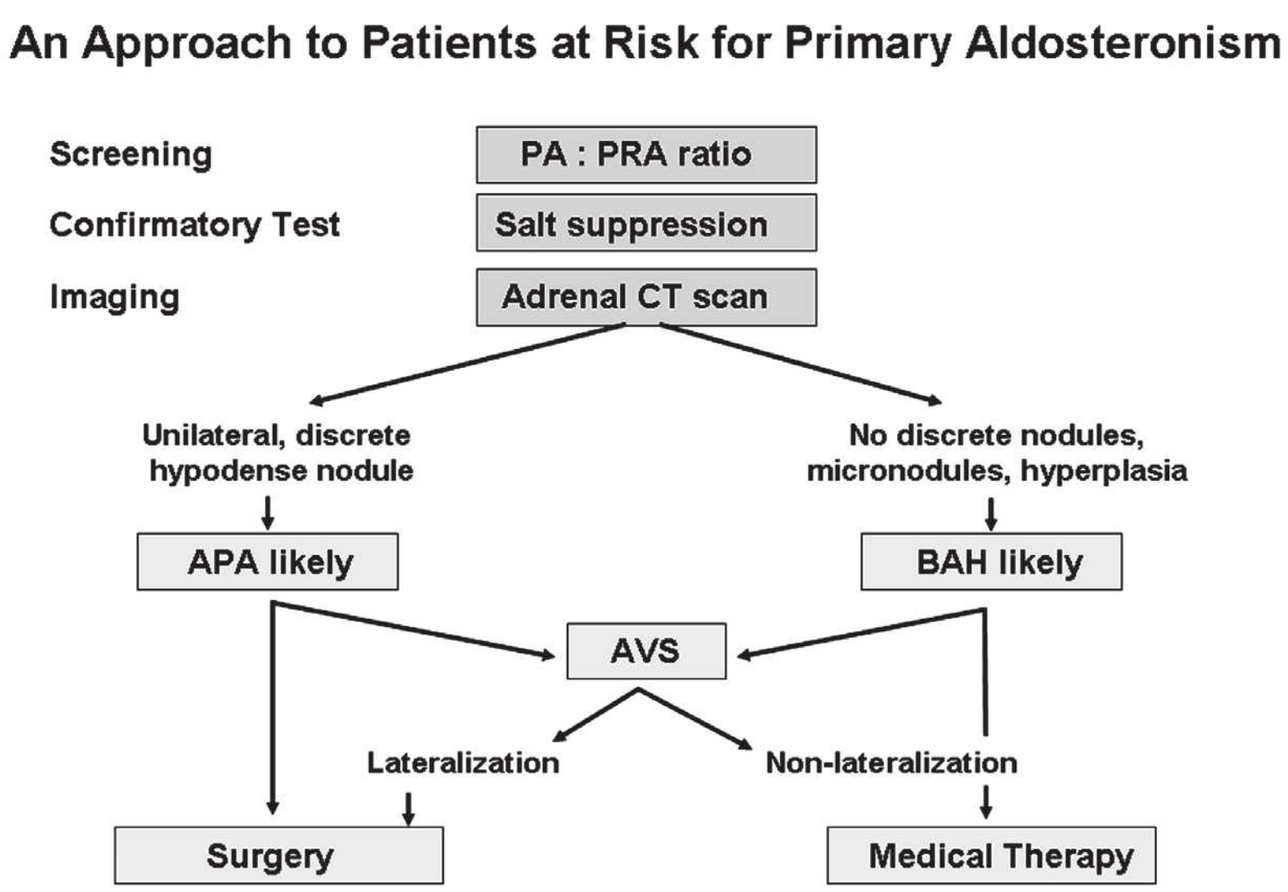

FIGURE 43.3 An approach to patients at risk for primary aldosteronism. *PA*, plasma aldosterone; *PRA*, plasma renin activity; *APA*, aldosterone-producing adenoma; *BAH*, bilateral adrenal hyperplasia; *AVS*, adrenal vein sampling.

Treatment

Medical

Medical therapy for the management of PA is directed not only at controlling blood pressure, but also at protecting end organs from the deleterious effects of excess aldosterone levels.[43] Medical therapy is indicated for those with bilateral adrenal hyperplasia or with an adenoma who are poor candidates for surgical intervention. Surgery is the treatment of choice for those with APA, although medical therapy remains an option because these tumors rarely undergo malignant transformation.[43] The hypertension associated with primary aldosteronism is dependent on excess salt and water retention and is best treated by sustained salt and water depletion (Fig. 43.4).[44] The usual doses of hydrochlorothiazide (12.5 to 50 mg per day) or furosemide (80 to 160 mg per day) in combination with an aldosterone antagonist spironolactone (100 to 200 mg per day) provides for an adequate control of blood pressure and a correction of hypokalemia within 2 to 4 weeks. Additional antihypertensive medications may be required for improved blood pressure control.[45] Among potassium sparing diuretics, spironolactone, an aldosterone antagonist, is the preferred agent because of the adverse cardiovascular effects of prolonged exposure to aldosterone. Several studies have documented a mean reduction of systolic blood pressure by 25% and diastolic blood pressure by 22% with spironolactone therapy in patients with primary hyperaldosteronism.[46,47] The most common side effects of spironolactone include dose-dependent breast and nipple tenderness and gynecomastia. Decreased libido and erectile dysfunction in men and menstrual abnormalities and breast tenderness in women have also been reported.

Eplerenone is a highly selective mineralocorticoid antagonist with efficacy similar to spironolactone.[46] It does not have androgen and progestin receptor activity and is better tolerated and a reasonable alternative in those patients who experience adverse effects with spironolactone. Parthasarathy and coworkers[47] conducted a study comparing the antihypertensive effect of eplerenone and spironolactone in patients with PA. They found a significantly greater antihypertensive effect from spironolactone than that from eplerenone. Alternatively, potassium-sparing diuretics such as triamterene or amiloride combined with hydrochlorothiazide may be used when aldosterone antagonist use is limited by its adverse effects (spironolactone) or prohibitive cost (eplerenone).

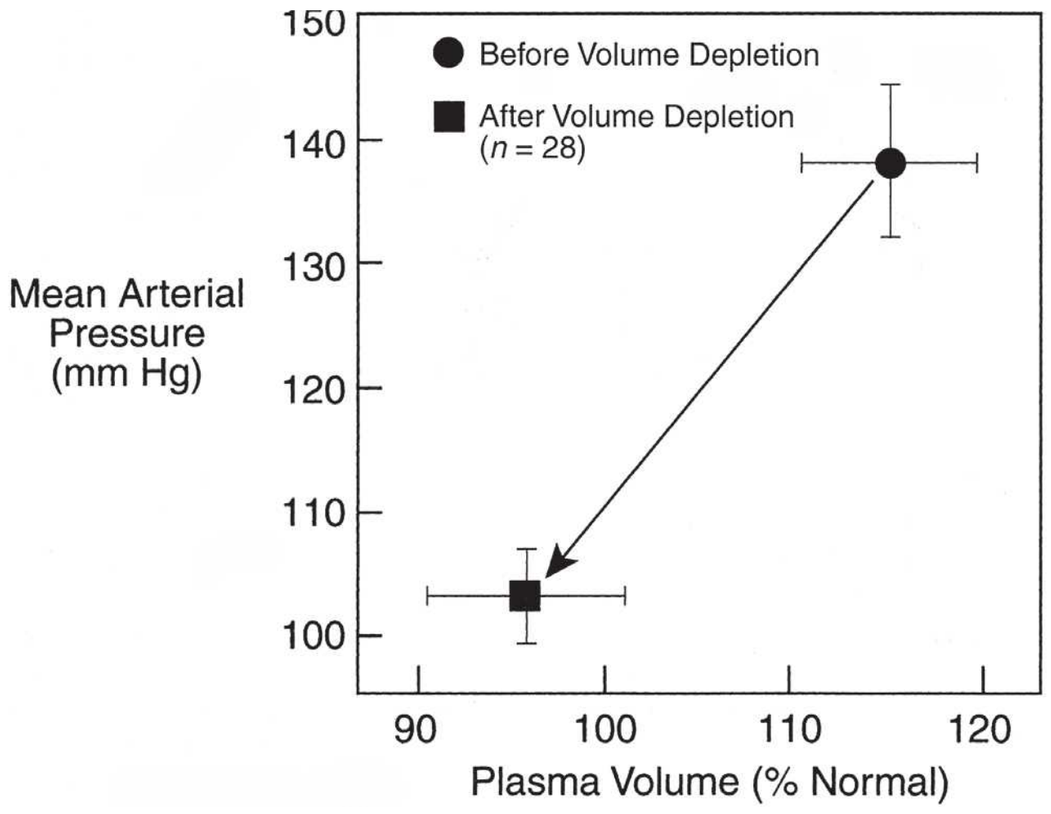

FIGURE 43.4 The effect of diuretic therapy on the blood pressure of patients with primary aldosteronism. Spironolactone (100 mg twice daily) and hydrochlorothiazide (50 to 100 mg per day) were added to current therapy. Blood pressure and plasma volume values were obtained after 8 to 12 weeks of continued therapy. Mean arterial pressure was significantly reduced in all. For the group as a whole, it fell from 138 +/− 2 to 103 +/− 9 (SEM) mm Hg ($P < .01$). Associated with reductions in mean arterial pressure were decreases in plasma volume (from 114% +/− 3% to 97% +/− 2% (SEM), $p < 0.01$. (From Bravo EL. Primary aldosteronism. Issues in diagnosis and management. *Endocrinol Metab Clin North Am*. 1994;23(2):217–282.)

Surgical

In unilateral APA, a laparoscopic adrenalectomy should be considered to minimize risk and postoperative recovery time. In those with bilateral adrenal adenomas, the surgical removal of both adrenal glands is not an option because the adverse metabolic and cardiovascular consequences of adrenal insufficiency are more difficult to treat than the hypertension caused by hyperaldosteronism. Postadrenalectomy, serum potassium levels normalize in all patients. Elevated blood pressure improves to normal levels in 35% to 50% of patients following adrenalectomy and, in those patients who remain hypertensive following surgery, there is a reduction in the number of antihypertensive medications required.[47] In a recent study that followed patients with unilateral APA, there was significant improvement in quality of life after undergoing adrenalectomy.[48] Patients undergoing surgery should receive medical therapy with an aldosterone antagonist for 8 to 10 weeks preoperatively to normalize blood pressure and serum potassium concentrations.

Clinical Outcomes. Significant lowering of blood pressure levels and the normalization of serum potassium occur with both medical[49] (spironolactone) and surgical intervention. After removal of the solitary adenoma, one-third of all cases are cured and free of all therapy, 75% of cases improved with the reduction of antihypertensive therapy, and 100% will have a reversal of hypokalemia. Factors reported to predict cure after an adrenalectomy are response to spironolactone therapy, younger age, shorter duration of hypertension, family history of hypertension in at least one first-degree relative, preoperative use of at least two antihypertensive agents, higher ARR, and 24-hour urinary aldosterone levels.[50,51] A recent study suggests that a unilateral adrenalectomy may be beneficial in carefully selected patients with BAH.[49]

OTHER HYPERTENSIVE DISORDERS ASSOCIATED WITH THE OVERPRODUCTION OF MINERALOCORTICOIDS

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA), also known as familial hyperaldosteronism type 1 (FH-1), is an inherited autosomal disorder that mimics an APA. It is characterized by a strong family history of hypertension and moderate-to-severe hypertension often associated with early death from hemorrhagic stroke as the result of ruptured intracranial aneurysms. In a retrospective review of the International Registry of GRA, 48% of all GRA pedigrees and 18% of all GRA patients had cerebrovascular complications.[52] The frequency of intracranial aneurysms is similar to that of adult polycystic kidney disease, and it has been recommended that screening with MRI angiography should be performed in affected patients beginning at puberty, and every 5 years thereafter.

This disorder is caused by a genetic mutation that results in a chimeric gene product that fuses nucleotide sequences of the 11β-hydroxylase[53] and is regulated by ACTH (Fig. 43.5). In addition, the chimeric gene allows for the

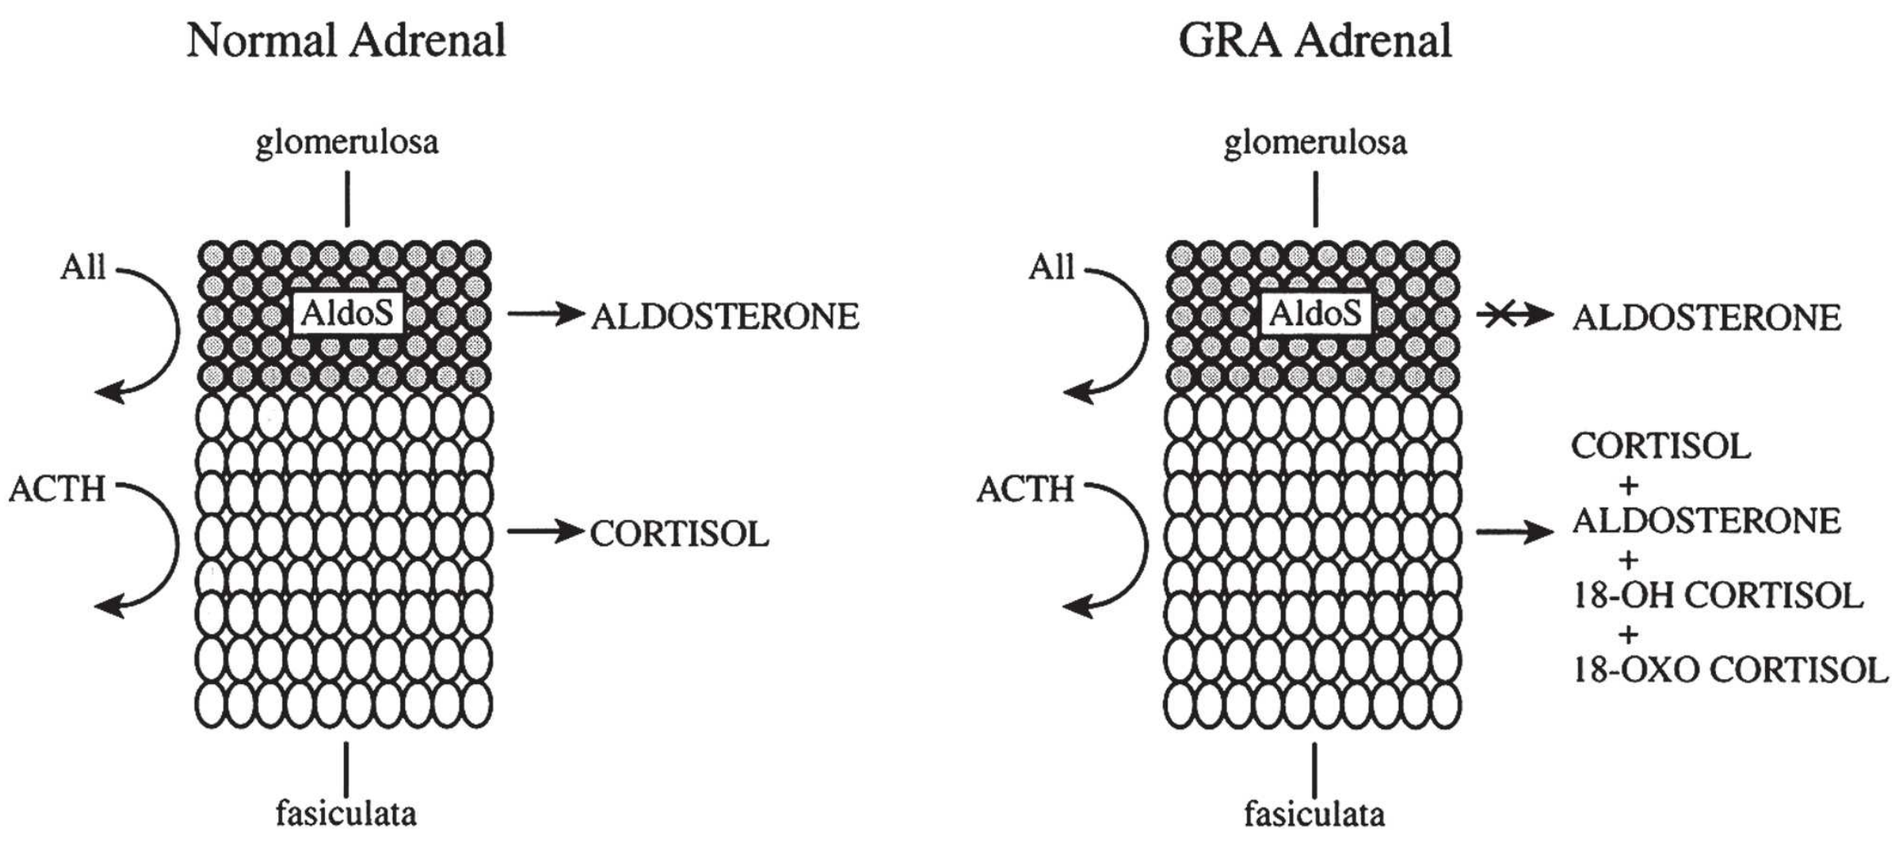

FIGURE 43.5 A model of the physiologic abnormalities in the adrenal cortex in glucocorticoid-remediable aldosteronism (GRA). In the normal adrenal gland, AldoS activity is present only in the adrenal zona glomerulosa. Aldosterone is produced in the glomerulosa layer under the regulation of angiotensin II, and cortisol is secreted from the adrenal fasciculata under the regulation of adrenocorticotropic hormone (ACTH). Steroid 11β-hydroxylase is involved in the biosynthesis of both of these hormones and is expressed in both tissues. The gene is under positive control of ACTH in fasciculata. Ectopic activity of the enzyme in fasciculata results in the metabolism of cortisol to 18-hydroxycortisol and 18-oxocortisol, as well as production of aldosterone from high levels of corticosterone present in fasciculata. These mineralocorticoids are under the control of ACTH, and can consequently be suppressed by exogenous glucocorticoids. (From Lifton RP et al., *Nature Genetics*. 1992;2:66–74.)

ectopic expression of aldosterone synthase enzyme activity in the ACTH-regulated zona fasciculata, which normally secretes only cortisol, but now also secretes aldosterone. Aldosterone secretion is positively and solely regulated by ACTH, not by potassium or angiotensin II. As a consequence, exogenous administration of low-dose glucocorticoid (which suppresses aldosterone secretion in affected individuals) reverses the clinical manifestations of the syndrome.

As in PA, PRA is suppressed, and increased aldosterone production is nonsuppressible by salt loading. Most patients with GRA are not hypokalemic; therefore, serum potassium lacks sensitivity as a screening test for this disorder. Because aldosterone secretion is solely regulated by ACTH, the dexamethasone suppression test has been employed as a diagnostic test. However, the test has a high false-positive rate. For example, Fogari and coworkers[54] reported that only one of eight of their patients with PA that tested positive with the dexamethasone suppression test had the chimeric gene for GRA. Direct genetic screening for the presence of the gene duplication in GRA is 100% sensitive and specific. It is recommended for patients with PA without a radiographic evidence of tumor, for young hypertensive individuals with suppressed PRA (especially children), and for at-risk individuals in affected families. Treatment with low-dose glucocorticoids, amiloride, and aldosterone receptor antagonists effectively controls elevated blood pressure in GRA.

Congenital Disorders of Steroid Hormone Production

P450C11β and 17α deficiencies cause hypertensive variants of congenital adrenal hyperplasia (CAH). Both enzyme deficiencies result in reduced cortisol production with subsequent overproduction of ACTH. In turn, ACTH drives the zona fasciculata to increase the production of precursor steroids with an accumulation of 11–deoxycorticosterone (DOC), a potent mineralocorticoid, leading to hypertension and hypokalemia with suppressed PRA and, unlike PA, virtual absence of aldosterone production. In both enzyme deficiency disorders, inhibiting ACTH release with glucocorticoids decreases DOC production, which results in the normalization of blood pressure and the serum potassium concentration.

In 11β-hydroxylase deficiency, there is a shunting of precursor steroids into the androgen pathway, resulting in the increased formation of androgens, which produce virilization in females or precocious puberty with advanced masculinization in males.[55] This enzyme deficiency clusters in exon 6 to 8 of the CYP11β1 gene and accounts for 15% of cases of CAH in Muslim and Jewish Middle Eastern populations.

By contrast, patients with 17α-hydroxylase deficiency present with hypogonadism in addition to hypertension, hypokalemia, suppressed PRA, and absent aldosterone production.[56] This enzyme deficiency reduces the production of all adrenal and gonadal androgens, resulting in a form of hypergonadotropic hypogonadism and abnormalities of sexual development. The hypogonadal consequence accounts for most of the clinical features of the disorder. Females with this disorder have primary amenorrhea, disproportionately long limbs relative to the trunk, and absent secondary sexual characteristics. Male patients have either ambiguous external genitalia or a female phenotype (male pseudohermaphroditism). A large number of random mutations can cause 17α-hydroxylase deficiency, making genetic diagnosis difficult.

Glucocorticoid Resistance

Cortisol synthesis is regulated through a negative feedback loop in which cortisol feeds back on the pituitary to inhibit ACTH secretion. In generalized inherited glucocorticoid resistance, cortisol remains ACTH dependent but is reset to a higher level than normal.[57] Because the peripheral tissues and pituitary are equally resistant to cortisol, affected individuals do not develop features of Cushing syndrome despite marked elevations in circulating cortisol levels. An ACTH-dependent increase in DOC and in adrenal androgens occurs. The clinical presentation is characterized by virilization and precocious puberty (due to excess adrenal androgens) and by hypertension and hypokalemia (due to excess DOC).

Two strategies are used to treat generalized glucocorticoid resistance. The first employs high amounts of glucocorticoids, such as dexamethasone, to suppress adrenal stimulation by ACTH. Alternatively, mineralocorticoid or androgen antagonists can be used.

HYPERTENSION DUE TO ACTIVATION OF MINERALOCORTICOID RECEPTORS

Syndrome of Apparent Mineralocorticoid Excess

Mineralocorticoid receptors (MR) in the distal nephron of the kidney have equal affinity for their two ligands—aldosterone and cortisol—but are protected from cortisol by the presence of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which inactivates cortisol by converting it to cortisone, preventing full MR occupancy by cortisol despite 100- to 1,000-fold plasma concentrations greater than those of aldosterone (Fig. 43.6).[58] The 11, 18 hemiacetal structure of aldosterone protects it from the action of 11β-HSD2 so that aldosterone has unimpeded access to the receptors. When this mechanism is defective, intrarenal levels of cortisol increase, causing its inappropriate access to MR.[59] The resulting antinatriuresis and kaliuresis leads to hypertension and hypokalemia. Biochemically, PRA is suppressed and aldosterone production is markedly decreased. Elevations in urinary free cortisol excretion and in the ratio of the urinary metabolites of cortisol to those of cortisone, as well as prolongation of the half-life of cortisol, are noted. Plasma cortisol concentrations usually are not elevated.

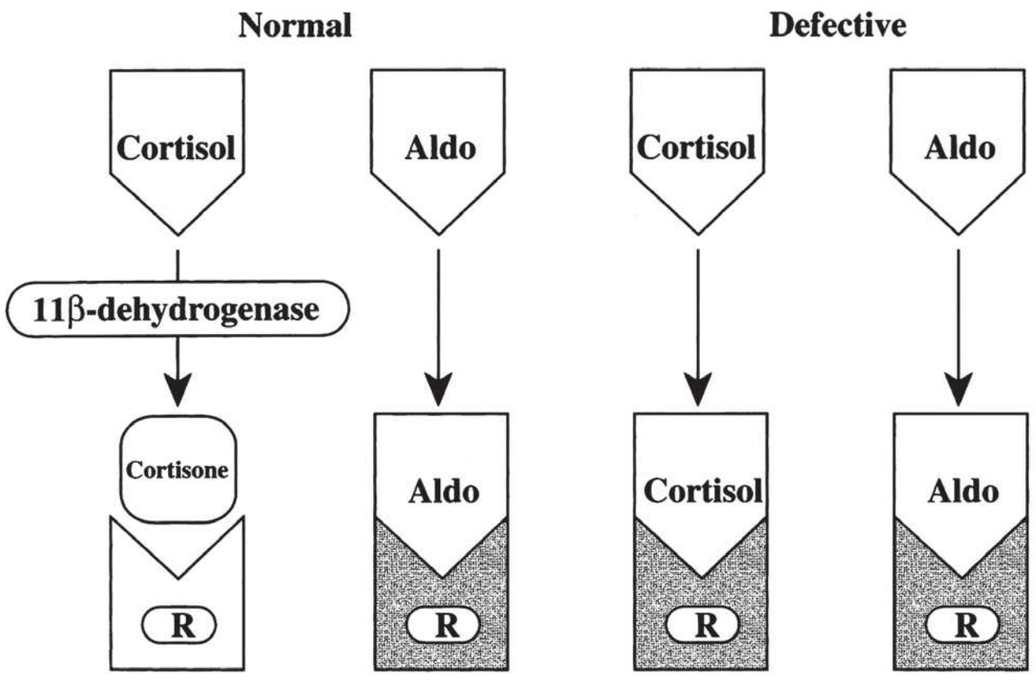

FIGURE 43.6 Enzyme-mediated receptor protection. Normal 11β-hydroxysteroid dehydrogenase converts cortisol to inactive cortisone, protecting mineralocorticoid receptors (R) from cortisol and allowing selective access for aldosterone (Aldo). When 11β-dehydrogenase is defective, cortisol gains inappropriate access to mineralocorticoid receptors with resulting antinatriuresis and kaliuresis. (From Walker BR, Edwards CR. *Endocrinol Metab North Am*. 1994;23:359–377.)

The hypertensive syndrome is reversed by spironolactone or dexamethasone and is exacerbated by the administration of physiologic doses of cortisol.

The recessively inherited apparent mineralocorticoid excess (AME) is caused by a genetic deficiency of 11β-HSD2.[60] Cortisol-mediated excessive mineralocorticoid action results in early-onset severe hypertension, failure to thrive, hypokalemia, suppressed PRA, and low aldosterone levels. The phenotype–genotype of AME may vary widely from mild to severe hypertension depending on the effect of mutation on 11β-HSD2.

Excessive licorice ingestion is known to cause an acquired form of AME. Licorice contains glycyrrhizinic acid, which is hydrolyzed to glycyrrhetinic acid, an inhibitor of 11β-HSD2. This results in an AME-phenotype, including hypertension, hypokalemia, suppressed PRA, and low plasma aldosterone levels. However, because licorice consumption does not always lead to the hypertensive syndrome, Miettinen and coworkers[61] reasoned that genes influencing licorice action may partly determine susceptibility to its side effects. In preliminary studies in human volunteers, those investigators found that a mutation of the 11β-HSD2 gene does not appear to constitute a common cause for licorice-induced hypertensive syndrome. Their studies suggest that subtle variants of the α, β, and λ subunits of the ENaC may render some individuals sensitive to licorice-induced metabolic cardiovascular alterations.

Cushing Syndrome (Resulting from Ectopic Adrenocorticotropic Hormone Excess)

The recognizable causes of Cushing syndrome include Cushing disease (72%), ectopic ACTH excess (12%), adrenal adenoma (8%), carcinoma (6%), and hyperplasia (4%). The typical clinical presentation of Cushing syndrome includes truncal obesity, moon facies, hypertension, plethora, muscle weakness and fatigue, hirsutism, emotional disturbances, and typical purple skin striae. Carbohydrate intolerance or diabetes, amenorrhea, loss of libido, easy bruising, and spontaneous fracture of ribs and vertebrae may also be encountered. Patients with ectopic ACTH excess may not have the typical manifestations of cortisol excess, but they may present with hyperpigmentation of the skin, severe hypertension, and marked hypokalemic alkalosis.

The incidence of hypokalemic alkalosis in the ectopic ACTH syndrome is greater than 90%, compared with only 10% in Cushing syndrome of other causes.[62] It is widely supposed that corticosterone or 11-DOC is responsible for mineralocorticoid excess, but poor correlation exists between the levels of these steroids and the degree of hypokalemia. A better predictor of hypokalemia is the level of cortisol.[63,64] Several studies suggest that the ratio of cortisol to cortisone metabolites is increased in all forms of Cushing syndrome. Ulick and associates[65] advanced the hypothesis that excessive circulating cortisol overwhelms the enzyme, thus escaping conversion of cortisol to cortisone and gaining inappropriate access to Mrs. Walker and coworkers[66] demonstrated a negative correlation between the extent of impairment of 11β-hydroxysteroid dehydrogenase and plasma potassium concentration in 26 patients with Cushing syndrome, 9 of whom had higher cortisol-to-cortisone ratios than the 15 patients with pituitary Cushing and the 2 patients with adrenal adenomas.

The determination of a 24-hour urinary free cortisol concentration is the best available test for documenting endogenous hypercortisolism.[67] A level of higher than 100 μg per 24 hours suggests excessive cortisol production. There are virtually no false-negative results. False-positive results may be obtained in non-Cushing hypercortisolemic states (e.g., stress, chronic strenuous exercise, psychiatric states, glucocorticoid resistance, malnutrition). If a differentiation between pituitary and ectopic sources of ACTH cannot be made based on plasma levels alone, pharmacologic manipulation of ACTH secretion should be performed. The overnight dexamethasone suppression test requires only a blood collection for serum cortisol the morning after the patient has taken a 1.0-mg dose of dexamethasone at 11 p.m. the previous evening. In physiologically normal subjects, cortisol levels at 8 a.m. will be suppressed to 5.0 μg per deciliter or less.

When the syndrome has been diagnosed by appropriate biochemical testing, the cause must be identified. A radioimmunoassay of plasma ACTH is the procedure of choice for pinpointing the basis of hypercortisolism, but this test is not available in many hospitals. In patients with ACTH-independent Cushing syndrome, ACTH levels have usually been suppressed to less than 5 pg per milliliter. In contrast, patients with the ACTH-dependent form tend to have either normal or elevated levels of ACTH, usually higher than 10 pg per milliliter. In patients with Cushing disease

43.3 Humoral Characteristics of Mineralocorticoid-Dependent Hypertension

Disorder	Aldosterone	Cortisol	Androgen
Primary aldosteronism (PA)	High	Normal	Normal
Glucocorticoid-remediable aldosteronism (GRA)	High	Normal	Normal
Excess deoxycorticosterone production			
– 11β-hydroxylase deficiency	**Low**	**Low**	**High**
– 17α-hydroxylase deficiency	**Low**	**Low**	**Low**
– Glucocorticoid resistance	**Low**	**Very high**	**High**
Apparent mineralocorticoid excess	Low	Normal	Normal
Ectopic ACTH excess	Low	Very high	Normal

ACTH, adrenocorticotropic hormone.

(i.e., basophilic pituitary microadenomas), ACTH release can be inhibited only at much higher doses of dexamethasone (2 mg every 6 hours for 2 days). The established criterion for the test is that suppression of the 24-hour urine and plasma steroids to less than 50% of baseline indicates pituitary Cushing syndrome (i.e., Cushing disease). Failure to suppress these concentrations to less than 50% of baseline is considered consistent with an ectopic source of ACTH or ACTH-independent Cushing syndrome. The best way to differentiate pituitary ACTH excess from the ectopic production of ACTH is with the inferior petrosal sinus procedure for ACTH concentration, which is invasive and carries its own risks.[68] The test has been characterized in the literature as having 100% sensitivity and 100% specificity. The criterion currently used after corticotropin-releasing hormone administration is that the ACTH gradient between the inferior petrosal sinus and the peripheral site will be greater than 2 if the patient has Cushing disease.

Table 43.3 shows the humoral characteristics of mineralocorticoid-dependent hypertension.

Liddle Syndrome

Liddle syndrome is a rare autosomal dominant disorder with variable penetrance. Patients with Liddle syndrome clinically present with hypertension, hypokalemia, and metabolic alkalosis at a relatively young age. However, some patients with Liddle syndrome are not hypokalemic[69] at presentation. Sporadic cases of Liddle syndrome have also been described.[70] Thus, the absence of hypokalemia at presentation and/or the absence of a family history do not preclude the diagnosis. In the absence of hypokalemia, a positive family history of hypertension at a young age, with some members being hypokalemic, should lead to the suspicion of the genetic disorder.

The defect in Liddle syndrome results from the constitutive activation of amiloride-sensitive epithelial sodium channels (ENaC) on distal renal tubules, which causes excessive sodium reabsorption. This channel is composed of at least three subunits and is normally regulated by aldosterone. The mutations causing Liddle syndrome have been localized to genes on chromosome 16p12 that encodes the β and λ subunits of ENaC.[71] Deletions or substitutions in a short proline-rich segment of the intracytoplasmic C-terminus result in the inability of these subunits to bind with an intracellular protein ligase (Nedd4) that normally removes the luminal sodium channel from the cell surface in response to decreased circulating aldosterone.[72] Failure to remove sodium channels results in an increased number of ENaC at the renal distal apical cell surface. These mutations in "gain-of-function" result in excessive sodium reabsorption (leading to hypertension and suppressed PRA) and increased potassium secretion (producing hypokalemia and metabolic alkalosis). Aldosterone levels are undetectable, and antagonism of MR with specific aldosterone receptor antagonists have no effect on either blood pressure or serum potassium. Hypertension and hypokalemia are effectively treated with sodium deprivation or potassium-sparing agents that block the collecting tubule sodium channels (amiloride or triamterene).[73] Genetic testing is the most reliable method of establishing the diagnosis of Liddle syndrome.[74]

Activating Mutations of Mineralocorticoid receptors

In 2000, Geller and coworkers[75] described a group of women with early onset hypertension (<20 years of age), which was markedly exacerbated by pregnancy. Hypertension in these patients could be very severe and unresponsive to antihypertensive therapy. There were no proteinuria, edema, or neurologic changes, excluding preeclampsia. Hypertension was often accompanied by hypokalemia (with renal potassium-wasting), and suppressed PRA and aldosterone levels, which normally increase 10-fold in pregnancy, were undetectable.

These investigators found a mutation in the MR, S810L, which results in constitutive MR activity and alters specificity, with progesterone and other steroids, lacking 21-hydroxyl groups that are normally MR antagonists, becoming potent agonists of MR L80. Similarly, spironolactone, another MR antagonist commonly used in the treatment of patients with hypertension and hypokalemia, is also a potent agonist of MR L810 and is contraindicated in MR L810 carriers. The hypertension is promptly reversed by delivery.

CHAPTER

44 Malignant Hypertension and Other Hypertensive Crises

Charles R. Nolan • Stuart L. Linas

THE CLINICAL SPECTRUM OF SEVERE HYPERTENSION

The vast majority of hypertensive patients are asymptomatic for many years until complications due to atherosclerosis, cerebrovascular disease, or congestive heart failure develop. In a minority of patients this "benign" course is punctuated by a hypertensive crisis.

A hypertensive crisis is defined as the turning point in the course of an illness at which acute management of the elevated blood pressure plays a decisive role in the eventual outcome. The haste with which the elevated blood pressure must be controlled varies with each crisis. However, the crucial role of hypertension in the disease process must be identified and a plan for management of the blood pressure successfully implemented if the outcome is to be optimal. The absolute level of blood pressure is not the most important factor in determining the existence of a hypertensive crisis. In children, pregnant women, and other previously normotensive individuals in whom moderate hypertension develops suddenly, a hypertensive crisis can occur at a diastolic blood pressure normally well tolerated by adults with chronic hypertension. Furthermore, in adults with only mild to moderate hypertension, a crisis can occur when there is concomitant acute end-organ dysfunction involving the heart or brain.

Approximately 1% to 2% of patients with hypertension will have a hypertensive emergency at some time in their life. A recent study explored changes in the frequency of hospitalizations and in-hospital mortality for hypertensive emergencies before and after the publication of the Seventh Joint National Committee (JNC7) on the prevention, detection, evaluation, and treatment of high blood pressure.[1] Using the Nationwide Inpatient Sample from 2000 to 2007, adult patients hospitalized with a diagnosis of hypertensive emergency were identified based on International Classification of Diseases, 9th revision, clinical modification codes. A total of 456,259 hospitalizations with the diagnosis of hypertensive emergency occurred from the start of calendar year 2000 to the end of calendar year 2007. Analysis revealed that the frequency of hospitalizations in the United States with a hypertensive emergency increased about 1.11% over this time period from 101/100,000 population in 2000 to 111/100,000 population in 2007. Despite this increase in hospitalizations, the all-cause in-hospital mortality rate for hypertensive emergencies decreased from 2.8% in the pre-JNC7 era to 2.6% in the post-JNC7 era (odds ratio [OR] 0.91, 95% confidence interval [CI] 0.86–0.96). The authors conclude that although the number of patients with hypertensive emergency increased from 2000 to 2007, the mortality rates decreased significantly after publication of the JNC7 guidelines. The spectrum of hypertensive crises and other categories of severe hypertension are outlined in Table 44.1.

Malignant hypertension is a clinical syndrome characterized by marked elevation of blood pressure with widespread acute arteriolar injury. The clinical sine qua non of malignant hypertension is the finding of hypertensive neuroretinopathy. Hypertensive encephalopathy is a medical emergency in which cerebral malfunction is attributed to the severe elevation of blood pressure. It is one of the most serious complications of malignant hypertension. However, hypertensive encephalopathy can also occur in the absence of malignant hypertension (neuroretinopathy). Hypertensive encephalopathy can develop in the setting of severe hypertension of any cause, especially when acute blood pressure elevation occurs in previously normotensive individuals with eclampsia, acute glomerulonephritis, pheochromocytoma, or drug withdrawal hypertension. Clinical features include severe headache, blurred vision or blindness, nausea, vomiting, and mental confusion. If aggressive treatment is not initiated, stupor, convulsions, and death can ensue within hours. There is a prompt and dramatic clinical response to antihypertensive therapy.

On occasion, hypertension that is not in the malignant phase (hypertensive neuroretinopathy is absent) may still qualify as a hypertensive crisis when acute end-organ dysfunction occurs in the presence of even moderate hypertension. The term benign hypertension with acute complications includes hypertension complicating acute

44.1 The Clinical Syndromes of Severe Hypertension

Hypertensive crises

- Malignant hypertension (hypertensive neuroretinopathy present)
- Hypertensive encephalopathy
- Benign hypertension with acute complications (acute organ system dysfunction but no hypertensive neuroretinopathy)
  - Acute hypertensive heart failure (acute diastolic dysfunction with pulmonary edema)
  - Atherosclerotic coronary vascular disease
    - Acute myocardial infarction
    - Unstable angina
  - Acute aortic dissection
  - Active bleeding including postoperative bleeding
  - Central nervous system catastrophe
    - Hypertensive encephalopathy
    - Intracerebral hemorrhage
    - Subarachnoid hemorrhage
    - Severe head trauma
  - Catecholamine excess states
    - Pheochromocytoma crisis
    - Monoamine oxidase inhibitor-tyramine interactions
    - Antihypertensive drug withdrawal syndromes
    - Phenylpropanolamine overdose
  - Preeclampsia and eclampsia
  - Poorly controlled hypertension in a patient requiring emergency surgery
  - Severe postoperative hypertension
  - Scleroderma renal crisis
  - Miscellaneous hypertensive crises
    - Severe hypertension complicating extensive burn injury
    - High-dose cyclosporine in children after bone marrow transplantation
    - Autonomic hyperreflexia in quadriplegic patients
    - Severe hypertension with acute rejection or transplant renal artery stenosis in renal allograft recipients
    - Hypoglycemia in patients receiving β-adrenergic receptor blockers

(continued)

44.1 The Clinical Syndromes of Severe Hypertension (continued)

Benign hypertension with chronic stable complications (chronic end-organ dysfunction but no hypertensive neuroretinopathy)
Chronic renal insufficiency due to primary renal parenchymal disease
Chronic congestive heart failure with diastolic dysfunction
Atherosclerotic coronary vascular disease
Stable angina
Previous myocardial infarction
Chronic cerebrovascular disease
Transient ischemic attacks
Prior cerebrovascular accident
Severe uncomplicated hypertension (severe hypertension without hypertensive neuroretinopathy or end-organ dysfunction)

pulmonary edema (acute diastolic dysfunction), acute myocardial infarction or unstable angina, acute aortic dissection, active bleeding, or central nervous system (CNS) catastrophe (hypertensive encephalopathy, intracerebral or subarachnoid hemorrhage, or severe head trauma). In each case, adequate control of the blood pressure is the cornerstone of successful therapy.

Catecholamine excess states—such as pheochromocytoma crisis, monoamine oxidase inhibitor–tyramine interactions, use of sympathomimetic drugs (cocaine, amphetamines, phencyclidine, or high-dose phenylpropanolamine), and abrupt withdrawal of antihypertensive medications (clonidine, methyldopa, or guanabenz)—can produce life-threatening hypertensive crises. The clinical presentation usually includes marked elevation of blood pressure with headache, diaphoresis, and tachycardia. With the severe acute elevation of blood pressure a number of complications can occur, including hypertensive encephalopathy, intracerebral hemorrhage, and pulmonary edema due to acute left ventricular diastolic dysfunction. Thus, catecholamine-related hypertensive crises require prompt recognition and control of blood pressure to avert disaster.

Preeclampsia is a hypertensive disorder unique to pregnancy that usually presents after the 20th week of gestation with proteinuria, edema, and hypertension. Eclamptic seizures may ensue and without treatment may result in death. Eclampsia is considered to be a subtype of hypertensive encephalopathy.[2]

Poorly controlled hypertension in a patient requiring emergency surgery is a hypertensive crisis because of the increased cardiovascular risk that accompanies inadequate preoperative blood pressure control. Surgical manipulation of the carotid arteries or open heart surgery (especially coronary artery bypass) is occasionally followed by severe hypertension in the immediate postoperative period. Severe postoperative hypertension represents a crisis requiring immediate blood pressure control because it can cause hypertensive encephalopathy or intracerebral hemorrhage, or jeopardize the integrity of vascular suture lines and thereby lead to postoperative hemorrhage.

In patients with progressive systemic sclerosis, scleroderma renal crisis can occur with sudden onset of hypertension that may enter the malignant phase. There is a rapid progression to end-stage renal disease (ESRD) within days to weeks unless the vicious cycle of hypertension, renal ischemia, and activation of the renin–angiotensin–aldosterone axis is interrupted.

Severe acute hypertension can also occur in patients with extensive burns or children receiving high-dose cyclosporine for allogeneic bone marrow transplantation. In quadriplegic patients, hypertensive crises may develop due to autonomic hyperreflexia resulting from stimulation of nerves below the level of the spinal cord injury. Hypertensive crises due to autonomic hyperreflexia can also develop in Guillain-Barré syndrome. Hypertensive crises may also complicate acute rejection or transplant renal artery stenosis

in patients with renal allografts. In each of these conditions, a sudden increase in blood pressure may cause acute pulmonary edema, hypertensive encephalopathy, cerebrovascular accident, and death.

On the other hand, severe hypertension or the presence of hypertensive complications does not always imply the existence of a hypertensive crisis requiring immediate control of the blood pressure. Patients with benign hypertension (no hypertensive neuroretinopathy) and chronic stable end-organ dysfunction do not require emergent reduction of blood pressure, although a long-term lack of adequate blood pressure control often results in further deterioration of end-organ function. The term benign hypertension with chronic stable complications includes hypertension occurring in the setting of primary renal parenchymal disease with chronic kidney disease, chronic congestive heart failure, atherosclerotic coronary vascular disease (stable angina pectoris or prior myocardial infarction), or chronic cerebral vascular disease (prior transient ischemic attacks or cerebrovascular accident).

It is important to emphasize that the finding of severe hypertension does not always imply that a hypertensive crisis is present. In patients with severe hypertension that is not accompanied by acute end-organ dysfunction or evidence of malignant hypertension (hypertensive neuroretinopathy) eventual complications due to stroke, myocardial infarction, or congestive heart failure occur over a time frame of months to years rather than hours to days. Although long-term control of blood pressure can prevent these complications, a hypertensive crisis cannot be diagnosed, as there is no evidence that acute reduction of blood pressure results in any improvement in short-term or long-term prognosis. Severe uncomplicated hypertension is defined by a diastolic blood pressure higher than 115 mm Hg without evidence of malignant hypertension (no hypertensive neuroretinopathy) or signs of acute end-organ dysfunction. Although this is not a true hypertensive crisis as defined earlier, it is the most common presentation of severe hypertension. Severe uncomplicated hypertension is usually found in patients with chronic essential hypertension who are undiagnosed, undertreated, or not adherent with medical therapy. It is most often discovered incidentally in an otherwise asymptomatic patient. There is no evidence of hypertensive encephalopathy or other acute end-organ dysfunction. The fundi do not show striate hemorrhages, cotton-wool spots, or papilledema. Because the potential complications of severe uncomplicated hypertension develop with a time frame of months to years, the once common practice of abrupt reduction of blood pressure with oral antihypertensive agents prior to discharge from the acute care setting is no longer accepted as the standard of care.[3–5] Instead, the goal of treatment should be the gradual reduction of blood pressure to normotensive levels over a few days in conjunction with frequent outpatient follow-up visits to modify the antihypertensive regimen and reinforce the importance of lifelong adherence with medical therapy. In the past this entity has been termed urgent hypertension. Use of the more descriptive term severe uncomplicated hypertension is preferable because there is no need for urgent reduction of blood pressure as would be required in patients with true hypertensive crises.

MALIGNANT HYPERTENSION

Etiologies of Malignant Hypertension

Hypertension of virtually any etiology can enter a malignant phase (Table 44.2). Thus, malignant hypertension is not a single disease entity but rather a syndrome in which hypertension can be either primary (essential) or secondary to

44.2 Etiologies of Malignant Hypertension

Primary (essential) malignant hypertension[a]
Secondary malignant hypertension
Chronic kidney disease
Chronic glomerulonephritis[a]
Chronic pyelonephritis[a]
Analgesic nephropathy[a]
Immunoglobulin A nephropathy[a]
Acute glomerulonephritis
Radiation nephritis
Ask-Upmark kidney
Renovascular hypertension[a]
Oral contraceptives
Renal cholesterol embolization
Scleroderma renal crisis
Antiphospholipid (anticardiolipin) antibody syndrome
Chronic lead poisoning
Endocrine hypertension
Pheochromocytoma
Aldosterone-producing adenoma
Cushing syndrome
Congenital adrenal hyperplasia

[a]Most common underlying etiologies.

one of any number of different etiologies.[10] Moreover, in the individual patient with malignant hypertension, on clinical grounds it is often difficult to distinguish whether the underlying hypertension is primary or secondary.

Malignant hypertension usually develops in patients with preexisting, poorly controlled, or undiagnosed hypertension. However, occasional patients have been described who experience an abrupt onset of so-called de novo malignant hypertension without a preceding phase of benign hypertension.[7] The presence of de novo malignant hypertension almost always indicates an underlying secondary cause of hypertension.[7]

Primary (Essential) Malignant Hypertension

In the era prior to the introduction of antihypertensive drugs, malignant hypertension evolved from underlying essential hypertension in more than 50% of patients.[8] However, more recent series found a lower incidence of primary malignant hypertension, most likely reflecting prevention of malignant hypertension through effective control of blood pressure among patients with essential hypertension.[9] In a series of patients collected between 1979 and 1985, primary malignant hypertension was found in only 20%.[10] This observation may not apply to black patients, because among blacks, essential hypertension continues to represent the most common underlying etiology of malignant hypertension.[11–13] Essential hypertension appears to be a rare cause of malignant hypertension in children. Secondary causes of hypertension such as chronic pyelonephritis, chronic glomerulonephritis, and renovascular hypertension are much more common in this younger age group.[14]

Secondary Malignant Hypertension

The most common secondary cause of malignant hypertension is primary renal parenchymal disease. Chronic glomerulonephritis was reported to underlie the development of malignant hypertension in up to 20% of patients.[10] Unless a history of an acute nephritic episode or long-standing hematuria or proteinuria is available, the underlying glomerulonephritis may be apparent only if a renal biopsy is performed. Underlying IgA nephropathy has been reported as a relatively common secondary cause of malignant hypertension.[14,15] Vesicoureteral reflux with chronic pyelonephritis may lead to malignant hypertension in children and young adults.[16] Superimposed malignant hypertension may also occur as a complication of analgesic nephropathy.[23] Malignant hypertension may develop as an early or late complication of radiation nephritis.[17] Renovascular hypertension due to either fibromuscular dysplasia or atherosclerotic renal artery stenosis is a well-recognized cause of malignant hypertension. In a series of 123 patients with malignant hypertension, renovascular hypertension was found in 43% of white patients and 7% of black patients.[18] Scleroderma renal crisis is the most acute and life-threatening manifestation of progressive systemic sclerosis. It is characterized by severe hypertension (sometimes malignant) with rapidly progressive renal failure. In one large series, scleroderma renal crisis occurred in 7% of white patients and 21% of black patients with progressive systemic sclerosis.[19] The renal histology in scleroderma renal crisis is often virtually indistinguishable from that of primary malignant nephrosclerosis.[20] However, in progressive systemic sclerosis, involvement of the renal vasculature, with proliferative endarteritis involving the interlobular arteries and fibrinoid necrosis of the afferent arterioles, may be a primary event that precedes either hypertension or renal insufficiency.[20] The renal ischemia that results from these lesions causes hypertension through activation of the renin–angiotensin system, leading to a vicious cycle of severe hypertension and renal ischemic injury. Scleroderma renal crisis was once a uniformly fatal complication of progressive systemic sclerosis. With the introduction of angiotensin-converting enzyme (ACE) inhibitors as treatment, outcomes have improved significantly, although 39% to 50% of patients with scleroderma renal crisis continue to have poor outcomes, including ESRD and death.

Epidemiology of Malignant Hypertension

Incidence

Although malignant hypertension is often a complication of preexisting hypertension, the risk of its development in hypertensive patients is difficult to estimate. In early series the incidence of malignant hypertension among hypertensive patients was 1% to 7%.[21] In the era of effective antihypertensive therapy for benign hypertension, the incidence of malignant hypertension appears to have declined to some extent. A review of death certificates in New York City between 1958 and 1974 revealed that the overall mortality due to malignant hypertension had declined by 78% from 2.25 deaths to 0.48 deaths/100,000 population/year.[22] Although some of the decreased mortality was probably due to successful treatment of patients with malignant hypertension with antihypertensive drugs and dialysis, the authors speculated that the overall incidence of malignant hypertension had declined to less than 1% due to successful treatment of benign hypertension. However, despite recent advances in the treatment of essential hypertension, malignant hypertension is clearly not a disease that has vanished. In the United States, during the period from 1983 to 1992, the number of hospital admissions with malignant hypertension or accelerated hypertension as the primary diagnosis (International Classification of Diseases, ICD-9 Code 401.0) doubled from approximately 16,000 to 32,000. Moreover, the number of admissions in which one of these conditions was listed as a diagnosis tripled from approximately 23,000 to 75,000.[23] Reported experience in a multiracial population in England indicates that malignant hypertension is still common with a small proportion of hypertensive patients presenting with malignant hypertension each year.[24] The incidence rate of malignant hypertension for the entire population was approximately one to two cases/100,000/year. Moreover, the

incidence rate did not change over the 24-year period from 1970 to 1993. Recent studies have examined the changing demography of patients with malignant hypertension over the last 40 years.[25,26] The incidence rate for malignant hypertension has remained relatively stable over time. In one study from the United Kingdom, 446 patients with malignant hypertension were included.[25] Mean age was 48 ± 12 years, 65.5% were male gender, 64.7% white European, 20.4% African-Caribbean, and 14.8% South Asian. No significant demographic differences at diagnosis were evident over the 40 years, with the exception of a significant increase in the proportion of malignant hypertension among ethnic minorities (South Asian and Afro-Caribbeans).

Age

Malignant hypertension tends to occurs more frequently in younger subjects. The mean age of patients with malignant hypertension ranges from 40 to 50 years, with 57% of patients between 30 and 50 years old.[21] No difference has been found in the age at onset in men compared to women or whites compared to blacks.[21,27] The age dependency of malignant hypertension could be related to the increased frequency of secondary, more severe forms of hypertension in the young. Alternatively, it is possible that hypertension in patients destined to enter the malignant phase may be more rapidly progressive from the onset, so that the disease would be expected to occur predominantly in younger patients. Malignant hypertension is a rare development in patients beyond the age of 65.[28] The declining incidence of malignant hypertension in patients with essential hypertension relative to age is in marked contrast to the overall incidence of benign hypertension, which reaches a peak in the eighth decade. Patients over age 60 with malignant hypertension usually have underlying renovascular hypertension or primary renal parenchymal disease.[21] In most series of patients with malignant hypertension, males predominate over females by as much as 2 to 1.[21,27]

Race

Blacks have an increased incidence of essential hypertension compared to whites. Moreover, several studies demonstrate that blacks with essential hypertension also have an increased risk of developing malignant hypertension. In a population in which 31% of all hypertensive patients were black, 46% of 200 patients with malignant hypertension were found to be black.[29] In a study of 135 pairs of black and white hypertensive patients matched for age and gender, 4.4% of the black patients had retinopathy consistent with malignant hypertension, whereas only 0.74% of the white patients had these funduscopic findings.[29] The increased frequency of malignant hypertension among blacks may be due to the fact that they presented later in the course of essential hypertension, that antihypertensive therapy in blacks was inadequate to prevent the development of malignant hypertension, or that essential hypertension may be more aggressive and likely to enter the malignant phase in blacks than whites.[30]

Preceding Duration of Benign Hypertension

Although there are occasional case reports in which the malignant phase appears to begin de novo, the majority of patients show evidence of a variable period of preceding benign hypertension before the onset of malignant hypertension. Among 77 patients with malignant hypertension, the documented duration of benign hypertension was 0 to 6 months in 4%, 6 months to 1 year in 10%, 1 to 2 years in 12%, 2 to 4 years in 23%, 4 to 6 years in 16%, 6 to 8 years in 17%, and 8 to 10 years in 4%. Only 14% had benign hypertension for more than 10 years prior to the onset of the malignant phase.[21]

Additional Risk factors for Hypertensive Crisis

A number of additional risk factors have been associated with hypertensive crisis. These include smoking[31,33] and obesity.[41] However, a major under recognized risk factor for hypertensive crisis is nonadherence to therapeutic regimens. In a recent study of 89 patients at a single center, 33 potential risk factors were assessed. Nonadherence to antihypertensive medications was the most important risk identified.[34]

Clinical Features of Malignant Hypertension

The clinical features of untreated malignant hypertension as outlined by Volhard and Fahr in 1914[35] are still valid today: (1) elevation of diastolic blood pressure, usually fixed and severe; (2) funduscopic changes of hypertensive neuroretinopathy with striate hemorrhages, cotton-wool spots, and papilledema; (3) renal insufficiency; (4) rapid progression to a fatal outcome, usually due to uremia if inadequately treated; and (5) renal histology demonstrating malignant nephrosclerosis with fibrinoid necrosis of afferent arterioles and proliferative endarteritis of interlobular arteries.

Unless hypertensive neuroretinopathy is present, malignant hypertension cannot be diagnosed regardless of the height of the arterial blood pressure.[36] However, the other clinical features need not be present initially to substantiate a diagnosis of malignant hypertension. There is no critical level of blood pressure that defines the presence of malignant hypertension. An acute increase in blood pressure in previously normotensive individuals can precipitate the malignant phase at a diastolic blood pressure as low as 100 to 110 mm Hg. Conversely, very high diastolic blood pressures may persist for many years in patients with essential hypertension without the development of malignant hypertension.[37]

With untreated malignant hypertension, severe renal impairment inevitably occurs, although there may be minimal renal involvement at the time of presentation. In this regard, in patients dying early in the course of malignant hypertension due to cerebrovascular accident or congestive heart failure, histologic features of malignant nephrosclerosis may be absent.

Some authors have distinguished accelerated hypertension (hemorrhages and cotton-wool spots) from malignant hypertension (hemorrhages, cotton-wool spots, and papilledema). However, since the finding of striate hemorrhages and cotton-wool spots has the same prognostic significance whether or not papilledema is present,[38,39] it has been recommended that accelerated hypertension and malignant hypertension be regarded as synonymous terms for a clinical syndrome in which there is widespread hypertension-induced acute arteriolar injury. In this regard, the World Health Organization has recommended that the term malignant hypertension be used to describe this disease process.[36]

Presenting Symptoms

The most common presenting complaints in patients with malignant hypertension are headache, blurred vision, and weight loss. Less common presenting symptoms include dyspnea, fatigue, malaise, gastrointestinal complaints (nausea, vomiting, epigastric pain), polyuria, nocturia, and gross hematuria. In many series, the onset of symptoms was noted to be remarkably sudden, such that it could often be dated precisely. In contrast, an "asymptomatic" presentation of malignant hypertension is not uncommon, especially in young black males who deny any prior symptoms when they present in the end-stage of the hypertensive process with florid failure of the brain, heart, and kidneys.

Weight loss is a very common symptom early in the course of malignant hypertension, and often occurs before the onset of anorexia or uremia.[21] In many patients, at least a portion of the weight loss can be attributed to volume depletion resulting from a spontaneous natriuresis with the onset of malignant hypertension.[17,21]

Level of Blood Pressure

There is apparently no absolute level of blood pressure above which malignant hypertension invariably occurs. In most series of patients with malignant hypertension, the average diastolic blood pressure is higher than 120 to 130 mm Hg.[21] However, two series found considerable overlap of blood pressure levels in patients with benign and malignant hypertension.[21,40]

Funduscopic Manifestations

Examination of the ocular fundus is of great importance in the assessment of patients with severe hypertension, especially with regard to prognosis.[41–44]

Although the original classification of hypertensive retinopathy by Keith[45] has proven useful, a number of authorities have recommended abandonment of the Keith and Wagener classification in favor of the hypertensive retinopathy classification initially proposed by Fishberg and Oppenheimer.[42] This classification draws a distinction between retinal arteriosclerosis with arteriosclerotic retinopathy, which is characteristic of benign hypertension, and hypertensive neuroretinopathy, which defines the presence of malignant hypertension (Table 44.3). In essence, two different types of retinal disease occur in patients with hypertension: one that reflects changes induced by arteriolar narrowing (retinal arteriosclerosis) and one that represents acute retinal vascular injury induced by severe hypertension (hypertensive neuroretinopathy).

Retinal arteriosclerosis with or without arteriosclerotic retinopathy is seen in patients with long-standing benign hypertension from either primary or secondary causes. Retinal arteriosclerosis (arteriolosclerosis) is characterized histologically by the accumulation of hyaline material in arterioles. Funduscopic changes reflecting retinal arteriosclerosis include irregularity of the lumen and focal narrowing, arteriovenous crossing changes, broadening of the light reflex, copper or silver wiring, perivasculitis (parallel white lines around blood column), and generalized arteriolar narrowing. Arteriosclerotic retinopathy, which results from this arteriosclerotic process, is manifested by the presence of hemorrhages and hard exudates. The hemorrhages are usually solitary, round, or oval and confined to the

44.3 Retinal Changes in Hypertension

Arteriolar narrowing (diffuse)
Focal arteriolar narrowing
Arteriovenous crossing changes
Broadening of the light reflex
Copper or silver wiring
Perivasculitis
Solitary round hemorrhages
Hard exudates
Central or branch venous occlusion
Hypertensive neuroretinopathy
Generalized arteriolar narrowing
Striate (flame-shaped) hemorrhages[a]
Cotton-wool spots (soft exudates)[a]
Bilateral papilledema[a]
Macular star

[a]Features that distinguish hypertensive neuroretinopathy (characteristic of malignant hypertension) from retinal arteriosclerosis (characteristic of benign hypertension).

periphery of the fundus. They are caused by venous or arterial occlusion.[43] Hard exudates may appear as multiple small white dots that give a powdery appearance to the retina, or they may appear as large glistening spots that are sharply defined from the adjacent retina. Arteriosclerotic retinopathy can also cause localized areas of retinal edema and hemorrhage due to occlusion of small branch veins. However, the principal findings of hypertensive neuroretinopathy, namely, striate hemorrhages, cotton-wool spots, and papilledema, are absent (Table 44.3). The finding of retinal arteriosclerosis in hypertensive patients usually does not imply a poor prognosis.

The lack of clinical significance of retinal arteriosclerosis in hypertensive patients contrasts markedly with the importance and prognostic significance of the finding of hypertensive neuroretinopathy. The appearance of striate hemorrhages and cotton-wool spots with or without papilledema closely parallels the development of severe arteriolar damage (fibrinoid necrosis and proliferative endarteritis) in the circulation of other organs including the brain and kidneys. Hypertensive neuroretinopathy is the clinical sine qua non of malignant hypertension and therefore signifies a far more ominous prognosis than does the finding of retinal arteriosclerosis in benign hypertension.

The appearance of small striate (so-called flame-shaped) hemorrhages is often the first sign that malignant hypertension has developed (Fig. 44.1).

Cotton-wool spots are the most characteristic feature of malignant hypertension and are the result of ischemic infarction of nerve fiber bundles caused by arteriolar occlusion. They usually surround the optic disc and most commonly occur within three disc diameters of the optic disc (Figs. 44.2 to 44.4). Cotton-wool spots begin as grayish-white discoloration of the retina, but within 24 hours they become shiny white with fluffy margins. Red dots may be seen in the bed of the exudate (microaneurysms). Cotton-wool spots are not specific for hypertensive neuroretinopathy and can also be seen with diabetic retinopathy, retinal emboli, and central and branch retinal vein occlusion. However, differentiation of these disorders from malignant hypertension is usually not difficult.

Papilledema can occur in patients with hypertensive neuroretinopathy, but it is not invariably present. In malignant

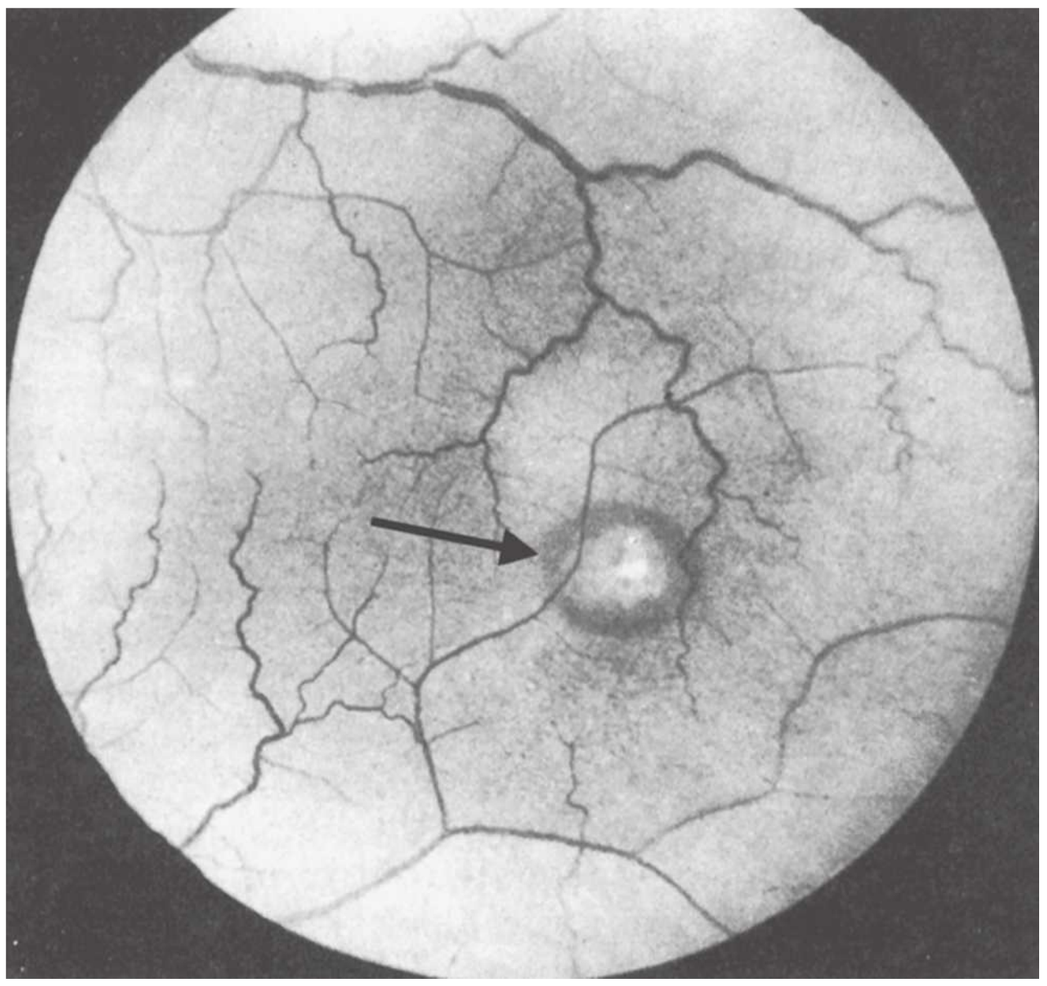

FIGURE 44.5 Hypertensive choroidopathy in malignant hypertension demonstrating focal serous detachment of the sensory retina with a whitish lesion at the level of the retinal pigment epithelium (acute Elschnig's spot). (From de Venecia G, Jampol LM. The eye in accelerated hypertension: II. Localized serous detachments of the retina in patients. *Arch Ophthalmol.* 1984;102:68, © 1984, American Medical Association, with permission.)

hypertension, papilledema is usually accompanied by striate hemorrhages and cotton-wool spots (Figs. 44.3 and 44.4). When papilledema occurs alone, the possibility of a primary intracranial process such as a tumor or cerebrovascular accident should be considered.

Hypertensive neuroretinopathy almost always precedes clinically apparent damage in other end organs but there are occasional reports of malignant nephrosclerosis appearing before the onset of hypertensive neuroretinopathy.[46] It should also be noted that the findings of striate hemorrhages, cotton-wool spots, and papilledema are not specific for malignant hypertension. Funduscopic findings that are indistinguishable from those of hypertensive neuroretinopathy can occur with severe anemia, subacute bacterial endocarditis, systemic lupus erythematosus, polyarteritis, temporal arteritis, and scleroderma. In these disorders the retinopathy may develop even in the absence of hypertension. Central retinal vein occlusion can also mimic hypertensive neuroretinopathy but is usually unilateral, whereas hypertensive neuroretinopathy is almost always bilateral.

Severe hypertension can also affect the choroidal as well as the retinal circulation. Hypertensive choroidopathy can occur with malignant hypertension and is manifested by lesions known as acute Elschnig spots, which are white areas of retinal pigment epithelial necrosis with overlying localized serous detachments of the retina (Fig. 44.5).[47] The serous retinal detachments may vary from one-third to six disc diameters. Fluorescein angiography reveals staining of the damaged pigment epithelium and leakage into the subretinal space.[47] Although most patients with this hypertensive choroidopathy also have typical changes of hypertensive neuroretinopathy with striate hemorrhages and cotton-wool spots, if the elevation of blood pressure is relatively sudden, the changes of hypertensive choroidopathy may predominate.[47]

It is important to note that papilledema should not be regarded as an essential requirement for the diagnosis of malignant hypertension. By life table analysis, the 10-year survival rate for hypertensive patients was 46% in patients with hemorrhages and exudates and 48% when papilledema was also present.[48] The lack of association between papilledema and the length of survival was confirmed using the Cox's proportional hazards model, which revealed associations between survival and age, smoking habit, initial serum creatinine concentration, and the level of blood pressure control achieved with therapy. No association was found with papilledema. When controlled for these covariates, no association was found between the presence of papilledema and survival (Fig. 44.6). There is no evidence to indicate that the apparent severity of hypertensive neuroretinopathy is predictive of a more severe hypertensive vasculopathy or more advanced end-organ destruction. Papilledema is not always present even when there is severe malignant nephrosclerosis presenting as oliguric acute renal failure. In four series with a total of 25 patients presenting with malignant hypertension and acute renal failure, only 14 patients had papilledema. The other 11 patients had hemorrhages and cotton-wool spots

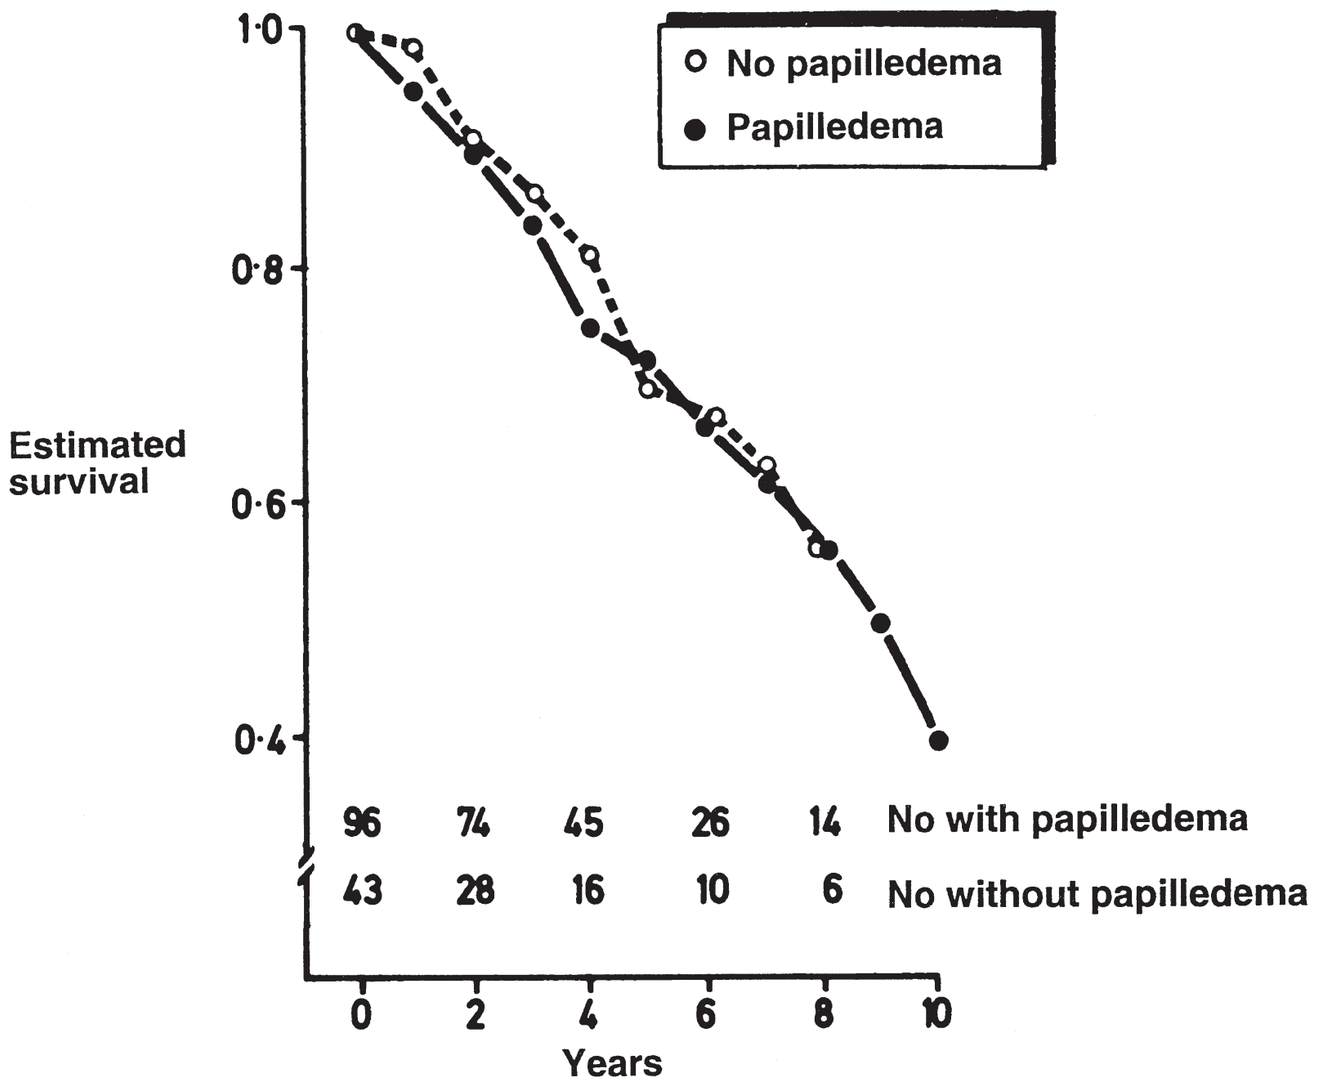

FIGURE 44.6 Relation between papilledema and survival in 139 hypertensive patients with bilateral retinal hemorrhages and exudates after controlling for age, gender, smoking habit, initial serum creatinine concentration, and initial and achieved blood pressure by multivariate analysis. Failure of papilledema to influence prognosis was confirmed by likelihood ratio test ($X = 0.89$, 1 df, $P = .34$). (From McGregor E, et al. Retinal changes in malignant hypertension. *Br Med J.* 1986;292:233, with permission.)

but no papilledema.[49–52] This lack of a difference in prognosis for patients with hypertensive neuroretinopathy whether or not it is accompanied by papilledema may be explained by the fact that cotton-wool spots and papilledema share a similar pathogenesis (see later discussion).[53,54]

Renal Manifestations

Malignant hypertension is a progressive systemic vasculopathy in which renal involvement is a secondary and relatively late development. Patients with malignant hypertension may present with a spectrum of renal involvement ranging from minimal albuminuria with normal renal function to ESRD indistinguishable from that seen in patients with primary renal parenchymal disease.[21,27]

The first sign of renal involvement in malignant hypertension is often the abrupt appearance of proteinuria. About 20% of patients also have painless gross hematuria, while 50% have microhematuria.[21] Quantitation of 24-hour protein excretion in patients with malignant hypertension has revealed less than 2 g in one third, between 2 and 4 g in one third, and more than 4 g in one third of patients.[26] The level of protein excretion is of little value in the differentiation of primary (essential) malignant hypertension from malignant hypertension due to secondary causes.[21,27]

Renal size is variable and depends on the duration of prior benign hypertension. In patients with primary (essential) malignant hypertension, the size of the kidneys may be normal to only slightly reduced. In fact, there may be little reduction in renal size even when patients develop terminal renal failure.[21]

The clinical spectrum of renal involvement in malignant hypertension is variable. Four clinical renal syndromes have been described. Progressive subacute deterioration of renal function leading to ESRD occurs in some patients. In patients presenting with malignant hypertension and initially normal renal function, in the absence of adequate treatment, it is common to observe deterioration of renal function with progression to ESRD over a period of weeks to months. The second clinical renal syndrome observed in malignant hypertension is transient deterioration of renal function following the initial control of blood pressure. This well-described entity occurs in patients presenting with mild to moderate renal impairment. In the third clinical renal syndrome, patients with malignant hypertension present with established renal failure. The close similarity between the terminal stage of primary malignant nephrosclerosis and chronic kidney disease with superimposed malignant hypertension has long been recognized. In this regard, it may not be possible to ascertain whether a patient presenting with severe hypertension, hypertensive neuroretinopathy, and renal failure has primary or secondary malignant hypertension. In the fourth clinical renal syndrome, patients with malignant hypertension present with oliguric acute renal failure. Cases of malignant hypertension have been described that were characterized by diastolic blood pressure higher than 130 mm Hg; advanced hypertensive neuroretinopathy; marked weight loss; and with an active urine sediment with proteinuria, hematuria, and red blood cell casts.[51,52] Renal size was normal. There was often evidence of microangiopathic hemolytic anemia. Although the initial blood urea nitrogen (BUN) concentration was less than 60 mg per dL, in each case oliguric renal failure occurred and necessitated the initiation of dialysis within a few days of hospitalization. Despite dialytic therapy, the blood pressure was extremely difficult to control and each patient died. Renal histology revealed malignant nephrosclerosis with fibrinoid necrosis

and proliferative endarteritis. The glomeruli were normal except for ischemic changes. Multifocal tubular necrosis was present and presumed to be secondary to ischemia. In most of these patients, the diagnosis of malignant hypertension was delayed because the patients were initially considered to have rapidly progressive glomerulonephritis or systemic vasculitis, which was treated with high-dose steroids. The diagnosis of malignant hypertension was not suspected until autopsy revealed malignant nephrosclerosis.

Neurologic Manifestations

Clarke and Murphy[55] detail the neurologic findings among 190 patients with malignant hypertension. CNS involvement was present at some time during the course in 42% of patients. Of the 65 patients for whom a cause of death could be ascertained, 33 had a fatal neurologic event. Of the total deaths, 20% were due to a neurologic cause. Intracerebral hemorrhage occurred in 23 patients. Episodes of focal brain ischemia, presumed due to cerebral thrombosis, occurred in 35 patients. Generalized seizures occurred in 11 patients and focal seizures in 8. Bell's palsy occurred in seven patients. Primary subarachnoid hemorrhage occurred in four patients. In this series, hypertensive encephalopathy was found in only 1% of patients; however, other series reported a higher incidence.[56] The clinical presentation, pathophysiology, and treatment of hypertensive encephalopathy are discussed in detail later in this chapter within Hypertensive Encephalopathy.

Gastrointestinal Manifestations

The most common gastrointestinal (GI) manifestations of malignant hypertension are nonspecific symptoms including nausea, vomiting, and epigastric pain. However, acute pancreatitis has been reported as a rare complication. In a series of 42 patients with malignant hypertension, severe acute pancreatitis that could not be attributed to gallstones or alcohol abuse developed in seven patients.[57]

Patients with malignant hypertension can present with an acute abdomen.[58] Abdominal exploration revealed necrotic bowel with involvement of the distal ileum and ascending colon. Moreover, malignant hypertension may increase the risk of subsequent development of mesenteric ischemia in patients on chronic hemodialysis.[59] GI hemorrhage can occur in patients with malignant hypertension due to hypertension-induced necrotizing mesenteric arteriolitis.[60]

Hematologic Manifestations

A variety of hematologic findings have been observed in patients with malignant hypertension. The hemoglobin concentration at the time of presentation may correlate with the etiology of the malignant phase. A hemoglobin concentration higher than 12.5 g per dL is more often associated with primary malignant hypertension, whereas a lower value is more often associated with chronic glomerulonephritis or pyelonephritis.[21]

There are numerous reports of microangiopathic hemolytic anemia in association with malignant hypertension. In one series of 24 patients with malignant hypertension, 16 were found to have evidence of microangiopathic hemolysis.[61] Other significant abnormalities reported with malignant hypertension include thrombocytopenia, increased fibrin degradation products, increased factor VIII levels, increased fibrinogen, and increased urokinase sensitivity consistent with decreased fibrinolysis.[62]

Cardiac Manifestations

Congestive heart failure can be a presenting feature of malignant hypertension. Moreover, heart failure, alone or in combination with uremia, was a common cause of death prior to the advent of effective antihypertensive drugs. Heart failure in patients with malignant hypertension is predominantly left-sided with pulmonary congestion resulting in orthopnea, paroxysmal nocturnal dyspnea, cardiac asthma, and recurrent episodes of acute pulmonary edema. Peripheral venous congestion with dependent edema or hepatic congestion may be minimal or absent even when death results from congestive heart failure.

Angina and acute myocardial infarction, although common with long-standing benign hypertension, are uncommon with malignant hypertension.[21] Aortic dissection is also rare in patients with malignant hypertension.[22]

Abnormalities of the Renin-Angiotensin-Aldosterone Axis

Evidence of activation of the renin–angiotensin–aldosterone axis is present in many, but not all, patients with malignant hypertension.[63] Among 53 patients with malignant hypertension not secondary to renal artery stenosis, 55% had increased plasma renin activity (PRA).[64] Among 25 patients with malignant hypertension secondary to renal artery stenosis, PRA was consistently elevated.[64]

Aldosterone secretion rate has been studied in patients with malignant hypertension.[65] There was a marked increase in secretion rate in seven of eight patients with malignant hypertension (papilledema present), and in five of eight patients with accelerated hypertension (retinal hemorrhages without papilledema). The aldosterone secretion rate in these patients was often higher than that seen in patients with aldosterone-producing adenoma.

Electrolyte Abnormalities

Hypokalemic metabolic alkalosis was found in up to 50% of patients with malignant hypertension, presumably reflecting a state of hyperreninemia and secondary hyperaldosteronism.[65] After effective therapy, aldosterone hypersecretion can persist long after volume depletion is corrected and renin levels have returned to normal. Thus, the findings of hypokalemia, increased urinary potassium losses, and aldosterone hypersecretion with suppressed PRA may mimic the findings of primary hyperaldosteronism.[63]

Hyponatremia is not uncommon in patients with malignant hypertension, particularly when sodium restriction is instituted. Patients with malignant hypertension due to renal artery stenosis occasionally present with the striking hyponatremic hypertensive syndrome.[66,67] The characteristic features of this syndrome include severe hypertension, hypertensive neuroretinopathy, polyuria, polydipsia, weight loss, and salt craving. Biochemical changes include hyponatremia, hypokalemia, and low total exchangeable sodium and potassium, with markedly elevated PRA, angiotensin II, aldosterone, and arginine vasopressin (AVP) levels. This syndrome may result from a vicious cycle of volume depletion with further activation of the renin–angiotensin–aldosterone axis as a result of a pressure-induced natriuresis from the contralateral kidney.

Pathologic Findings

Renal Pathology

With malignant nephrosclerosis, small pinpoint petechial hemorrhages may be present on the cortical surface, giving the kidney a peculiar flea-bitten appearance. The renal size varies depending on the duration of preexisting benign hypertension or the presence of underlying primary renal parenchymal disease. When terminal renal failure occurs in patients with primary malignant hypertension, the kidneys may be normal in size.[37] However, when secondary malignant hypertension is superimposed on primary renal disease, the kidneys may be small.

Fibrinoid necrosis of the afferent arterioles has traditionally been regarded as the hallmark of malignant nephrosclerosis (Fig. 44.7).[21] The characteristic finding is the deposition in the arteriolar wall of a granular material that appears bright pink with hematoxylin and eosin stain. On trichrome staining, this granular material is deep red. This fibrinoid material is usually found in the media, but it may also be present in the intima. Histochemical and immunofluorescent techniques have identified this material as fibrin. Within the media, muscle fibers cannot be identified and cell nuclei are lost or fragmented. Whole or fragmented erythrocytes may be extravasated into the arteriolar wall. The hemorrhages that occur may account for the petechiae observed on the cortical surface. The arteriolar lumen may be reduced in size as a result of wall thickening and intraluminal fibrin thrombi. Infrequently, polymorphonuclear leukocytes and monocytes may infiltrate the arterioles, giving the appearance of necrotizing arteriolitis.

The interlobular arteries reveal characteristic lesions variously referred to as proliferative endarteritis, productive endarteritis, endarteritis *fi*brosa, or the onionskin lesion. The typical finding is intimal thickening that causes moderate to severe luminal narrowing. In severely affected vessels, the luminal diameter may be reduced to the size of a single red blood cell. Occasionally, there is complete obliteration of the lumen by a fibrin thrombus.

Traditionally, three patterns of intimal thickening in malignant nephrosclerosis have been described.[68] The onionskin pattern consists of pale layers of elongated, concentrically arranged, myointimal cells. Delicate connective tissue fibrils give rise to a lamellated appearance (Fig. 44.8). The media often appears as an attenuated layer stretched around the expanded intima. Mucinous intimal thickening consists of a scarcely cellular lesion containing a lucent, faintly basophilic-staining

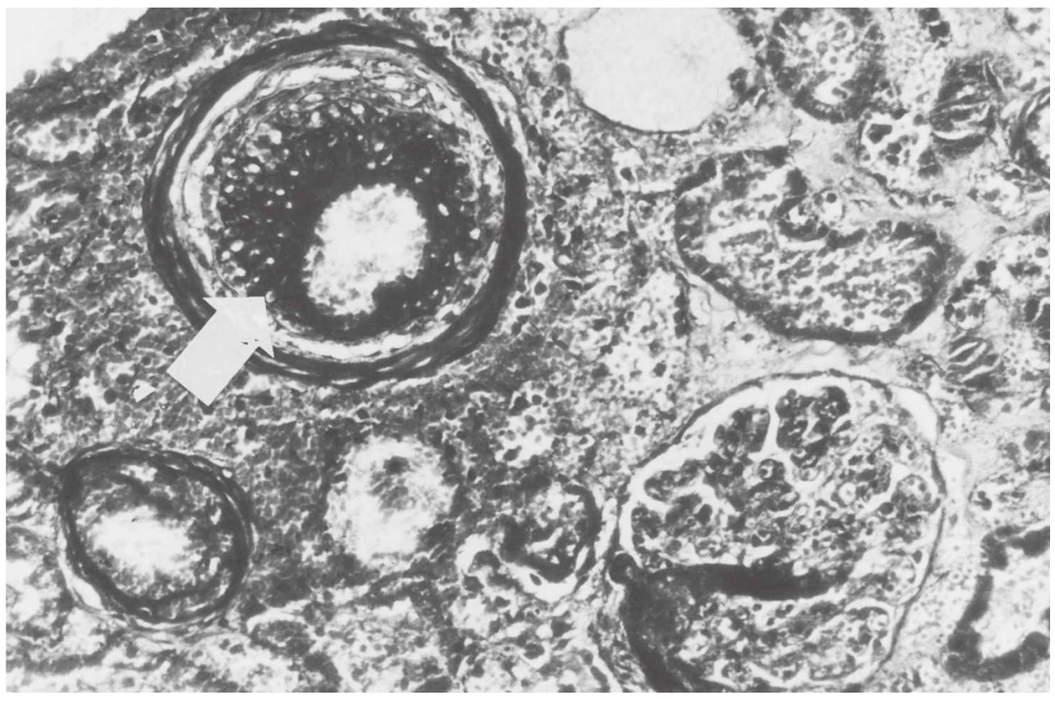

FIGURE 44.7 Fibrinoid necrosis in a large arteriole (*arrow*). Intimal onionskin formation is also present. (Trichrome stain.) (Photograph courtesy of Steve Guggenheim, MD.)

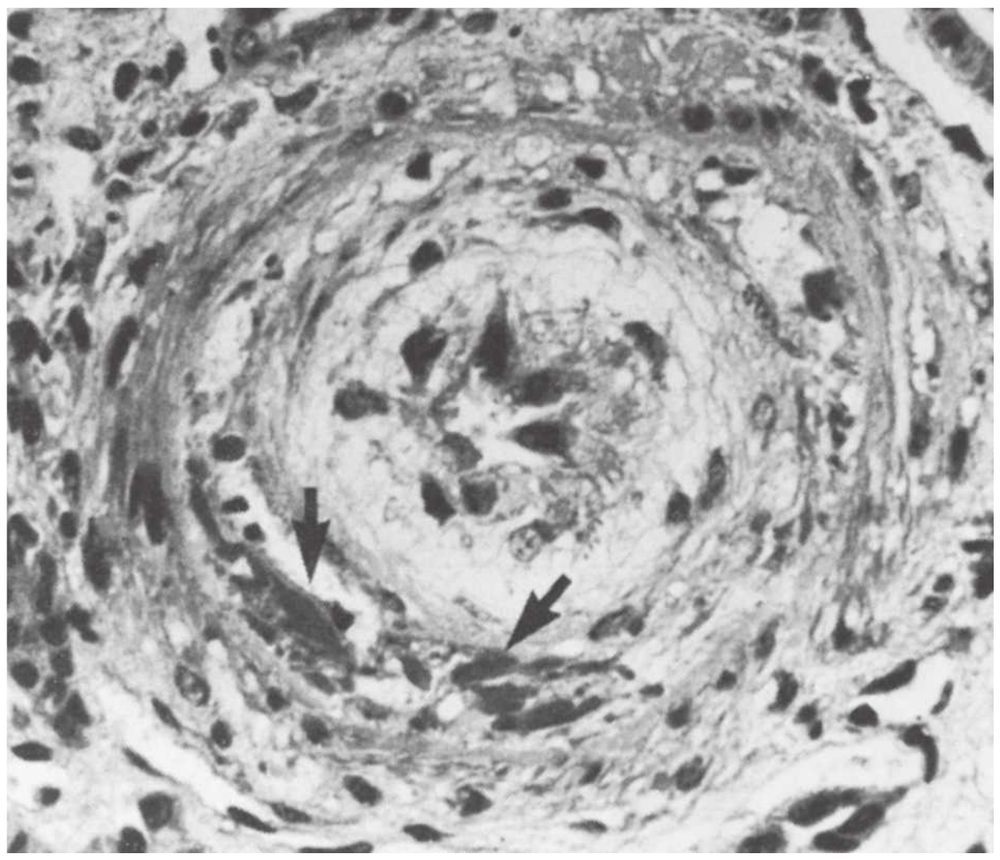

FIGURE 44.9 Mucinous intimal thickening. The lesion is sparsely cellular and consists mainly of a lucent, faintly basophilic-staining amorphous material. There are small foci of fibrinoid necrosis (*arrows*) deep within the intima. (Hematoxylin and eosin stain ×350.) (From Sinclair RA, Antonovych TT, Mostofi FK. Renal proliferative arteriopathies and associated glomerular changes: a light and electron microscopic study. *Hum Pathol.* 1976;7:565, with permission.)

amorphous material (Fig. 44.9). In *f*ibrous intimal thickening, there are hyaline deposits, reduplicated bands of elastica, and coarse layers of pale connective tissue with the staining properties of collagen (Fig. 44.10). In rare cases, fibrinoid necrosis may also be apparent in the interlobular arteries.[68]

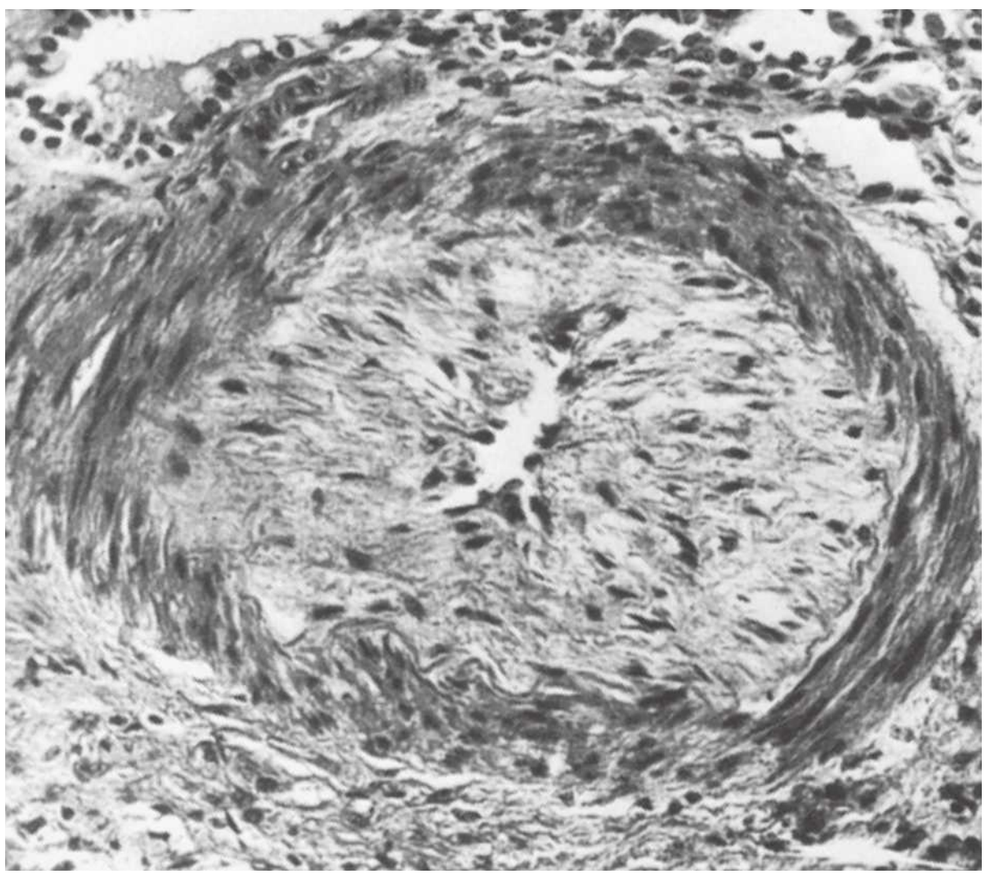

FIGURE 44.10 Fibrous intimal thickening. The lesion consists of a thick layer of connective tissue, which stains for collagen and elastin. (Hematoxylin and eosin stain ×300.) (From Sinclair RA, Antonovych TT, Mostofi FK. Renal proliferative arteriopathies and associated glomerular changes: a light and electron microscopic study. *Hum Pathol.* 1976;7:565, with permission.)

The renal histology in blacks with malignant hypertension may be somewhat different.[69,70] Although fibrinoid necrosis of the afferent arterioles is not found, there is instead a marked degree of arteriolar hyalinization. In addition, there is a prominent and characteristic finding in the larger arterioles and interlobular arteries known as musculomucoid intimal hyperplasia (Fig. 44.11).[69–71] The arterial walls are thickened due to the presence of hyperplastic smooth muscle cells. A small amount of myxoid material, which stains light blue with hematoxylin and eosin, is observed between the cells. With periodic acid-Schiff staining this material resembles basement membrane. Staining for acid mucopolysaccharide suggests the presence of chondroitin sulfate and possibly hyaluronic acid.

By electron microscopy, in each of the above-mentioned types of intimal thickening, the most abundant cellular element is a modified smooth muscle cell called a myointimal cell. In these cells there are smooth musclelike ultrastructural features including cytoplasmic myofilaments and abundant rough endoplasmic reticulum.[68,72] In the pure onionskin variant, the intercellular space is occupied by multiple strands of nonperiodic fibrils with the ultrastructural features of basement membrane.[68] In the mucinous variant, broad electron-lucent zones with scattered finely granular material are found in the intercellular space.[72] With the fibrous variant, numerous bundles of collagen, recognizable by characteristic banding, are dispersed between the myointimal cells.[72]

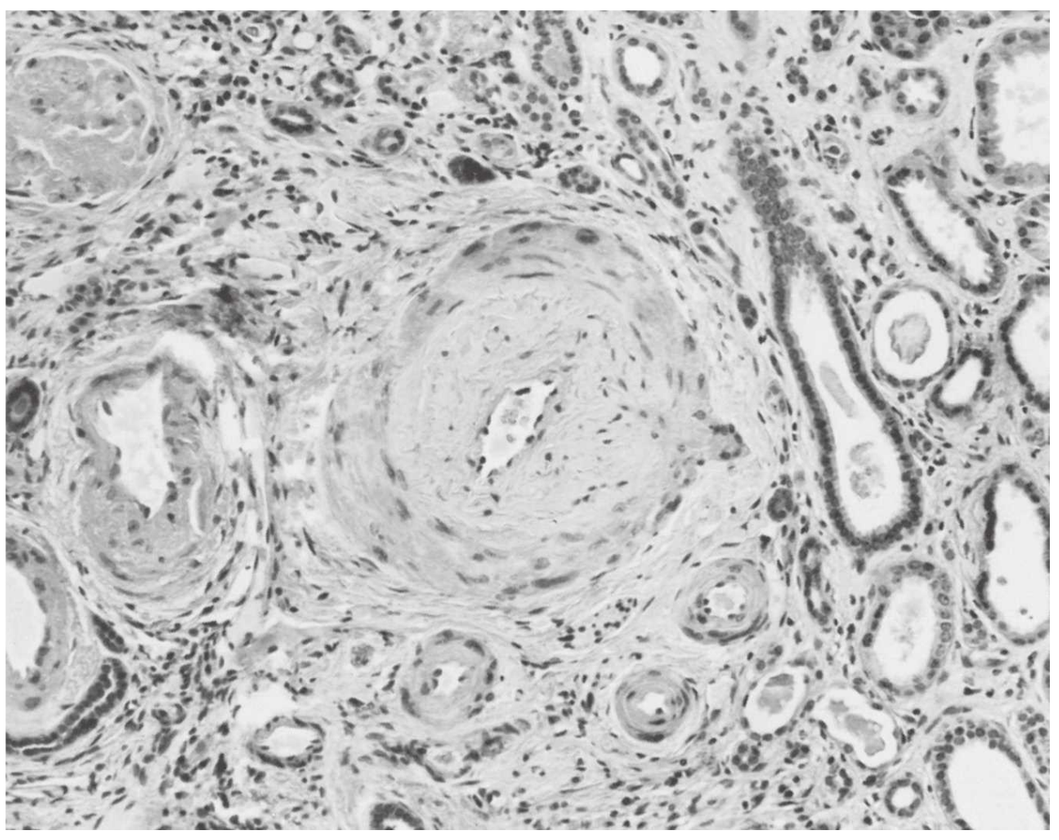

FIGURE 44.11 Musculomucoid intimal hyperplasia of an interlobular artery. The arterial walls are thickened by hyperplastic smooth muscle cells. A small amount of myxoid material is seen between the smooth muscle cells. (Hematoxylin and eosin stain ×170.) (From Pitcock JA, Johnson JG, Hatch FE, et al. Malignant hypertension in blacks: malignant intrarenal arterial disease as observed by light and electron microscopy. *Hum Pathol.* 1976;7:333, with permission.)

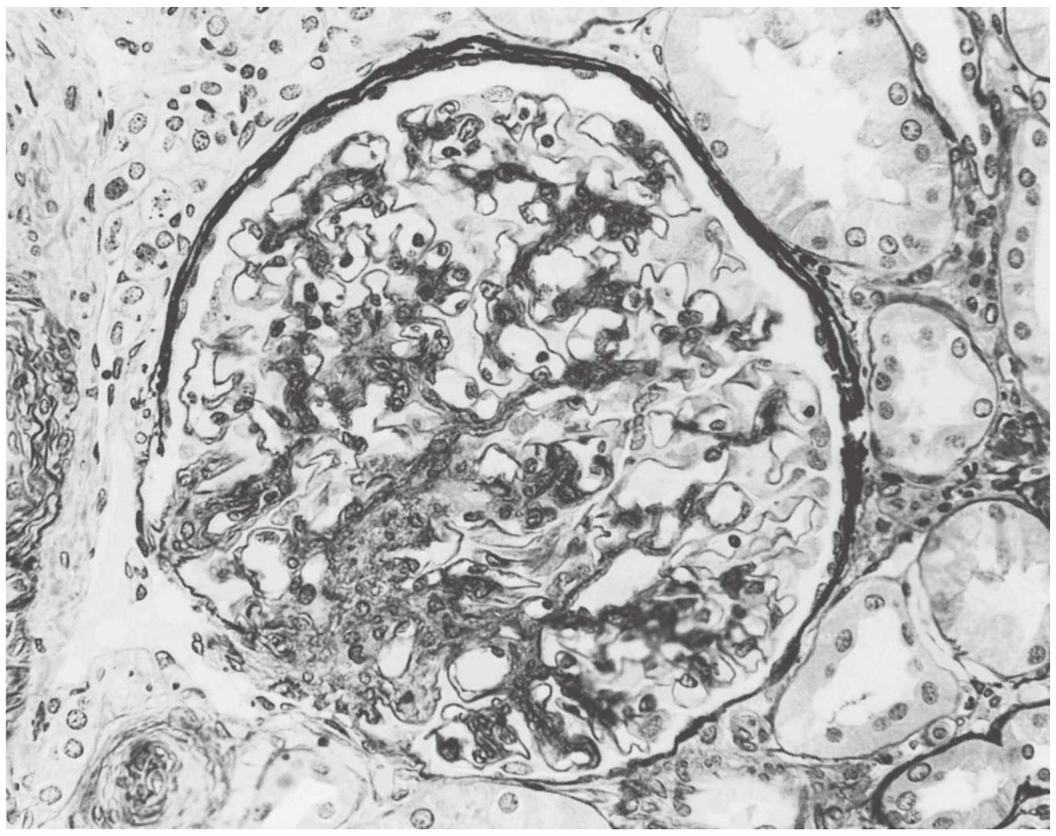

FIGURE 44.12 The earliest ischemic glomerular change in malignant hypertension consists of some basement membrane wrinkling, particularly in areas adjacent to the mesangium, with a slight increase in mesangial matrix. (Periodic acid–silver methenamine stain ×250.) (From Pitcock JA, Johnson JG, Hatch FE, et al. Malignant hypertension in blacks: malignant intrarenal arterial disease as observed by light and electron microscopy. *Hum Pathol.* 1976; 7:333, with permission.)

In patients who have received antihypertensive therapy, as well as blacks with treated or untreated malignant hypertension, the most characteristic glomerular lesion in malignant nephrosclerosis is accelerated glomerular obsolescence secondary to the intense ischemia produced by the obliterative arterial lesions.[70,73] The earliest glomerular changes consist of thickening and wrinkling of the basement membrane (Fig. 44.12).[75,78] Later, there is shrinkage of the tuft such that it does not fill Bowman's space. There is laminar reduplication of Bowman's capsule around the shrunken glomerulus.[68] The end stage is the obsolescent glomerulus, which is an avascular, wrinkled glomerular tuft surrounded by a collagenous scar that fills Bowman's space (Fig. 44.13). Focal segmental glomerulosclerosis may occur in primary malignant hypertension either as the result of glomerular hyperfiltration or fibrinoid necrosis, and may contribute to renal dysfunction. In an autopsy series of 38 black South Africans with primary malignant hypertension, mucoid intimal hyperplasia was present in all sections whereas fibrinoid necrosis was seen in 76%. Glomerulosclerosis was present in 38 cases, and was axially distributed in 18%, segmental in 58%, and global in 24% of sections. Cases with segmental sclerosis tended to have the highest proteinuria, whereas those with global glomerulosclerosis had the highest serum creatinine levels.[74]

By electron microscopy, the lamina densa of the glomerular capillary basement membrane is thickened and wrinkled (Fig. 44.14).[73] Eventually, the entire basement membrane becomes thickened. These glomerular

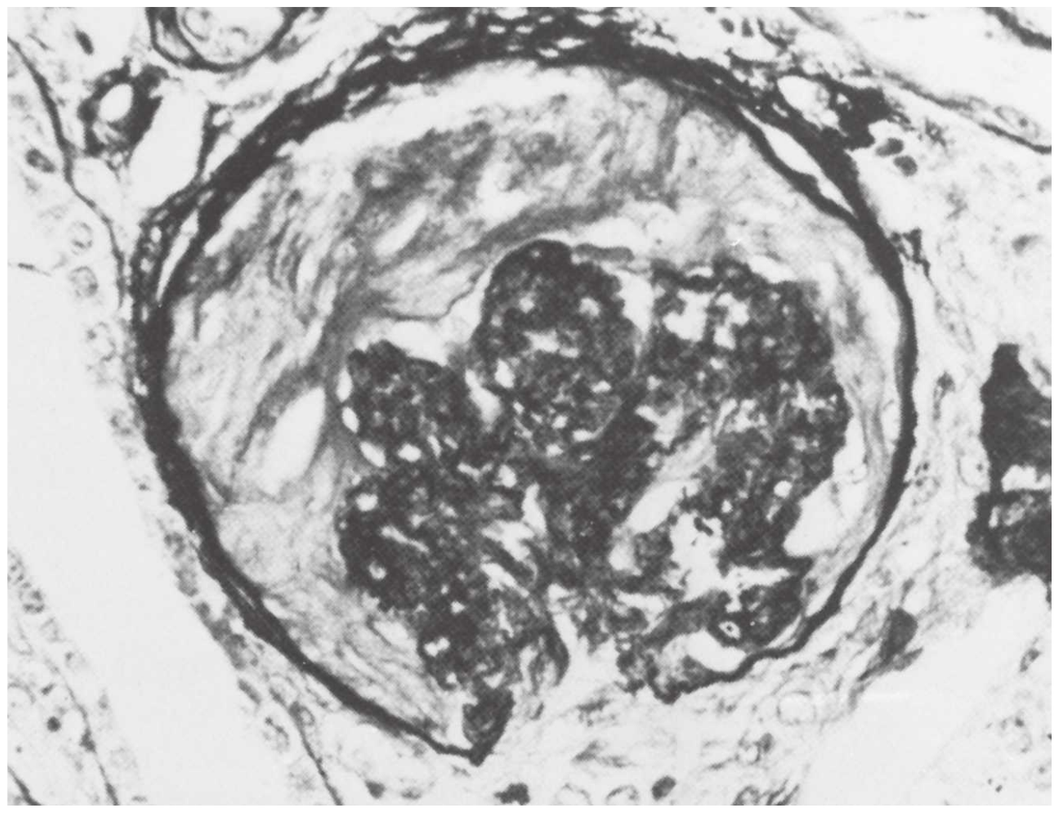

FIGURE 44.13 Glomerular obsolescence in malignant hypertension. The collapsed, avascular glomerular tuft consists predominantly of markedly convoluted basement membranes. The sclerosed tuft is partially enclosed within a collar of hyaline material filling Bowman's space. (Periodic acid–silver methenamine stain ×485.) (From Sinclair RA, Antonovych TT, Mostofi FK. Renal proliferative arteriopathies and associated glomerular changes: a light and electron microscopic study. *Hum Pathol.* 1976; 7:565, with permission.)

changes are not specific for malignant nephrosclerosis as they also can occur in scleroderma renal crisis, hemolytic–uremic syndrome, and even severe benign nephrosclerosis. However, the glomerular changes in malignant nephrosclerosis differ from the simple ischemic

FIGURE 44.14 Accelerated glomerular obsolescence in malignant hypertension. The glomerular capillaries show striking basement membrane wrinkling (*arrow*) and some reduplication of the inner basement membrane. (Uranyl acetate and lead citrate ×4,250.) (From Jones DB. Arterial and glomerular lesions associated with severe hypertension: light and electron microscopic studies. *Lab Invest.* 1974; 31:303, with permission.)

FIGURE 44.15 Accelerated glomerular obsolescence in malignant hypertension. The outer basement membrane (*O*) is thickened and wrinkled. There is a reduplicated inner basement membrane (*I*) with the capillary lumen still patent. (Uranyl acetate and lead citrate stain ×4,250.) (From Jones DB. Arterial and glomerular lesions associated with severe hypertension: light and electron microscopic studies. *Lab Invest.* 1974;31:303, with permission.)

obsolescence observed in benign hypertension. In addition to the wrinkled basement membrane observed in benign nephrosclerosis, there is constriction of the glomerular vascular bed in malignant nephrosclerosis due to the deposition of a new subendothelial layer of basement membrane material inside the original basement membrane (Fig. 44.15).[73] The new capillary lumen formed by this process is smaller, resulting in decreased blood volume in the ischemic glomerulus.

In malignant nephrosclerosis, the tubules may be atrophied and focally destroyed in areas supplied by severely narrowed arteries. Occasional tubules may be dilated and filled with eosinophilic cast material.[75] In the interstitium in these areas, there may be a fine reticular fibrosis and chronic inflammatory cells. In malignant hypertension, as in primary renal parenchymal diseases, renal insufficiency appears to correlate best with the degree of tubular atrophy.[70]

Immunofluorescence microscopy in patients with malignant nephrosclerosis has demonstrated deposition of gamma globulin, fibrinogen, albumin, and sometimes complement components in the walls of arterioles demonstrating fibrinoid necrosis by light microscopy.[81] Some of the glomeruli, especially those with focal necrosis, may contain immunoglobulin, albumin, and complement. Fibrinogen may be found diffusely along capillary basement membranes. Fibrinogen may also be found in the intima of interlobular arteries that by light microscopy show cellular or mucinous thickening.[76]

Striking juxtaglomerular hyperplasia has been reported in patients with malignant hypertension.[77] This ultrastructural finding is consistent with the hyperreninemic state often noted clinically.

Effective antihypertensive therapy may alter the pathology of malignant nephrosclerosis.[78–80] Within days, there may be resolution of fibrinoid necrosis, which leaves behind residual hyaline deposits in the arteriolar wall. In contrast to benign nephrosclerosis in which arteriolar hyaline change is often subendothelial, in treated malignant hypertension the hyaline material may be present throughout the entire vessel wall. Fibrosis of the arterioles with collagen replacement of the arteriolar muscle and elastica may also occur. Within several weeks after initiation of therapy, segmental fibrinoid necrosis in the glomeruli may also resolve, leaving behind an area of hyaline deposition that can mimic focal segmental glomerulosclerosis (FSGS). Furthermore, with treatment, in the intima of the interlobular arteries there may be an evolution from cellular hyperplasia to a more fibrous form of intimal thickening. A newly formed internal elastic lamina often separates this new collagen from the narrowed lumen. Heptinstall has postulated that the cellular lesion is an early finding implying active disease, whereas the acellular fibrotic lesion is a later process often reflecting a response to treatment.[75] These modifications in the interlobular arteries that occur following treatment may not be accompanied by any increase in the caliber of the lumen. Severely narrowed interlobular arteries often do not improve and the renal parenchyma distal to these arteries undergoes severe ischemic atrophy and scarring.[79] However, the nephrons supplied by interlobular arteries of normal caliber may undergo substantial hypertrophy following treatment of malignant hypertension. These histologic changes may explain the improvement in renal function that sometimes occurs in some patients following institution of antihypertensive therapy with resolution of malignant hypertension.

In summary, although fibrinoid necrosis was the hallmark of malignant nephrosclerosis in untreated patients at autopsy, it is now rarely observed. In treated patients with malignant hypertension or blacks with untreated malignant hypertension, closed renal biopsy most often reveals marked intimal hyperplasia of the interlobular arteries in association with accelerated glomerular obsolescence.[70,73]

Pathophysiology

Pathophysiology of Malignant Hypertension

The exact pathophysiologic mechanism underlying the transition from benign to malignant hypertension is not fully understood. The postulated pathogenesis of malignant hypertension is outlined in Figure 44.16. According to the pressure hypothesis, the development of fibrinoid necrosis and proliferative endarteritis is a direct consequence of the mechanical stress placed on vessel walls

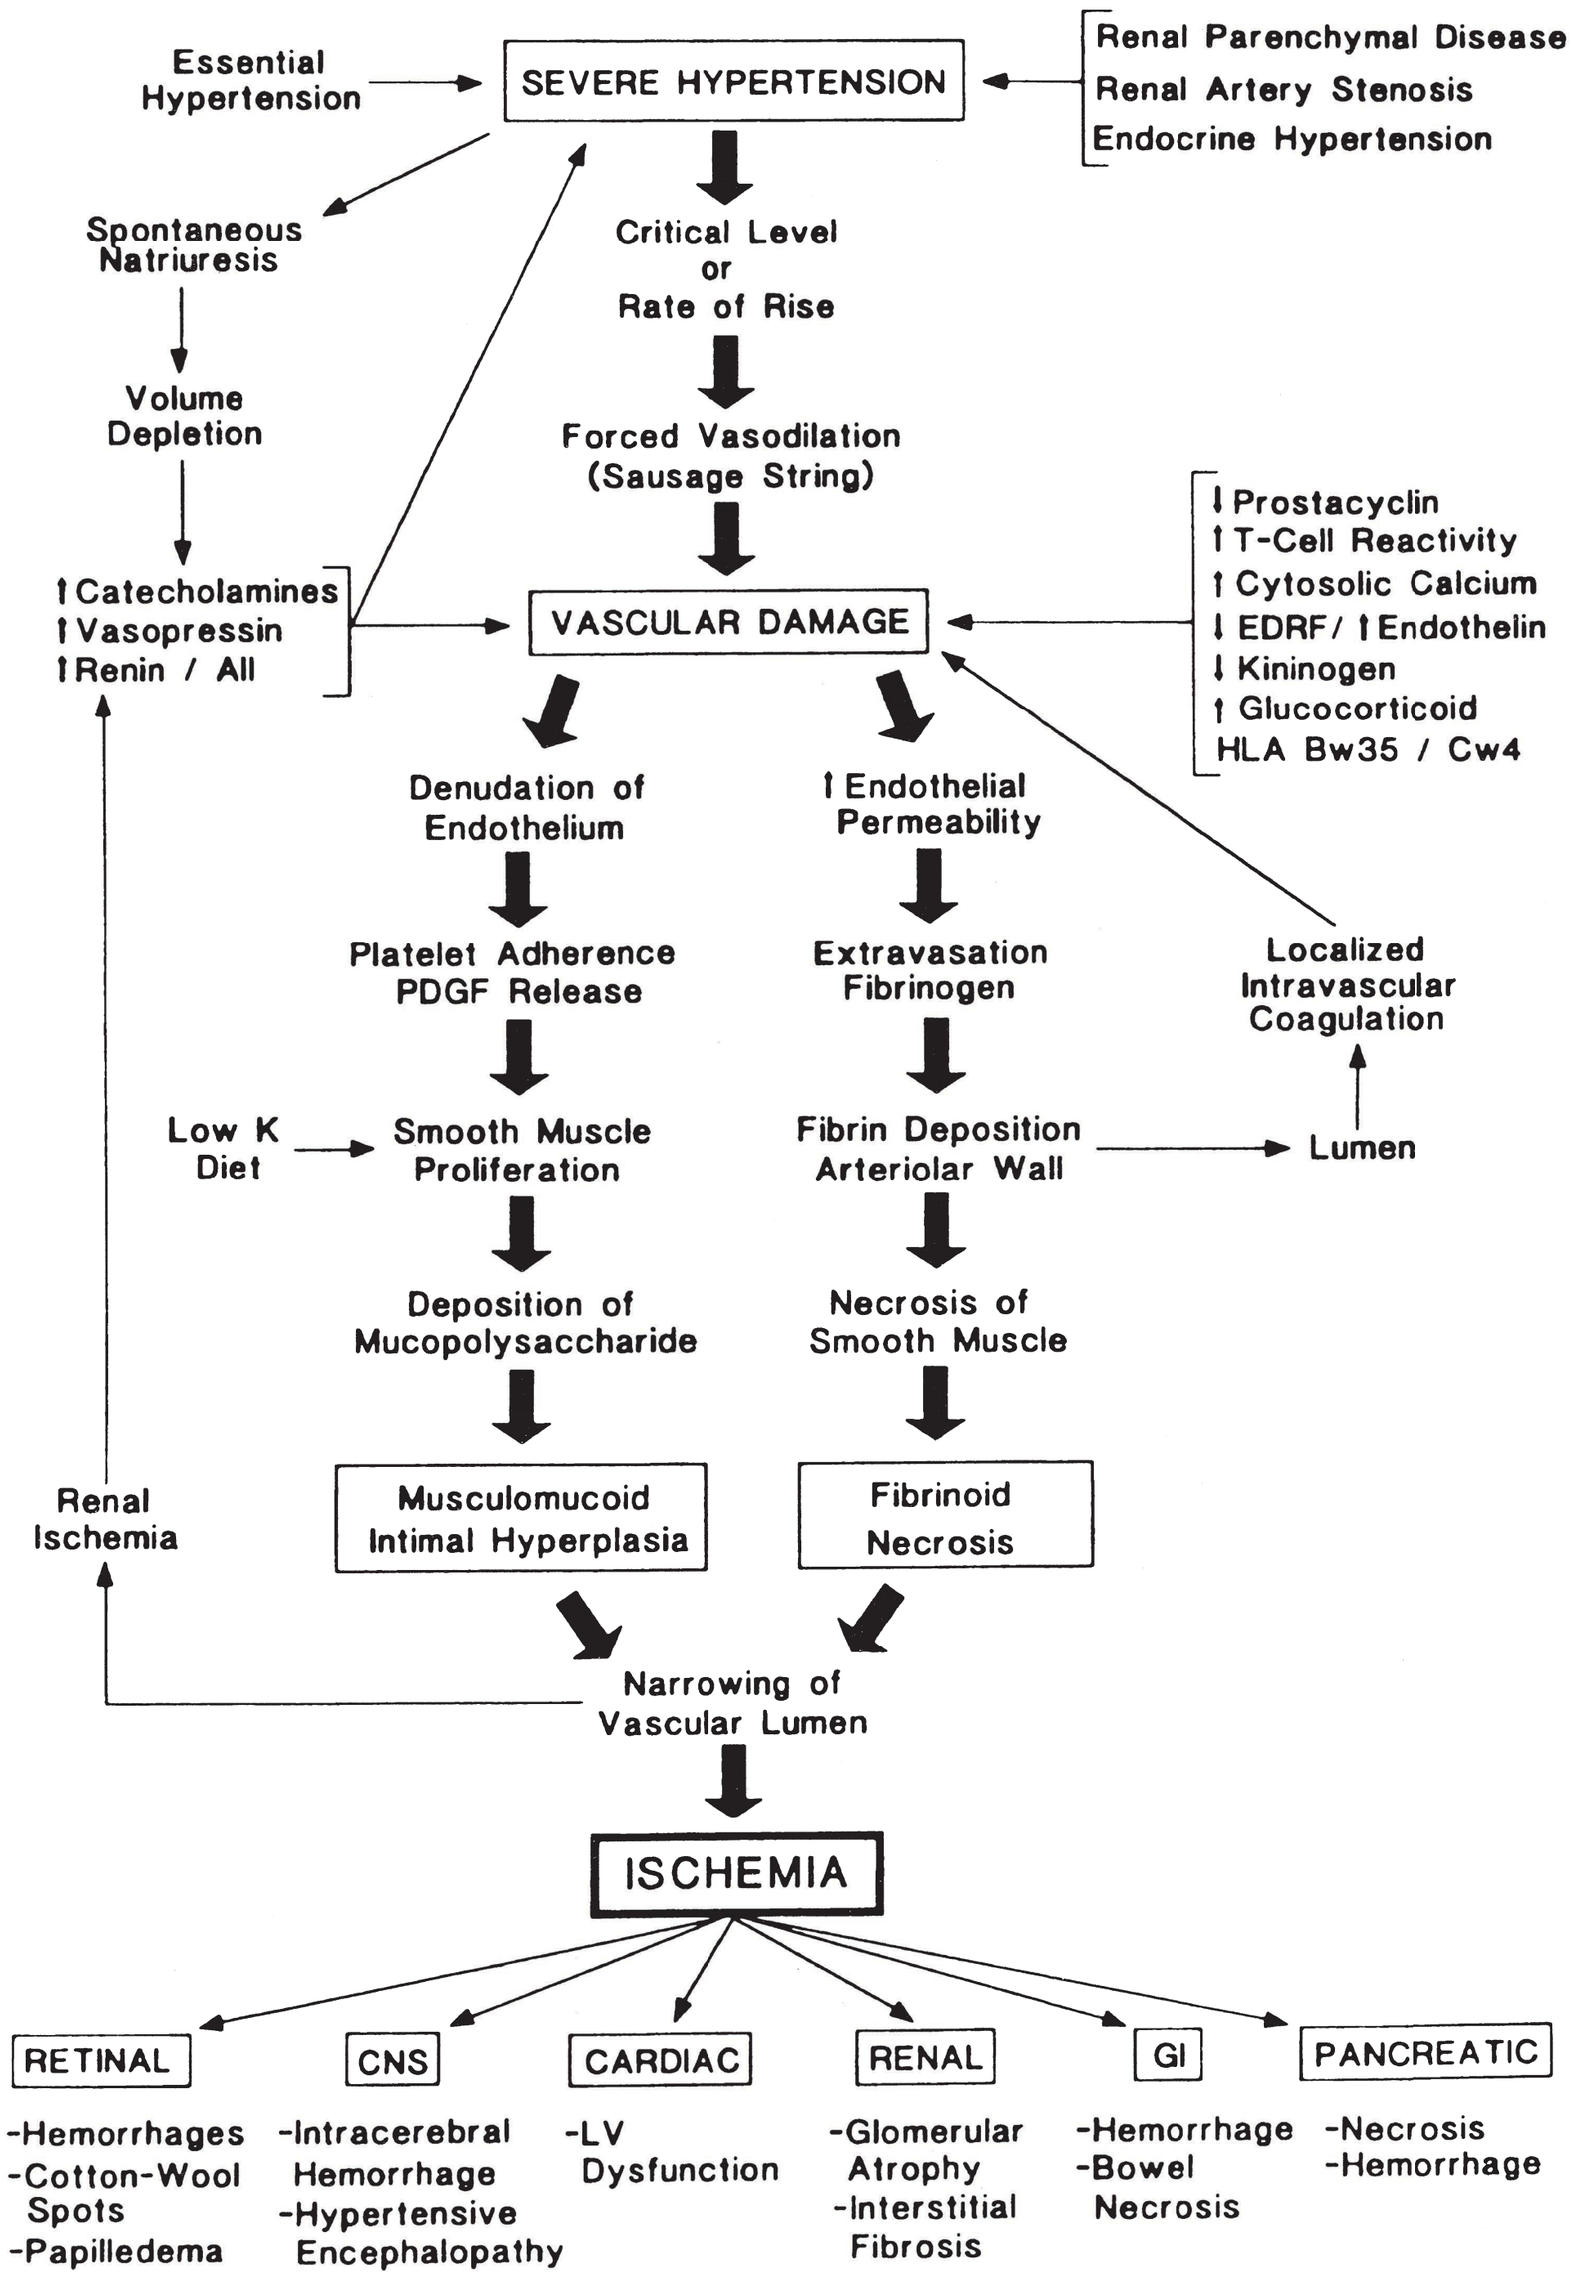

FIGURE 44.16 Pathophysiology of malignant hypertension. *AII,* angiotensin II; *EDRF,* endothelium-derived relaxing factor; *PDGF,* platelet-derived growth factor; *LV,* left ventricular.

by severe hypertension.[81] Undoubtedly, a marked increase in blood pressure is pivotal. Severe hypertension is the common element in malignant hypertension in humans and in each of the animal models of malignant hypertension. Moreover, reduction of the blood pressure leads to a resolution of the malignant phase regardless of the underlying etiology. Thus, a significant elevation of the blood pressure is necessary for the development and progression of malignant hypertension. The major issue is whether the mechanical stress of severe hypertension alone is sufficient to cause the transition from benign to malignant hypertension. Because there is considerable overlap in the levels of blood pressure seen in patients with benign and those with malignant hypertension, it is likely that severe hypertension alone is not sufficient to cause the malignant hypertension in all patients and that additional factor(s) probably participate. The vasculotoxic theory proposes that humoral factors interact with the hypertension-induced hemodynamic stress to cause the vascular damage observed in malignant hypertension.

These cofactors are not necessarily the same in every case. For example, activation of the renin–angiotensin axis may be important in some patients but not in others. In some patients, perhaps catecholamines, vasopressin, endothelin, or activation of the clotting cascade interact with hemodynamic stress to induce malignant hypertension. In several experimental models, spontaneous natriuresis appears to be the initiating event in the transition from benign to malignant hypertension.[82–84] In patients with malignant hypertension, an abrupt onset of weight loss early in the course of the disease has been reported. In the series of Kincaid-Smith et al.,[21] the onset of malignant hypertension often appeared suddenly. Despite minor increases in blood pressure, the patients became suddenly ill with weakness, wasting, and profound weight loss. The rapidity of the weight loss could only be explained by natriuresis-induced volume depletion and may be the human counterpart of the rat two-kidney, one-clip model of malignant hypertension in which spontaneous natriuresis is the inciting event.[82,83]

Pathophysiology of Hypertensive Neuroretinopathy

Retinal arteriolar vasculopathy in malignant hypertension leads to obliteration or rupture of vessels, resulting in striate hemorrhages, cotton-wool spots, and papilledema. Hypertensive neuroretinopathy is not simply the result of renal failure as hypertensive neuroretinopathy can clearly occur in malignant hypertension prior to the onset of clinically significant renal disease.[42] It also appears that hypertensive neuroretinopathy often occurs in the absence of increased intracranial pressure.[42]

The retinal circulation is under autoregulatory control and does not have a sympathetic nerve supply. As the systemic blood pressure increases, if autoregulation is intact, the retinal arterioles constrict to keep the retinal blood flow constant. The appearance of hypertensive neuroretinopathy implies that autoregulation has failed.[41]

Striate hemorrhages result from bleeding from superficial capillaries in the nerve fiber bundles near the optic disc. These capillaries originate from arterioles, so that when autoregulation fails, the high systemic pressure is transmitted directly to the capillaries. This leads to breaks in the continuity of the capillary endothelium with subsequent hemorrhage.[41]

Cotton-wool spots result from ischemic infarction of nerve fiber bundles due to arteriolar occlusion.[41] Fluorescein angiography demonstrates that cotton-wool spots are areas of retinal nonperfusion.[85] Embolization of pig retina with glass beads produces immediate intracellular edema followed by accumulation of mitochondria and other subcellular organelles in the ischemic nerve fibers.[87] It has been postulated that the normal axoplasmic flow of subcellular organelles is disrupted by ischemia such that accumulation of organelles in ischemic nerve fiber bundles results in a visible white patch.[53,54] Cotton-wool spots tend to distribute around the optic disc because the nerve fiber bundles are most dense in this region.

The pathogenesis of papilledema in malignant hypertension has been controversial. Papilledema may result from increased intracranial pressure. However, intracranial pressure is not always increased in malignant hypertension.[42] Papilledema has been produced in rhesus monkeys by occlusion of the long posterior ciliary artery, which supplies the optic disc.[88] Thus papilledema, like cotton-wool spots, most likely results from ischemia of nerve fibers in the optic disc.[87,88]

Treatment

Malignant hypertension must be treated expeditiously in order to prevent complications such as hypertensive encephalopathy, intracerebral hemorrhage, acute pulmonary edema, and renal failure. The hypertensive patient with hypertensive neuroretinopathy (hemorrhages, cotton-wool spots with or without papilledema) should be hospitalized for intensive medical therapy. Initiation of appropriate therapy should not be delayed pending extensive laboratory and roentgenographic examinations aimed at defining a potential underlying etiology. The workup for secondary causes should be deferred until the blood pressure has been controlled and the patient stabilized.

The traditional approach to patients with malignant hypertension has been the initiation of therapy with rapid-acting parenteral hypotensive agents such as sodium nitroprusside.[89] Table 44.4 lists the settings in which the use of

44.4 Indications for Parenteral Therapy in Malignant Hypertension

Patients unable to tolerate oral therapy due to intractable vomiting
Hypertensive encephalopathy
Rapidly failing vision
Intracerebral hemorrhage
Acute pulmonary edema
Acute myocardial infarction
Rapid deterioration of renal function
Acute pancreatitis
Gastrointestinal hemorrhage
Acute abdomen secondary to mesenteric vasculitis

parenteral antihypertensive agents is recommended for the initial management of malignant hypertension. In general, parenteral therapy should be utilized in patients who have evidence of acute end-organ damage or who are unable to tolerate oral medications.

The drug of choice for the management of patients with malignant hypertension requiring parenteral therapy is sodium nitroprusside.[90] Nicardipine and labetalol administered by continuous infusion are useful alternative agents.[90,91] The dopamine receptor (DA_1 selective) agonist fenoldopam may also be useful for parenteral treatment of malignant hypertension.[91,92] There are no absolute guidelines for the blood pressure goal during parenteral therapy. The theoretic risks of rapid reduction of blood pressure are discussed later in the section on the controversy over gradual versus rapid reduction of blood pressure. As a general rule, it is safe to initially reduce the mean arterial pressure by 20% or to a level of 160 to 170 mm Hg systolic and 100 to 110 mm Hg diastolic.[93] During the reduction of blood pressure with parenteral antihypertensives, the patient should be monitored closely for evidence of cerebral or myocardial hypoperfusion. The use of a short-acting agent such as sodium nitroprusside or fenoldopam has obvious advantages because the blood pressure can be stabilized quickly at a higher level if complications develop during rapid blood pressure reduction. If there is no evidence of vital organ hypoperfusion following this initial reduction of blood pressure, the diastolic blood pressure can gradually be lowered to 90 mm Hg over a period of 12 to 36 hours.

Oral antihypertensive agents should be initiated as soon as possible so that the duration of parenteral therapy can be minimized. However, a common error in the management of patients with malignant hypertension is the abrupt discontinuation of parenteral therapy immediately after oral therapy has been initiated. With this approach, severe rebound hypertension often develops before the oral antihypertensive regimen becomes effective. Ideally, oral antihypertensives should be initiated as soon as the patient has been stabilized and is able to tolerate medications by mouth. The nitroprusside infusion should be continued until the oral agents have taken effect and have been titrated to an effective dose. The nitroprusside or fenoldopam infusion can then be weaned as the oral regimen is gradually increased.

Although other agents may be effective in the long-term management of patients with malignant hypertension, the cornerstone of initial oral therapy should be an arteriolar vasodilator such as hydralazine, dihydropyridine calcium channel blocker, or minoxidil. Vasodilators may reflexively activate the adrenergic system and cause tachycardia with an increase in cardiac output, which may blunt the hypotensive response. Therefore, treatment with β-adrenergic blockers is usually also required. Direct-acting vasodilators also cause renal salt and water retention, fluid overload, and the development of pseudotolerance to the hypotensive effect of the drug. Thus, although diuretics may not be required for the initial management of patients with malignant hypertension (see later), they are usually required as a part of the long-term maintenance antihypertensive regimen. The regimen that follows has proved to be generally effective in the conversion from parenteral to oral therapy. After the blood pressure has been controlled with sodium nitroprusside and while the infusion is continued, hydralazine (50 mg) and beta-blocker are administered orally. As the oral agents become effective and the blood pressure declines, the nitroprusside infusion is tapered. Brief interruption of the infusion can be used to assess the hypotensive response to oral agents. If after 6 to 8 hours the diastolic blood pressure remains higher than 100 mm Hg, a second dose of hydralazine (100 mg) should be given. The beta blocker dose is increased as needed to maintain the heart rate in the 60 to 80 beats per minute range. If the blood pressure is not controlled with hydralazine at a dose of 100 mg twice daily, minoxidil should be substituted for hydralazine. The starting dose of minoxidil (2.5 mg) is increased by 2.5 to 5.0 mg every 6 to 8 hours until the blood pressure is adequately controlled. The usual effective dose is 5 to 10 mg twice daily. Treatment with a beta-blocker is recommended as for hydralazine. As the blood pressure is brought under control with oral agents, the sodium nitroprusside infusion is gradually weaned. When the convalescing patient is mobilized, upright blood pressure should be carefully monitored to avoid significant orthostatic hypotension. A diuretic, usually furosemide at a starting dose of 40 mg twice daily, is added to either the hydralazine or the minoxidil regimen when it becomes evident that salt and water retention is beginning to occur.

Volume Status and the Role of Diuretics

Routine parenteral diuretic therapy during the acute phase of treatment for malignant hypertension may actually be deleterious. Overdiuresis may result in deterioration of renal function due to superimposed prerenal azotemia. Moreover, volume depletion may activate the renin–angiotensin axis and other pressor hormone systems.

Even patients with malignant hypertension and pulmonary edema may not have an increase in total body salt and water content. Pulmonary congestion in this setting may result from an increase in left ventricular filling pressure due to a decrease in the compliance of the left ventricle (diastolic dysfunction) rather than an increase in left ventricular volume per se. With severe hypertension, the ventricle may become noncompliant due to the excessive workload imposed by the elevated systemic vascular resistance. As a result, left ventricular end-diastolic pressure (LVEDP) increases dramatically even though left ventricular end-diastolic volume may be near normal. With vasodilator therapy, the systemic vascular resistance decreases, left ventricular compliance improves, LVEDP decreases, and left ventricular end-diastolic volume may actually increase.[94] Despite the increase in left ventricular

end-diastolic volume, pulmonary congestion improves because of the reduction in pulmonary capillary pressure. Thus, even in patients with malignant hypertension complicated by pulmonary edema, afterload reduction rather than vigorous diuretic therapy should be the mainstay of initial therapy.

Some patients with malignant hypertension may actually benefit from a cautious trial of volume expansion. Intravascular volume depletion in patients with malignant hypertension should be considered in patients with exquisite sensitivity to vasodilator therapy manifest by a precipitous drop in blood pressure at relatively low infusion rates. Patients with malignant hypertension due to analgesic nephropathy are particularly prone to be severely volume-depleted at presentation due to the presence of chronic interstitial damage with a salt-wasting nephropathy.[17]

In summary, the need for diuretic therapy during the initial phase of treatment for malignant hypertension depends on an assessment of volume status. Unless obvious fluid overload is present, diuretics should not be given initially.

Management of Malignant Hypertension Complicated by Renal Insufficiency

All patients with malignant hypertension should receive aggressive antihypertensive therapy to prevent further renal damage, regardless of the degree of renal impairment. Control of blood pressure in patients with malignant hypertension and renal insufficiency occasionally precipitates oliguric acute renal failure, especially when the initial glomerular filtration rate is less than 20 mL per minute. However, this is not a contraindication to aggressive antihypertensive therapy aimed at normalization of the blood pressure. Control of hypertension protects other vital organs such as the brain and heart whose function cannot be replaced. Moreover, with tight blood pressure control, even patients who appear to have ESRD due to malignant nephrosclerosis have recovered renal function.[95–100]

In patients in whom aggressive control of hypertension precipitates the need for dialysis, dialysis is utilized to control serum chemistry values, treat uremia, and correct fluid overload. However, since dialysis alone rarely results in adequate control of blood pressure in patients with malignant hypertension, concomitant antihypertensive drug therapy is almost always required. A regimen with minoxidil and beta-blocker has proved to be particularly efficacious in this setting.[98,99]

Initial Oral Therapy

Although many patients with malignant hypertension require prompt treatment with parenteral antihypertensive agents, some patients may not yet have evidence of cerebral or cardiac complications, or rapidly deteriorating renal function and therefore do not require instantaneous control of the blood pressure.[89,101,102] These patients may be safely managed with an intensive oral regimen designed to bring the blood pressure under control over a period of 12 to 24 hours.

In patients with malignant hypertension, a multidrug oral regimen is often required to achieve adequate blood pressure control. The most useful combinations include a diuretic, a β-adrenergic blocker, and an arteriolar vasodilator. Minoxidil appears to be particularly well suited for the initial management of malignant hypertension that requires prompt but not immediate blood pressure reduction.[103–105] Alpert and Bauer[105] describe the use of a triple regimen of furosemide, beta-blocker, and minoxidil in nine patients with a diastolic blood pressure higher than 120 mm Hg. Seven of these patients had malignant hypertension. Furosemide (40 mg) and propranolol (40 mg) were given initially by mouth. Two hours later, if the diastolic pressure was higher than 120 mm Hg, a loading dose of minoxidil (20 mg) was administered. If the diastolic pressure was still over 100 mm Hg 4 hours after the loading dose, a booster dose of minoxidil was given. The amount of the booster dose was estimated based on the magnitude of the response to the loading dose. Maintenance therapy with minoxidil was begun with one half the sum of the loading and booster doses given twice daily, with adjustment of beta-blocker and diuretic doses as necessary for control of heart rate and fluid balance. Following the booster dose of minoxidil, a sustained decrease in blood pressure was seen in all patients. No overshoot hypotension or other adverse effects were encountered. During long-term therapy, the physicians were able to substitute hydralazine for minoxidil in five patients. However, the remaining four patients required chronic minoxidil therapy for adequate blood pressure control.[101]

Initial oral therapy with the dihydropyridine calcium channel blocker nifedipine has been shown to be effective in the management of malignant hypertension in black patients who did not require parenteral therapy for hypertensive encephalopathy or acute pulmonary edema.[102] No precipitous decreases in blood pressure or neurologic complications were encountered. However, despite adequate control of blood pressure during the first 24 hours with sustained-released nifedipine, all patients eventually required one or more additional drugs for long-term blood pressure control. Oral loading regimens with clonidine have been advocated in severe uncomplicated (urgent) hypertension.[106] However, there is limited information on the use of oral clonidine loading in the initial management of malignant hypertension. Clonidine loading can cause significant sedation, which may interfere with the assessment of potential neurologic complications during acute blood pressure reduction. Moreover, common side effects such as sedation and dry mouth can have a negative impact on compliance in patients treated with clonidine for the long term. Thus, oral clonidine loading regimens are not indicated for the initial management of malignant hypertension.

Long-Term Management

After the immediate crisis has resolved and the blood pressure has been brought under control with parenteral therapy, oral therapy, or both, lifelong surveillance of the blood pressure is essential. Close follow-up and aggressive treatment are mandatory because noncompliance or inadequate therapy may have devastating consequences. If blood pressure control becomes inadequate, malignant hypertension may recur even after years of successful antihypertensive therapy. In a study of the quality of care provided to patients with a history of malignant hypertension who subsequently died, only 27% of patients had an average treated diastolic blood pressure of less than 110 mm Hg.[107] Thus, meticulous long-term treatment of hypertension is imperative in patients with a history of malignant hypertension. Triple therapy with a diuretic, a beta-blocker, and a vasodilator is often required to achieve satisfactory blood pressure control.

Response to Therapy

In the absence of adequate blood pressure control, malignant hypertension has a uniformly poor prognosis. Without treatment, the 1-year mortality rate approaches 80% to 90%, and uremia is the most common cause of death.[21] However, since the introduction of potent antihypertensive agents, studies have shown that with control of blood pressure, dialysis-free survival can be substantially prolonged. A recent study of survival trends for patients with malignant hypertension (n = 446) over the last 40 years found that there was a significant improvement in 5-year survival from 32% prior to 1977 to 91% for patients diagnosed between 1997 and 2006.[25] Multivariate analysis revealed that age, decade of diagnosis of malignant hypertension, baseline creatinine, and follow-up systolic blood pressure were independent predictors of survival. In a another single-center retrospective analysis of 197 patients with malignant hypertension diagnosed in the period 1974 to 2007, renal damage at presentation was common (63%) but renal function improved or remained stable after diagnosis in the majority of patients.[26] The probability of renal survival was 84% and 72% after 5 and 10 years, respectively. The number of patients with malignant hypertension who improved or stabilized their renal function significantly increased in the second and third periods of the study (1987–2007). Diagnosis during the early study period (1974–1985), baseline renal function, proteinuria, and the presence of microhematuria were associated with an unfavorable outcome. However, by multivariate analysis, mean proteinuria during follow-up remained as the only significant risk factor (OR 2.72; 95% CI, 1.59–4.64). Renal survival for patients with mean protein excretion less than 0.5 g per 24 hours was 100% and 95% at 5 and 10 years, respectively.

The severity of renal impairment at the time of presentation with severe hypertension may also have prognostic significance.[108] Chronic kidney disease and acute kidney injury are common in patients hospitalized with severe hypertension. In the ongoing STAT trial, a U.S.-based, retrospective observational study of management practices and outcomes of patients with severe hypertension, both chronic kidney disease (CKD) and acute kidney injury (AKI) were common. AKI was a strong predictor of greater morbidity and cardiovascular mortality.[109]

Reversal of Hypertensive Neuroretinopathy

The funduscopic changes associated with hypertensive neuroretinopathy are reversible with control of blood pressure.[110] Striate hemorrhages cease to form as soon as the blood pressure is controlled. Clearance of existing hemorrhages takes 2 to 8 weeks. Cotton-wool spots may continue to form for several days after the blood pressure is controlled. The cellular (axonal) debris that comprises the cotton-wool spots is cleared away within 2 to 12 weeks. Hard exudates clear more slowly. A macular star may require more than a year to resolve completely. Papilledema often continues to increase during the first few days of treatment. However, in the majority of patients, it resolves slowly over several weeks. In contrast, the changes reflecting retinal arteriolosclerosis such as arteriolar narrowing, arteriovenous crossing defects, and changes in the light reflexes usually persist despite adequate blood pressure control.[110]

Evaluation for Secondary Causes

The various secondary causes of malignant hypertension were discussed previously in the section on etiologies of malignant hypertension. Whereas less than 5% of patients with benign hypertension have an underlying secondary cause of hypertension, malignant hypertension may be associated with a secondary cause in up to 50% of patients. For example, among patients with benign hypertension, the incidence of renovascular hypertension was less than 0.5%.[111] In contrast, there is a substantial incidence of renovascular hypertension (43% in whites, 7% in blacks) among patients with malignant hypertension.[18] Thus, after malignant hypertension has been treated successfully, the possibility of underlying renovascular hypertension should be investigated. Noninvasive screening tests such as radionuclide renal scans are of little value because of the high frequency of false-positive and false-negative results.[111] Renal arteriography is the procedure of choice to exclude the possibility of anatomic renal artery stenosis. The diagnosis and treatment of renovascular hypertension is discussed in detail in Chapter 42.

Pheochromocytoma is a rare cause of malignant hypertension. However, given the likelihood of surgical cure or amelioration of hypertension, pheochromocytoma should be considered if symptoms consistent with catecholamine excess persist following control of blood pressure. The approach to the diagnosis of pheochromocytoma is discussed in Chapter 43.

The role of renal biopsy in the diagnosis of possible underlying primary renal parenchymal disease in patients with malignant hypertension is controversial. In patients

presenting with malignant hypertension and renal failure, it may not be possible on clinical grounds to distinguish primary malignant hypertension from chronic glomerulonephritis or chronic interstitial nephritis with superimposed malignant nephrosclerosis. A renal biopsy may be required to make this distinction. When the kidneys appear small by ultrasonography, a biopsy is not indicated because it is unlikely that the results of the biopsy will alter therapy. In contrast, when the kidneys are normal in size, a renal biopsy may provide useful information. If primary malignant nephrosclerosis with ischemic but viable glomeruli is found, then intensive antihypertensive therapy may be associated with the eventual recovery of renal function, even after months of maintenance dialysis. Conversely, the finding of chronic glomerulonephritis or chronic interstitial nephritis with superimposed malignant nephrosclerosis suggests a less favorable long-term outcome.

Malignant hypertension can mimic acute glomerulonephritis or vasculitis. Patients can present with severe hypertension and oliguric acute renal failure with nephritic urinary sediment. In this setting, diagnostic renal biopsy is essential since acute glomerulonephritis or vasculitis may require specific therapy in addition to antihypertensive treatment.

Because uremia and severe hypertension predispose to serious hemorrhagic complications after renal biopsy, it is prudent to manage the patient with dialysis and blood pressure control for 1 to 3 weeks prior to performance of a percutaneous renal biopsy. Unfortunately, this delay in obtaining tissue may make the diagnosis of malignant nephrosclerosis more difficult because the lesions of fibrinoid necrosis may heal rapidly with the institution of antihypertensive treatment, leaving a residual hyaline or fibrous scar.[80] Moreover, given the sampling error inherent in closed renal biopsy, the patchy lesions of malignant nephrosclerosis might be missed. Thus, the diagnosis of malignant nephrosclerosis is often made on the basis of the findings of accelerated glomerular obsolescence and marked intimal hyperplasia of the arterioles.[73]

Benign Versus Malignant Hypertension

Since the original description by Volhard and Fahr,[35] two forms of essential hypertension have been recognized: benign and malignant. It is worth emphasizing that these two forms of hypertension should be conceptualized as distinct clinical and pathologic entities. In benign hypertension there is usually a long asymptomatic phase, with death resulting from complications of cerebrovascular disease, atherosclerotic disease, or congestive heart failure, rather than renal disease. In benign essential hypertension (i.e., without underlying primary renal disease or superimposition of malignant hypertension), ESRD seldom occurs.[112–115] In contrast, malignant hypertension left untreated uniformly progresses to ESRD.

There is much controversy in the field of hypertension regarding the frequency with which benign hypertension (benign arteriolar nephrosclerosis), in the absence of occult primary renal disease or superimposed malignant hypertension, causes ESRD. Recent reviews suggest that the number of patients reaching ESRD attributable to benign nephrosclerosis might have been significantly overestimated.[114,115] Goldring and Chasis[46] extensively evaluated renal function in a large group of patients with essential hypertension in the preantihypertensive treatment era. Most patients with long-standing essential hypertension had anatomic lesions in their kidneys consistent with hyaline arteriolar nephrosclerosis. Moreover, the majority had demonstrable renal abnormalities including abnormal urinalysis with hyaline and granular casts, low-grade proteinuria (less than 1 g per day), decreased tubular maximum for para-aminohippurate, decreased renal blood flow, normal to slightly decreased glomerular filtration rate, and increased filtration fraction. However, they found that ESRD rarely occurred in patients with benign hypertension. Among 150 hypertensive patients with ESRD, only one was found to have benign nephrosclerosis as the sole underlying etiology.[46] These authors concluded that in patients with benign hypertension, functional failure occurred earlier in the heart and brain than in the kidney and that death from renal failure without superimposed malignant hypertension was a rare event.

In contrast to these early reports, which were based principally on renal histologic findings at autopsy, in more recent series, "hypertensive nephrosclerosis" is listed as a common cause of ESRD, especially among African American patients. For example, blacks have a four- to eightfold elevation in the risk of hypertension-induced ESRD compared to whites.[116,117] The studies suggest that much of the excess risk of ESRD among blacks can be explained by an extraordinarily high rate of renal failure from hypertensive nephrosclerosis. On a national scale, an estimated 29% of blacks with ESRD have hypertension as the primary cause.[116] However, in these recent studies, classification of the causes of ESRD was based on clinical rather than histologic evidence. Furthermore, in these studies it was not clear whether the term hypertensive nephrosclerosis refers to benign or malignant nephrosclerosis. In the few available studies detailing the pathologic findings in blacks with ESRD due to hypertension, the characteristic findings have been those of malignant nephrosclerosis, namely, musculomucoid intimal hyperplasia of the interlobular arteries and accelerated glomerular obsolescence.[13] Moreover, there appears to be a racial bias with regard to the diagnosis of hypertensive nephrosclerosis. When nephrologists were asked to review identical case histories of patients with ESRD in which only the race of the patient was randomly assigned as either black or white, it was found that black patients were twice as likely as white patients to be labeled as having ESRD secondary to hypertensive nephrosclerosis.[118]

The relationship between essential hypertension and ESRD remains circumstantial despite the fact that these syndromes have long been associated in the medical literature.[115] Nephrologists credit essential hypertension as the cause of ESRD in 25% of patients initiating Medicare-supported renal

replacement therapy. Surprisingly, the widely held notion that benign hypertension with benign nephrosclerosis is a common cause of ESRD is difficult to support.[114,115,119] In contrast to the large body of literature relating mild to moderate benign hypertension to excessive cardiovascular morbidity, there is a dearth of information available regarding the corresponding risk of significant renal disease.[119] In available studies, serum creatinine levels infrequently increase in patients with long-standing mild to moderate hypertension. An analysis of the data from three large clinical trials in patients with essential hypertension revealed that advanced renal failure developed in less than 1% of 10,000 patients during the 4 to 6 years of follow-up.[120–122] Moreover, a very low incidence of clinically significant deterioration of renal function was also noted in the Hypertension Detection and Follow-up Program.[123] Another study of untreated patients with mild to moderate essential hypertension found only minor declines in glomerular filtration rate (1.6% per year) and renal blood flow (2.1% per year), which did not differ from the renal function decline associated with aging in normotensive individuals.[124] Even severe untreated hypertension (diastolic blood pressure, 120 to 150 mm Hg), in the absence of a malignant hypertension (hypertensive neuroretinopathy), caused only a minor decrement in glomerular filtration rate (1.7% per year).[124] Thus, hypertensive nephrosclerosis is commonly reported to Medicare as the cause of ESRD despite the fact that the risk of progressive renal dysfunction in clinical studies of patients with essential hypertension appears to be very low. This paradox could possibly be explained by the fact that the number of patients with essential hypertension is so large that even the small percentage at risk constitutes a relatively large number of patients who eventually develop ESRD. Long-term follow-up data from the Multiple Risk Factor Intervention Trial (MRFIT), in which over 322,000 men were screened for possible entry, support this hypothesis.[125] A direct correlation was found between the initial blood pressure and the risk of development of ESRD from any cause at 16-year follow-up. Nonetheless, the age-adjusted rate of ESRD in this group was only 0.34% at 16 years.

Patients classified as having hypertensive ESRD typically present with advanced disease, making the processes that initiated the renal disease difficult to discern. It has been proposed that many patients classified as having hypertensive nephrosclerosis actually have intrinsic renal parenchymal disease (often immunoglobulin A [IgA] nephropathy), unrecognized renal artery stenosis with ischemic nephropathy, unrecognized episodes of malignant hypertension, or primary renal microvascular disease.[114,115] At least among white patients with hypertension and renal impairment, if renal artery stenosis and malignant hypertension have been excluded, the most likely diagnosis is underlying primary renal parenchymal disease rather than benign nephrosclerosis.[126]

In contrast to these studies, a provocative study found that mild to moderate benign hypertension did cause renal insufficiency that progressed despite adequate blood pressure control.[127] However, since renal biopsies were not performed, the data do not exclude the possibility of occult primary renal parenchymal disease in patients demonstrating progressive renal insufficiency.[128]

In summary, although it is clear that malignant hypertension is a frequent cause of ESRD, especially among blacks, there remains considerable controversy regarding the commonly held belief that benign hypertension per se commonly causes ESRD. The critical issue that has yet to be resolved is why blacks constitute a disproportionately high percentage of patients with ESRD in the United States.[116] Epidemiologic studies suggest that essential hypertension occurs more frequently in blacks and is associated with more severe cardiovascular end-organ damage for any given level of blood pressure.[129] In angiographic studies of patients with mild to moderate essential hypertension and normal renal function, blacks tended to have more severe angiographic evidence of nephrosclerosis than did whites.[130] There are several other plausible explanations for the high frequency with which hypertensive nephrosclerosis is reported as a cause of ESRD in the black population. Since most of the available data are based on clinical diagnoses, there may be a tendency on the part of physicians to identify hypertension as the cause of ESRD given the known high prevalence of hypertension in blacks, even when a primary renal parenchymal disease cannot be excluded on clinical grounds.[119] Another possibility is that blacks with essential hypertension tend to develop more severe benign nephrosclerosis, which, unlike benign nephrosclerosis in whites, more often results in progressive renal insufficiency and ESRD.[115] Results from the African American Study of Kidney Disease (AASK) Trial indicate that benign nephrosclerosis can be accurately diagnosed in black patients with hypertension and renal insufficiency. A renal biopsy was performed in 39 nondiabetic black patients with chronic renal failure who did not have marked proteinuria (urine protein to creatinine ratio less than 2.0). Changes compatible with benign nephrosclerosis were seen in 38 patients. The remaining patient most likely had primary focal segmental glomerulosclerosis.[131] It is possible that genetic factors may increase the susceptibility of blacks to renal damage induced by benign hypertension. On the other hand, the AASK trial demonstrated that strict blood pressure control, including use of ACE inhibitors, failed to halt the progression of renal disease in these black patients with biopsy-proven hypertensive nephrosclerosis.[132] This finding suggests that the focal global glomerulosclerosis lesion identified in AASK trial participants may represent a form of primary renal disease rather than a primary consequence of hypertension-induced renal injury per se. Finally, it is possible that recurrent bouts of unrecognized or inadequately treated malignant hypertension are an underestimated cause of the high incidence of ESRD in minority populations. In this regard, a study of 100 patients admitted to an inner city hospital with a diagnosis of hypertensive emergency showed that two thirds had malignant hypertension based on funduscopic findings.[133] These patients were predominantly

young, male, black, or Hispanic individuals of lower socioeconomic status. At least 93% of these patients had been previously diagnosed as hypertensive, and at least 83% were aware of their diagnosis of hypertension. At least 87% were known to have received prior pharmacologic treatment for hypertension. However, no source of regular health care could be documented in 60% of patients. More than 50% were noted to have stopped their antihypertensive medications more than 30 days prior to admission and only 24% had taken any medication on the day of admission. If the overrepresentation of young blacks with ESRD is due to undiagnosed or inadequately treated malignant hypertension, this would have tremendous public health implications given that malignant hypertension is clearly preventable, and even significant renal dysfunction is potentially reversible with tight control of blood pressure.

HYPERTENSIVE ENCEPHALOPATHY

Most of the deleterious effects of hypertension on the brain are the result of long-standing mild to moderate elevations of blood pressure, including atherothrombotic infarction, lacunar infarction, and intracerebral hemorrhage. Occasionally, severe acute hypertension can produce dramatic and life-threatening cerebral complications. Hypertensive encephalopathy is an acute cerebral syndrome that develops in association with a sudden, sustained elevation of blood pressure.[56] It can occur with malignant hypertension or severe "benign" hypertension that is not accompanied by hypertensive neuroretinopathy. Hypertensive encephalopathy is a medical emergency that demands prompt diagnosis and rapid control of blood pressure to prevent irreversible brain damage or death. The clinical sine qua non of hypertensive encephalopathy is the prompt resolution of symptoms when the blood pressure is brought under control.

Clinical Presentation

The diagnosis of hypertensive encephalopathy is usually made on clinical grounds. The appearance of cerebral symptoms usually follows the sudden onset of hypertension in previously normotensive individuals or an abrupt increase in blood pressure in patients with chronic hypertension. The abrupt blood pressure elevation usually occurs 12 to 48 hours before the onset of symptoms, although this is often difficult to document. Symptoms may appear at lower levels of blood pressure in previously normotensive individuals compared to those with chronic hypertension. For example, in children with acute glomerulonephritis or pregnant women with eclampsia, hypertensive encephalopathy may occur when the blood pressure is no higher than 160/100 mm Hg.[134] However, the syndrome rarely occurs in chronically hypertensive individuals at pressures less than 200/120 mm Hg and may not occur until the blood pressure is more than 250/150 mm Hg.

The initial symptom of hypertensive encephalopathy is usually a severe, generalized headache that increases steadily in severity.[135] Unfortunately, headache is a nonspecific symptom, and even among patients with malignant hypertension, it does not necessarily imply CNS damage. Weakness, nausea, and vomiting (sometimes projectile) are often present. Neck stiffness is an occasional finding. Loss of vision is another common feature. Visual loss may be caused by the retinal edema and hemorrhages that accompany hypertensive neuroretinopathy or as the result of cortical (occipital) blindness.[136] Denial of visual loss or loss of vision in the presence of a normal light reflex suggests cortical blindness.

Altered mental status is a prominent clinical feature of hypertensive encephalopathy. Apathy, somnolence, and confusion are the initial manifestations that usually appear several hours to days after the onset of headache. If treatment is not instituted, coma and death can occur. Recurrent seizures are common, and they can be either focal or generalized.

There are numerous reports of transient focal neurologic disturbances in patients with hypertensive encephalopathy including fleeting paresthesias and numbness in the extremities, transient paralysis, and aphasia.[56,136] Thus, the presence of focal neurologic deficit in a patient with severe hypertension does not necessarily exclude the diagnosis of hypertensive encephalopathy.

Hypertensive neuroretinopathy (striate hemorrhages, cotton-wool spots, and papilledema) is present when hypertensive encephalopathy occurs in patients with malignant hypertension. However, it may be absent when hypertensive encephalopathy develops in the setting of acute glomerulonephritis, eclampsia, monoamine oxidase inhibitor–tyramine interactions, antihypertensive drug withdrawal syndromes, or pheochromocytoma.[134,136,137]

Many authors have cautioned that lumbar puncture should be avoided in patients with suspected hypertensive encephalopathy because of the risk of cerebellar herniation.[138] When performed, lumbar puncture has revealed elevated cerebrospinal fluid (CSF) pressure in most patients ranging from 230 to 560 mm of water.[136] CSF protein concentration is usually moderately elevated (48 to 90 mg per dL) but may be normal. The cell count is usually normal,[136] but neutrophilic pleocytosis has also been reported in hypertensive encephalopathy.[138]

Computed tomography (CT) and magnetic resonance imaging (MRI) reveal characteristic findings in hypertensive encephalopathy.[139–143] Abnormalities on imaging include areas of low white matter attenuation on CT scans and T1-weighted hypointense and T2-weighted hyperintense areas on MRI. These changes probably represent cerebral edema with increased water in the white matter. The most common location of the white matter abnormalities on neuroimaging is the posterior regions of the cerebral hemispheres. The multifocal abnormalities include both hemispheres and tend to be symmetric. Commonly involved areas in descending order of frequency include the occipital lobes, the posterior parietal lobes, and the posterior temporal lobes. The pons, the thalamus, and the cerebellum are occasionally involved. The term reversible posterior leukoencephalopathy syndrome

has been coined to describe patients with these typical radiographic findings and a reversible syndrome of headache, altered mental status, seizures, and loss of vision.[140] A reversible hypertensive brainstem encephalopathy with predominant involvement of the brainstem and relative sparing of supratentorial regions has also been reported.[143]

Etiologies

Although hypertensive encephalopathy can complicate malignant hypertension, not all patients with hypertensive encephalopathy have malignant hypertension. In fact, it most commonly occurs in previously normotensive individuals who experience sudden, severe hypertension (Table 44.5). The reported causes of hypertensive encephalopathy include acute glomerulonephritis,[134,135] eclampsia,[144,145] renovascular hypertension,[134] postcoronary artery bypass hypertension, clonidine withdrawal,[146] monoamine oxidase inhibitor–tyramine interactions,[147] pheochromocytoma,[148] phencyclidine (PCP) poisoning,[149] licorice ingestion,[150] phenylpropanolamine overdose,[151,152] acute renal artery occlusion,[136] acute lead poisoning,[136] immunosuppressive therapy with cyclosporine or tacrolimus for kidney, liver, or bone marrow transplantation,[153,154] chemotherapy for acute leukemia in children,[155] transplant renal artery stenosis or acute rejection,[156,157] and femoral lengthening procedures in children.[158] The preeclampsia–eclampsia syndrome has been hypothesized to reflect a subtype of hypertensive encephalopathy accompanied by impaired cerebral autoregulation and endothelial dysfunction.[137,141,144,145] The clinical and radiographic findings in patients with cyclosporine-induced neurotoxicity have been found to be identical to those seen in hypertensive encephalopathy.[154] The only major factor found to be associated with the neurotoxic effect of cyclosporine in all patients was hypertension. Subcortical edema, affecting the posterior regions of the brain, tends to resolve following reduction in blood pressure, with or without concomitant reduction in cyclosporine dose. Hypertensive encephalopathy may also occur in patients with acute or chronic spinal cord injuries if there is autonomic hyperreflexia due to bowel or bladder distention.[159,160] Acute elevation of blood pressure during recombinant human erythropoietin therapy occasionally results in hypertensive encephalopathy and seizures.[161] This complication is unrelated to the extent or rate of increase in hematocrit, but is associated with a rapid increase in blood pressure and may occur in previously normotensive patients. Scorpion envenomization results in stimulation of the autonomic nervous system and adrenals and in children can lead to severe hypertension and a clinical picture consistent with hypertensive encephalopathy.[162] Cocaine use can also induce a sudden increase in blood pressure accompanied by hypertensive encephalopathy.[163]

44.5 Etiologies of Hypertensive Encephalopathy

Malignant hypertension of any etiology
Acute glomerulonephritis
Eclampsia
Renovascular hypertension
Postcoronary artery bypass hypertension
Abrupt withdrawal of antihypertensive therapy
Monoamine oxidase inhibitor-tyramine interactions
Pheochromocytoma
Phencyclidine (PCP) poisoning
Phenylpropanolamine overdose
Recombinant erythropoietin therapy in dialysis patients
Scorpion envenomation, especially in children
Cocaine hydrochloride or alkaloidal (crack) cocaine
Acute renal artery occlusion
Acute lead poisoning in children
Cyclosporine-induced or tacrolimus-induced hypertension
Transplant renal artery stenosis or acute rejection
Femoral lengthening procedures
Acute or chronic spinal cord injuries

Pathogenesis

The breakthrough theory of autoregulation originally proposed by Lassen and Angoli[164] is the generally accepted view of the pathogenesis of hypertensive encephalopathy (Fig. 44.17). Under normal circumstances, there is autoregulation of the cerebral microcirculation such that, over a wide range of perfusion pressures, cerebral blood flow remains constant. It has been proposed that in the setting of a sudden, severe increase in blood pressure, autoregulatory vasoconstriction fails and there is forced vasodilation. The dilation is initially segmental (sausage-string pattern), but eventually becomes diffuse. The endothelium in the dilated segments becomes abnormally permeable, and there is extravasation of plasma components with the development of cerebral edema. This theory may explain the clinical observation that hypertensive encephalopathy develops at a much lower blood pressure in previously normotensive individuals than it does in those with chronic hypertension. With long-standing hypertension, structural changes and remodeling

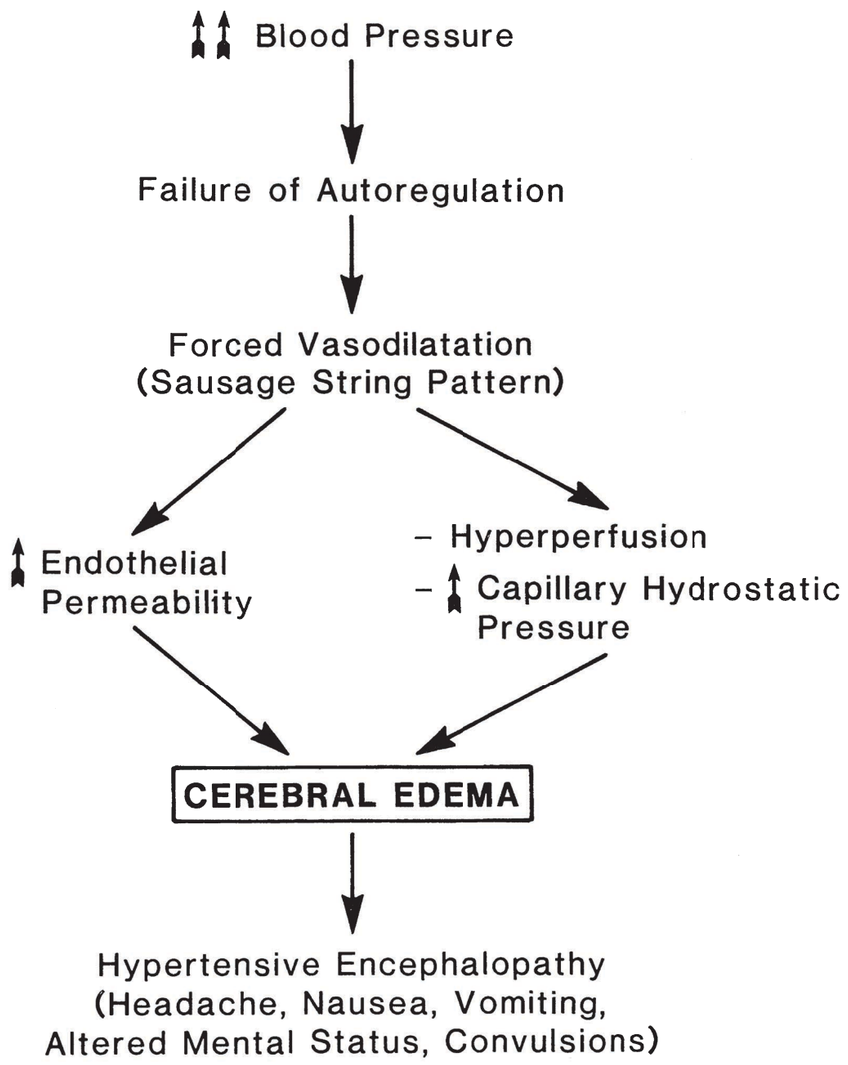

FIGURE 44.17 The breakthrough theory of hypertensive encephalopathy.

of the cerebral arterioles may lead to a shift in the autoregulatory curve such that much higher perfusion pressures can be tolerated before forced vasodilation and breakthrough of autoregulation occur.[165,166]

Treatment

The treatment of choice for hypertensive encephalopathy is prompt reduction of blood pressure. When the diagnosis of hypertensive encephalopathy seems likely, antihypertensive therapy should be initiated prior to obtaining the results of time-consuming laboratory and radiologic examinations. The goal of therapy, especially in the previously normotensive patient with acute hypertension, should be the reduction of blood pressure to normal or near-normal levels as quickly as possible.[134] Although cerebral blood flow could theoretically be jeopardized by failure of autoregulation during rapid reduction of blood pressure in patients with chronic hypertension, clinical experience has shown that the prompt reduction of blood pressure with the avoidance of frank hypotension is beneficial in patients with hypertensive encephalopathy.[134] Of the conditions in the differential diagnosis of hypertension with acute cerebral dysfunction, only cerebral infarction might be adversely affected by the abrupt reduction of blood pressure. Pharmacologic agents that have a rapid onset and short duration of action such as sodium nitroprusside, continuous infusion labetalol, or possibly fenoldopam should be utilized so that the blood pressure can be carefully titrated with close monitoring of the patient's neurologic status. There is some evidence that compared to labetalol, nitroprusside reduces systemic vascular resistance more than cerebral vascular resistance and could, therefore, result in shunting of blood from the brain.[167] The clinical sine qua non of hypertensive encephalopathy is a prompt clinical response to blood pressure reduction. Conversely, when antihypertensive therapy is associated with the development of new or progressive neurologic deficits, other diagnoses should be considered, and the blood pressure should be stabilized at a higher level.

In women with eclampsia, convulsions and other neurologic manifestations occur and are indistinguishable from those observed in nonpregnant individuals with hypertensive encephalopathy, except that in eclampsia they occur at a lower level of blood pressure.[145] Eclampsia is associated with extreme risk to both the mother and the fetus. Although delivery of the fetus is the definitive cure in most cases, rapid control of the blood pressure and encephalopathic manifestations is essential before the induction of labor or performance of a cesarean section.[137,144]

ACUTE HYPERTENSION COMPLICATING CEREBROVASCULAR ACCIDENT

The importance of hypertension as a risk factor for cerebrovascular accident is well established. The Framingham Study shows that regardless of gender or age, hypertension is associated with an increased incidence of ischemic and hemorrhagic stroke.[168] Several prospective, randomized clinical trials demonstrate that long-term antihypertensive drug therapy results in a significant reduction in morbidity and mortality from cerebrovascular accident.[169] Despite the proven benefits of blood pressure control in the prevention of stroke, the role of treatment of hypertension in the acute phase of stroke remains controversial. Whether antihypertensive therapy is indicated depends not only on the magnitude of the blood pressure elevation, but also on the type of cerebrovascular accident. It should be emphasized that the management of hypertension accompanying cerebral infarction is different from that for hypertension complicating either intracerebral hemorrhage or subarachnoid hemorrhage.

Cerebral Infarction

In the cerebral circulation, the sites of predilection for atherosclerosis are the bifurcations of the common carotid arteries, the carotid siphons, the origins of the vertebral and basilar arteries, the circle of Willis, and the proximal parts of the cerebral arteries.[170] Cerebral infarction can result from partial or complete occlusion of an artery by a plaque or embolization of atherothrombotic debris from a plaque. The atherothromboembolic infarcts produced by one of these mechanisms typically involve the cerebral or cerebellar cortex or the pons.[170] In contrast, hypertension-induced lipohyalinosis of the small penetrating cerebral end arteries is the principal cause of the small, deep lacunar infarcts that occur in the basal ganglia, pons, thalamus, cerebellum, and deep hemispheric white matter.[170]

Hypertension is common in the setting of acute cerebral infarction. In a series of 334 consecutive patients admitted for acute stroke, the blood pressure was elevated in 84% of the patients on the day of admission. Even without specific antihypertensive treatment, the blood pressure decreased spontaneously by an average of 20 mm Hg systolic and 10 mm Hg diastolic in the 10 days following the acute event.[171] This early elevation in blood pressure most likely represents a physiologic response to brain ischemia. Decreases in blood pressure accompany recovery of brain function.

Because of the known benefits of antihypertensive therapy with regard to stroke prevention, it has been assumed that reduction in blood pressure would benefit patients with acute cerebral infarction. Unfortunately, because treatment of hypertension in this setting has never been evaluated in a prospective, randomized trial, there are no good data to guide management. Moreover, there is no evidence to suggest that rapid reduction of blood pressure is beneficial. In fact, several cases have been reported in which worsening of the patient's neurologic status was apparently precipitated by emergency treatment of hypertension.[172,173] The rationale for not treating hypertension in acute ischemic strokes is based on concerns regarding impairment in autoregulation of cerebral blood flow in this setting.[173,174] In normal individuals, cerebral blood flow is maintained constant at mean arterial pressures ranging between 60 and 120 mm Hg. However, in patients with chronic hypertension as well as older adult patients, the curve is shifted such that the lower limit of autoregulation occurs at a higher mean arterial pressure. Furthermore, there is evidence that local autoregulation of cerebral blood flow is disturbed in the so-called ischemic penumbra that surrounds an area of acute infarction.[173,174] Without intact autoregulation, the regional blood flow becomes critically dependent on the perfusion pressure. Thus, to some extent, the presence of hypertension may be beneficial in the setting of acute cerebral infarction, whereas reduction of blood pressure may cause a regional decrease in blood flow with extension of the infarct.

The recently published SCAST trial examined whether careful blood pressure reduction with the angiotensin-receptor blocker candesartan is beneficial in the treatment of patients with acute stroke accompanied by elevated blood pressure.[175] Participants were recruited from 146 centers in nine northern European countries. Patients older than 18 years with acute stroke (ischemic or hemorrhagic) and systolic blood pressure of 140 mm Hg or higher were initiated on study drug or placebo therapy within 30 hours of onset of symptoms. Patients were randomly allocated to candesartan ($n = 1017$) or placebo treatment ($n = 1012$) for 7 days, with doses increasing from 4 mg on day 1 to 16 mg on days 3 to 7. There were two coprimary outcome variables: the composite endpoint of vascular death, myocardial infarction, or stroke within the first 6 months; and the functional outcome at 6 months. During the 7-day treatment period, blood pressures were significantly lower in the candesartan group (147/82 mm Hg, standard deviation [SD] 23/14 mm Hg) compared to the placebo group (152/84 mm Hg, SD 22/14 mm Hg; $P < .0001$). During the 6 months of follow-up, the risk of the composite vascular endpoint did not differ between treatment groups (candesartan, 120 events, versus placebo, 111 events; adjusted hazard ratio 1.09, 95% CI 0.84–1.41; $P = .52$). Analysis of functional outcomes suggested a higher risk of poor outcomes in the candesartan group (adjusted common OR 1.17, 95% CI 1.00–1.38; $P = .048$, not significant at $P \leq .025$ level). The observed effects were similar for all prespecified secondary endpoints including death from any cause, vascular death, ischemic stroke, hemorrhagic stroke, stroke progression, myocardial infarction, symptomatic hypotension, and renal failure. The authors conclude that there was no indication that careful blood pressure reduction with candesartan in the setting of acute stroke is beneficial; if anything, the evidence suggested a harmful effect of blood pressure reduction.

A recent metaregression analysis of the differences in on-treatment blood pressure and odds ratio for outcomes after acute stroke has been performed.[176] In an analysis of 37 trials involving 9008 patients, a U or J shaped relationship was identified amongst on-treatment blood pressure differences and early or 90-day death rates. Although large increases in blood pressure were associated with worse outcomes, modest reductions in blood pressure were beneficial in this large observational study.

Because there is no evidence that mild to moderate hypertension has a deleterious effect on the outcome of cerebral infarction during the acute stage, it is probably wise to allow the blood pressure to seek its own level during the first few days to weeks after the event. In most cases, the hypertension tends to resolve spontaneously over the first week without specific therapy.[171] On the other hand, if hypertension persists for more than 3 weeks in a patient with a completed stroke, gradual reduction of blood pressure into the normal range can be accomplished safely. The goal of long-term antihypertensive treatment in hypertensive stroke survivors is the prevention of stroke recurrence. The benefits of antihypertensive therapy in secondary stroke prevention are uncertain, but large clinical trials are in progress that should provide helpful guidelines for clinical practice.

Although benign neglect of mild to moderate hypertension is prudent in the setting of acute cerebral infarction, there may be certain indications for active treatment of hypertension. When the diastolic blood pressure is sustained at more than 130 mm Hg, many authorities recommend cautious reduction of the systolic blood pressure to 160 to 170 mm Hg and diastolic to 100 to 110 mm Hg with a short-acting parenteral agent such as sodium nitroprusside.[173,177–179] Stroke accompanied by other hypertensive crises such as acute myocardial ischemia or left ventricular dysfunction with acute pulmonary edema is also an indication for cautious blood pressure reduction.[173,178] Stroke due to carotid occlusion caused by aortic dissection mandates aggressive blood pressure reduction to prevent propagation of the dissection.[173,178] In some patients with severe hypertension,

it may be impossible to distinguish between hypertensive encephalopathy and cerebral infarction on clinical grounds. Because rapid lowering of the blood pressure may be life-saving in the patient with hypertensive encephalopathy, a cautious diagnostic trial of blood pressure reduction with a short-acting parenteral antihypertensive agent, such as sodium nitroprusside, may be indicated.[178] In patients who have suffered a stroke and require anticoagulation therapy, moderate control of severe hypertension into the 160 to 170 mm Hg systolic and 100 to 110 mm Hg diastolic range may also be prudent. In the severely hypertensive patient with progressing stroke in whom continued deterioration is believed to be secondary to concomitant cerebral edema, cautious blood pressure reduction may be warranted. Appropriate management of such patients may require continuous intracranial as well as intra-arterial pressure monitoring so that cerebral perfusion pressure can be optimized.[178]

It has been demonstrated that sodium nitroprusside, given at a dose that reduced mean arterial pressure by 10 mm Hg, significantly inhibited platelet aggregation and adhesion molecule expression and improved regional cerebral blood flow in patients with acute ischemic stroke.[180] These findings were attributed to beneficial effects of nitric oxide on platelet function and local vasodilation in the area of the ischemic penumbra.

In the setting of acute cerebral infarction, hypertension tends to be very labile and exquisitely sensitive to hypotensive therapy. Even modest doses of oral antihypertensive agents may cause profound and devastating overshoot hypotension.[172] Antihypertensive treatment, when indicated, should be initiated with extreme caution using small doses of short-acting agents such as sodium nitroprusside. Use of oral or sublingual nifedipine may be associated with overshoot hypotension resulting in extension of the infarct and is contraindicated for the treatment of hypertension accompanying acute cerebral infarction. Oral clonidine loading is also contraindicated because it may induce overshoot hypotension or lead to sedation, which will interfere with assessment of mental status. It had been proposed that there the calcium channel blocker nimodipine, which is a cerebral vasodilator, might theoretically minimize arterial spasm and therefore improve cerebral ischemia. However, a large controlled clinical trial demonstrated no improvement in outcome in patients with thrombotic stroke treated with nimodipine when compared to placebo treatment.[181]

Intracerebral Hemorrhage

Hypertension is a major risk factor for intracerebral hemorrhage. The small-diameter, penetrating cerebral end arteries are especially vulnerable to the deleterious effects of hypertension because they arise directly from the main arterial trunks.[170] The most common sites of hypertension-associated hemorrhage include the basal ganglia, pons, thalamus, cerebellum, and deep hemispheric white matter.[182] Lacunar infarcts arise from the same vessels and are similarly distributed.

Hypertensive hemorrhage most often occurs in patients older than 50 years of age. Intracerebral hemorrhage characteristically begins abruptly with headache and vomiting followed by steadily increasing focal neurologic deficits and alteration of consciousness.[182] More than 90% of hemorrhages rupture through brain parenchyma into the ventricles, producing a bloody CSF.[182] Patients presenting with acute intracerebral hemorrhage invariably have elevated blood pressure. In fact, the finding of a normal or low blood pressure makes the diagnosis of intracerebral hemorrhage unlikely.[182] In contrast to cerebral infarction, the blood pressure does not tend to decrease spontaneously during the first week after the event.[171] Once the hemorrhage has occurred, the patient's condition worsens steadily over a period of minutes to days until either the neurologic deficit stabilizes, or the patient dies. When death occurs, it is most often due to herniation caused by the expanding hematoma and surrounding edema.

Small hemorrhages, which may be clinically indistinguishable from cerebral infarction, probably require no specific therapy.[170] The issue of treatment of hypertension in the setting of a large (greater than 3 cm) intracerebral hemorrhage is controversial. There is almost always a rise in intracranial pressure accompanied by a reflex increase in systemic blood pressure.[171] Because cerebral perfusion pressure is a function of the difference between systemic arterial pressure and intracranial pressure, reduction of blood pressure may compromise cerebral perfusion. Furthermore, the hematoma impairs the local autoregulatory response in the surrounding area of marginal ischemia.[173] Because there is no good evidence that persistent hypertension promotes further bleeding, some authorities strongly advise against treating hypertension in patients with intracerebral hemorrhage.[172] On the other hand, cerebral vasogenic edema may develop as a consequence of an abrupt, severe increase in blood pressure,[170] and treatment of hypertension may be beneficial by virtue of a reduction in cerebral edema and intracranial pressure. Thus, in deciding to treat hypertension, a precarious balance must be struck between prevention of cerebral edema on the one hand, and deleterious reduction of cerebral blood flow on the other. In a study of eight patients with intracerebral hemorrhage treated with trimethaphan, cerebral blood flow measurements revealed that the cerebral autoregulation curve was intact but shifted such that the lower limit of autoregulation was at 80% of the initial level of blood pressure.[183] Thus, a 20% decrease in mean arterial pressure should be considered the maximal reduction of blood pressure during the acute stage. Active treatment of the blood pressure should only be undertaken in the intensive care environment where intracranial pressure and intra-arterial pressure can be closely monitored.[170,184]

Although current specific therapeutic guidelines for blood pressure treatment in intracerebral hemorrhage are not based on strong evidence, a large ongoing therapeutic trial has reported on the value of intensive blood pressure reduction in acute cerebral hemorrhage—the INTERACT Trial.[184] Patients with acute hemorrhage were randomized

within 6 hours to targeted systolic blood pressure of 140 mm Hg (intensive group) or to targeted systolic blood pressure of 180 mm Hg (guideline group). The primary endpoint was hematoma growth at 24 hours. At 24 hours the achieved blood pressure was 146 mm Hg in the intensive group and 157 mm Hg in the guideline group. Hematoma growth was reduced in the intensive group with an absolute risk reduction of 8% ($P < .05$). There were no differences in adverse events between the two groups. The authors concluded that early blood pressure lowering in hemorrhagic stroke is feasible, safe, and reduces hematoma growth. It will be important to determine if these results yield better functional outcomes in further larger trials.

The drug of choice for the management of hypertension in the setting of intracerebral hemorrhage is a matter of debate. Sodium nitroprusside has traditionally been regarded as the best agent because its brief duration of action allows for rapid titration with avoidance of the catastrophic consequence of sustained overshoot hypotension.[179] However, concern has been expressed that because sodium nitroprusside causes an increase in venous capacitance as well as cerebral arterial vasodilation, the resulting increase in cerebral blood volume may cause a further elevation of intracranial pressure.[185,186] Other cerebral vasodilators such as intravenous nitroglycerin, hydralazine, or calcium channel blockers also can cause potentially deleterious elevations of intracranial pressure in patients with compromised intracranial compliance due to intracranial disease.[186] Because labetalol and urapidil (a postsynaptic α-receptor blocker) may not alter intracranial pressure, they have been recommended for treatment of hypertension in patients undergoing neurosurgery.[186] Unfortunately, these agents have the potential to cause overshoot hypotension, which may be difficult to quickly reverse. Thus, despite the theoretic risk of elevation of intracranial pressure, sodium nitroprusside remains the treatment of choice when severe hypertension must be treated in the patient with intracerebral hemorrhage because its brief duration of action allows for cautious, graded blood pressure reduction, which can be quickly reversed if the patient's neurologic status deteriorates or a further increase in intracranial pressure occurs. Of interest, some patients with cerebral infarction or hemorrhage have extreme elevations of catecholamine levels that may render hypertension refractory to sodium nitroprusside in the absence of concomitant beta-blocker therapy.[187]

A recent prospective randomized trial compared safety and efficacy of intravenous nicardipine and sodium nitroprusside drip for control of hypertension in the neurosurgical intensive care unit in patients with subarachnoid hemorrhage or intracerebral hemorrhage.[188] One hundred and sixty-three patients were randomized including 89 in the sodium nitroprusside group and 74 in the nicardipine group. Both drugs proved safe and effective for control of hypertension. However, patients randomized to nicardipine had fewer dose adjustments per day: 5.7 versus 8.8 in the nitroprusside group ($P = .0012$). There were fewer additional medications per day to maintain blood pressure control in the nicardipine group: 1.4 versus 1.9 ($P = .043$). Moreover, blood pressure control was similar in the two groups: 66% versus 69% of the time within study-defined parameters for nicardipine versus nifedipine respectively ($P =$ not significant).

Another recent study compared the clinical outcomes between patients with intracerebral hemorrhage treated with different antihypertensive medications during the first 24 hours after admission.[189] Analysis of the Premier database, a nationally representative hospital discharge database, was used to compare discharge outcomes, length of stay, and cost of hospitalization between groups of patients with intracerebral hemorrhage who were treated with either intravenous nicardipine or nitroprusside infusion. Logistic and linear regression analyses were performed to adjust for baseline risk of mortality between the two groups. A total of 12,767 admissions with primary diagnosis of intracerebral hemorrhage were identified. Nicardipine was administered in 926 patients (7.3%) and nitroprusside was administered in 530 (4.3%). There were no differences in baseline disease severity or risk of mortality between the two groups. After adjustment for baseline risk of mortality, the risk of in-hospital mortality was higher among patients treated with nitroprusside compared with nicardipine (OR 1.7, 95% CI 1.3–2.2). There was no difference in length of stay or total hospital costs in the multivariate analysis. The authors conclude that nicardipine compared with nitroprusside during the first 24 hours after intracerebral hemorrhage was associated with a significantly reduced risk of in-hospital mortality.

Cerebellar hemorrhage represents a neurosurgical emergency requiring prompt diagnosis and treatment.[170] Typically, patients complain of the sudden onset of dizziness, nausea, vomiting, headache, and difficulty walking. Truncal ataxia, nystagmus, and ipsilateral sixth nerve paresis may be present. If the process continues unchecked, brainstem compression or herniation produces progressive stupor and coma. The untreated mortality is extremely high. The diagnosis can usually be confirmed by computerized tomography. Treatment consists of emergency suboccipital craniotomy with evacuation of the hematoma.[170]

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) accounts for less than 10% of all cerebrovascular accidents. Rupture of a congenital aneurysm is the most common cause. Rupture is heralded by the sudden onset of a profound headache and is often followed by brief syncope. If the mass of the hemorrhage is large, patients rapidly become comatose. As the hemorrhage diffuses throughout the subarachnoid space, the patient may awaken and experience headache, nausea, vomiting, and seizures. Within 24 hours, nuchal rigidity and other meningeal signs develop. Initially, neurologic findings are nonfocal. CT can be used to confirm the diagnosis.

Recurrent hemorrhage is a potential complication associated with high mortality. Whether treatment of hypertension after SAH reduces the risk of recurrent bleeding or

improves prognosis is uncertain. In the setting of elevated intracranial pressure or cerebral arterial vasospasm, hypertension may actually be protective because it helps to maintain cerebral perfusion pressure. Thus, reduction of the blood pressure could conceivably result in aggravation of cerebral vasospasm and ischemia.

Early surgical repair of the aneurysm has reduced the incidence of rebleeding in patients with SAH. In fact, delayed cerebral ischemia due to cerebral arterial vasospasm has been found to be the most important cause of morbidity and mortality in patients who survive the initial hemorrhage.[190] Vasospasm, which is probably caused by the irritating effects of blood in the subarachnoid space closely opposed to the large arteries, usually develops 4 to 12 days after the acute hemorrhage. Symptoms include a gradual deterioration of the level of consciousness, accompanied by focal neurologic deficits.

Surgical clipping of the aneurysm is usually undertaken as soon as possible to prevent rebleeding.[190,191] There is conflicting evidence as to whether or not postoperative treatment with intravascular volume expansion, in conjunction with deliberate induction of arterial hypertension using dopamine or dobutamine, may be an effective means of reversing the ischemic neurologic deficits caused by cerebral vasospasm.[192,193]

Nimodipine, a 1,4-dihydropyridine calcium channel blocker, has been approved for the prevention and treatment of delayed cerebral ischemia caused by subarachnoid hemorrhage from ruptured congenital aneurysms. Nimodipine is highly lipid-soluble and readily crosses the blood–brain barrier.[194] It dilates cerebral blood vessels at concentrations lower than those required for dilation of the peripheral vasculature.[194] Thus, it may dilate intracerebral vessels at doses that do not result in a significant reduction in mean arterial pressure. Furthermore, inhibition of calcium uptake by neurons may also protect against ischemic injury at the cellular level, independent of an effect on cerebral blood flow.[194] Nimodipine has been shown, in randomized, placebo-controlled trials, to reduce the severity of neurologic deficits resulting from vasospasm in patients who have had a recent SAH.[194–196] The recommended dosage is 60 mg orally every 4 hours for 21 consecutive days beginning within 96 hours of the SAH. The liquid content of the capsules can be given through a nasogastric tube in unconscious patients. The optimal timing of surgery in nimodipine-treated patients has not yet been defined.

CATECHOLAMINE-RELATED HYPERTENSIVE CRISES

Hypertensive Crises with Pheochromocytoma

The diagnosis and treatment of pheochromocytoma are discussed in detail in Chapter 43. The comments here are restricted to treatment of hypertensive crises in patients with pheochromocytoma, with emphasis on the perioperative management of hypertension. In the majority of patients, pheochromocytoma causes sustained hypertension that occasionally enters the malignant phase. In roughly 30% of patients, paroxysmal hypertension is present. Paroxysms usually occur spontaneously and consist of severe hypertension, headache, profuse diaphoresis, pallor of the face, coldness of the hands and feet, palpitations, and abdominal discomfort. Marked elevation of blood pressure can lead to intracerebral hemorrhage, hypertensive encephalopathy, or acute pulmonary edema.[198] Prompt reduction of blood pressure is mandatory to prevent these life-threatening complications. Although the nonselective α-adrenergic receptor blocker phentolamine is often cited as the treatment of choice for pheochromocytoma-related hypertensive crises, sodium nitroprusside is equally effective.[198,199] Phentolamine is given in 5- to 10-mg intravenous boluses every 5 minutes as necessary to control blood pressure. Given its short duration of action, a continuous infusion of phentolamine can also be utilized. After the blood pressure has been controlled with sodium nitroprusside or phentolamine, intravenous β-adrenergic receptor blockers such as esmolol and metoprolol can be used to control tachycardia or arrhythmias. After resolution of the hypertensive crisis, oral antihypertensive agents should be instituted as the parenteral agents are weaned.

Skillful preoperative management of blood pressure and volume status is clearly a prerequisite to successful surgical intervention.[198–200]Usually, the nonselective α-blocker phenoxybenzamine is administered for 1 to 2 weeks prior to elective surgery. The initial dose of 10 mg twice daily is increased every other day until normotension, accompanied by moderate (15 mm Hg) asymptomatic orthostatic hypertension, has been attained and paroxysms are well controlled.[199,200] The last dose of phenoxybenzamine is usually administered at 10 PM on the evening before surgery. After adequate α-blockade has been achieved, oral beta-blocker therapy can be initiated if needed to control tachycardia. Oral or intravenous beta-blockers should never be administered before adequate α-adrenergic blockade has been achieved. Administration of a beta-blocker to patients with catecholamine-secreting tumors can lead to severe hypertension with acute pulmonary edema as the result of intense α-adrenergic-mediated vasoconstriction that is no longer opposed by β-adrenergic vasodilatory stimuli. Prazosin, a selective α_1-antagonist, has been used for preoperative management of hypertension.[201] However, hypertensive crises responsive to low-dose phenoxybenzamine have been observed in patients receiving apparently adequate α-blockade with prazosin.[202] Labetalol has also been advocated for the preoperative management of hypertension in patients with pheochromocytoma.[203] However, hypertensive crises precipitated by the use of labetalol have been reported.[204] The paradoxical increase in blood pressure is due to the fact that labetalol exhibits more potent β-blockade than α-blockade.

Careful attention to volume status is imperative in the preoperative period.[199,200] Alleviation of the chronic state of catecholamine-induced vasoconstriction by α-blockade results in increases in both arterial and venous capacitance. Preoperative volume expansion guided by measurements of central venous pressure or pulmonary capillary wedge pressure has been advocated to reduce the severity of intraoperative hypotension.[200] However, other authors maintain that a high-salt diet or infusions of crystalloid are usually not necessary in the majority of patients during the preoperative period because treatment with α-adrenergic blockade for 1 to 2 weeks alleviates the chronic state of vasoconstriction and allows for spontaneous restoration of normal plasma volume.[198] Moreover, caution has been advised if intravenous fluids are administered during the preoperative period because pulmonary edema can occur if an underlying catecholamine-induced cardiomyopathy is present.[198]

Cardiac status should be evaluated carefully in the preoperative period. Approximately 25% of patients with catecholamine-secreting tumors have some degree of cardiomyopathy with biventricular dysfunction caused either by a direct toxic effect of catecholamines on the myocardium or indirectly by chronic hypertension.[206] This catecholamine-induced cardiomyopathy is associated with an increased risk of sudden death from arrhythmias, as well as increased surgical risk. Thus, preoperative evaluation should include echocardiography to assess ventricular function. The cardiomyopathy is usually reversible with adequate preoperative chronic adrenergic blockade. Surgical intervention should generally be deferred until serial echocardiograms confirm that ventricular function has improved in response to treatment with adrenergic blocking drugs.

During surgery, rapid and wide fluctuation in blood pressure should be anticipated.[199] Adequate premedication should be used to minimize the risk of sympathetic activation during endotracheal intubation and induction of anesthesia. Diazepam and short-acting barbiturates are the agents of choice for premedication.[199] Droperidol, phenothiazines, and morphine are contraindicated because they can cause catecholamine release. Atropine should be avoided because its vagolytic effect results in tachycardia in the setting of high-circulating catecholamine levels.

Careful intraoperative monitoring of intraarterial blood pressure, cardiac output, pulmonary capillary wedge pressure, and systemic vascular resistance is required to manage rapid swings in blood pressure.[199] Despite adequate preoperative α-blockade with phenoxybenzamine, severe hypertension can occur during intubation or intraoperatively due to catecholamine release during tumor manipulation. Although intermittent bolus phentolamine has been advocated in this setting, prolonged α-blockade may predispose to significant hypotension following tumor devascularization.[199] Therefore, sodium nitroprusside, with its immediate onset and short duration of action, is the agent of choice for controlling acute hypertension during pheochromocytoma surgery.[199] Infusions of esmolol can be used for short-term control of arrhythmias.[198,199]

At the opposite end of the spectrum, severe intraoperative hypotension can occur. Hypotension or even frank shock can supervene following isolation of tumor venous drainage from the circulation, with a resultant abrupt decrease in circulating catecholamine levels. This hypotension is caused by a precipitous reduction in vascular tone, which can be aggravated further by operative blood loss, downregulation of adrenergic receptors in response to chronic increases in catecholamines, α-adrenergic blockade, or impaired heart rate response resulting from β-adrenergic blocking drugs.[199] Volume expansion with crystalloid, colloid, or blood as needed is the recommended treatment for intraoperative hypotension. Volume repletion should be guided by measurements of pulmonary capillary wedge pressure and cardiac output. Pressors should only be employed when hypotension is unresponsive to adequate volume repletion.[199] The risk of hypotension due to hypovolemia extends into the postoperative period during which close monitoring of volume status is essential. In the postoperative period, required volume replacement not uncommonly exceeds measured fluid losses.[199]

Hypertensive Crises Secondary to Withdrawal of Antihypertensive Therapy

Abrupt discontinuation of high doses of centrally acting antihypertensive agents such as clonidine,[205] methyldopa,[206] and guanabenz[205,207] can produce a withdrawal syndrome characterized by sympathetic overactivity.[208] Symptoms consisting of headache, nausea, restlessness, agitation, insomnia, and tremor usually begin 12 to 72 hours after discontinuation of the drug. Occasionally, this withdrawal syndrome is accompanied by a rapid increase in blood pressure to above pretreatment levels (overshoot hypertension).[209] The abrupt rise in blood pressure can precipitate a hypertensive crisis with hypertensive encephalopathy or acute pulmonary edema.

The symptoms that develop following cessation of centrally acting α-receptor agonists are suggestive of sympathetic overactivity. It has been postulated that the syndrome may be related to excessive circulating catecholamine levels.[208] Because the antihypertensive action of central α-agonists is due to a reduction in catecholamine release from nerve terminals, abrupt discontinuation may provoke a sudden catecholamine surge. Increased plasma and urine catecholamine levels have been found after abrupt discontinuation of high-dose clonidine. The renin–angiotensin system may also be involved in withdrawal phenomenon. As clonidine and methyldopa suppress PRA, it is possible that a rebound increase in PRA and angiotensin II could mediate the hypertensive overshoot following drug withdrawal.[210]

In general, withdrawal symptoms or rebound hypertension occur only after cessation of large doses of drugs. Withdrawal symptoms rarely appear after discontinuation of clonidine in doses less than 1.2 mg per day.[211] The average dose of guanabenz in the reported cases of withdrawal syndrome was 48 mg per day.[207] However, the withdrawal syndrome can occasionally be precipitated by cessation of lower

doses of drugs. This is especially apt to occur in patients with underlying renal insufficiency or renovascular hypertension.[210] Patients treated with beta-blockers may be predisposed to develop severe hypertension during withdrawal of centrally acting α-agonists.[212] Beta-adrenergic receptor blockade inhibits the vasodilatory effect of β_2-receptors on the peripheral vasculature, leaving vasoconstrictor α_1-receptors unopposed.

Treatment of antihypertensive drug withdrawal syndromes should be individualized. In patients with generalized symptoms of sympathetic overactivity but without excessive blood pressure elevation, reinstitution of the previously administered drug is usually all that is required.[210] However, if the withdrawal syndrome is associated with severe hypertension, hypertensive encephalopathy, or acute pulmonary edema, rapid control of blood pressure with parenteral antihypertensive agents is imperative. Sodium nitroprusside or phentolamine should be used for the management of these hypertensive crises. After the blood pressure is controlled with parenteral agents, oral clonidine, guanabenz, or methyldopa should be restarted. The offending drug should then be gradually withdrawn with close monitoring for withdrawal symptoms and rebound hypertension. Another oral antihypertensive regimen, preferably without a beta-blocker, should be initiated simultaneously.

THE CONTROVERSY OVER GRADUAL VERSUS RAPID REDUCTION OF BLOOD PRESSURE

Some authors have cautioned against rapid lowering of blood pressure in patients with hypertensive crises and have recommended a more gradual reduction of blood pressure.[213,214] The case for gradual reduction of blood pressure is based largely on the finding of altered autoregulation of cerebral blood flow in hypertensive patients and scattered case reports of serious neurologic sequelae resulting from overly aggressive reduction of blood pressure in patients with severe hypertension or hypertensive crises.[215–221]

In both hypertensive and normotensive individuals, cerebral blood flow is maintained constant, at approximately 50 mL/minute/100 g of brain tissue, over a wide range of perfusion pressures, by virtue of various intrinsic and neurohumoral autoregulatory mechanisms. The lower limit of cerebral blood flow autoregulation is the blood pressure below which autoregulatory vasodilation becomes maximal and cerebral blood flow decreases. In normotensive subjects, the lower limit of autoregulation is a mean arterial pressure of 60 to 70 mm Hg. In chronically hypertensive patients, the lower limit of autoregulation is shifted so that autoregulation fails and cerebral blood flow decreases at a higher blood pressure than in normotensive individuals.[222,223] This effect may be the result of hypertension-induced changes in the cerebral arterioles. In animal models, chronic hypertension causes hypertrophy of the walls of cerebral vessels with a reduction in internal diameter. Moreover, during chronic hypertension, cerebral arterioles undergo structural remodeling, which results in a smaller external diameter and encroachment on the vascular lumen.[224]

On the one hand, these structural changes are protective in that the thickened cerebral arterioles are able to maintain constant cerebral blood flow at a higher perfusion pressure than would be tolerated by normotensive individuals. In this regard, in chronically hypertensive individuals, the mean arterial pressure at which autoregulatory vasoconstriction gives way to pressure-induced forced vasodilation and hyperperfusion—that is, the upper limit of cerebral blood flow autoregulation—is shifted to a higher level compared to the upper limit in normotensive individuals (see discussion of breakthrough theory in the above section on hypertensive encephalopathy). However, as a consequence of these structural changes, the arterioles are not able to dilate fully at low mean arterial pressures, which could predispose hypertensive patients to cerebral ischemia if the blood pressure is lowered excessively.

Fortunately, with long-term control of blood pressure these changes in cerebral arterioles appear to be at least partially reversible given the observation that patients with previously severe but adequately treated hypertension have a lower limit of autoregulation, which is shifted toward the range for normotensive subjects (Table 44.6).[222]

The upward shift in the autoregulatory curve in patients with chronic hypertension is one of the major arguments put forward by those who favor gradual reduction of blood pressure in patients with hypertensive crises.[222] However, the clinical importance and therapeutic implications of this shift in the autoregulatory curve may have been overemphasized. The demonstration of hypertensive adaptation of cerebral autoregulation should not be interpreted to mean that acute reduction of blood pressure in hypertensive crises is unwise. In the various hypertensive crises in which rapid reduction of blood pressure is indicated (see later), the proven benefits of acute reduction of blood pressure (i.e., decreased risk of intracerebral hemorrhage, hypertensive encephalopathy, or acute pulmonary edema) clearly outweigh the theoretic risk of blood pressure reduction (i.e., possible cerebral ischemia).

In practice, moderate, controlled reduction of blood pressure in hypertensive crises rarely causes cerebral ischemia. This clinical observation may be explained by the fact that even though the autoregulatory curve is shifted toward a higher blood pressure in chronically hypertensive patients, there is still a considerable difference between the presenting blood pressure and the lower limit of autoregulation (Table 44.6). Strandgaard[223] has studied the autoregulation of cerebral blood flow during controlled hypotension produced with trimethaphan and a 25-degree head-up tilt in 13 patients with untreated or ineffectively treated hypertension. At least eight of these patients had grade III or grade IV changes on funduscopy consistent with the diagnosis of malignant hypertension. The control groups included nine patients who had been severely hypertensive in the past but whose blood pressure was effectively controlled at the time of the study, and 10 normotensive subjects. Baseline

44.6 Autoregulation of Cerebral Blood Flow During Trimethaphan-Induced Hypotension[a]

Group	MAP (mm Hg)		Percent of Resting MAP %	
	Resting Level	Autoregulation	Tolerated MAP	Autoregulation	Tolerated
Uncontrolled severe hypertensives (n = 13)	145 ± 17	113 ± 17[b,c]	65 ± 10[b]	79 ± 10	45 ± 6
Controlled hypertensives (n = 9)	116 ± 18	96 ± 17	53 ± 18	72 ± 29	46 ± 16
Normotensives (n = 10)	98 ± 10	73 ± 9	43 ± 8	74 ± 12	45 ± 12

[a]Values given as mean ± SD.
[b]$P < .01$ for difference between normotensives and uncontrolled hypertensives.
[c]$P < .01$ for difference between controlled and uncontrolled hypertensives.
MAP, mean arterial pressure.
Adapted from Gifford RW Jr. Effect of reducing elevated blood pressure on cerebral circulation. Hypertension. 1983;5[Suppl III]:III-17, with permission.)

mean arterial pressures in the three groups were 145 ± 17, 116 ± 18, and 98 ± 10 mm Hg, respectively (Table 44.6). The lower limit of mean arterial pressure at which autoregulation of cerebral blood flow failed was 113 ± 17 mm Hg in uncontrolled hypertensives, 96 ± 17 mm Hg in controlled hypertensives, and 73 ± 9 mm Hg in normotensive individuals. Although the absolute level at which autoregulation failed differed substantially in the three groups, the percentage reduction of mean arterial pressure at which autoregulation failed was similar. The mean arterial pressure at the lower limit of autoregulation was 79 ± 10% of the resting mean arterial pressure in the uncontrolled hypertensives, 72 ± 29% in the controlled hypertensive group, and 74 ± 12% in the normotensive group. Thus, a reduction in mean arterial pressure of approximately 20% to 25% from the baseline level was required in each group to reach the lower limit of autoregulation. Therefore, even in uncontrolled hypertensive patients, there was a considerable safety margin before the limit of autoregulation was reached. Another important observation from this study was that symptoms of cerebral hypoperfusion did not occur until the blood pressure was reduced substantially below the lower limit of autoregulation.[223] Studies have shown that with normal cerebral blood flow, oxygen extraction is not maximal because oxygen saturation in the jugular venous blood at rest is normally 60% to 70%. Thus, even when the mean arterial pressure is reduced below the lower limit of autoregulation, cerebral metabolism can be maintained and ischemia prevented by increasing oxygen extraction from the blood. The lowest tolerated blood pressure, which was defined as the level at which mild symptoms of brain hypoperfusion were encountered (yawning, nausea, and hyperventilation with hypocapnia), was 65 ± 10 mm Hg in patients with uncontrolled hypertension, 53 ± 18 mm Hg in patients with controlled hypertension, and 43 ± 8 mm Hg in normotensive subjects. These values were 45 ± 6%, 46 ± 16%, and 45 ± 12% of the resting baseline mean arterial pressures, respectively. Thus, symptoms of cerebral hypoperfusion did not occur until the mean arterial pressure was reduced by an average of 55% from the resting level (Table 44.6).

In summary, with regard to the shift in cerebral autoregulation in chronically hypertensive patients, there is a therapeutic threshold above which the blood pressure can be reduced safely in patients with hypertensive crises who require immediate control of hypertension. Strandgaard concludes that the upward shift in cerebral autoregulation should not be taken as a warning against aggressive antihypertensive therapy in hypertensive crises. It merely implies that the initial treatment should be aimed at partial reduction but not complete normalization of blood pressure.[222,223]

The second argument used to support the recommendation for gradual reduction of blood pressure is based on case reports of the occurrence of acute neurologic sequelae during rapid blood pressure reduction in the treatment of severe hypertension or hypertensive crises.[215–221]

Franklin reviews 19 reported cases of neurologic complications following aggressive antihypertensive therapy.[93] The average age of the patients was 36 years. All had evidence of severe antecedent hypertension with an average mean arterial pressure of 188 ± 19 mm Hg. Malignant hypertension, based on the finding of hypertensive neuroretinopathy, was present in 79% and hypertensive encephalopathy was present in 53% of these patients. Aggressive antihypertensive treatment resulted in a reduction of mean arterial pressure to 84 ± 18 mm Hg. This represented a 56% decrease from the baseline blood pressure level, a level clearly below the predicted autoregulatory range for hypertensive patients. The time course of blood pressure reduction was

within minutes in 26% and over hours in 74% of patients. However, the most critical factor in the development of neurologic sequelae was the long duration of drug-induced overshoot hypotension, which varied from a period of hours to days. Neurologic complications consisted of permanent blindness in 47%, coma in 32%, pyramidal tract signs in 32%, residual neurologic deficits after therapy in 58%, and death in three patients. The majority of these patients (80%) had received a large intravenous bolus of diazoxide. Three patients received no parenteral agents but had sustained hypotension induced with multiple oral agents. Franklin concludes that rather than the rapidity with which blood pressure was reduced, the duration of excessive hypotension was the factor that correlated best with the development of neurologic complications.

In summary, the data suggest that in the treatment of patients with hypertensive crises who require prompt control of blood pressure, potent parenteral agents can be used safely if excessive lowering of blood pressure is avoided. The studies of Strandgaard suggest that autoregulation of cerebral blood flow can be maintained in hypertensive patients as long as the mean arterial pressure is not reduced below 120 mm Hg.[222,223] This value is two standard deviations above the average mean arterial pressure at which patients in the reported series developed neurologic sequelae.

In general, an initial blood pressure reduction to 160 to 170 mm Hg systolic and 100 to 110 mm Hg diastolic or to a mean arterial pressure of 120 to 130 mm Hg can be safely accomplished in patients who require immediate control of blood pressure in the setting of hypertensive crises.[93] Alternatively, the initial antihypertensive therapy can be individualized based on the pretreatment level of blood pressure. In the individual patient, reduction of the mean arterial pressure by 20% should be the initial therapeutic goal. At this level, the blood pressure should still be above the predicted autoregulatory lower limit. Once this goal is obtained, the patient should be carefully evaluated for evidence of cerebral hypoperfusion. Further reduction of blood pressure can then be undertaken if necessary in a controlled fashion based on the overall status of the patient. In previously normotensive individuals in whom acute hypertensive crises develop, such as patients with acute glomerulonephritis complicated by hypertensive encephalopathy, eclampsia, and autonomic hyperreflexia, the autoregulatory curve may not yet be shifted and the initial goal of therapy will often be normalization of the blood pressure.

The use of potent parenteral agents with a rapid onset and short duration of action, such as sodium nitroprusside, has obvious advantages. If overshoot hypotension or neurologic sequelae develop, they can be quickly reversed by allowing the blood pressure to stabilize at a higher level. Agents with a long duration of action all have an inherent disadvantage in that excessive reduction of blood pressure cannot be easily reversed. Thus, diazoxide, labetalol, minoxidil, hydralazine, converting enzyme inhibitors, calcium channel blockers, and central α-agonists should be used with extreme caution in patients requiring rapid blood pressure reduction in order to avoid prolonged overshoot hypotension.

Although in the great majority of hypertensive patients, cautious blood pressure reduction can be undertaken without a significant risk of causing cerebral hypoperfusion, it should be noted that there is one clinical setting in which there is a significant risk of causing cerebral ischemia even with moderate blood pressure reduction. In patients with acute cerebral infarction, because of failure of autoregulation in the surrounding marginally ischemic zone, even moderate blood pressure reduction can be detrimental. Therefore, in acute cerebral infarction, the aforementioned considerations regarding the general safety of acute blood pressure reduction do not apply. The management of hypertension complicating acute cerebral infarction is outlined in the section entitled Hypertension Complicating Cerebrovascular Accident.

PHARMACOLOGY OF DRUGS USEFUL IN THE TREATMENT OF HYPERTENSIVE CRISES

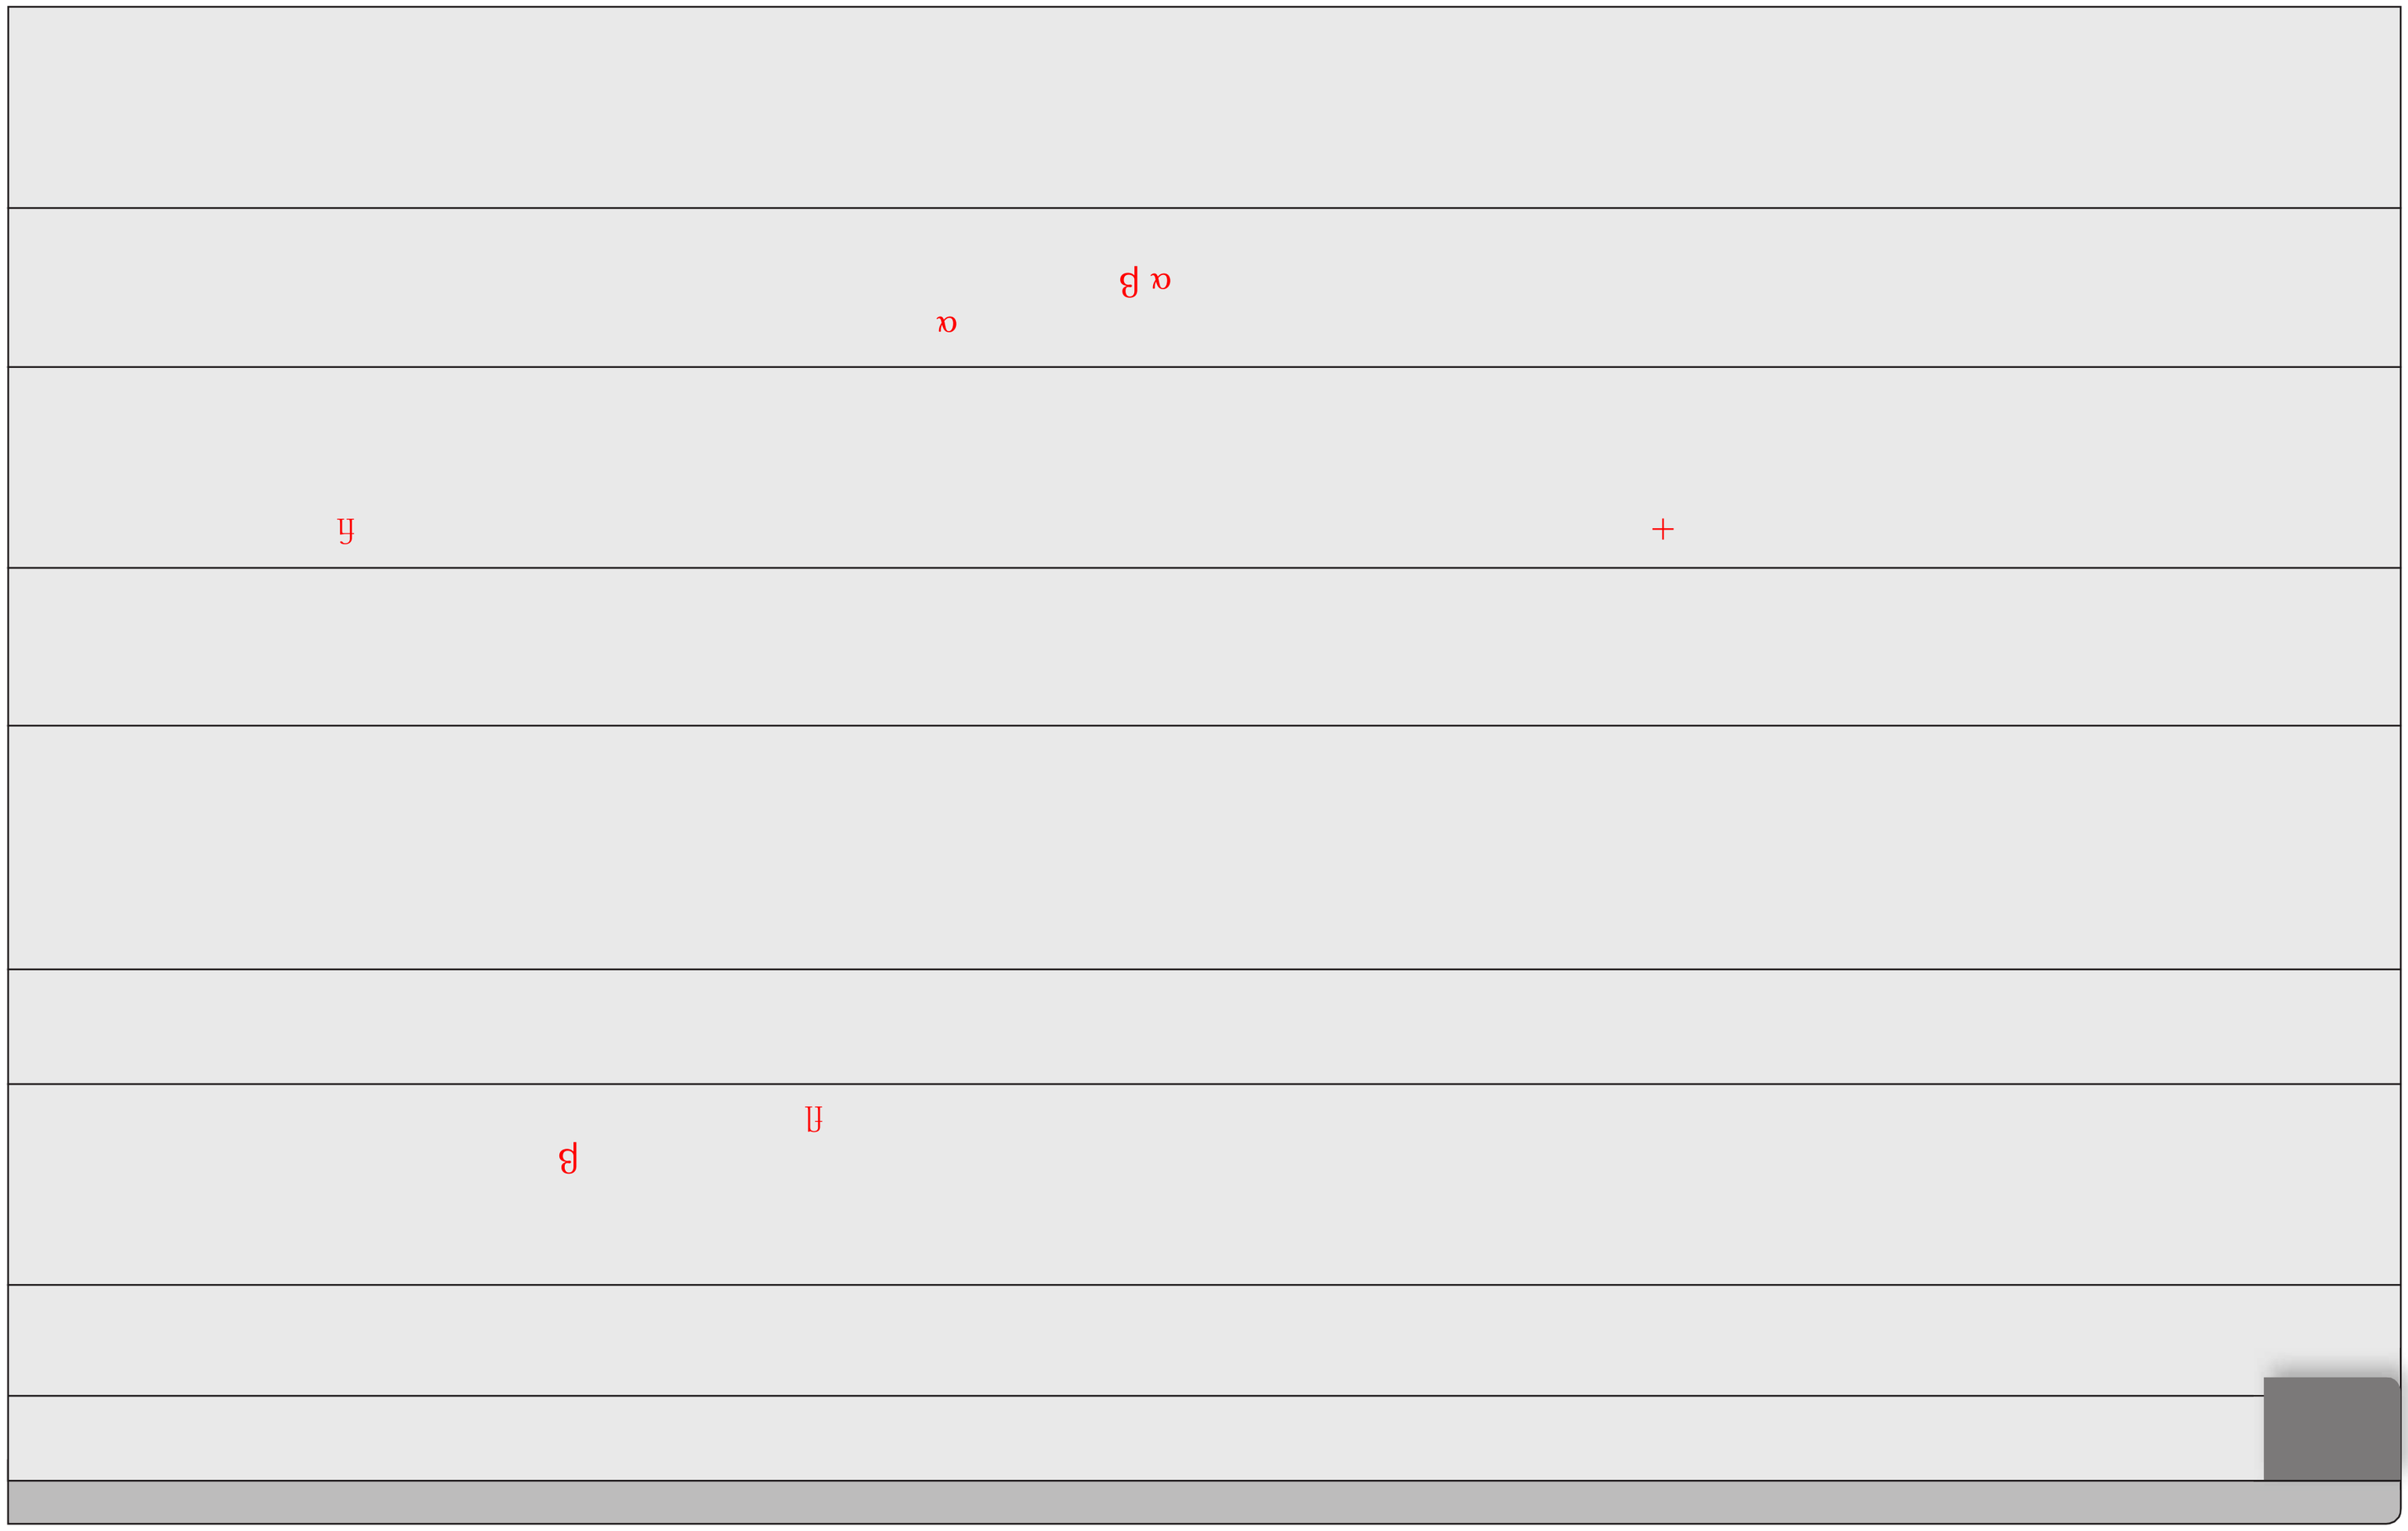
The pharmacopeia of parenteral vasodilators and adrenergic blockers available for the treatment of hypertensive crises is outlined in Table 44.7. Preferred parenteral agents for the treatment of selected hypertensive crises are detailed in Table 44.8.

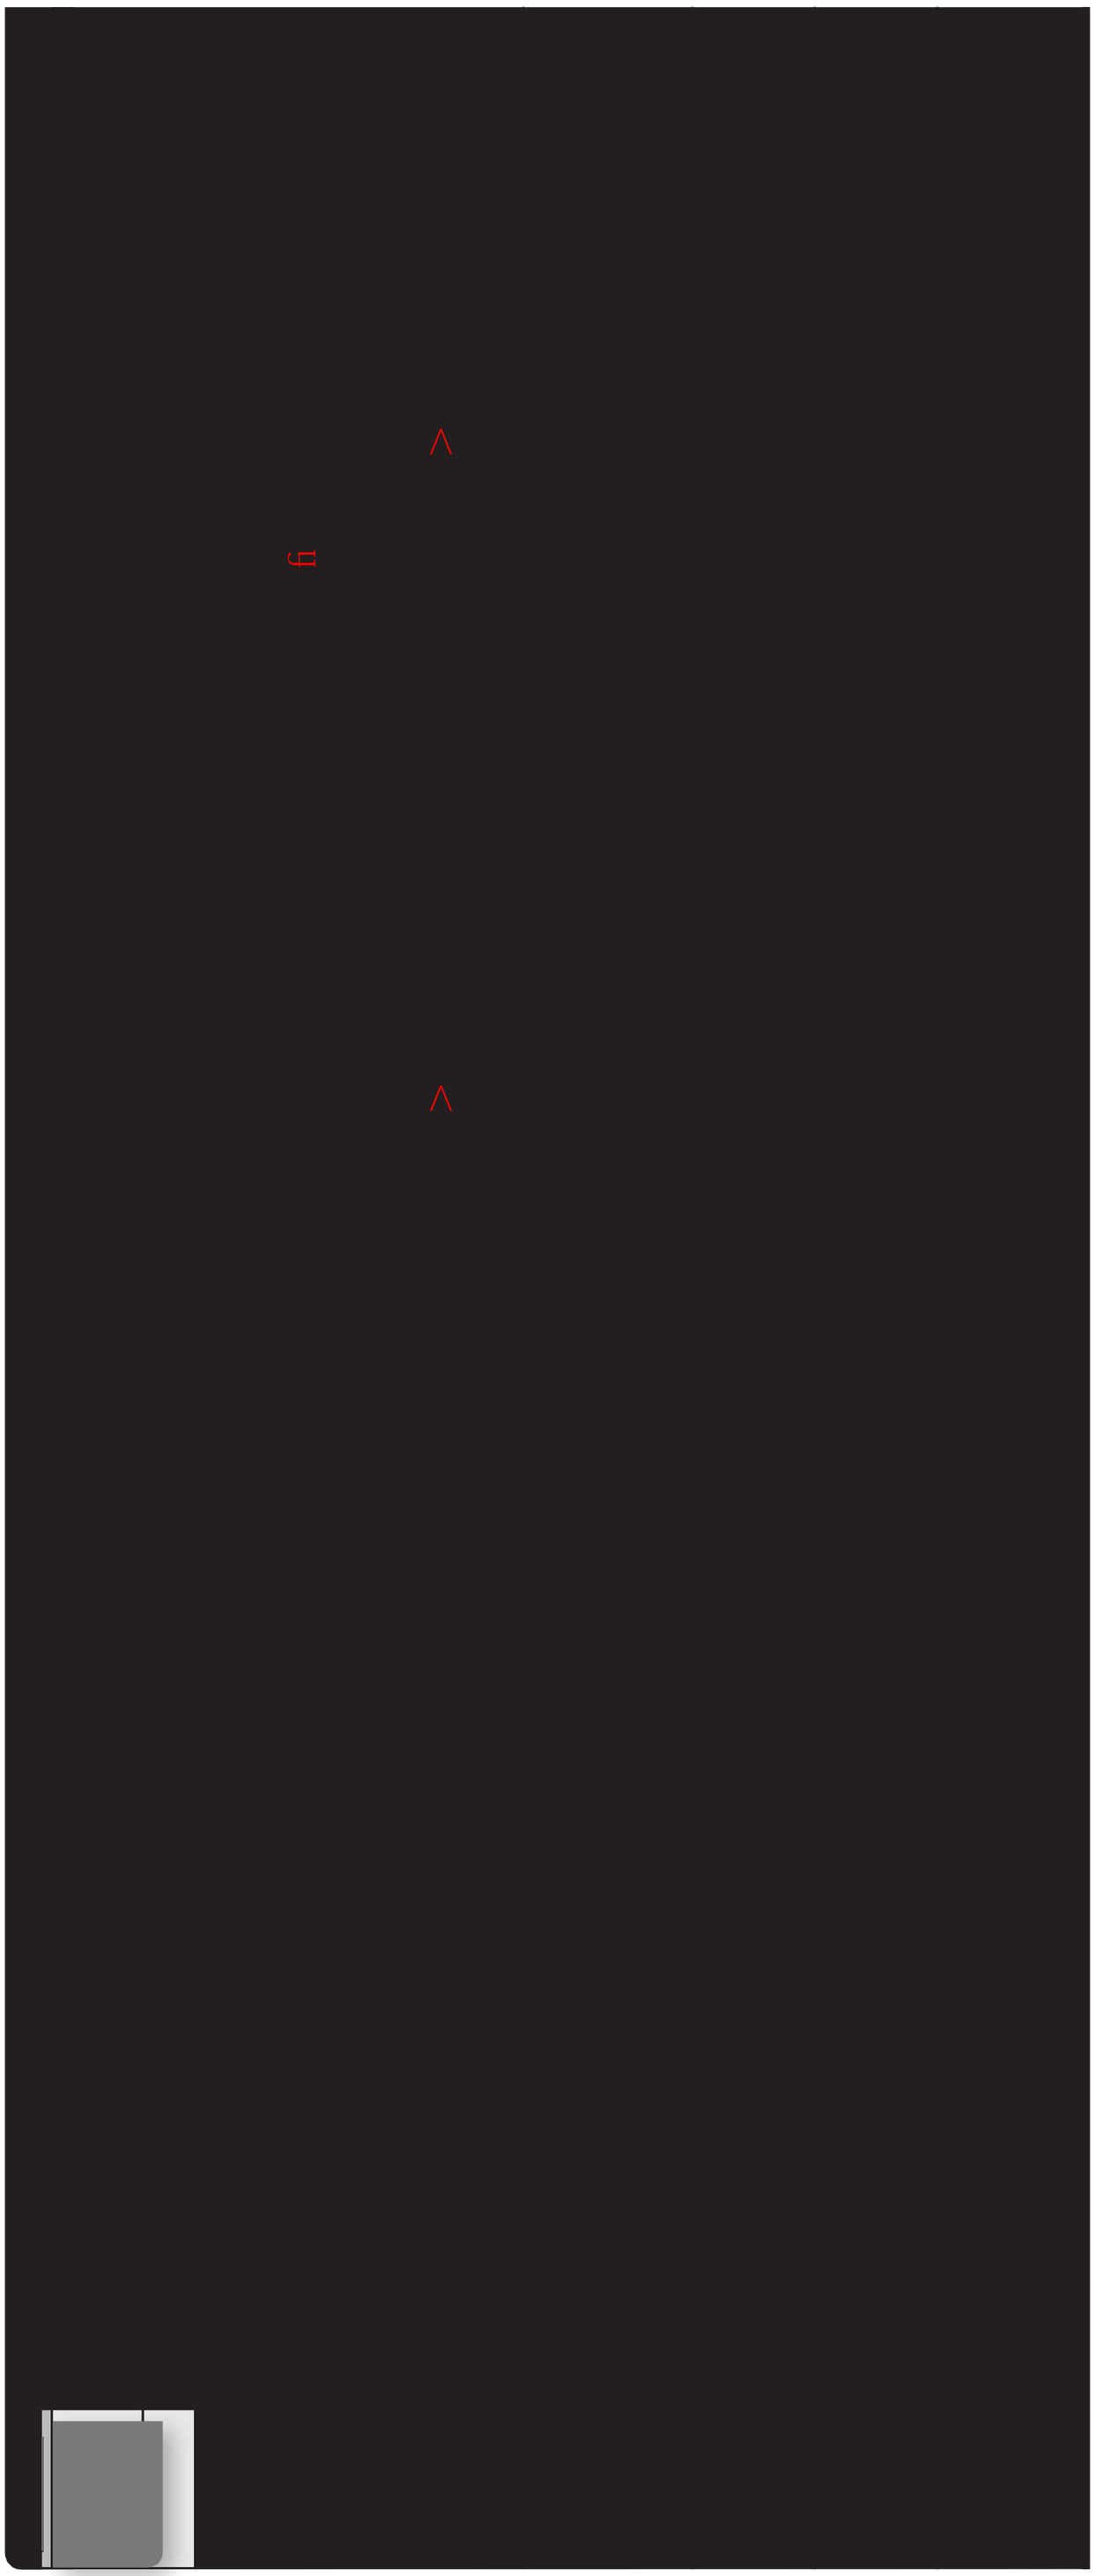
Sodium Nitroprusside

In 1929, intravenous administration of the color indicator sodium nitroprusside was reported to lower blood pressure.[225] Nonetheless, concern that the hypotensive action of the drug was related to the release of cyanide led to a delay in the introduction of the drug. In 1955, intravenous infusion of sodium nitroprusside was shown to be a safe and effective method for achieving short-term blood pressure control.[226] However, it was not until 1974 that sodium nitroprusside (Nipride) was approved for clinical use. Over the ensuing decades, it has remained the drug of choice for the management of virtually all hypertensive crises. Sodium nitroprusside is useful for the management of hypertensive crises due to malignant hypertension, pheochromocytoma, and other catecholamine-related hypertensive crises, hypertensive encephalopathy, acute pulmonary edema, intracerebral hemorrhage, aortic dissection (in combination with a beta-blocker), and perioperative hypertension.[227]

Mechanism of Action

Sodium nitroprusside is a potent intravenous hypotensive agent with an immediate onset and brief duration of action. The site of action is the vascular smooth muscle. It has no direct effect on the myocardium, although it may indirectly affect cardiac performance through alterations in systemic hemodynamics. In therapeutic doses it has no effect on





duodenal or uterine smooth muscle.[226] It has no direct CNS effect. Sodium nitroprusside causes vasodilation of both arteriolar resistance vessels and venous capacitance vessels. Its hypotensive action is the result of a decrease in systemic vascular resistance. Venodilation results in a decrease in venous return; hence, preload is reduced. The combined decrease in preload and afterload reduces left ventricular wall tension and myocardial oxygen demand.

The net effect of sodium nitroprusside on cardiac output and heart rate depends on the intrinsic state of the myocardium.[227] In the absence of congestive heart failure, venodilation and preload reduction can result in a small decrease in cardiac output with a reflex increase in sympathetic tone and heart rate.In contrast, in patients with left ventricular dysfunction and elevated left ventricular end-diastolic volume or pressure, sodium nitroprusside causes an increase in stroke volume and cardiac output as the result of a reduction in afterload and impedance to left ventricular ejection. There is usually a reduction in heart rate as the result of improved cardiac performance.[228–230]

The cellular mechanism of action of nitroprusside has been well defined.[231,232] Nitroprusside is an iron coordination complex with five cyanide moieties and a nitroso group. The action of sodium nitroprusside, as well as that of other nitrogen oxide-containing vasodilators, is mediated by a reaction with cysteine to form nitrosocysteine and other short-acting S-nitrosothiols. Nitrosocysteine, a potent activator of guanylate cyclase, causes cyclic guanosine monophosphate accumulation and relaxation of vascular smooth muscle.

Pharmacokinetics

The hypotensive effect of sodium nitroprusside appears within seconds and is immediately reversible when the infusion is stopped. It is rapidly metabolized, with a reported half-life of 3 to 4 minutes. Cyanide is formed, as a short-lived intermediate product, by direct combination of sodium nitroprusside with sulfhydryl groups in red cells and tissues.[226] The cyanide groups are rapidly converted to thiocyanate by the liver in a reaction in which thiosulfate acts as a sulfur donor. Thiocyanate is excreted unchanged by the kidney with a half-life of 1 week in patients with normal renal function.[227]

Dosage and Administration

The contents of a 50-mg sodium nitroprusside vial should be dissolved in 2 mL of dextrose in water. No other diluent should be used. The stock solution is diluted in 250 mL of dextrose in water to yield a concentration of 200 μg/mL. The container is immediately wrapped in aluminum foil to prevent decomposition on exposure to light. A small portion of the tubing can be left uncovered to observe the solution for color changes during administration. The freshly prepared solution has a faint brownish tint. The nitroprusside molecule reacts with a wide variety of organic and inorganic substances to yield highly colored reaction products. Therefore, the infusion fluid should not be used as a vehicle for the delivery of other drugs. If a color change occurs, the solution should be replaced. Regardless, the solution should be changed every 24 hours.

In patients who are not taking other antihypertensive agents, the average effective dose is 3.0 μg/kg/minute (range, 0.5 to 10.0 μg/kg/minute). The initial infusion rate should be 0.5 μg/kg/minute. The flow rate should be increased in increments of 1 μg/kg/minute every 2 to 3 minutes until the desired hypotensive response is obtained. The solution should be administered by infusion pump or microdrip regulator to allow for precise measurement of flow rate. The blood pressure should be monitored every 30 to 60 seconds during the initial titration and every 15 minutes thereafter. To avoid excessive accumulation of thiocyanate and the risk of cyanide toxicity, the infusion rate should not be increased above 10 μg/kg/minute. Sodium nitroprusside failures are extremely rare, and tachyphylaxis does not occur. Concomitant oral antihypertensive agents should be initiated as soon as possible and the sodium nitroprusside infusion weaned as it becomes effective.

Adequate facilities, equipment, and personnel must be available for close monitoring of blood pressure during sodium nitroprusside administration. Auscultatory or oscillometric pressure is usually adequate, so that intra-arterial pressure monitoring is not routinely required. However, in hypertensive patients with acute myocardial infarction or acute pulmonary edema, hemodynamic monitoring may be required for assessment of left ventricular filling pressure and cardiac output.[227]

Adverse Effects

Nitroprusside is the most effective parenteral agent for the management of hypertensive crises. When properly administered in an intensive care unit setting, it is very safe and clinically significant adverse reactions are uncommon. Overshoot hypotension can result from accidental bolus infusion, faulty infusion equipment, or failure to frequently monitor the blood pressure. However, the hypotensive action is evanescent and hypotension can be reversed easily by slowing or discontinuing the infusion.

The most frequent side effects include anorexia, nausea, vomiting, abdominal cramps, diaphoresis, headache, apprehension, restlessness, and palpitations. Most of these adverse reactions result from rapid blood pressure reduction per se and they usually disappear if the infusion is slowed.

Thiocyanate accumulation and toxicity can occur when a high-dose or prolonged infusion is required, especially in the setting of renal insufficiency. When these factors are present, thiocyanate levels should be monitored and the infusion reduced or discontinued if the plasma level exceeds 10 mg per dL. Thiocyanate toxicity is rare in patients with normal renal function requiring less than 3 μg/kg/minute for less than 72 hours. Symptoms of thiocyanate toxicity include fatigue, anorexia, weakness, tinnitus, blurred vision, and disorientation, which may progress to frank organic

psychosis with hallucinations. Seizures have also been reported. Treatment consists of discontinuing the infusion. Thiocyanate is also efficiently removed by both peritoneal dialysis and hemodialysis.[227]

Cyanide poisoning is a very rare complication of sodium nitroprusside use. Since hepatic clearance of cyanide may be deficient in patients with severe liver disease and in rare conditions such as Leber's optic atrophy or tobacco amblyopia,[233] the use of sodium nitroprusside is contraindicated in these settings. Most of the reported deaths from cyanide poisoning occurred when very high doses of nitroprusside (20 μg/kg/minute) were required for the control of refractory hypertension or in normotensive patients in whom very large doses were used to induce deliberate surgical hypotension.[234,235] The cyanide ion combines with cytochrome c and inhibits aerobic metabolism so that lactic acidosis results. Cyanide toxicity most often occurs within the first 6 to 8 hours of therapy. Cyanide toxicity should be considered if there appears to be increased tolerance to the drug. Tachyphylaxis and an increased anion gap metabolic acidosis are the most reliable early signs of cyanide toxicity. Other signs include the smell of bitter almonds on the breath, anxiety, headache, stiffness of the lower jaw, dyspnea, and widely dilated pupils. Coma, seizures, and death may follow. Occult cyanide toxicity has been reported in patients who are treated with prolonged low-dose infusion of sodium nitroprusside following cardiac surgery. Treatment of cyanide toxicity consists of amyl nitrite inhalation, and sodium nitrite, thiosulfate, and hydroxocobalamin infusions.[236]

The safe use of sodium nitroprusside during pregnancy has not been established. In animals, nitroprusside readily crosses the placenta. In a study of eight normotensive gravid ewes, five required high doses of nitroprusside (mean, 25 μg/kg/minute) to reduce blood pressure by 20% for 1 hour.[237] Among these five animals, a marked accumulation of maternal cyanide occurred. Fetal blood levels of cyanide were even higher and all of these fetuses died. However, in the other three ewes, hypotension was achieved with low doses of sodium nitroprusside (less than 1 μg/kg/minute). In this group, all of the fetuses survived and umbilical cord blood cyanide levels were low.

When sodium nitroprusside was used to achieve normotension for 50 minutes in ewes with norepinephrine-induced hypertension, the mean infusion rate required to control blood pressure was only 2.3 μg/kg/minute, and no fetal or maternal deaths occurred.[238] Neither maternal nor fetal blood samples contained more than 50 μg per L of cyanide (toxic levels in humans, 5,000 μg per L).

There are some reports on the safe use of sodium nitroprusside for hypertensive crises in pregnant women.[239,241] It has been recommended that the use of sodium nitroprusside for hypertensive crises during pregnancy be restricted to patients who are unresponsive to intravenous hydralazine or diazoxide.[242] When nitroprusside is required, it should only be used briefly to manage the acute crisis, and delivery should be performed as quickly as possible.

In summary, sodium nitroprusside has several characteristics that make it nearly the ideal drug for the short-term management of hypertensive crises. These include rapid onset of action, immediate reversibility, specific effects on resistance and capacitance vessels with no direct effect on the myocardium or CNS, lack of tachyphylaxis, and high potency. It is also a very safe drug when used appropriately. It is the most useful and consistently effective drug available for parenteral use in the treatment of hypertensive crises.

Fenoldopam

Fenoldopam is a selective dopamine receptor (DA_1) agonist. Recent studies have shown that intravenous fenoldopam, when used in the setting of hypertensive crises or perioperative hypertension, can safely lower blood pressure while maintaining or improving renal function.[243] Fenoldopam, a benazepine derivative of dopamine, was initially developed as an oral agent for the treatment of hypertension, renal insufficiency, and congestive heart failure. However, it was eventually withdrawn from development because of poor oral bioavailability. When subsequent studies demonstrated that intravenous fenoldopam exhibited a short-half life and predictable pharmacokinetics and dose-response characteristics, it was subsequently evaluated as a potential alternative to sodium nitroprusside for parenteral treatment of hypertension. Intravenous fenoldopam mesylate (Corlopam) was approved by the U.S. Food and Drug Administration (FDA) in 1997 for use in hypertension when oral therapy is not feasible or possible and for use in patients with severe hypertension, with or without target-organ damage.

Pharmacology and Pharmacokinetics

Fenoldopam selectively binds to DA_1 receptors and functions as a dopamine agonist. It does not bind to DA_2 receptors or β-adrenergic receptors. Fenoldopam is also an α-adrenergic receptor antagonist with greater activity at α_2 than α_1 receptors. However, this activity is observed only at higher concentrations than those required for activation of DA_1 receptors and it is unlikely that α-adrenoreceptor antagonism contributes to the hemodynamic and renal effects of therapeutic doses of fenoldopam. Peripheral DA_1 receptors are located postsynaptically in the systemic and renal vasculature, and at various sites in the nephron and GI tract. These receptors mediate systemic, renal, and mesenteric vasodilation. Fenoldopam exerts its hypotensive effect by decreasing systemic vascular resistance. Unlike sodium nitroprusside, it also increases renal blood flow and causes a natriuresis and diuresis. It is six times as potent as dopamine in causing renal vasodilation. In patients with severe hypertension, intravenous infusion of fenoldopam significantly increases renal blood flow, and decreases renal vascular resistance with a significant increase in creatinine clearance, urine flow rate, and sodium excretion.[244] Because of its selective receptor binding characteristics, fenoldopam exhibits minimal adrenergic effects. Although DA_1 receptors are present in the

CNS, fenoldopam does not have any direct CNS effect because it does not cross the blood–brain barrier. Fenoldopam is metabolized in the liver to a variety of nontoxic methyl, sulfate, and glucuronide metabolites. There are two principal inactive metabolites, 7- and 8-methoxy-fenoldopam, that are eliminated by the kidney (80%) and in the feces (20%). Less than 1% is excreted unchanged in the urine; therefore, dosage adjustment is not required in the setting of renal insufficiency. Moreover, pharmacokinetic parameters do not appear to be significantly altered in the setting of hepatic insufficiency.[244] Fenoldopam is not metabolized by the cytochrome P 450 system and has no major drug–drug interactions although concomitant acetaminophen administration may increase fenoldopam levels by 30% to 70%. Following intravenous administration, the onset of action is within 10 minutes, and the half-life is 9.8 minutes. There is no evidence of rebound hypertension after stopping the infusion. The volume of distribution is 0.6 L per kg.

Dosage and Administration

Fenoldopam is available in 5-mL ampules at a concentration of 10 mg per mL. Following dilution, the solution, which is light stable, can be used for up to 24 hours. For the treatment of severe hypertension or hypertensive crises, fenoldopam is administered by continuous infusion with an initial dose of 0.1 μg/kg/minute. The infusion may be increased in increments of 0.1 μg/kg/minute every 20 minutes until the target blood pressure is achieved. The maximum recommended dosage is 1.7 μg/kg/minute. The average infusion rate required is 0.25 to 0.5 μg/kg/minute. Mean plasma fenoldopam levels after a 2-hour infusion at 0.5 μg/kg/minute is between 13 to 50 ng per mL. When the desired response has been achieved, fenoldopam infusion may be discontinued gradually or abruptly, as rebound elevation of blood pressure has not been observed. Oral antihypertensive medications may be started as the fenoldopam infusion is weaned.

Adverse Effects

Adverse events attributed to fenoldopam in the treatment of hypertensive emergencies and urgencies were generally mild, occurred within the first 24 hours, and were related to the vasodilatory action of the drug.[244] Headache was reported in 11% to 36% of patients, flushing in 7% to 11%, nausea in 20%, and dizziness in 10%. Asymptomatic ST-segment abnormalities occurred in 6% to 33% of patients. The etiology of these nonspecific ST- and T-wave abnormalities, which are similar to those seen with the use of other vasodilators, is unknown. They appear to be a benign phenomenon related to blood pressure lowering with alterations in myocardial repolarization rather than an indication of subclinical myocardial ischemia.[244] Less frequently reported adverse events included palpitations, transient hypotension, asthenia, and sinus bradycardia. Fenoldopam, unlike sodium nitroprusside, produced a reversible, dose-related increase in intraocular pressure and should be used with caution in patients with glaucoma. In comparative trials, the adverse event profiles of fenoldopam and sodium nitroprusside were generally similar, although fenoldopam may be associated with a lower incidence of transient hypotension than sodium nitroprusside.

Use for Treatment of Hypertensive Crises

Fenoldopam has been compared mostly with sodium nitroprusside in patients with acute severe hypertension (either severe uncomplicated hypertension or true hypertensive crises).[243,245,246] Treatment with fenoldopam or sodium nitroprusside reduced mean diastolic blood pressure to a similar extent and to goal levels in most patients.[244] The time to achievement of goal blood pressure was similar to that with sodium nitroprusside. There was no evidence of rebound hypertension following cessation of either drug. There was no evidence of tolerance to the antihypertensive effect of either drug during maintenance infusion. In patients with hypertension following noncardiac surgery or coronary artery bypass grafting, fenoldopam and sodium nitroprusside were equally efficacious in lowering blood pressure.[247,248]

The efficacy, safety, and cost of sodium nitroprusside versus fenoldopam has been compared in a retrospective analysis of consecutive patients with hypertensive crises admitted to a level 1 trauma center and treated with nitroprusside (n = 21) or fenoldopam (n = 22).[246] Neither the mean pretreatment mean arterial pressure (nitroprusside 168 ± 19; fenoldopam 163 ± 9; P = .45), time to reach MAP goal (3.6, range 0.4 to 30 hours vs. 4.0, range 1 to 22 hours; P = .5), nor the duration of infusion (18, range 0.7 to 113 hours vs. 18, range 3 to 74 hours; P = .45) differed between the treatment groups. Time to imitation of oral antihypertensive therapy was similar between nitroprusside (4.5, range 0.5 to 22 hours) and fenoldopam (6.5, range 1 to 100 hours) treated patients (P = .45). Change in creatinine clearance and the incidence of tachycardia did not differ between the two groups. No symptoms of cyanide toxicity were detected in nitroprusside-treated patients. Cost of therapy was less with nitroprusside ($2.66, range $1.68 to $3.48) than with fenoldopam ($567, range $199 to $6,675 dollars). Thus, treatment of hypertensive crises with fenoldopam appears to result in patient outcomes equal to those with nitroprusside but at substantially higher cost.

Additional studies are needed to compare fenoldopam and sodium nitroprusside in the treatment of true hypertensive crises. Because fenoldopam preferentially dilates the renal vasculature, it has theoretical advantages in the treatment of patients with severe hypertension associated with renal impairment. Moreover, fenoldopam is not associated with the risk of toxicity from thiocyanate accumulation or cyanide. It is possible that it may also offer advantages in patients in whom cross clamping of the aorta above the level of the renal arteries is required.

Esmolol Hydrochloride

Pharmacology and Pharmacokinetics

Esmolol hydrochloride is a $beta_1$-selective (cardioselective) adrenergic receptor blocking agent with rapid onset of action and a very short duration of action. At therapeutic doses it has no significant intrinsic sympathomimetic activity. Elimination half-life after intravenous infusion is approximately 9 minutes. Esmolol inhibits $beta_1$ receptors located chiefly in cardiac muscle, but this preferential effect is not absolute and at higher doses it begins to inhibit $beta_2$ receptors located chiefly in the bronchial and vascular smooth muscle. Esmolol hydrochloride is rapidly metabolized by hydrolysis of the ester linkage by the esterases in the cytosol of red blood cells. Total body clearance is about 20 L/kg/hour which is greater than cardiac output, thus metabolism is not limited by the rate of hepatic or renal blood flow. Esmolol at doses of 200 μg/kg/minute produces reductions in heart rate, systolic blood pressure, rate-pressure product, left and right ventricular ejection fraction, and cardiac index.

Dosage and Administration

Esmolol hydrochloride is supplied as ready-to-use 10-mL vials containing 100 mg per 10 mL (10 mg per mL) and 250-mL bags containing 2,500 mg per 250 mL (10 mg per mL) and double strength vials containing 100 mg per 5 mL (20 mg per mL) and double strength bags containing 2,000 mg per 100 mL (20 mg per mL). Esmolol hydrochloride is titrated based on ventricular rate response and blood pressure. An initial loading dose of 500 μg per kg is infused over 1 minute followed by a maintenance infusion of 50 μg/kg/minute for 4 minutes. If adequate therapeutic response is not observed within 5 minutes, repeat the same loading dose and follow with a maintenance infusion increased to 100 μg/kg/minute. Higher maintenance infusion rates (250–300 μg/kg/minute) may be required for adequate control of blood pressure in up to one third of patients with postoperative hypertensive crises. In the absence of loading doses, constant infusion of any given maintenance dose reaches pharmacokinetic and pharmacodynamics steady-state in about 30 minutes. Maintenance infusions (with or without loading doses) may be continued for as long as 24 hours.

Adverse Effects

Adverse reaction rates are based on use of esmolol hydrochloride in clinical trials involving nearly 1000 patients with supraventricular tachycardia or intraoperative and postoperative hypertension enrolled in clinical trials. Symptomatic hypotension with diaphoresis and dizziness was the most common side effect occurring in 12% of patients. Asymptomatic hypotension occurred in about 25% of patients. Pallor, flushing, bradycardia with heart rate less than 50 beats per minute, chest pain, syncope, pulmonary edema, and heart block have each been reported in less than 1% of treated patients. Bronchospasm, wheezing, and dyspnea were reported in less than 1% of patients.

Use for Treatment of Hypertensive Crises

Esmolol hydrochloride is indicated for treatment of tachycardia and hypertension that occur during induction of anesthesia and tracheal intubation, during surgery, on emergence from anesthesia, and in the postoperative period. Esmolol hydrochloride may also be useful in conjunction with sodium nitroprusside to achieve blood pressure reduction and reduction in heart rate and dV/dP in patients with dissecting aortic aneurysm.

Intravenous Nitroglycerin

Intravenous nitroglycerin is particularly useful for the management of hypertension complicating acute myocardial infarction and hypertension occurring after coronary artery bypass. Nitroglycerin causes relaxation of vascular smooth muscle. The predominant effect at lower doses is venodilation. At higher doses, both venous and arterial dilation occur in a dose-dependent fashion.[249] As with nitroprusside, the effects of intravenous nitroglycerin on stroke volume and cardiac output vary, depending on the presence or absence of left ventricular dysfunction. In patients without heart failure, the reduction in preload usually predominates and stroke volume falls. In contrast, in patients with left ventricular systolic dysfunction, the decrease in afterload results in a decrease in the impedance to left ventricular ejection such that stroke volume is maintained despite a reduction in preload.

For the treatment of hypertension complicating acute myocardial infarction or postcardiac bypass hypertension, nitroglycerin may have an advantage over sodium nitroprusside.[250] Nitroglycerin and nitroprusside have different effects on regional myocardial blood flow.[251–253] Although both drugs dilate coronary vessels, nitroglycerin has a predominant effect on large coronary conductance arteries, including intercoronary collaterals, and relatively little effect on small resistance arterioles. This phenomenon is explained by the fact that coronary resistance vessels less than 100 microns in diameter cannot convert nitrates to nitric oxide such that there is preferential dilation of the larger epicardial collateral vessels.[254] In contrast, sodium nitroprusside predominantly dilates the resistance vessels and has less effect on intercoronary collaterals. In the setting of regional myocardial ischemia, resistance vessels in the ischemic region are already maximally dilated. Thus, sodium nitroprusside may dilate resistance vessels in nonischemic areas and shunt blood away from ischemic areas (coronary steal). Nitroglycerin, by predominantly dilating conductance vessels, improves blood flow to the ischemic region. Given the potentially deleterious effect of nitroprusside on regional myocardial blood flow, it has been recommended that intravenous nitroglycerin be used in preference to nitroprusside for the treatment of hypertension with left ventricular dysfunction in association with acute myocardial infarction.[250]

Nitrates produce vasodilation through the formation of nitric oxide (endothelium-derived relaxing factor), which

activates guanylate cyclase.[250] There appears to be tight coupling between the cyclic guanosine monophosphate (cGMP) production and smooth muscle relaxation. A cGMP-dependent protein kinase is stimulated, resulting in alterations in the phosphorylation of various proteins in smooth muscle. Dephosphorylation of the light chain of myosin leads to smooth muscle relaxation.[256]

Intravenous nitroglycerin has a rapid onset and brief duration of action with a half-life of 1 to 4 minutes. It is metabolized in the liver by a glutathione-dependent organic nitrate reductase. Intravenous nitroglycerin is supplied in 10-mL bottles containing 50 mg, which should be diluted in 5% dextrose in water or 0.9% sodium chloride. Usually one bottle is diluted in a 250 mL volume to yield a final concentration of 200 μg per mL. Nitroglycerin interacts with many types of plastic. Thus, the drug should be diluted only in glass parenteral solution bottles. Special infusion sets that have been developed absorb fewer nitroglycerins than standard polyvinyl chloride tubing. The initial infusion rate should not exceed 5 μg per minute. The dose is titrated in 5 μg per minute increments every 3 to 5 minutes until the desired hypotensive response is achieved. There is no standard optimal dose of nitroglycerin. There tends to be great variability in response from patient to patient. Blood pressure should be monitored every 30 seconds during the titration phase and every 15 minutes thereafter. As with nitroprusside, close monitoring in an intensive care unit setting is required. In the setting of acute myocardial infarction, monitoring of cardiac output and left ventricular filling pressure is essential.

Intravenous nitroglycerin has also been recommended for the management of the potentially dangerous posttreatment hypertensive response that inevitably follows electroconvulsive therapy.[257]

Labetalol

Intravenous labetalol may be of value in a variety of hypertensive crises including malignant hypertension, hypertensive encephalopathy,[258] aortic dissection,[259] and hypertensive crises during pregnancy.[259]

Labetalol has selective α_1- and nonselective beta-blocking properties.[260,261] The ratio of beta- to α-blocking potency is 7:1 for intravenous labetalol. The acute antihypertensive effect after intravenous administration appears to be caused by a decrease in systemic vascular resistance without an appreciable change in cardiac output.[261] However, when used in the treatment of hypertension following open heart surgery, labetalol causes a significant reduction in cardiac output.[262] The beta-blocking effect offsets the baroreceptor-mediated sympathetic response to hypotension. Thus, heart rate remains unchanged or decreases slightly.

After intravenous bolus injection, the full antihypertensive effect occurs within 5 to 10 minutes, and the blood pressure gradually rises to pretreatment levels over 16 to 18 hours. The duration of action, defined as the time from the last injection until the diastolic blood pressure rises 10 mm Hg above the nadir pressure, ranges from 2.0 to 6.5 hours. The major route of elimination is via glycuronide conjugation in the liver. Thus, the labetalol dose must be decreased in patients with liver dysfunction but need not be modified in patients with renal failure.

Labetalol is supplied in 20-mL ampules containing 100 mg of drug. It is usually administered by repeated mini-bolus injections through an intravenous line. The initial dose is 20 mg (4 mL) injected slowly over a 2-minute period. The maximum hypotensive response usually occurs within 5 minutes of the injection. If the desired hypotensive response is not obtained after 10 minutes, a 40-mg bolus is administered over 2 minutes. Additional injections of 40 to 80 mg can be given at 10-minute intervals until the desired hypotensive response is obtained or the maximum total dose of 300 mg has been given.

Labetalol can also be given by continuous infusion. The contents of two ampules (200 mg, 40 mL) are added to 160 mL of diluent to yield a volume of 200 mL with a final concentration of 1 mg per mL. The infusion is begun at 2 mg per minute. The infusion is continued until the desired response is obtained and then discontinued. Again, the maximum total dose of 300 mg should not be exceeded. Continuous infusion may be preferable to bolus therapy in patients at risk for ischemic complications due to overshoot hypotension.

After the blood pressure is controlled with either the mini-bolus or the continuous infusion technique, oral therapy can be initiated with labetalol as soon as the supine diastolic pressure increases by 10 mm Hg above the minimum obtained with parenteral therapy. The initial oral dose is 200 mg. Thereafter the oral dose is titrated beginning at 200 mg twice daily and increased to 600 mg twice daily as required. The addition of a diuretic often enhances the long-term blood pressure response.

As with other parenteral antihypertensive agents, intravenous labetalol can cause precipitous hypotension, which can result in cerebral ischemia. Exaggerated hypotensive responses are usually reported when the initial injection is large (1.5 to 2.0 mg per kg); however, overshoot hypotension can also develop with either the mini-bolus or the continuous infusion technique. Chronically hypertensive patients sometimes develop paradoxical hypertension in response to volume depletion.[263] In this setting treatment with labetalol leads to reduction in systemic vascular resistance leading to sustained overshoot hypotension. Thus, before labetalol is used to treat a patient with postoperative hypertension and tachycardia, the possibility of physiologic tachycardia due to volume depletion should be considered.

Other side effects of labetalol are related to its nonselective beta-blocking properties. It should be avoided in patients with severe sinus bradycardia, heart block greater than first degree, bronchial asthma, or congestive heart failure.

Oral labetalol has been used safely for treatment of hypertensive crises of pregnancy.[264] However, intravenous labetalol should be used with caution because it has been associated with evidence of neonatal β-adrenergic blockade such as hypoglycemia, bradycardia, and hypotension.[265]

Labetalol can cause a significant reduction in cardiac index when used in the setting of hypertension after open heart surgery.[262] The hypotensive action of the drug in this setting appears to result from a decrease in cardiac output rather than from a decrease in systemic vascular resistance. Thus, labetalol should be avoided after open heart surgery, a setting in which nitroglycerin or sodium nitroprusside is preferred for management of hypertension.

Although there are reports of preoperative management of pheochromocytoma with labetalol,[266] beta-blockade can result in exacerbation of hypertension if α-blockade is incomplete. In this regard, there have been reports of paradoxical hypertension when labetalol was used to treat pheochromocytoma.[267] Therefore, routine use of labetalol for the preoperative management of pheochromocytoma is not recommended.

Several deaths have been reported to the FDA with use of parenteral labetalol injection to treat intraoperative hypertension (including cases where it is used to control intraoperative bleeding).

Although intravenous labetalol has been recommended as an effective agent for the treatment of severe acute hypertension in patients with chronic renal failure,[268] life-threatening hyperkalemia has been reported in patients with renal failure that received intravenous labetalol for the treatment of hypertensive crises.[269,270] Beta-adrenergic stimulation is known to shift potassium into cells and beta-agonists have been proposed as acute therapy for hyperkalemia in dialysis patients. Conversely, hyperkalemia may be caused by nonselective beta-blockers through inhibition of Na-K-ATPase with decreased cellular uptake of potassium, independent of effects on insulin or aldosterone.[271] Thus, labetalol and other nonselective beta-blockers should probably be avoided for the acute management of postoperative hypertension and other hypertensive crises in patients with renal failure.

In summary, although intravenous labetalol has been used to treat a variety of hypertensive crises, its long duration of action and beta-blocking properties are potential disadvantages. Slow continuous infusion may be preferred over intravenous bolus therapy to minimize the risk of sustained overshoot hypotension. For this reason, sodium nitroprusside or nicardipine usually represents more logical choices for the acute management of patients with hypertensive crises requiring parenteral therapy.

Phentolamine

Phentolamine is useful in the management of catecholamine-related hypertensive crises including pheochromocytoma, monoamine oxidase (MAO) inhibitor–tyramine interactions, and clonidine, methyldopa, or guanabenz withdrawal reactions. It is not consistently effective in other hypertensive crises. In fact, phentolamine has largely been replaced by sodium nitroprusside in the management of catecholamine-related hypertensive crises.

Phentolamine is a nonselective α-adrenergic blocking agent that competitively inhibits the effect of norepinephrine on vascular smooth muscle α_1-receptors. It does not have beta-blocking activity and therefore does not block the cardiac effects associated with β_1-receptor activation by catecholamines. Phentolamine produces dilation of both arteriolar resistance vessels and venous capacitance vessels.[273]

The intravenous injection of 1 to 5 mg produces a hypotensive effect within 2 to 3 minutes; however, the duration of action may be only 15 to 30 minutes, so that frequent dosing is required to control blood pressure. Phentolamine is supplied in ampules containing 5 mg. The initial dose should be 1 mg. Subsequent boluses of 1 to 5 mg are administered up to a total dose of 20 to 30 mg or until the blood pressure is controlled. After the desired blood pressure is achieved, intermittent injections are given as necessary to maintain the response.

Side effects due to phentolamine are common. Tachycardia and arrhythmias can occur due to β-adrenergic cardiac stimuli that are not blocked by phentolamine. GI side effects include abdominal pain, nausea, vomiting, and diarrhea. Exacerbation of peptic ulcer disease can occur, so phentolamine should be used with caution in patients with a history of gastritis or peptic ulcer disease.

Hydralazine

In the past, parenteral hydralazine was often used for the treatment of hypertensive crises. Most obstetricians still consider hydralazine to be the drug of choice for the management of hypertensive crises during pregnancy.[273] However, aside from its use during pregnancy, hydralazine has largely been replaced by other agents in the treatment of hypertensive crises.

The hypotensive response to either intramuscular or intravenous hydralazine is unpredictable. The onset of action occurs 10 to 30 minutes after a parenteral dose. The duration of action is 3 to 9 hours. The dose and frequency of administration needed to control the blood pressure are highly variable.[274] Profound and sustained hypotension can occur with an intravenous dose as low as 10 mg. Hydralazine is a direct-acting arteriolar vasodilator. It causes reflex activation of the adrenergic nervous system.[274] Because venous capacitance vessels are not affected, venous return is maintained. In association with activation of the adrenergic system, there are increases in heart rate and stroke volume.[274] Hydralazine is contraindicated in the treatment of aortic dissection because the increase in myocardial contractility can result in propagation of the dissection. It is also contraindicated in patients with ischemic heart disease because the increased myocardial oxygen demand can precipitate angina or myocardial infarction.

Parenteral hydralazine is still used in acute hypertensive crises of pregnancy. In the majority of patients, hydralazine reduces the blood pressure to acceptable levels and is well tolerated by both mother and fetus, despite reflex activation of the adrenergic system.[273] Dosing guidelines for the use of parenteral hydralazine during pregnancy are well established.[273] Because maternal hypertension helps to maintain placental perfusion, there is concern that aggressive treatment aimed at normalization of blood pressure might

further compromise placental perfusion to the detriment of the fetus. Therefore, hydralazine treatment is usually instituted only if the diastolic blood pressure is more than 110 mm Hg and the goal of therapy is a diastolic pressure in the 90 to 100 mm Hg range. After an initial intravenous dose of 5 mg, additional 5- to 10-mg doses are administered every 15 to 20 minutes until the desired response is obtained. Because preeclampsia is associated with intravascular volume depletion, it is important to initiate therapy with a low dose to avoid overshoot hypotension. Intramuscular injection of hydralazine is unsatisfactory because the onset of action and magnitude of response are unpredictable.

Calcium Channel Blockers

Intravenous nicardipine has been reported to be effective in the acute treatment of severe hypertension in both adults and children.[275–277] It may be useful in the management of postoperative hypertension in both cardiac and noncardiac patients.[277] Intravenous nicardipine is also effective in preventing circulatory responses to laryngoscopy and tracheal intubation in hypertensive patients.[278] Safe use of nicardipine in preeclamptic patients has also been reported.[279]

Nicardipine is a dihydropyridine calcium channel blocker that inhibits the transmembrane influx of calcium into vascular smooth muscle, resulting in vasodilation with a decrease in systemic vascular resistance. The effect on heart rate is dependent on the intrinsic state of the myocardium. In patients with intact systolic function, reflex increases in heart rate may occur in response to blood pressure reduction. In patients with impaired left ventricular function, cardiac output may increase in response to afterload reduction.

Compared to other parenteral medications available for the treatment of hypertensive crises, the pharmacokinetic properties of nicardipine (as well as other calcium channel blockers) are unfavorable. The currently available dihydropyridine calcium channel blockers have very long half-lives. The beta half-life of nicardipine is 40 minutes, whereas its gamma half-life is approximately 13 hours. Because about 14% of the drug is eliminated during the gamma phase, the hypotensive effect is prolonged. Discontinuation of the infusion is followed by a 50% reduction in the hypotensive action within 30 minutes but a gradually decreasing antihypertensive effect may last for about 50 hours. Thus, nicardipine may not be the best choice for true hypertensive crises in which moment-to-moment titration of the blood pressure is the desired therapeutic goal.

In the past, nimodipine had been recommended for the treatment of patients undergoing cardiac valve replacement to decrease the incidence of postoperative neurologic sequelae by increasing cerebral blood flow and protecting against anoxic brain cell damage. However, a recent placebo controlled trial of oral nimodipine following cardiac valve replacement was terminated prematurely because of a lack of evidence of benefit of nimodipine and an unexpected increase in the death rate of patients treated with nimodipine compared to placebo.[280] The higher mortality rate was attributed to an increased risk of major bleeding in patients treated with nimodipine. Excess bleeding in patients treated with calcium channel blockers may be explained by the combination of vasodilation and the antiplatelet action of calcium antagonists.

The clinical use of nifedipine for severe uncomplicated hypertension and hypertensive crises has been reviewed.[281,282] Nifedipine produces a prompt fall in systemic arterial pressure after a single oral dose. The antihypertensive effect results from arteriolar vasodilation with a decrease in systemic vascular resistance. Nifedipine produces a prompt reduction in systolic, diastolic, and mean arterial pressures of about 25% below the baseline value in most patients.[282]

The major acute side effects of nifedipine include a burning sensation in the face and legs, facial flushing, headache, and palpitations. Overshoot hypotension has been observed, especially in hypovolemic patients or patients pretreated with diuretics.[283,284] Exaggerated hypotension can cause myocardial ischemia in patients with underlying coronary atherosclerosis.[285]

Oral nifedipine may be useful in the management of patients with malignant hypertension who do not have an absolute indication for parenteral antihypertensive therapy. However, in patients with hypertensive crises requiring careful titration of the hypotensive response, the prolonged duration of action and the potential risk of overshoot hypotension with nifedipine are major disadvantages. Sodium nitroprusside is clearly preferable for the management of true hypertensive crises. The role of nifedipine in the acute treatment of severe uncomplicated hypertension in the emergency room setting prior to discharge is discussed in the section entitled Severe Uncomplicated Hypertension.

Minoxidil

Minoxidil is a potent antihypertensive agent that is available only for oral use. In combination with a potent diuretic and a beta-blocker, it is very useful in the control of hypertension refractory to conventional antihypertensive regimens. The efficacy of a triple drug regimen with minoxidil in the management of the patient with malignant hypertension and azotemia has already been discussed. Minoxidil is often employed for the long-term control of blood pressure in patients with malignant hypertension after initial control of the blood pressure with parenteral medications. Furthermore, in patients with malignant hypertension not requiring immediate blood pressure reduction, an oral triple drug regimen consisting of minoxidil, a beta-blocker, and a loop diuretic can effectively control the blood pressure over a period of hours to days and thereby eliminate the need for parenteral antihypertensive therapy (see Treatment subsection under Malignant Hypertension earlier in this chapter).

Minoxidil is a direct-acting arteriolar vasodilator. Its antihypertensive effect results from a decrease in systemic vascular resistance.[286] It has no effect on venous capacitance vessels. The hypotensive response to minoxidil is accompanied by a baroreceptor-mediated reflex increase in

sympathetic tone, which results in an increase in heart rate, contractility, and cardiac output. Unopposed, the cardiac output may increase threefold to fourfold and attenuate the fall in blood pressure.[286,287] The resulting increase in myocardial oxygen demand may precipitate ischemia in patients with limited coronary reserve. For this reason minoxidil is usually given concomitantly with a β-adrenergic blocking drug.

As with other peripheral vasodilators, minoxidil induces profound renal salt and water retention.[286] This fluid retention is probably related to the hypotensive effect of the drug. A similar antinatriuresis occurs with both hydralazine and diazoxide. Minoxidil causes more fluid retention because it is a more potent arteriolar vasodilator. Several factors enhance renal salt and water retention.[287] Decreased peritubular capillary pressure is a potent stimulus for salt and water reabsorption in the proximal tubule. Increased adrenergic tone also enhances proximal tubular salt and water reabsorption. Like other vasodilators, minoxidil increases renin release, which leads to increased aldosterone production and enhanced distal tubular sodium reabsorption.[287] Pseudotachyphylaxis to the original hypotensive effect of minoxidil can occur if either beta-blockade or diuretic therapy is inadequate.

The serum half-life of minoxidil is 4.5 hours; however, the duration of action is longer than the half-life would predict.[287] After oral administration, the antihypertensive effect begins within 30 to 60 minutes, reaches a maximum in 2 to 4 hours, and slowly abates over the next 12 to 18 hours. The prolonged hypotensive effect is probably due to persistent binding of minoxidil at the site of action in vascular smooth muscle. About 15% of the parent compound is excreted in the urine, whereas the remainder is metabolized in the liver by glucuronide conjugation.[287]

Although the serum half-life is 4 hours, the persistent hypotensive effect allows for a twice daily dosing schedule. Prior to the initiation of minoxidil, all other antihypertensives except diuretics and beta-blockers should be discontinued. Minoxidil is started at a dose of 2.5 mg twice daily and increased in 5-mg per day increments every 2 to 3 days until the desired response is obtained. The usual effective dose is 10 to 40 mg per day. The doses of loop diuretic and beta-blocker are titrated to maintain dry weight and prevent tachycardia, respectively.

When more rapid control of arterial pressure is required, incremental changes in minoxidil dosage can be made every 6 hours. The initial 2.5-mg dose is doubled every 6 hours up to a maximum dose of 20 mg, or until the desired response is obtained. The effective dose should then be administered every 12 hours and the dose of diuretic and beta-blocker titrated as necessary.[287]

The dose of beta-blocker required to prevent reflex tachycardia in patients treated with minoxidil is often in excess of the usual beta-blocking dose. This is because the sympathetic nervous system is activated by minoxidil and beta-blockers compete with catecholamines for receptor binding.[287] The dose of beta-blocker should be titrated to maintain resting heart rate at 70 to 80 beats per minute.

In general, thiazide diuretics are not potent enough to counteract minoxidil-induced antinatriuresis, especially if renal insufficiency is present. The starting dose of furosemide is 40 mg twice daily. However, a dose of 300 to 400 mg per day may be required to prevent fluid retention and maintain dry weight.

The most common side effects of minoxidil are related to its pharmacologic properties. Fluid retention can lead to weight gain, edema, anasarca, congestive heart failure, and pericardial effusion. With inadequate beta-blockade, reflex sympathetic stimulation can lead to angina or myocardial infarction in patients with underlying coronary disease. Electrocardiographic changes following the initiation of minoxidil have been reported. In more than 90% of patients flattening or inversion of T waves develops.[287] Although often marked, these changes do not necessarily indicate myocardial ischemia, and they usually resolve with continued therapy.[286,287]

Pericardial effusion has been reported with minoxidil treatment; however, progression to cardiac tamponade is rare. The cause of the effusion is unknown, but it occurs most commonly in patients with renal failure, collagen vascular diseases, or inadequate diuretic therapy. A hemodynamically insignificant effusion is not necessarily a reason to discontinue minoxidil, but the patient should be treated aggressively with diuretics and followed closely for signs of tamponade.[286,287] Patients on dialysis should have a trial of intensive daily dialysis to achieve and maintain dry weight.

Reversible hypertrichosis of the face, back, and arms occurs in almost all patients taking minoxidil and is the most frequent reason for discontinuation of the drug, especially among female patients. Calcium thioglycolate depilatory agents and shaving are used to control this cosmetic side effect.

Triple therapy with minoxidil, a beta-blocker, and a loop diuretic is often dramatically effective in the long-term management of malignant hypertension, even when conventional antihypertensive regimens are unsuccessful or produce intolerable side effects.[288]

SEVERE UNCOMPLICATED HYPERTENSION

The benefits of acute reduction of blood pressure in the setting of true hypertensive crises are obvious. Fortunately, hypertensive crises are relatively rare events that never affect the vast majority of hypertensive patients. Another type of presentation that is more common than true hypertensive crisis is the patient who presents with severe hypertension (diastolic blood pressure greater than 115 mm Hg) in the absence of the hypertensive neuroretinopathy or other acute end-organ damage that would signify a true crisis. This entity, which is known as severe uncomplicated hypertension, is very common in the emergency department setting. In a recent study of severe uncomplicated hypertension treated in an emergency room, 60% of the patients were

entirely asymptomatic and had presented for prescription refills or routine blood pressure checks, or were found to have elevated blood pressure during routine examinations. The other 40% presented with nonspecific symptoms such as headache, dizziness, and weakness in the absence of evidence of acute end-organ dysfunction.[289]

In the past, this entity has been referred to as urgent hypertension, reflecting the widely accepted notion that acute reduction of blood pressure, over a few hours prior to discharge from the emergency room, was essential to minimize the risk of short-term complications from the severe hypertension.[290] Commonly used treatment regimens include oral clonidine loading, or sublingual nifedipine given to acutely reduce the blood pressure prior to initiation of a maintenance antihypertensive regimen.[289,290]

In recent years, however, the urgency of treatment in patients with severe uncomplicated hypertension has been questioned.[3,5,291] Although it is clear that in comparison to patients with mild or moderate hypertension, patients with severe uncomplicated hypertension are at increased long-term risk of cardiovascular complications,[292] they are generally not in any immediate danger of an untoward event. The argument supporting the acute reduction of blood pressure is based on the following assumptions: (1) it is important to reduce blood pressure immediately to avoid complications; (2) oral antihypertensive loading prior to initiation of maintenance therapy produces improved immediate and long-term blood pressure control; and (3) there are no adverse consequences of this form of treatment.[3] Two classical studies provided some useful information regarding the need to reduce blood pressure immediately with the aim of preventing hypertensive complications. In the Veterans Administration Cooperative Study of patients with severe hypertension,[293] there were 70 untreated patients who had no evidence of malignant hypertension or significant end-organ dysfunction despite the presence of diastolic blood pressures averaging 121 mm Hg. Among these patients, 27 experienced morbid events at an average of 11 ± 8 months into follow-up. The earliest morbid event occurred after 2 months. Likewise, a similar study in Baltimore showed that among 42 untreated patients with severe but uncomplicated hypertension, 19 patients experienced morbid events (congestive heart failure, onset of malignant hypertension, cerebrovascular accident, or evidence of declining renal function) at a mean of 12 ± 7 months into follow-up. The earliest morbid event occurred at 2 months.[293] These data suggest that patients who have severe but uncomplicated hypertension need not be exposed to the risk of "urgent" blood pressure reduction in the emergency room setting because hypertensive complications tend to occur over a matter of months to years rather than hours to days.

Another study addressed the question of whether antihypertensive loading prior to the initiation of maintenance therapy improves or hastens blood pressure control.[5] Sixty-four asymptomatic patients with severe hypertension were randomized to treatment with hourly doses of clonidine followed by clonidine and thiazide diuretic maintenance therapy, or an initial dose of clonidine followed by hourly placebo and then subsequent maintenance therapy, or initiation of maintenance therapy without prior antihypertensive loading. There was no difference between the first two groups with regard to the time required to achieve acceptable blood pressure control during loading therapy. Furthermore, there were no differences between the three groups with regard to adequacy of blood pressure control at 24 hours or 1 week. The authors conclude that sustained blood pressure control resulted solely from maintenance therapy and that the time to adequate control and eventual level of blood pressure were independent of the administration of an initial loading dose. They suggest that the common practice of acute oral antihypertensive loading to treat severe, asymptomatic hypertension should be reconsidered.[5] In this regard, a study of 32 patients with severe uncomplicated hypertension found that a significant decrease in blood pressure frequently occurred in the emergency department even before pharmacologic intervention was initiated. The mean arterial pressure decreased by 6% without treatment within 1 hour after the initial blood pressure reading.[294] The authors suggest that given a short period of observation, many patients with severe uncomplicated hypertension will experience a decrease in blood pressure to mildly or moderately hypertensive levels, which would clearly make acute blood pressure reduction with an antihypertensive loading regimen unnecessary.

Although generally safe, the oral antihypertensive loading regimens occasionally cause significant adverse effects. Sublingual nifedipine can produce severe headache and profound overshoot hypotension.[284] The marked blood pressure reduction can exacerbate underlying ischemic heart disease, resulting in angina or myocardial infarction. It has even been suggested that a moratorium be placed on the use of sublingual nifedipine for the treatment of severe uncomplicated hypertension.[295] Loading doses of clonidine cause sedation in 60% of patients and some of these patients are difficult to awaken and require assistance in returning home.[289] Furthermore, the recommended conversion from the oral loading dose to a twice-daily dose of clonidine may represent special problems in the treatment of patients with severe uncomplicated hypertension. Clonidine produces a number of common side effects including dry mouth, drowsiness, and constipation, which may interfere with long-term compliance with medical therapy. The risk of hypertensive rebound on abrupt discontinuation of clonidine[290] should also be considered since many patients with this form of hypertension are noncompliant with medical therapy.[5]

Although the acute reduction of blood pressure in patients with severe uncomplicated hypertension with sublingual nifedipine or oral clonidine loading regimens has become the de facto standard of care in the acute care setting, this practice is often an emotional response on the part of the treating physician to the dramatic elevation of blood pressure. This aggressive approach may also be motivated

by fear of medicolegal repercussions in the unlikely event that an untoward hypertensive complication occurs shortly after the emergency room visit. Although observing and documenting the dramatic fall in blood pressure prior to discharge is a satisfying therapeutic maneuver, there is no scientific basis for this approach and it is unclear if even the small but definite risks of acute blood pressure reduction are justified. There is, at present, no literature to support the notion of an absolute level of blood pressure above which the acute reduction of blood pressure is mandatory before the patient can be discharged from the acute care setting. For asymptomatic patients with severe uncomplicated hypertension, acute reduction of blood pressure in the emergency room is often counterproductive because it can produce untoward symptoms that render the patient less likely to comply with long-term drug therapy. Because the available data suggest that the risks to the patient are not immediate, therapeutic intervention should focus on tailoring an effective, well-tolerated maintenance antihypertensive regimen with emphasis on patient education to enhance long-term compliance.[5] Therefore, oral antihypertensive loading in this setting is of little value. If the patient has simply run out of medications, reinstitution of the previous regimen should suffice. If the patient is thought to be compliant with an existing drug regimen, a sensible change in therapy such as an increase in a suboptimal dosage of an existing drug or the addition of a drug of another class is appropriate. Addition of a low dose of a thiazide diuretic as a second-step agent to existing monotherapy with converting enzyme inhibitor, calcium channel blocker, beta-blocker, or central α_2-agonist is often efficacious. Another essential goal of the intervention should be to arrange for suitable outpatient follow-up within a few days. Gradual reduction of blood pressure to normotensive levels over the next few days to a week should be accomplished in conjunction with frequent outpatient follow-up visits to modify drug regimens and reinforce the importance of lifelong compliance with therapy. Although less dramatic than acute reduction of blood pressure in the emergency room, this type of approach to the treatment of this chronic disease is more likely to prevent long-term hypertensive complications as well as recurrent episodes of severe uncomplicated hypertension.

A recent multicenter study evaluated the level of adherence to current guidelines that recommend that patients in the emergency department with severely elevated blood pressure be evaluated for target organ damage (to exclude hypertensive crisis requiring immediate blood pressure reduction), have their outpatient medical regimen adjusted, and be instructed to follow-up promptly for reassessment.[296] This observational study was conducted during 1 week at four urban academic emergency departments. Severely elevated blood pressure was defined as systolic blood pressure greater than or equal to 180 mm Hg or diastolic blood pressure greater than or equal to 110 mm Hg on at least one measurement. Among 423 patients with severely elevated blood pressure, serum chemistry was obtained in 73%, ECG in 53%, chest radiograph in 46%, urinalysis in 43%, and funduscopic examination to exclude malignant hypertension in 36%. All recommended studies were performed in only 6% of patients. Acute reduction of blood pressure with oral medications was undertaken in 36% of patients and intravenous antihypertensive agents were given to 4% of patients. Modification of the outpatient antihypertensive regimen was documented in only 19% of discharged patients. The authors conclude that the majority of emergency department patients with severely elevated blood pressure do not receive the evaluation, medical regimen modification, and discharge instructions advised by current guidelines.

Finally, an important entity that can masquerade as severe uncomplicated hypertension deserves special mention. Pseudohypertension is a condition in which indirect measurement of arterial pressure using a cuff sphygmomanometer is artificially high in comparison to direct intra-arterial pressure measurements.[297] Failure to recognize pseudohypertension can result in unwarranted and sometimes frankly dangerous treatment. Pseudohypertension can result from Mönckeberg's medial calcification, advanced atherosclerosis with widespread calcification of intimal plaques, or azotemic arteriopathy (metastatic vascular calcification in patients with ESRD).[297] In these entities, stiffening of the arterial wall may prevent its collapse by externally applied pressure, resulting in artificially high indirect blood pressure readings affecting both systolic and diastolic measurements. Pseudohypertension should be suspected in the patient with severe hypertension in the absence of significant target-organ damage. The presence of a positive Osler's maneuver, in which the radial or brachial artery remains clearly palpable despite being made pulseless by proximal inflation of a cuff above systolic blood pressure, is an important physical examination finding that should suggest the diagnosis.[298] Roentgenograms of the extremities will often reveal calcified vessels.[297] However, the diagnosis can only be made definitively by direct measurement of intra-arterial pressure. If unrecognized, pseudohypertension may result in unwarranted treatment. Patients with pseudohypertension are often older adults and therefore may have critical limitation of blood flow to the brain or heart such that inappropriate blood pressure reduction may precipitate life-threatening ischemic events.[297]

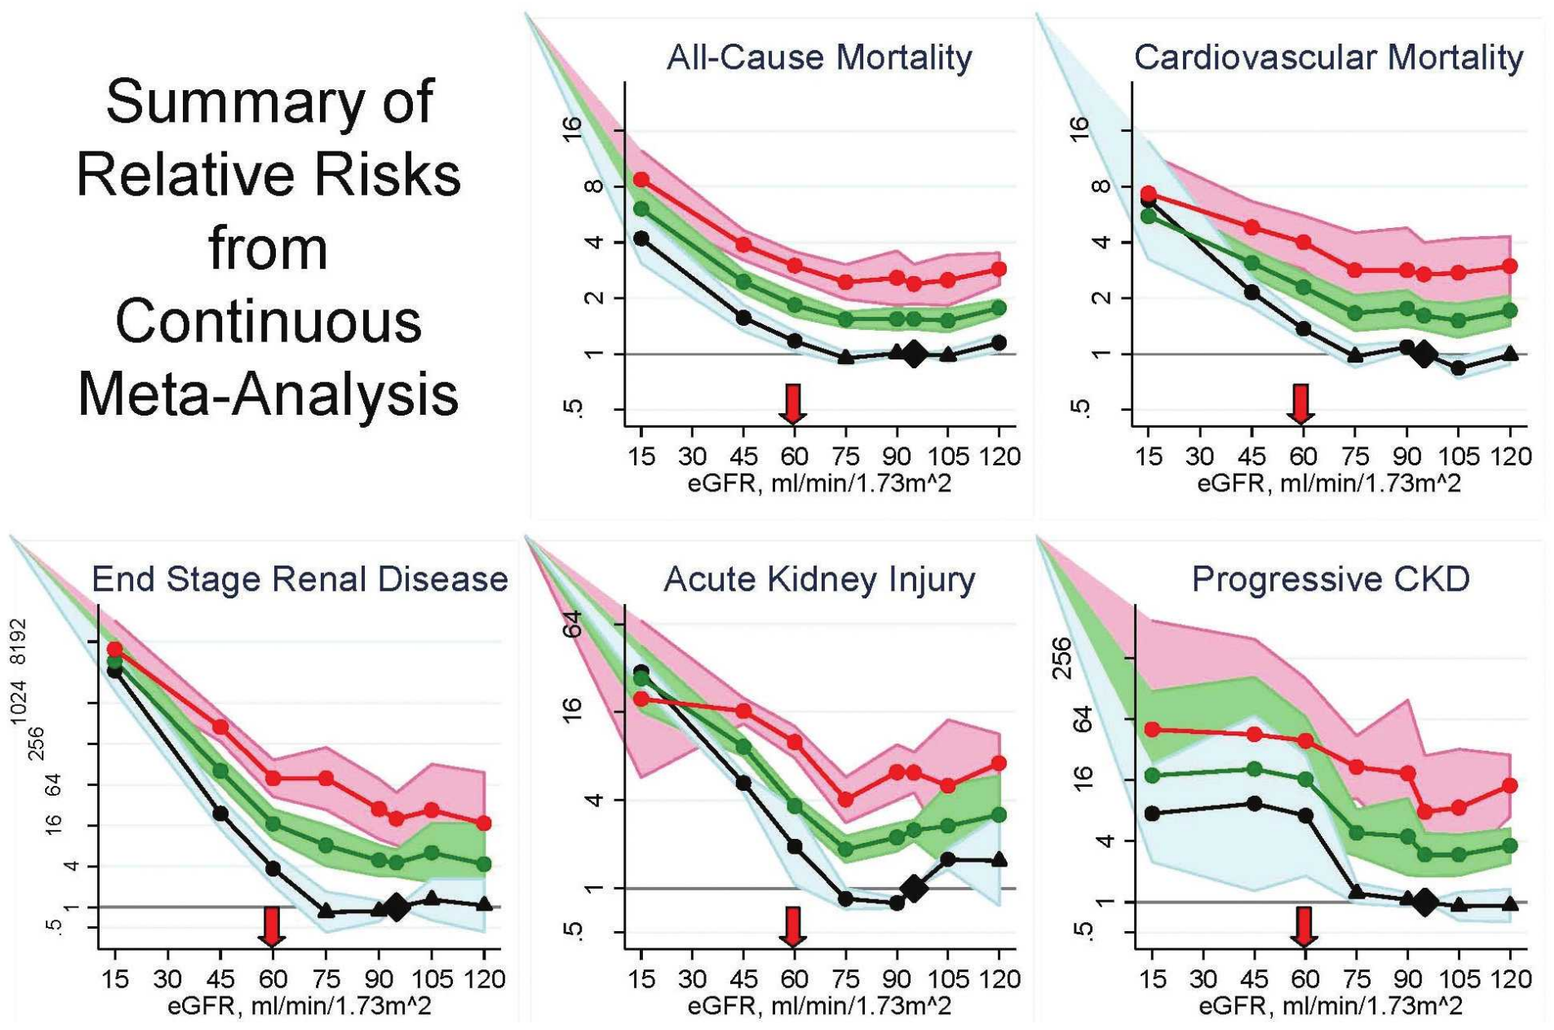

FIGURE 9.2

Summary of Relative Risks from Categorical Meta-Analysis

(dipstick included [-, ±, +, ≥++])

All-Cause Mortality

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥300
eGFR > 105	1.1	1.5	2.2	5.0
eGFR 90-105	Ref	1.4	1.5	3.1
eGFR 75-90	1.0	1.3	1.7	2.3
eGFR 60-75	1.0	1.4	1.8	2.7
eGFR 45-60	1.3	1.7	2.2	3.6
eGFR 30-45	1.9	2.3	3.3	4.9
eGFR 15-30	5.3	3.6	4.7	6.6

Cardiovascular Mortality

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥300
eGFR > 105	0.9	1.3	2.3	2.1
eGFR 90-105	Ref	1.5	1.7	3.7
eGFR 75-90	1.0	1.3	1.6	3.7
eGFR 60-75	1.1	1.4	2.0	4.1
eGFR 45-60	1.5	2.2	2.8	4.3
eGFR 30-45	2.2	2.7	3.4	5.2
eGFR 15-30	14	7.9	4.8	8.1

Kidney Failure (ESRD)

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥300
eGFR > 105	Ref	Ref	7.8	18
eGFR 90-105	Ref	Ref	11	20
eGFR 75-90	Ref	Ref	3.8	48
eGFR 60-75	Ref	Ref	7.4	67
eGFR 45-60	5.2	22	40	147
eGFR 30-45	56	74	294	763
eGFR 15-30	433	1044	1056	2286

Acute Kidney Injury (AKI)

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥300
eGFR > 105	Ref	Ref	2.7	8.4
eGFR 90-105	Ref	Ref	2.4	5.8
eGFR 75-90	Ref	Ref	2.5	4.1
eGFR 60-75	Ref	Ref	3.3	6.4
eGFR 45-60	2.2	4.9	6.4	5.9
eGFR 30-45	7.3	10	12	20
eGFR 15-30	17	17	21	29

Progressive CKD

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥300
eGFR > 105	Ref	Ref	0.4	3.0
eGFR 90-105	Ref	Ref	0.9	3.3
eGFR 75-90	Ref	Ref	1.9	5.0
eGFR 60-75	Ref	Ref	3.2	8.1
eGFR 45-60	3.1	4.0	9.4	57
eGFR 30-45	3.0	19	15	22
eGFR 15-30	4.0	12	21	7.7
