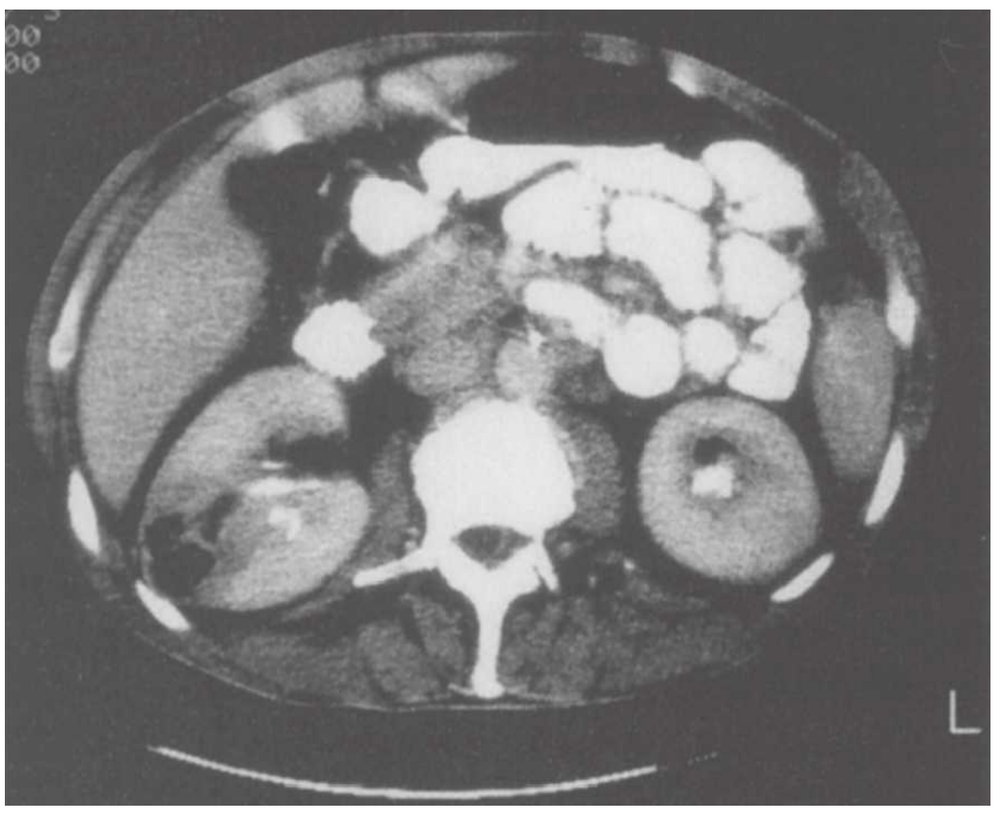
Renal corticomedullary abscesses must be differentiated from other space-occupying lesions in the kidney. Renal tumors, intrarenal cysts, renal cortical abscesses, and perinephric abscesses may mimic renal corticomedullary abscesses because the clinical presentation of each of these conditions is similar. Fever, chills, malaise, and back pain may be seen in each. Clinical signs of urosepsis may be present in patients with renal corticomedullary abscesses and, to a lesser extent, in patients with perinephric abscesses. In contrast, these signs are usually absent in patients with renal tumors, cysts, and renal cortical abscesses. Patients with renal corticomedullary abscesses often have an abnormal urinalysis (70%) with pyuria, proteinuria, and bacteriuria and blood cultures frequently are positive.[43]

Radiographic techniques are essential to identify renal corticomedullary abscesses. The urographic findings in patients with acute focal bacterial nephritis are: (1) a poorly marginated and relatively sonolucent ovoid mass disrupting the corticomedullary definition and producing some low-level echoes on ultrasound examination; (2) a solid-appearing mass on excretory urography, CT, or angiography; and (3) abnormal uptake of gallium at the location of the mass, which may be associated with increased activity elsewhere in the same or opposite kidney.[42] A fluid-filled mass or a fluid debris level typical of a frank renal abscess is not found in acute focal bacterial nephritis on ultrasonography.[42,43] In the pediatric population if there is evidence of nephromegaly (more than 3 standard deviations greater than the mean for age) on ultrasound or a focal mass is present, the probability of acute focal bacterial nephritis is high in the appropriate clinical setting.[57] On a non–contrast-enhanced CT, the lesion of acute focal bacterial nephritis is typically imperceptible. There are three characteristics seen with contrast-enhanced CT: lobar distribution of inflammatory areas, poorly defined wedge-shaped areas of diminished contrast enhancement without frank liquefaction, and masslike hypodense lesions in severe cases.[43,58] Renal abscesses, however, are usually round, have liquid centers, and are visible with and without contrast enhancement. The lack of a defined wall by ultrasound or CT in acute focal bacterial nephritis is an important factor distinguishing this entity from an abscess.[28] On angiography, narrowing and obstruction of veins within the mass, along with only minor arteriographic abnormalities, are characteristic of acute focal bacterial nephritis.[42] Focal abnormalities in the kidney on gallium images may be seen in some neoplasms and renal abscesses as well as acute focal bacterial nephritis. However, the diagnosis of acute focal bacterial nephritis is strongly suggested whenever the abnormalities are larger on the gallium image than on the urogram or sonogram or whenever bilateral abnormalities are seen on gallium images that correlate with a focal mass on the urogram or sonogram.[42] The distinction between acute focal bacterial nephritis, renal abscess, and tumor can be made also by needle aspiration. However, in most patients, a combination of imaging techniques is sufficient to diagnose acute focal bacterial nephritis and permit conservative medical therapy without confirmation by needle biopsy or surgery.[42,59] In this context, serial uroradiologic studies should be performed in 4 to 6 weeks, to follow the process to resolution.[26,51,60,61]

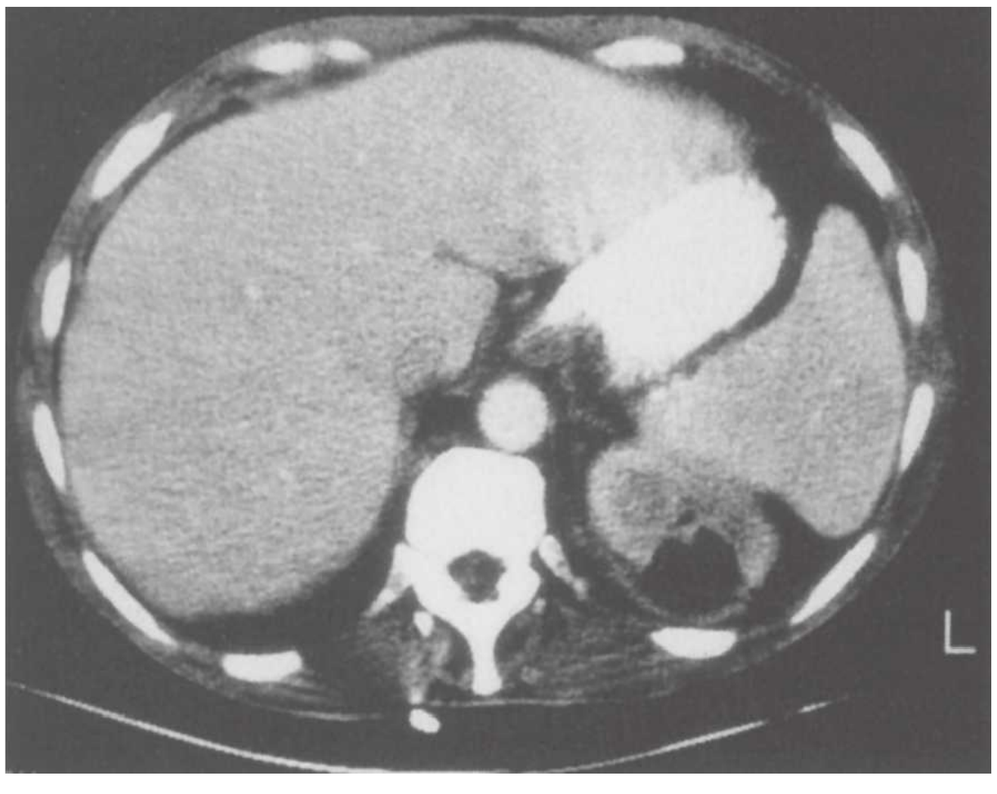
The urographic findings in patients with acute multifocal bacterial nephritis typically show severe impairment of

excretion of contrast material on the affected side, with renal enlargement, a diminished nephrogram, and a delayed pyelogram.[43,62,63] Ultrasonography may demonstrate areas of decreased echogenicity throughout the affected kidney. Poorly defined wedge-shaped areas of decreased contrast enhancement similar to those described in patients with acute focal bacterial nephritis can be seen on contrast-enhanced CT, except that multiple renal lobes are involved[43,64] (Fig. 24.6). If angiography is performed, the number and caliber of interlobar arterial branches are diminished, and fine linear stripes of alternating density and lucency in the angiographic nephrogram are present throughout the kidney.[43] CT is more sensitive than ultrasonography for the detection of intrarenal bacterial infections and defining the extent of disease.[26,28,65]

The radiographic findings in patients with xanthogranulomatous pyelonephritis are varied and uncharacteristic. The xanthogranulomatous process may occur in a localized (unifocal) or diffuse (multifocal) form in either a previously normal kidney or one that is obstructed, contains a stone, or has an anomalous collecting system or calyceal diverticulum.



A



B

FIGURE 24.6 Computed tomography scans of a patient with bilateral intrarenal abscesses.

Perinephric extension of the xanthogranulomatous process produces obscure renal margins and ablation of the perinephric and paranephric fat.[47] Radiographically, xanthogranulomatous pyelonephritis appears as either localized or diffuse enlargement of one kidney with an indistinct renal outline. Urographically, the most frequent finding has been a stone-bearing (70%) and functionless (80%) kidney.[66] Calyceal deformity and irregularity (46%) may be present.[47,56] Neovascularity may be present on angiography, but most xanthogranulomatous renal masses are hypovascular or avascular, and the majority cannot be definitively distinguished from renal cell carcinoma.[47,67,68] There are no specific ultrasonographic findings that reliably distinguish renal tumors and abscesses from xanthogranulomatous pyelonephritis.[69] The sonographic features of xanthogranulomatous pyelonephritis include a diffusely enlarged kidney with multiple areas of increased anechoicity and a central echogenic focus with acoustic shadowing.[70] Although these findings are also seen in a hydronephrotic kidney, the presence of a central strongly echogenic focus suggests xanthogranulomatous pyelonephritis.[70,71] On CT, focal xanthogranulomatous pyelonephritis appears as low-density mass lesions, with wall enhancement surrounding dilated calyces, which may contain stones, or as a focal mass in one pole of a duplicated kidney.[72] In diffuse xanthogranulomatous pyelonephritis, CT demonstrates an enlarged kidney, often with central calcification in the renal pelvis without dilatation, and with multiple, rounded, low-density areas representing dilated calyces and abscess cavities. On enhanced scans, the walls of these cavities demonstrate a prominent blush because of increased vascularity within the granulation tissue and the compressed normal parenchyma.[66,72] Extension of the xanthogranulomatous process through the renal capsule, with involvement of the perirenal and pararenal spaces and the psoas muscle, when present, also can be observed on CT.[66,72] The diagnosis is suggested by CT findings in 44% of cases. This imaging study plays an important role in determining the extent of extrarenal disease and planning of operative treatment. Ultrasound examination is less specific than CT, and MRI generally offers no additional information over CT scans but may be useful in patients with renal insufficiency or allergy to iodinated contrast material.[28,73]

Treatment

In the past, surgical drainage, débridement, or nephrectomy was the accepted treatment for renal corticomedullary abscesses. Recent experience indicates that successful therapy of acute focal and multifocal bacterial nephritis with antimicrobial agents alone will produce a symptomatic response within 1 week in most patients and result in no sequelae.[29,34,41,43,49,50,74] Radiologic techniques should be used to document resolution of the infection[26]; nevertheless, the time at which the intrarenal infection is discovered and its degree of suppuration should guide its management. A well-established large abscess cavity may be more difficult to eradicate with antibiotics alone than an earlier lesion in the preabscess state; however, a trial of intensive antibiotic treatment is appropriate for lesions localized to the renal parenchyma before determining the need

for operative drainage, particularly in a promptly diagnosed and otherwise healthy person. Intravenous fluids and parenteral antibiotics should be started as soon as the diagnosis is entertained. In patients with acute focal or multifocal bacterial nephritis, initial antibiotic selection (empiric therapy), before the results of urine cultures and sensitivities are available, should be aimed at the most common uropathic, enteric gram-negative aerobic bacilli (e.g., E. coli, Klebsiella, and Proteus spp.). Monotherapy with a third generation cephalosporin (e.g., cefotaxime, ceftriaxone, or ceftazidime), an extended-spectrum penicillin (e.g., piperacillin), or ciprofloxacin is acceptable empiric therapy.

Combined therapy with a β-lactam, such as ampicillin or cefazolin, with an aminoglycoside is no more successful than single-agent therapy in the treatment of acute focal or multifocal bacterial nephritis.[41] Empiric therapy should be modified to the most effective single agent based on the results of the antibiotic sensitivities of the organisms recovered from cultures of urine, blood, or both. Although the duration of treatment has not been defined, current recommendations are to continue parenteral antibiotics for at least 24 to 48 hours after the resolution of fever and clinical improvement are attained. Oral antibiotic therapy, based on the results of antimicrobial susceptibility tests, can then be continued for an additional 2 weeks. Patients with acute focal bacterial nephritis typically respond to medical therapy alone (at least 14 days of an appropriate antimicrobial agent), and follow-up studies have shown resolution of the intrarenal lesion without the need for surgical drainage.[43,51,59] Although many patients with acute multifocal bacterial nephritis slowly improve with antibiotic therapy alone, some may require surgical intervention.

Patients who are likely to fail appropriate antibiotic therapy alone are those who have radiologic evidence of a large intrarenal abscess, significant obstructive uropathy, severe vesicoureteral reflux (primarily in children with gram-negative bacillary multifocal bacterial nephritis) with extensive parenchymal involvement, patients with diabetes mellitus with gas-forming infections, and patients of advanced age or with urosepsis.[14,43,48–50,75] In general, surgical intervention is indicated in the patient who has radiologic evidence of a large intrarenal abscess and persistent fever, with an absence of clinical response after 5 to 7 days of adequate antibiotic therapy. In patients requiring drainage, percutaneous aspiration of the abscess combined with systemic antibiotic therapy has been successful.[50,76,77] If a significant obstructive uropathy is present, prompt drainage, usually by percutaneous nephrostomy, is necessary with correction of the lesion, if possible, when the patient is afebrile and stable.[43] If surgical intervention is necessary, the abscess should be incised and drained, and nephrectomy should be reserved for diffusely damaged kidneys or for patients of advanced age who are septic and require urgent surgical intervention for survival.[48] Also, all children with renal parenchymal infection caused by gram-negative bacilli should undergo voiding cystourethrography to look for lower urinary tract abnormalities.[14] Thus, current clinical experience indicates that many patients with acute multifocal bacterial nephritis may not require surgery as they did in the past but may be treated successfully with antibiotics alone. The decision to drain the abscess mechanically should be based on the radiologic findings and response of the patient to initial drug therapy.

In contrast, patients with xanthogranulomatous pyelonephritis generally are not cured by antibiotic therapy alone. These patients often require surgical removal of the xanthogranulomatous process to cure this disease; however, there have been several case reports of successful treatment with antibiotics without surgical intervention.[53] The diagnosis of xanthogranulomatous pyelonephritis is not commonly made preoperatively; however, once the involved tissue is resected, the xanthogranulomatous process ceases and does not seem to recur. The prognosis in patients who have an otherwise normal urinary tract is excellent. Total nephrectomy is the usual procedure, but Malek and Elder[47] suggested that partial nephrectomy for selected localized disease, such as cases confined to the kidney (stage I) or involving the perinephric fat (stage II), may be sufficient. Partial nephrectomy is especially suitable in children, who usually present with localized disease.[47] In adults, the disease is frequently diffuse throughout most, or all, of the kidney and in advanced stages extend to the perinephric fat (stage II) and beyond (stage III). Although removal of the kidney and perirenal fat is preferred, it may be technically difficult and complicated by fistulization of adjacent bowel. Open surgical nephrectomy is preferred over laparoscopic nephrectomy as it is quicker, leads to less complications, and results in a similar postoperative course.[78] Even though xanthogranulomatous pyelonephritis does not recur following successful surgery, bacteriuria may continue in some patients and will require appropriate treatment.[47,56]

Infected Renal Cyst

Spontaneous infection of preexisting solitary renal cysts has been described.[43,79,80] In contrast, patients with autosomal dominant polycystic renal disease may have one or more cysts that become infected.[81] The most common etiologic agents are gram-negative uropathogens (especially E. coli) that are thought to infect the cysts as a consequence of bacteriuria and ascending infection.[82,83] Infection may also occur as a result of iatrogenic cyst instrumentation.[43] The clinical features of infected cysts are similar to those of an acute renal abscess and include nausea, chills, fever, flank or back pain, and dysuria. The diagnosis is made radiographically. Ultrasonography or CT may demonstrate a solitary renal mass that is compatible with an uncomplicated simple renal cyst or multiple lesions characteristic of polycystic renal disease. Gallium or indium imaging, gadolinium-enhanced MRI, or positron emission tomography may help to identify the infected cyst (or cysts) in patients with polycystic kidneys.[83,84] A definitive diagnosis can be made by ultrasound or CT-guided percutaneous cyst puncture with culture.

Effective treatment for infected solitary cysts includes percutaneous drainage combined with 2 weeks of appropriate antimicrobial therapy.[41] Fluoroquinolones and third generation cephaloporins have better penetration into the intrarenal cyst

compared to β-lactams.[83] Surgical drainage is rarely required. In contrast, the therapy of infected cysts in patients with polycystic renal disease is more difficult and not well defined. A conservative approach with long-term (6 to 8 weeks) oral antibiotic treatment directed against the most likely pathogens or those isolated from urine or blood cultures is successful in some cases.[82] In general, surgical drainage is generally avoided because of the difficulty in identifying which cyst is infected.

PERINEPHRIC ABSCESS

Etiology

S. aureus, E. coli, and Proteus spp. are the most common causes of perinephric abscesses. Other, less common causes include Klebsiella spp., Enterobacter spp., Pseudomonas spp., Serratia spp., and Citrobacter spp. Occasionally enterococci and streptococci are implicated, including two cases of S. pneumoniae[85,86] and one case of group B streptococcus in a diabetic patient.[87] Perinephric abscesses also may be caused by various anaerobic bacteria, including gram-negative bacilli and anaerobic cocci, Clostridium spp., and Actinomyces spp.[88] These anaerobic bacteria may be the pathogens in patients with abscess cultures reported to be sterile.[29,50] Mycobacterium tuberculosis is also an important cause of perinephric abscess, as are certain fungi, particularly Candida spp. Nocardia has been reported as a cause of perinephric abscess in immunocompromised patients.[89] More than one microorganism has been simultaneously recovered from perinephric abscesses in as many as 25% of patients.[48,50,90,91] Although bacteria isolated from the urine frequently correlate with those isolated from the abscess, in some patients, urine cultures are positive for microorganisms different from those subsequently isolated from the abscess material.[50,90,92] Blood cultures may be positive (20% to 40%) in some patients.[90]

Pathogenesis

A perinephric abscess is a collection of purulent material in the space between the capsule of the kidney and Gerota's fascia (Fig. 24.7). The abscess usually is confined to this space but may extend beyond Gerota's fascia into the pararenal space or even into the flank muscles or psoas muscle.[93] It may present as a draining flank abscess through Petit's triangle or as an abscess in the groin or paravesical area by extending caudally between the diverging layers of Gerota's fascia. It rarely perforates into the peritoneal cavity or ruptures into the colon. Cephalad extension may result in a subphrenic abscess, penetration of the diaphragm and empyema, lung abscess, or formation of a nephrobronchial fistula.[2,50,76,91] The most frequent initiating event is the direct extension or rupture of an abscess within the renal parenchyma into the perinephric space.[10,13] This is the most common mechanism responsible for staphylococcal perinephric abscesses that occur when a renal cortical abscess ruptures into the perinephric space.[9] Other causes include hematogenous or regional lymphatic seeding of the perinephric space, usually from sites of skin infection.[50,90] Rarely, spread of

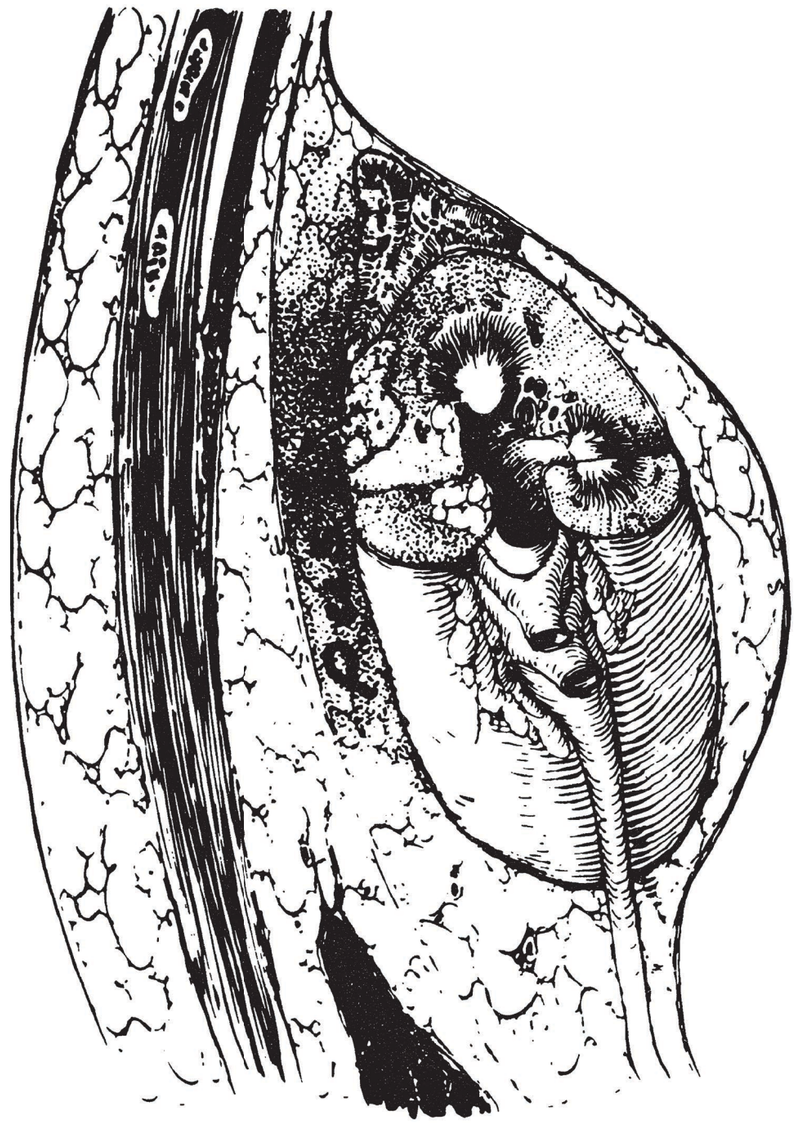


FIGURE 24.7 Diagram of the pathogenesis of a perinephric abscess.

infection from inflammatory lesions of the liver, gallbladder, pancreas, pleura, prostate, or female reproductive organs as well as diverticulitis, appendicitis, perforated carcinoma of the colon, and osteomyelitis of adjacent ribs or vertebrae has been implicated in the pathogenesis of perinephric abscess.[29,50,94–96] The majority of patients with perinephric abscesses have some form of obstruction to urinary outflow. Specific predisposing factors include renal or ureteral calculi, ureteral stricture, neurogenic bladder, vesicoureteral reflux, mechanical bladder outlet obstruction, neoplasm, renal papillary necrosis, polycystic kidney disease, genitourinary tuberculosis, immunosuppresion including renal transplantation, trauma (including urinary tract instrumentation, renal biopsy, or aspiration), and the associated conditions of diabetes mellitus (a major contributing factor), glucocorticoid therapy, and injection drug use.[43,50,81,85,97]

Clinical Features

The onset of perinephric abscess is characteristically insidious. Patients are often ill for 1 to 3 weeks before they seek medical care, and early recognition of this condition is difficult. The most common symptoms are fever, which occurs in almost all patients; unilateral flank pain, in 70% to 80%; and chills and dysuria, in 40% of patients.[50,90,98,99] Weight loss, nausea, and vomiting are less common. Diarrhea is very rarely a symptom associated with perinephric abscess.[100] Interestingly, in renal transplant recipients, the aforementioned symptoms are not masked despite immunosuppression.[101] On physical examination, flank and costovertebral angle tenderness are the most common findings, but abdominal tenderness may be present in about 60% of cases. In some patients, the pain may be

referred to the corresponding hip, thigh, or knee. Scoliosis, with splinting on the affected side, pain on bending toward the contralateral side and during either active flexion of the ipsilateral thigh against pressure, or extension of the thigh while walking may be present in some patients. A flank or abdominal mass is present in less than half the patients.[29,43,50,90] Routine laboratory studies are nonspecific. The peripheral white blood cell count is usually modestly elevated with associated neutrophilia. Anemia and azotemia may be present in 40% and 25% of patients, respectively.[98] Pyuria and proteinuria are common; however, hematuria is present in only 10% of patients and the urinalysis may be entirely normal in 25% to 30% of cases. Two thirds of patients have positive urine cultures, with more than 10^5 bacteria per mL of urine. Approximately 40% of patients are bacteremic.[29,43,50,90]

Diagnosis

A perinephric abscess must be differentiated from other infections of the urinary tract and from other occult abscesses. Patients with this disease may present with fever of undetermined origin or with unexplained peritonitis, empyema, or pelvic abscess resulting from extension of the perinephric abscess. The diagnosis should also be considered in patients with urinary tract infection who do not respond promptly to antibiotics and have an abnormality of the urinary tract or diabetes. Prompt diagnosis of this disease is made in less than one third of patients at the time of admission.[50,90] Up to 25% to 30% of patients are diagnosed only at autopsy.[50,90] This disease should be considered in the differential diagnosis of patients who present with the signs and symptoms described previously. Radiologic examinations with ultrasonography and CT are essential diagnostic aids in most cases. Roentgenogram of the chest may be normal or may show a pleural effusion, elevated hemidiaphragm either with or without decreased diaphragmatic excursion, or a lower lobe infiltrate.[50,90] Supine abdominal roentgenogram may demonstrate an upper quadrant mass, obliteration of the renal outline, vertebral scoliosis, or absent psoas shadows. However, obliteration of the psoas margin is not a reliable diagnostic sign for perinephric abscess.[9,13] Although uncommon, the presence of extraluminal, retroperitoneal gas bubbles in the area of the kidney suggests a perinephric abscess produced by gas-forming organisms. This condition, termed emphysematous pyelonephritis, occurs primarily in patients with diabetes mellitus, with or without urinary obstruction, and more rarely in nondiabetic patients who have urinary obstruction.[75,102,103] On excretory urography, important radiographic findings of perirenal abscesses include decreased renal mobility with respiration or position, absent or diminished renal function, caliectasis and other calyceal abnormalities, and displacement (usually medially and upward) of the kidney or ureter. Extrarenal extravasation of contrast material, although uncommon, is virtually diagnostic of perirenal abscess.[50,93] Also, fistula formation occurs occasionally between the perirenal space and other structures, such as the colon. Retrograde pyelography is usually not necessary, but it is occasionally helpful in identifying obstructive lesions distal to the renal pelvis. Ultrasonography may demonstrate an intrinsic mass in addition to the more characteristic findings of a perinephric fluid collection, along with displacement of the kidney, loss of a distinct renal outline, and renal fixation. These findings indicate extension of the inflammatory process to the perinephric space.[9,13] The sonographic appearance may vary from a nearly anechoic mass, displacing the kidney, to an echogenic collection that merges with normally echogenic fat within Gerota's fascia.[43] Ultrasound also may be useful to determine the extent of the abscess (Fig. 24.8)

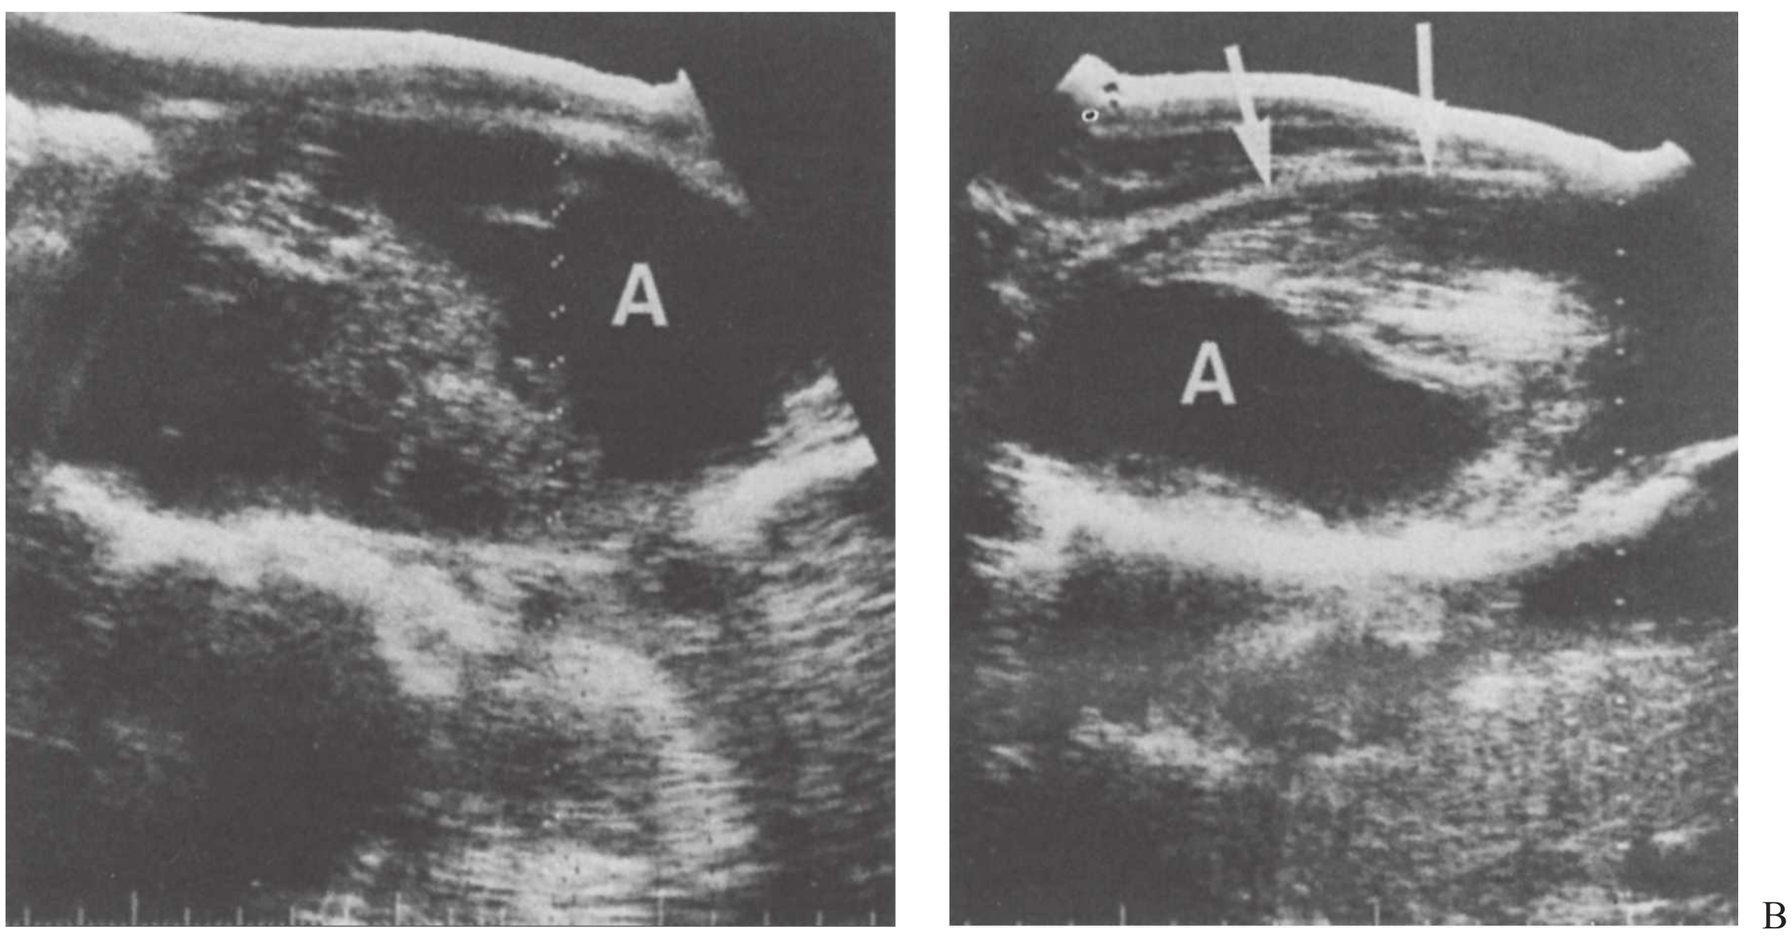

FIGURE 24.8 **A:** Longitudinal ultrasonogram down the right paravertebral region, demonstrating a huge complex mass with a large irregular fluid component, labeled *A*. **B:** Marked enlargement of the psoas major muscle *(arrows)* with a large contained fluid collection, labeled *A*. and detect associated obstruction of the collecting system. However, ultrasound may be falsely negative in 36% of cases as compared to CT.[98] Findings on CT include thickening of the renal fascia and perirenal fluid collection. In most cases, pus can be differentiated from other causes of perirenal fluid collections such as urine, blood, lymph, exudates, and transudates.[36] CT also provides the most precise anatomic information and can demonstrate the extent and route of the abscess beyond the renal capsule (e.g., extension to the flank or the psoas muscle) (Fig. 24.9). This detail is important in planning surgical drainage of the abscess. MRI has been used in conjunction with ultrasonography to detect perinephric abscess during pregnancy as CT is contraindicated.[104] Other modalities not used as frequently are ^{67}Ga or indium-111 (^{111}In) imaging and arteriography. Radionuclide imaging with ^{67}Ga or ^{111}In may be used occasionally to confirm the presence of renal or perirenal inflammation or evaluate renal function. Gallium or indium imaging may provide the first evidence of a perirenal abscess in patients with suspected infections but without localizing signs or symptoms. However, ^{67}Ga is not sufficiently definitive to exclude renal carcinoma, pyelonephritis, intrarenal abscess, or ureteral obstruction.[9,30,34] Thus a subtraction technique using ^{67}Ga citrate and ^{99m}Tc glucoheptonate has been used to define the extent of perinephric involvement as well as to eliminate any false-positive scans seen with gallium alone.[9,34] On angiography, characteristic findings of perinephric abscesses include an increase in number and size of the perforating arteries extending from the kidney into the abscess, stretching, and prominent tortuous capsular arteries around the abscess and a contrast blush.[7,9,21,22] Perirenal and renal abscesses can be arteriographically distinguished from tumors, as described previously; however, angiography is not necessary in most patients with perinephric abscess because of the availability of the newer, noninvasive imaging modalities.

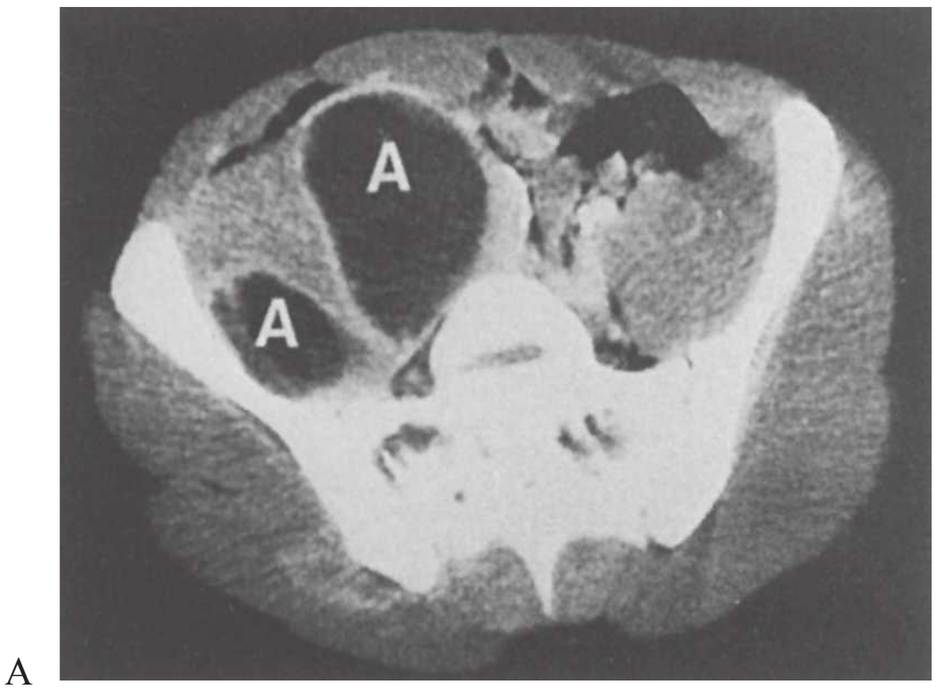

FIGURE 24.9 **A:** Computed tomography (CT) scan through midabdomen, demonstrating marked enlargement of the right psoas major muscle with a bilobed fluid-filled cavity, labeled *A* (from the same patient as in Fig. 24.8). **B:** Transverse CT scan through the level of the femoral head, showing the inferior extent of the abscess *(arrow)* pointing below the inguinal ligament. Treatment

Early surgical or percutaneous (under imaging guidance) drainage of the perinephric abscess is imperative.[43,50,90,105] Antibiotic therapy alone is inadequate and should be used as adjunctive treatment. In some patients, the perinephric abscess has been drained by percutaneous tube placement, aspiration of pus, and antibiotic irrigation prior to definitive surgery (nephrectomy), which is frequently necessary.[46,50] In others, acute nephrectomy is performed at the time of initial surgical drainage. There are rare case reports of immunocompetent patients with small (≤3.5 cm) abscesses who were successfully treated with prolonged courses of intravenous antibiotics without drainage[36,77]; however, immunocompromised patients or those with abscesses larger than 2 cm did poorly and had high mortality rates when treated with antibiotics alone. CT should be used to follow the response to treatment.

Initial antimicrobial therapy should be aimed at the most common uropathic gram-negative bacilli as well as against staphylococci, because some perinephric abscesses are a consequence of staphylococcal renal carbuncles. An aminoglycoside (gentamicin or tobramycin) in a dose of 1 to 1.5 mg per kg of body weight every 8 to 12 hours in patients with normal renal function should be combined with an antistaphylococcal β-lactam, oxacillin, nafcillin, or cefazolin, intravenously. The dose of gentamicin and tobramycin must be adjusted for those patients with compromised renal function. If suspicion of MRSA is high, vancomycin can be given empirically instead of a β-lactam. If an extended spectrum β-lactamase producing gram-negative organism is suspected, a carbapenem (e.g., doripenem, meropenem, and ertapenem) should be used in place of a β-lactam. Therapy should be modified based on the results of the antibiotic sensitivities of the organisms recovered from cultures of the abscess material. An antipseudomonal β-lactam (e.g., ticarcillin, piperacillin, cefoperazone, or ceftazidime) or a quinolone (ciprofloxacin) should be added to the aminoglycoside if Pseudomonas aeruginosa is the cause of the infection, and clindamycin or metronidazole should

be added if anaerobic bacteria are involved. A combination of penicillin or ampicillin plus gentamicin is the treatment of choice in enterococcal infections. Isoniazid plus rifampin and ethambutol or streptomycin is necessary for abscesses caused by M. tuberculosis and azoles (fluconazole or voriconazole) for those caused by fungi.

The prognosis in patients with perinephric abscess is poor. Even though there have been major improvements in diagnostic technology, surgical therapy, and antimicrobial treatment, the mortality associated with perinephric abscess remains high and is in a range from 20% to more than 50%.[29,48,50,77] Prompt diagnosis of perinephric abscess, immediate surgical or percutaneous drainage, appropriate antimicrobial therapy, followed by definitive surgical therapy for cases with poor response may be effective in reducing this high mortality rate.

CHAPTER

25 Complicated Urinary Tract Infections

Dennis J. Mikolich • Stephen H. Zinner

Complicated infections of the genitourinary (GU) tract refer to those infections that occur in the presence of anatomic or functional abnormalities in the kidney, bladder, or collecting systems (including vesicoureteral reflux and neurogenic bladders in patients with spinal cord injury); obstruction to normal urine flow (including renal, ureteric and bladder calculi, and prostatic hypertrophy); urinary tract catheterization or instrumentation; cystic renal disease; specific diseases such as diabetes mellitus; and abnormalities in host defense mechanisms and those infections that follow surgery or renal transplantation (Table 25.1). In addition, infections that are caused by organisms that resist antimicrobial therapy (such as multidrug-resistant gram-negative rods and enterococci) or that might otherwise be difficult to eradicate may be considered in this category. Aerobic or anaerobic bacteria, mycobacteria, fungi, parasites, and even viruses may cause complicated infections.

Other conditions associated with complicated urinary infections include prostatic, kidney, or perinephric abscesses; pyonephrosis; emphysematous pyelonephritis and cystitis; malakoplakia and xanthogranulomatous pyelonephritis; intramural vesicle abscesses; pyelonephritis with bacteremia and sepsis; and tuberculosis. Some of these conditions are discussed in other chapters. Complicated urinary infections occur either in the upper or lower urinary tract and may be acute or chronic. Not included in this category are asymptomatic bacteriuria, urethritis, acute cystitis, acute pyelonephritis, or recurrent upper or lower urinary tract infections (UTIs) occurring in the presence of a normal urinary system.

ANATOMIC OR STRUCTURAL RISK FACTORS

Obstructive Uropathy

Obstructive uropathy includes: calculi at any level of the urinary tract; prostatic hypertrophy; cancer of the prostate, bladder, or uterus; external compression by uterine or other tumors; neurogenic bladder; and congenital abnormalities. Any of these conditions may be associated with a complicated UTI. An obstruction above the bladder can lead to renal pelvic dilatation and hydronephrosis with subsequent pressure atrophy of renal cortical tissue. When an infection does occur in the setting of partial or complete obstruction, the clearance of an infection is more difficult because drainage may be limited, antibiotic penetration might decrease, and host responses may be impaired.

Obstruction of the urinary tract may be acute or chronic, unilateral or bilateral, and complete or incomplete. Acute obstruction of the upper urinary tract may be associated with retroperitoneal or flank pain, especially if calculi are present. Obstruction at the bladder level increases the risk of infection by decreasing the effect of micturition on reducing bacterial inocula as well as allowing for the multiplication of bacteria to the degree that mucosal antibacterial and other host factors are overwhelmed or inactivated. An obstruction at higher levels of the urinary tract may predispose the patient to infection because dilatation and pressure necrosis may decrease defense mechanisms in the kidney and may allow disseminating hematogenous bacteria to alight and form a nidus of infection in the renal cortex or medulla. Also, once the normal architecture of the urinary tract has been damaged, whether as a result of reflux or obstruction, bacteria that lack the virulence factors necessary to cause renal infection in the absence of structural lesions may be responsible for serious upper tract infection once introduced into the kidney.

The treatment of urinary infections in the face of obstructive uropathy or stone disease usually requires antibiotic therapy for a longer duration than that for uncomplicated infections; treatment may be required for up to 6 weeks. Obviously, correction of the obstruction and removal of calculi are important adjunctive measures. In general, a 6-week course of a bactericidal antibiotic that achieves adequate concentration in renal tissue and bladder urine is recommended. Depending on the organism and susceptibility testing results, intravenous or oral therapy can be used; for example, a fluoroquinolone or a β-lactam antibiotic. Susceptibility testing is particularly important given the increased frequency of antibiotic-resistant bacteria in complicated urinary tract infections.[1] Special consideration is needed in the

25.1 Complicated Infections of the Urinary Tract

Anatomic or Structural Risk Factors

- Obstructive uropathy—stones, strictures, tumors
  - Prostate associated (see Chapter 23)
- Instrumentation—catheter associated and nosocomial
- Renal cystic disease
- Ureteral stents and surgical urinary diversions
  - Ileal loop constructions
- Other anatomic risk factors
  - Vesicoureteral reflux
  - Urachal remnants

Functional Risk Factors

- Diabetes mellitus
- Renal transplantation
- Spinal cord injury and neurologic dysfunction
- Neutropenia
- HIV

Miscellaneous Complicated Infections

- Pyonephrosis
- Emphysematous pyelonephritis and cystitis
- Malakoplakia and xanthogranulomatous pyelonephritis
- Intramural vesicle abscess
- Urosepsis
- Tuberculosis (see Chapter 27)
- Infections caused by atypical or resistant organisms
  (e.g., vancomycin-resistant enterococci, ESBL-producing gram-negative rods, anaerobes)

ESBL, extended spectrum beta-lactamase.

face of staghorn calculi, which often form in the presence of urease-producing organisms such as Proteus spp. Once the organism has been eradicated with a long course of antibiotics, "prophylactic" or "suppressive" therapy can be given with low-dose trimethoprim-sulfamethoxazole, daily or every other day, or with a combination of trimethoprim and a methenamine compound. Nephrolithiasis is considered in more detail in Chapter 20.

Catheterization and Instrumentation

The distal third of the urethra is normally colonized with perineal and skin flora. Instrumentation for any reason may introduce these organisms into the bladder. In the presence of an indwelling catheter, bacteria can ascend from the periurethral area along the mucous sheath that develops between the urethral mucosa and the latex rubber catheter.[2] Although several techniques have been introduced to prevent urinary infection in chronically catheterized patients, such as closed sterile drainage, continuous irrigation through a three-way catheter with antibiotic or acetic acid, and systemic antibiotic prophylaxis, all patients with prolonged urinary catheter drainage ultimately become colonized with high counts of bacteria (from 2 to about 21 days).

Catheter-associated bacteriuria and catheter-associated urinary tract infections (CA-UTIs) are the most common infection acquired in hospitals and long-term care facilities (LTCF);[3] elderly patients are at greatest risk. Over 40% of nosocomial infections originate in the urinary tract and Escherichia coli is responsible for most of these infections, followed by Enterococcus spp., Pseudomonas aeruginosa, and Candida spp.[3–5] Bacteremia, an important sequela of complicated UTIs, develops in about 4% of patients with indwelling bladder catheter-associated urinary infections, and case-fatality rates of 13% to 30% have been reported for these bacteremic nosocomial urinary infections.[3,5–6]

Catheter-associated nosocomial UTIs (CA-UTI) have been described in a study of 1,497 patients. These infections were more frequent in women (23.2%) than men (8.9%). They were unimicrobial in 94% and polymicrobial (primarily with enterococci and gram-negative bacilli) in 6%. The distribution of single isolates in these patients included gram-negative bacilli in 34%, enterococci or staphylococci in 27%, and Candida spp. in 27%. Patients with CA-UTIs only rarely have symptoms (<10%) in the face of infections and pyuria, and they may not have peripheral leukocytosis.[7,8] Catheters left in place without bona fide medical necessity often contribute to nosocomial infections and are accompanied by an increase in associated antibiotic costs.[9]

Environmental factors may relate to the nosocomial acquisition of bacteriuria in catheterized patients. Prevalent bacteria in the hospital colonize patients, or the patient's endogenous flora may enter the urinary collecting system or drainage bag. Within 24 to 48 hours they may be found in the bladder, and they increase to high colony counts over the subsequent 48 hours.[10,11] Bacteria may attach to the luminal surface of the catheter in association with the production of a mucoid biofilm, and this may predispose the patient to urinary infection or catheter blockage and obstruction.[7,10]

Urea splitting bacteria may lead to mucosal encrustations and encrusted cystitis and pyelitis. Corynebacterium group D_2 also have been implicated.[12] There is often a history of a prior urologic procedure or chronic illness, including immune compromise or renal transplantation. Patients may describe symptoms of cystitis, dysuria, gross hematuria, passage of encrusted debris, often with complaints of an ammonia odor to the urine. Failure to diagnose this condition can lead to renal impairment or ureteric obstruction and loss of renal graft as a result of infection, renal abscess, or obstructive uropathy. Treatment consists of antibiotics. The glycopeptides vancomycin and teicoplanin have in vitro activity against Corynebacterium group D_2, which are frequently resistant to fluoroquinolone antibiotics (>50%).

Additional treatment includes acidification of urine as well as chemolysis and the removal of infected calcified plaques that contain the organisms.[12]

Some caution is warranted in interpreting the results of cultures of material obtained from urinary collection devices. Several populations of bacteria may grow within the catheter and include planktonic bacteria in the urine and surface bacteria associated with the bacterial biofilm.[13] Bacteria may be cultured from catheter lumen encrustations when bladder urine might be sterile.[14] Because bladder urine is normally sterile, Garibaldi and associates[15] suggested that the presence of 100 or more organisms per milliliter should be considered as evidence of a positive urine culture in a catheterized patient. These authors demonstrated that breaks in the catheter-collecting system junction were associated with an early acquisition of bacteriuria. Current guidelines from the Infectious Diseases Society of America (IDSA) suggest that infection is likely in the presence of compatible signs and symptoms and an indwelling catheter if the bacterial counts of one or more organisms are equal to or greater than 10^3 CFU per milliliter.[3]

Condom catheters are the usual alternatives to indwelling bladder catheters in incontinent male patients without obstructive uropathy. Although associated with fewer infectious complications, at least one outbreak implicated these devices in 64 geriatric patients, 40 (63%) of whom had asymptomatic infections, frequently with mechanical obstruction of urine flow including kinking of the outlet, or blockage of flow by adhesive devices with associated penile cyanosis and ulceration. These problems may lead to urinary stasis, bacteriuria, and bladder wall distention, all of which may predispose a patient to complicated urinary infections.[16]

Treatment of catheter-associated urinary infections depends on the clinical setting. In general, asymptomatic bacteriuria in catheterized patients is not treated. In patients with catheters in place for the long term, there is some risk of dissemination of bladder bacteriuria to the blood during manipulation of the urinary tract as during catheter changes (generally done to minimize concretions and obstruction). Antimicrobial agents have not been shown to prevent catheter associated UTIs in persons with long-term indwelling urethral catheters.[3] Preventive strategies that avoid antibiotics are needed for these patients. We occasionally advocate treating the colonizing bacteria 8 to 24 hours prior to the catheter change, with a single dose of a bactericidal antibiotic based on susceptibility testing of the organisms (e.g., a quinolone or an aminoglycoside). This topic is extensively reviewed in the new IDSA guidelines,[3] and they do not support antibiotics at catheter replacement.

Bacteriuria

Interventional attempts to decrease the incidence of nosocomial UTIs using a silver-alloy, hydrogel-coated latex urinary catheter have been compared with standard silicone-coated latex catheters.[17] In older studies, silver-coated catheters significantly reduced the rates of bacteriuria in male surgical patients not receiving antibiotics.[18] In the more recent study,[17] silver-coated catheters were associated with a 32% decrease in the infection risk in male patients. Infection rates in females were similar in both catheter groups. In addition to a decrease in nosocomial infection rates, significant savings on hospitalization and other infection-related costs were described. Another study estimated that economic consequences of nosocomial symptomatic UTIs can reach over US$650 and catheter-related bacteriuria over US$2,800 per incident.[19] A study by Rupp et al.[20] demonstrated additional cost savings with the silver-alloy hydrogen-coated urinary catheters and also showed a decline in nosocomial UTIs. No evidence of silver-resistant urinary pathogens was found.

Symptomatic urinary infections or urosepsis in the presence of an indwelling catheter is best treated with rapidly bactericidal antibiotics such as an aminoglycoside, a fluoroquinolone, or a β-lactam-aminoglycoside combination based on antimicrobial susceptibility testing.[1] Bacteremia is usually easily cleared, but eradication of the urinary infecting organism may be difficult in the continued presence of the catheter. Guidelines for the prevention and management of catheter-related urinary infections have been updated recently.[3]

Renal Cysts (Including Polycystic Renal Disease)

Complicated infections within or associated with isolated renal cysts, autosomal dominant polycystic renal disease (ADPKD), or acquired renal cystic disease (three or more renal cysts or cystic involvement of >25% of renal mass in the absence of autosomal dominant polycystic kidney disease) remain important diagnostic and therapeutic challenges.[21]

Patients with polycystic kidney disease may develop typical infections of the urinary bladder and ascending pyelonephritis with renal parenchymal involvement as well as infection within the renal cysts themselves.[22] The presence of polycystic kidney disease is associated with a 50% to 70% lifetime risk of some form of UTI.[23] In an autopsy study of 23 patients with polycystic kidney disease, 13 (56%) had findings consistent with pyelonephritis.[24] It may be difficult to implicate infection as a cause of hematuria or flank pain in patients with cystic abnormalities of the kidney because these symptoms may be present in the absence of infection.[25] Also, pyuria (≥10 leukocytes/high-power field) may be present in more than 40% of patients with polycystic kidney disease, with or without other symptoms suggestive of urinary tract infection; however, infection is documented in only about 10% of these patients.[26] Findings suggestive of a UTI in the presence of cystic renal disease include positive blood cultures, leukocytosis, fever, and lower GU tract symptoms such as dysuria. Negative urine cultures do not exclude infection of a renal cyst.

In a classic review of renal infections in patients with polycystic kidney disease, Sklar and associates[25] described

four types of infections according to anatomic involvement: (1) localized infected cyst (pyocyst), (2) pyonephrosis (intrarenal abscess associated with ureteral obstruction), (3) acute bacterial interstitial nephritis, and (4) perinephric abscess. Clinical findings may vary with the anatomic location of bacterial infections in these patients.

The diagnosis of complicated UTIs in patients with renal cystic disease is usually based on the results of clinical examination, laboratory testing, and diagnostic imaging. Radiologic evaluation with plain radiography, ultrasound, computed tomography (CT), and gallium imaging has been used to determine the presence and location of infection.[25] Gallium imaging may show uptake within the kidney, but it does not provide specific information to determine whether an abscess or an infected cyst is present. CT may be necessary to define pyocysts but CT scans are not optimal in distinguishing infected from noninfected cysts. Plain radiography may be useful if calculi are contributing to the clinical presentation. Renal ultrasonography also may identify calculi and can differentiate hydronephrosis from pyonephrosis and perinephric abscess. Recent studies suggest that positron emission tomography (PET) scanning and diffusion-weighted magnetic resonance imaging (MRI) might be useful in differentiating infected from noninfected cysts.[21,27] The percutaneous drainage of infected cysts in adult polycystic kidney disease has been described, as has laparoscopic cyst decortication using transperitoneal or retroperitoneal access.[28,29]

When cysts are infected, the Enterobacteriaceae (especially E. coli, Klebsiella spp., and Proteus spp.) and P. aeruginosa are most frequently implicated, with Staphylococcus aureus, Salmonella spp., Streptococcus spp., Corynebacterium spp., and others isolated less frequently.[21,30] A gas producing Clostridium perfringens infection in a renal cyst has been reported in a patient with ADPKD.[31]

Attempts should be made to isolate the infecting organism from the blood, urine, or cyst drainage. Appropriate treatment of infections in patients with polycystic kidney disease depends on the use of antibiotics that are able to concentrate within the infected cysts in addition to providing bactericidal activity against the infecting organism. Aminoglycosides, penicillins, and cephalosporins have relatively poor penetration into renal cysts, although pH, cyst physiology, and histology may affect the diffusion.[32] These antibiotics are relatively lipophobic and do not diffuse across cyst epithelial layers. Lipophilic agents such as clindamycin, chloramphenicol, macrolides, metronidazole, and trimethoprim are able to penetrate and accumulate within cysts, but they may or may not be active against the infecting organisms.[33] Fluoroquinolone antibiotics such as ciprofloxacin accumulate in cystic fluid, and they have been used successfully to treat infected renal cysts.[34,35] Because most of the causative organisms in infected cysts are facultative gram-negative bacilli with presumed fluoroquinolone susceptibility, these agents may still be quite useful clinically. Oral therapy is acceptable unless patients are septic. Infection in multiple cysts has been associated with sepsis and may require surgical intervention (nephrectomy) in rare cases.[36] Intravenous therapy should be used in bacteremic patients and in patients with decreased gastrointestinal (GI) quinolone absorption (e.g., antacid use). Antibiotic choice should be based on pharmacology and antibiotic susceptibility testing given the increased incidence of antibiotic resistance among gram-negative bacilli.[1]

Urinary Diversion

Ureteral Stents

Ureteral stents are placed in the treatment of hydronephrosis and obstruction caused by nephrolithiasis or malignancies, and as adjuncts to lithotripsy and open surgical procedures on the urinary tract. These stents are made of synthetic polymers and are either indwelling (self-retained in place between the renal pelvis and the bladder) or external.

Complications of indwelling ureteral stents include fever, infection, gross or microscopic hematuria, biofilm development and stent rupture, catheter migration, encrustation and bladder stone formation, and vesicoureteral reflux.[37] Infection in the presence of stent obstruction is problematic and difficult to eradicate. Also, it is often difficult to differentiate symptoms caused by an infection from those associated with the presence of a stent, which include hematuria, dysuria, increased urinary frequency, nocturia, and loin pain. Bacterial colonization of stents is common and Enterobacteriaceae, staphylococci, streptococci, and Pseudomonas aeruginosa are most frequent.[38,39]

Positive urine cultures with supporting clinical evidence for urinary infection should stimulate prompt antibiotic treatment to eradicate the infecting pathogens. Ureteral stents that develop biofilm formation and encrustations treated in vivo with oral ciprofloxacin or ofloxacin absorb these antibiotics.[40] Attempts to determine the presence of bacterial stent colonization are not reliable. Despite negative urine cultures, stents may be colonized with bacteria or fungi. Double-J ureteral stents can become colonized with gram-negative bacteria within 2 weeks of placement. Risk factors for stent colonization and urinary infection include diabetes mellitus, chronic renal failure, and pregnancy.[39] Silicone ureteral stents compared with low surface energy stents and hydrogel-coated stents demonstrated less encrustation in the presence of urease-producing bacteria (Proteus mirabilis). These results may indicate a reduced risk of encrustation and P. mirabilis infection with this stent,[41] but biofilm formation and subsequent colonization and encrustation remain important challenges.[37] Triclosan-eluting stents might result in a reduction in symptomatic infections and antibiotic use, but their ultimate role needs more study.[42] The presence of bacteremia and other signs of systemic infection suggest infection in the face of possible occlusion or obstruction of the stent, and stent removal is essential.

Surgical Urinary Diversion

Urinary diversions are performed to reroute urine in patients with obstructive uropathy from many causes—urinary bladder carcinoma or prostatic or gynecologic malignancies—and in

patients with congenital abnormalities, neurologic disorders, and pelvic trauma. Although intermittent catheterization may be preferable in some patients with neurogenic bladder dysfunction (e.g., multiple sclerosis, paraplegia), the creation of a ureteroileal conduit is a popular alternative to achieve control of urine excretion. This procedure does not carry the associated metabolic and electrolyte complications seen with jejunal bypass procedures. The surgical construction of an ileal loop conduit is associated with few serious complications and a low mortality rate.

Infectious complications have been well described in pediatric and adult populations, and an increased incidence of infections has been noted when the ureteric component becomes obstructed; pyelonephritis may result. Renal calculi are encountered frequently after urinary diversion and are often caused by urea-splitting organisms such as P. mirabilis and Proteus morganii. The urease produced by these organisms splits urea to form an alkaline pH, and the solubility product constant for calcium and phosphate is exceeded with the resultant precipitation of crystals, which form the nidus for renal stones.[43,44] Newer diversion procedures have been introduced (such as orthotopic urinary diversion or the neobladder) and also carry a risk of urinary infection.[45]

Recommendations for the management of these patients include aggressive control of the infection using bactericidal drugs active against urea-splitting organisms and acidification of the urine or avoidance of alkaline urinary pH, which encourages stone formation. The detection of urinary infection in these patients is difficult because the ileal loops are almost always colonized. Asymptomatic bacteriuria in the presence of a ureteroileal conduit should not be treated and prophylactic antibiotics are not recommended; this is less clear with orthotopic diversions.[45] However, positive urine cultures associated with physical findings of fever, chills, and flank pain should prompt the initiation of appropriate bactericidal antibiotics directed against gram-negative enteric rods including Proteus spp. Aminoglycosides, fluoroquinolones, third- or fourth-generation cephalosporins, carbapenems, and penicillin-β-lactamase inhibitor combinations (e.g., ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate) may be useful in this setting. When susceptibilities are known, specific therapy can be instituted. Septic complications often lead to failure of ileal diversions.[46]

Other Anatomic Risk Factors

Vesicoureteral Reflux

Conditions that allow for the reflux of urine from the bladder to the ureters and subsequently the kidneys are associated with increased frequencies of acute and chronic pyelonephritis. Various degrees of vesicoureteral reflux may occur congenitally, and once the bladder urine is infected, an upper tract infection is facilitated by the retrograde flow. In this setting, organisms that cause infection may be relatively free of virulence factors such as hemolysins, pili, and other adhesions (Chapter 55). Vesicoureteral reflux is associated with progressive renal scarring in children, even in the absence of infected urine, and these patients have an increased risk of renal damage and even renal failure when infection does occur.[47]

In a study of the etiologies of renal scarring, Huland and Busch[48] evaluated 213 patients with recurrent UTIs. Forty-two patients (26%) were found to have pyelonephritic scarring and renal insufficiency. Twenty-eight (67%) of these patients had urinary infections in the presence of vesicoureteral reflux. Young children under 4 years of age with intrarenal reflux have a well demonstrated risk of renal scarring.[47]

The approach to the treatment of patients with documented vesicoureteral reflux and recurrent UTIs includes antibiotic management plus surgical reconstruction (antireflux operation). Hendren[49] reported that more than 70% of very young children no longer had urinary infections after the surgical procedure. Long-term antibiotic chemoprophylaxis to prevent recurring UTIs has been studied in addition to surgical reconstruction. However, a recent review has questioned the use of this approach. A Cochrane Database review of several published randomized placebo-controlled trials showed a benefit of long-term antibiotics (10 to 52 weeks) to reduce the frequency of symptomatic UTI recurrences. However, this benefit was small and is associated with a risk of antimicrobial resistance.[50]

Two recent publications highlight ongoing controversies in the management of vesicoureteral reflux in children given newly developed endoscopic procedures in the face of the traditional approach of continuous antibiotic prophylaxis.[51,52] The optimal approach to the prevention of renal scarring remains under active investigation.[53]

Infected Urachal Remnants/Cysts

Acute and recurrent UTIs in the presence of abnormalities of urachal development with patent urachal remnants may be difficult to diagnose. Four primary developmental defects exist and present with varying signs and symptoms: patent urachus, umbilical urachal sinus, vesicourachal diverticulum, and urachal cyst.[54] Umbilical urachal sinuses and urachal cysts are only rarely infected and many urachal cysts are found incidentally during surgery or radiographic studies. Although most patent urachal remnants in adults are undetected and asymptomatic, umbilical urachal sinuses occasionally may be infected and present with purulent umbilical drainage or periumbilical erythema. These infections may present as infraumbilical abdominal wall abscesses or with contiguous involvement of the peritoneal cavity with an enteric fistula. Adult and pediatric cases have been reviewed.[54–56]

A vesicourachal diverticula may present with recurrent urinary infections, and urethral discharge, pneumaturia, and a suprapubic mass also may be found. Imaging studies may help make the diagnosis, but often cystoscopy may be necessary, especially if the diverticulum is associated with malignant transformation of the remnant. The organisms that infect the vesicourachal diverticula include E. coli and other Enterobacteriaceae, S. aureus, Enterococcus spp., and Actinomyces spp.[54,57]

FUNCTIONAL RISK FACTORS

Diabetes Mellitus

Many factors that predispose the diabetic patient to infections in the urinary tract have been described. Diabetes mellitus is putatively associated with an increased risk of these infections as a result of poorly controlled plasma glucose concentrations, which in turn may impair granulocyte function and cell-mediated immunity. Also, the neurologic dysfunction associated with diabetic neuropathy may result in a neurogenic bladder with incomplete bladder emptying, urinary stasis, and retention. The increased likelihood of urethral instrumentation may predispose these patients to infection, as may diabetic microangiopathy, which can contribute to local ischemia and impaired host defenses.[58,59]

Table 25.2 lists the manifestations of UTIs in patients with diabetes mellitus. Asymptomatic bacteriuria has been described as occurring two to four times more frequently in diabetic women[59,60] and as being more prevalent in diabetic women than men.[61] Although the treatment of asymptomatic bacteriuria in diabetic women reduced the duration of long-term bacteriuria, recolonization occurred after most treatment regimens.[62] A recent study in type 1 diabetic women suggested that sexual activity is more likely to be a risk factor for cystitis and pyelonephritis than diabetes control or complications.[63] In one recent small series, the distribution of responsible pathogens was similar among diabetic and nondiabetic patients, as was the frequency of infection with antibiotic-resistant organisms.[64] Bacteriuria in diabetic patients may be associated with a disproportionate risk of infection in the upper urinary tract and kidneys, and one study reported that upper tract infection could be documented in 79% of diabetic women with asymptomatic bacteriuria.[60] Other renal parenchymal complications of UTIs in diabetic patients include pyelonephritis, emphysematous pyelonephritis, papillary necrosis, and perinephric abscesses; these conditions should be considered in the evaluation of nonresponse to appropriate antibiotic therapy for urinary infections in diabetic patients.

Diabetic patients with urinary infections are more likely to be bacteremic or uroseptic than are nondiabetic patients.[65] These patients are also more likely to develop acute pyelonephritis at a fivefold greater risk than nondiabetic patients.[66] Diabetic patients with serious systemic signs of urinary infections should be studied with abdominal radiography to detect renal emphysematous pyelonephritis. Ultrasound or CT scans should be performed if an obstruction or an abscess is suspected. The urinary tract is implicated as the source of bacteremia more frequently in diabetic than in nondiabetic patients.[65] Postmenopausal women with diabetes are at a higher risk of a UTI and this is related to the duration of diabetes and insulin dependence.[67] Type 2 diabetic women with histories of UTIs (especially upper UTIs) are at increased risk for renal scarring and damage, as demonstrated by renal cortex scans.[68] Most of the bacteria responsible for urosepsis in diabetics are gram-negative rods, with E. coli and Klebsiella spp. accounting for about 70%. Notably, Klebsiella spp. are isolated frequently in diabetic patients with bacteremic urinary infections, and a large proportion of these patients have indwelling urinary bladder catheters.

In diabetic patients taking oral hypoglycemic agents, trimethoprim-sulfamethoxazole may lead to further hypoglycemia. No such potentiation is seen with most fluoroquinolone antibiotics, but hypoglycemia has been reported with gatifloxacin.[69] Invasive staphylococci also can cause complicated infections that might or might not result in abscess formation. Given the current high frequency of methicillin-resistant Staphylococcus aureus (MRSA), the treatment for staphylococcal urinary infections should begin with vancomycin, and can be modified based on susceptibility testing. Intravenous antibiotics should be administered for the first 2 to 4 days in complicated infections while monitoring for decreasing symptoms and fever. Oral step-down treatment should be continued for 14 days or longer in the presence of complicated infections.

Opal and associates[70] described 29 adult patients with Streptococcus agalactiae (group B streptococcus) bacteremia reviewed over 10 years at the Walter Reed Medical Center. Nine (31%) of these bacteremic patients had diabetes, and six of these had involvement of the urinary tract.

Renal papillary necrosis is a well-known complication of UTIs in diabetic patients. More than half of patients with renal papillary necrosis are diabetic, possibly reflecting microvascular insufficiency leading to ischemia and necrosis of the renal papilla.[71] These patients may present with flank pain, chills, and fever, and 15% may have renal insufficiency.[59]

25.2 Manifestations of Urinary Infections in Patients with Diabetes Mellitus

Clinical Manifestation	References
Asymptomatic bacteriuria	59,60,61,172
Acute papillary necrosis	59,71
Bacteremia	62, 65
Emphysematous cystitis	72,173,174
Emphysematous pyelonephritis	73–76,174,175
Fungal infections	176,177
Perinephric abscess	178,179
Xanthogranulomatous pyelonephritis	128,180

Emphysematous infectious processes may involve the bladder (emphysematous cystitis) or the kidney (emphysematous pyelonephritis) and are more frequent in diabetic patients. Emphysematous cystitis is usually caused by common facultative bacteria such as E. coli, although a few cases caused by Clostridium perfringens have been reported.[72] This condition is identified on plain films, urographic roentgenograms, or CT scans by finding gas in the bladder wall. Tissue ischemia or trauma is usually involved in the pathogenesis.

Emphysematous pyelonephritis usually results from an invasion of the renal parenchyma by gas-producing organisms. In patients with diabetes mellitus, high levels of blood glucose offer an enhanced environment for bacteria, and gas formation may result from the accompanying mixed acid fermentation of glucose by enteric organisms. In patients with diabetes, emphysematous pyelonephritis presents with fever, chills, flank pain and tenderness, and often the finding of a flank mass or a gas-containing renal mass on imaging studies.[73,74] E. coli is the most frequently isolated bacteria, followed by Proteus, Pseudomonas, and Klebsiella spp., with Clostridium spp. and Candida spp. reported occasionally. The diagnosis is established by the radiologic finding of gas in the renal parenchyma and bacteremia is usually present. Urine cultures are positive, and renal failure and hematuria may occur.[75,76]

Treatment includes intravenous fluid support, appropriate intravenous antibiotics, and percutaneous or renoureteral catheter drainage.[74–77] Hyperbaric oxygen might be useful as an adjunct to antibiotics.[78] Laparoscopic or open nephrectomy may be required if the response to medical therapy is delayed, especially in patients with extensive renal involvement and/or multiorgan system dysfunction. Emergency nephrectomy in these patients carries a high mortality and should be delayed for antibiotic treatment if possible.[74–77]

Renal Transplantation

UTIs may occur in patients following renal transplantation, with an incidence rate as high as 80% in some series.[79,80] Most of these infections occur within the first 6 months following transplantation and are usually caused by common Enterobacteriaceae, including E. coli, Klebsiella pneumoniae, or by P. aeruginosa, or fungi, especially Candida spp. and Aspergillus spp. Infections that occur 6 months or later after transplantation are less common and are more likely to involve the lower urinary tract, including the bladder. UTIs due to anaerobes, Ureaplasma urealyticum, and Gardnerella vaginalis have been reported posttransplant and the latter was implicated as a cause of a perinephric abscess in one patient.[81] Transmission of multidrug resistant (MDR) E. coli during kidney transplantation has been reported recently. A donor with MDR E. coli caused infection in two different kidney recipients. One developed sepsis and a complicated UTI, the other developed a perinephric abscess. This resulted in renal graft failure in both patients, but both survived.[82]

Risk factors for posttransplant UTIs include advanced age, pretransplant UTIs, female gender, diabetes mellitus, postoperative instrumentation and catheterization, cadaveric donors, intraoperative ureteral stents, immunosuppression, and acute graft rejection.[80,83]

In the early posttransplantation period, symptoms of a urinary infection may be mild or absent and fever may be absent; however, pyelonephritis and associated bacteremia are not uncommon.[79] Uremia and corticosteroid or other immunosuppressive therapy may contribute to this situation. Posttransplantation renal infection (especially with Enterococcus faecalis and occurring 6 months or more after a transplant) may lead to elevated serum creatinine levels and may result in a cascade of immunologic responses that ultimately precipitate allograft dysfunction or rejection.[80,83] In addition to common cytomegalovirus infections in transplant patients, infections with hepatitis C virus and BK polyomavirus have been described after renal transplantation, and viral-associated interstitial nephritis may occur. In one center, BK polyomavirus with an associated transplant dysfunction and a graft loss was reported in 2.5% of transplanted patients. Clinical features include ureteral obstruction, lymphocele, bacterial urinary infection, and hematuria. The diagnosis may be established with renal biopsy and electron microscopy of urine. Interruption of the progression may be achieved with immunosuppressive treatment.[84,85] Relapse rates may be high if posttransplantation urinary infections are not treated aggressively with antimicrobial agents.

Chronic urinary infections may occur in these patients and can be particularly problematic if associated with anatomic or structural defects in the ureter, bladder, or urethra as a result of the surgical procedure itself or secondary to a fistula formation. Vesicoureteral reflux may develop at the ureteral anastomotic site in up to 25% of patients and may lead to hydronephrosis and infection. Graft failure may also occur as a result of mesangiocapillary glomerulopathy.[86,87]

Prophylactic use of trimethoprim-sulfamethoxazole for 6 months following a renal transplantation may prevent complicated UTIs, including gram-negative rod bacteremia and sepsis[79,80,88,89] and may decrease the incidence of posttransplantation urinary infection to less than 10%. This drug also might reduce the development of opportunistic infections caused by Listeria monocytogenes, Nocardia asteroides, and Pneumocystis jiroveci.[79,80] However, reports of trimethoprim-sulfamethoxazole–induced alteration of renal function or synergistic exacerbation of cyclosporine nephrotoxicity have stimulated the search for other prophylactic compounds.

The treatment of pyelonephritis in the posttransplantation patient should include 6 weeks of an appropriate antibiotic based on susceptibility testing plus chronic "suppressive" antibiotic therapy thereafter.[79] A late UTI after renal transplantation may be a risk factor for serious complications including graft loss and death as described in a retrospective review of 728,000 renal transplant patients.[91]

Pharmacokinetic or pharmacodynamic interactions between ciprofloxacin and cyclosporine have not been reported, which suggests that they can be used together without additional monitoring.[90]

Patients are at increased risk of catheter-associated urinary infection because they often receive Foley catheters in the post-transplantation period. Catheter-tip cultures have been used to screen for these infections. Tolkoff-Rubin and colleagues[89,92] used prophylactic trimethoprim-sulfamethoxazole (160 mg of trimethoprim, 800 mg of sulfamethoxazole) for 4 months after urinary catheter removal and reported a decrease in the catheter-associated infection rate from 38% to 8%.

Spinal Cord Injury and Neurologic Dysfunction

Frequent bladder catheterization is necessary as a result of bladder neuropathy in paraplegic or quadriplegic patients following traumatic or surgical injury to the spinal cord. This leads to colonization of the lower urinary tract with pathogenic bacteria and results in bacteriuria in about 80% or more of these patients.[93] Bacteremia may follow and urinary infection may be associated with high mortality rates in patients with spinal cord injury and neuropathic bladders.

Urinary infections and the related sepsis as well as the high frequency of renal disease in these patients are probably associated with vesicoureteral reflux, hydronephrosis, accompanying renal calculi, and pyelonephritis, which are often responsible for death.

These patients may not present with typical symptoms of fever, chills, dysuria, or flank pain, and the presence or absence of symptoms usually is not helpful in predicting the results of urine cultures. Perkash and Giroux[94] found typical symptoms in only 3% of 110 patients with spinal cord injury and bacteriuria ($>10^5$ bacterial colonies per milliliter).

The prevention of infection in patients with spinal cord injury is a major priority. Unfortunately, intermittent catheterization or self-catheterization as an alternative to indwelling bladder catheters may be associated with complications, including urethral fistulization, stricture, periurethral abscess formation, and epididymitis.[3] Although several older publications reported modest success with methenamine compunds[95] or with some antibiotics including trimethoprim-sulfamethoxazole,[96] the current IDSA guidelines do not support these modalities in long-term catheterized patients.[3] In almost every case, modest reduction in bacteriuria or symptomatic infection was associated with an increased risk of antimicrobial resistance. Bladder irrigants are also not recommended and neither is routine screening for bacteriuria in these patients.[3]

The IDSA guidelines do recommend that a urine culture be obtained prior to treatment in catheterized patients who do develop symptomatic UTIs. Replacement of the catheter prior to the onset of treatment can hasten the response and can minimize the occurrence of polymicrobic bacteriuria. Optimal culture results are obtained through the replacement catheter. These guidelines recommend treatment for several days if the clinical response is prompt, or 10 to 14 days if not. The specific antibiotic choice should be made according to susceptibility test results.[1]

Recent attention to the development of adherent biofilms in the urinary tract may offer explanations for recurring and difficult-to-treat infections in this population. Uropathogens can develop dense urethral biofilms with glycocalyx material on the bladder wall or catheters. Recently, biofilms have been described with intracellular bacteria that cause bulges appearing like pods on the bladder surface of infected mice. The pods have been shown to have polysaccharide matrices with a protective shell of uroplakin. It is becoming increasingly more evident how bacteria may evade antimicrobial killing within an environment that protects microorganisms in a uroplakin shell. These mechanisms support the ability of biofilms to allow bacterial microcolonies to survive and cause chronic or recurrent infections.[97,98] This may contribute to the pathogenesis of recurrent urinary infections. Bacterial biofilms also can be detected on bladder epithelial cells and may respond better to fluoroquinolones than to trimethoprim-sulfamethoxazole. In addition to the clinical cure of urinary infections, ofloxacin eradicated bladder biofilms in patients with spinal cord injury.[99] Although silver alloy-hydrogel coated catheters might reduce biofilm formation and delay bacteriuria, they have not yet been shown to reduce bacteriuria or UTIs in patients with neurogenic bladders who require long-term catheterization.[100] Increasing antibiotic resistant gram-negative bacteria and MDR staphylococci are being reported in outpatients with spinal cord injury and UTIs.[101]

An experimental approach to prophylaxis has been reported that uses a nonpathogenic E. coli strain 83972 to colonize urinary bladders in spinal cord injury patients. Intravesical inoculation and colonization with this bacteria was not associated with urinary infection symptoms but was associated with an improved quality of life.[102] Other approaches, including cranberry products, may lead to a reduction of uroepithelial cell biofilms,[103] but these are not recommended in the IDSA guidelines because supporting data were not definitive.

As mentioned already, frequent monitoring and the treatment of symptomatic infection with appropriate bactericidal antibiotics may reduce the morbidity of urinary infections in spinal cord–injured patients with long-term indwelling catheters.

Neutropenia

Patients whose neutrophil count has fallen below 1,000 granulocytes per microliter are at an increased risk of bacterial infections. Most of these patients have received anticancer chemotherapy for leukemia, lymphoma, or solid tumors. The gastrointestinal (GI) flora is the usual source of bacteremia in these patients, and unless instrumentation in the urinary tract has been performed, urinary infections are not particularly frequent. In a recent series, about 6% of the infections in neutropenic patients arose from the urinary tract.[104] In patients with profound and prolonged granulocytopenia

(<100 cells per microliter), bacteremia is not uncommon; however, the urinary tract is infrequently the source of these infections. In fact, bacteremia in this population is more frequently caused by gram-positive cocci than gram-negative rods, probably in part because of the presence of chemotherapy-induced oral mucositis and the dissemination of oral gram-positive cocci to the bloodstream.

The usual symptoms and signs of bacterial urinary infection may not be manifest because granulocytopenic patients may not respond locally to the presence of infection. Dysuria and burning may or may not be present, and pyuria is often minimal because of the absence of granulocytes[105]; therefore, it is important to culture the urine in febrile granulocytopenic patients even though the yield may be low. Fungal urinary infections may occur, especially following long courses of antibiotics. Patients with hematologic malignancies and neutropenia have been reported to have Achromobacter and Alcaligenes spp. bacteremic infections, with urinary tract involvement or origin. Resistance patterns for these species show susceptibility to antipseudomonal penicillins, carbapenems, and trimethoprim-sulfamethoxazole, but resistance to fluoroquinolones and aminoglycosides.[106]

The empirical use of antimicrobial agents early in the course of a fever after appropriate cultures of blood, urine, and material from other presumed infected sites are obtained has reduced the mortality owing to infections in neutropenic patients. A Gram stain should be performed on urine specimens from these patients and antibiotics directed against the common bacterial pathogens in this population, such as E. coli, S. aureus, P. aeruginosa, and streptococci (especially viridans Streptococcus). Fluconazole or amphotericin B should be considered for candidal UTIs, but the new echinocandins do not achieve adequate concentrations in the urine.

AIDS and HIV Infection

AIDS and infection with HIV have been associated with infectious and noninfectious complications in the GU tract.[107–109] Noninfectious complications include HIV-associated nephropathy, which has become the third leading cause of end-stage renal disease in African Americans between 20 and 64 years old, but the progression of HIV nephropathy has been slowed by the use of highly active antiretroviral therapy (HAART).[110] Acute renal failure also develops in HIV-infected patients at rates that are enhanced at lower CD4 counts and are decreased with antiretroviral therapy.[110–112]

Other noninfectious complications are associated with antiretroviral drugs, especially protease inhibitors, and are usually used in combination with two other highly active agents to prevent HIV replication. Indinavir sulfate has been implicated with crystallization and stone formation in the urinary tract, which is not usually visible on plain radiographs. Patients complain of ipsilateral flank pain with nausea, vomiting, dysuria, and hematuria. CT scans are not diagnostic, but calcifications may be seen ultrasonically in approximately 35% of cases. Up to 20% of patients treated with indinavir may have urologic side effects. Conservative treatment with hydration, analgesia, and a brief discontinuation of therapy is effective, but permanent withdrawal may be necessary in 5% of patients.[113] Tenofovir and lopinovir-ritonavir combinations have been associated with an increased risk of acute renal failure (ARF), and renal function should be monitored during therapy.[114] However, more recent studies have suggested that these drugs were not as predictive of ARF as were levels of immunodeficiency.[110–112, 115]

Infections caused by commonly encountered bacteria are frequent and may present as cystitis, pyelonephritis, or renal abscesses. Also, Mycobacterium tuberculosis as well as atypical or nontuberculous mycobacteria may be found in upper and lower UTIs in these patients. Of the usual infecting bacteria, E. coli accounts for the most, and Pseudomonas, Proteus, Klebsiella, Enterobacter spp., and Enterococcus spp. are found frequently. Acinetobacter, Salmonella, and Candida spp., Aspergillus spp., Cryptococcus spp., and Mycobacterium spp. also may be encountered and should be looked for in patients whose CD4 counts are <500 or who do not respond quickly to antibiotics.[107,108] Upper and lower UTIs are probably more common in HIV-infected than in non-HIV-infected patients.[107,108]

Urethritis, prostatitis, and prostatic abscesses may occur due to infections with S. aureus, Enterococcus spp., Mycobacterium tuberculosis, Mycobacterium avium-intracellulare, and Histoplasma capsulatum.[107,116] In the case of a histoplasma abscess, urine cultures are positive only rarely. Granulomatous interstitial nephritis resulting from disseminated histoplasmosis has been reported.[117] Microsporidial infection of the urinary tract caused by Vittaforma corneae has been described.[118]

Urinary infection with Aspergillus presenting as a renal aspergilloma has been reported in an AIDS patient who was treated successfully with amphotericin B instillation via a nephrostomy tube, as well as with systemic antifungals.[119] Nosocomial infections with Stenotrophomonas maltophilia of presumed urinary tract origin have been reported in HIV-infected patients and were associated with high-level resistance to β-lactam antibiotics, monobactams, carbapenems, and aminoglycosides.[120]

Cytomegalovirus can cause cystitis with hematuria in HIV-infected persons,[92] and toxoplasmic cystitis also has been described.[121] Trichomonas vaginalis urethritis, documented both by wet-mount and culture and polymerase chain reaction, has been reported in men with and without symptoms.[122] Latent urinary BK virus, a human polyomavirus, can be activated in patients with AIDS, and nephritis may result.[123] Adenovirus hemorrhagic cystitis with gross hematuria and dysuria has been described in an HIV-infected patient with Burkitt lymphoma.[124] Noninfectious vesicle involvement with Kaposi sarcoma and urethral lymphoma in HIV-infected patients may have unusual presentations that initially could be confused with urinary infection.[108]

Patients with a neurogenic bladder that complicates HIV infection or AIDS may present with urinary retention, urinary frequency, and altered urinary flow as a result of bladder hyperreflexia or hyporeflexia. Most of the patients

with bladder hyperreflexia had concomitant cerebral toxoplasmosis.[125] Other patients with AIDS may have urinary retention secondary to central nervous system lymphoma, myelopathy, or prostatic hypertrophy. The incidence of many of these conditions has declined with the use of HAART.

MISCELLANEOUS CAUSES

Pyonephrosis is an acute suppurative infectious process with gross pus within the renal parenchyma that usually results from ureteral obstruction.[126] The clinical differentiation of pyonephrosis from infected hydronephrosis is difficult even with the use of ultrasound evaluation, but the finding of fluid-debris levels on MR urography is a strong indicator of pyonephrosis.[127] This infection may be associated with an obstruction secondary to congenital anomalies, calculi, malignancy, ureteral strictures, nephrolithiasis, diabetes, and functional disorders of the renal collecting system.

In a review of 23 patients with pyonephrosis, 15 patients presented with virgin stone formation that produced an obstruction at various sites including the calyces, renal pelvis, and middle and distal aspects of the ureter.[126] Clinical presentation may vary from asymptomatic bacteriuria to resembling that of pyelonephritis with fever, flank or abdominal pain, leukocytosis, pyuria, and septic shock. The responsible organisms include Enterobacteriaceae and anaerobic bacteria such as Bacteroides spp., and Candida spp.

Radiographic determination of pyonephrosis may be limited even with the use of ultrasonography and CT; the correct diagnosis requires a high degree of suspicion, and MR urography may be helpful.[127] Ultrasound or CT-guided renal urine aspiration or retrograde ureteral catheter placement may be required. Nephrectomy may be necessary if drainage and appropriate antibiotic therapy directed at organisms isolated from aspirated and drained infected material does not prove successful.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a unique pathologic presentation of chronic bacterial pyelonephritis. Schlagenhaufer initially described it in 1916, and more than 500 cases have been reported in the literature. However, xanthogranulomatous pyelonephritis remains relatively uncommon and accounts for less than 1% of surgically or pathologically proved cases of chronic pyelonephritis. Most cases are diagnosed in elderly patients, with almost 70% occurring in women. A recent review highlighted the risk factors for xanthogranulomatous pyelonephritis, which included female gender, obesity, elevated creatinine, and the presence of renal stones or staghorn calculi.[128]

The pathogenesis of xanthogranulomatous pyelonephritis is uncertain. Although P. mirabilis infection is present in most patients, it is not essential for the pathologic process to occur. Urinary obstruction usually has a role. Macrophages filled with periodic acid-Schiff (PAS)-positive granules have been produced in a rat infection model with P. mirabilis, E. coli, and S. aureus. On electron microscopy, macrophages appear to have ingested bacteria and developed phagolysosomes filled with amorphous material. It is hypothesized that xanthogranulomatous pyelonephritis may be caused by a lysosomal defect of macrophages that prevents the complete digestion of ingested bacteria. Familial disease has not been described.

Presenting symptoms are recurrent flank pain, fever, and constitutional fatigue. Persistent anemia and leukocytosis occur in about 75% of patients. The urinalysis shows pyuria and, often, hematuria. Urine cultures are positive for P. mirabilis in about two-thirds of patients, and E. coli, Klebsiella spp., and S. aureus are each reported from a small proportion of patients. Multiple pathogens occur in about 25% of patients. In a small proportion of patients, urine cultures are negative despite ongoing disease activity, and positive cultures may be obtained from resected renal tissue.[129] S. aureus may produce localized disease that might not be associated with nephrolithiasis, and MRSA infections have been reported.[130] Occasionally, pathogens isolated from resected renal tissue are different than those from voided urine.[129]

Most patients have a history of recurrent urinary infection, often complicated by renal calculi, obstructive uropathy, and previous urologic procedures. Often, patients have had a chronic undiagnosed illness for several months before the diagnosis of xanthogranulomatous pyelonephritis has been considered. On physical examination, a renal mass is palpable in more than 50% and hypertension is present in about 25% of patients.

Intravenous pyelography (IVP) discloses a nonfunctioning kidney in 85% of patients. Struvite renal calculi occur in 80% and are virtually universal with P. mirabilis infection. Radiologic investigation may also demonstrate cavitary masses and calyceal deformities. Angiography usually discloses hypovascular renal masses with no neovascularization. CT scan is the diagnostic procedure of choice. It demonstrates the extent of involvement of perirenal structures and may permit a specific diagnosis by the recognition of abnormal fatty tissue in the renal mass.

The disease is almost always unilateral and appears to be caused by chronic renal infection with an unusual inflammatory response. On a gross examination, the kidney is enlarged with either local or generalized involvement of renal tissue. Calyces are usually dilated and the renal parenchyma is replaced by yellow-orange soft tissue, which is usually surrounded by abscesses. The localization of this peculiar tissue in the renal pelvis is characteristic. Perirenal fat is usually inflamed, edematous, and adherent to the kidney. The inflammation may spread beyond Gerota's fascia and involve the perirenal fat of the retroperitoneal space. On a microscopic examination, the lipidlike tissue is composed of a mixture of large foamy lipid-laden macrophages (xanthoma cells) together with neutrophils, plasma cells, fibroblasts, and necrotic debris. The cytoplasm of the xanthoma cells stains strongly with PAS. Although these cells form the basis of the microscopic identification of the lesion, they are not specific

and may only reflect phagocytosis of tissue within the lipid. Foreign-body giant cells and microscopic calcification are also frequently present.[129]

Xanthogranulomatous pyelonephritis is frequently mistaken for renal carcinoma or renal tuberculosis. Prior to the availability of CT scanning, the diagnosis was seldom considered preoperatively. Kidneys were often removed surgically because of an incorrect preoperative diagnosis. Current organ imaging technologies enable a preoperative diagnosis. If the disease is localized in the kidney, total nephrectomy may be avoided, and local resection with the removal of renal calculi and intensive treatment of the urinary infection may salvage residual functioning renal tissue.[129] The disease rarely involves both kidneys and does not recur after treatment. The disease has not been observed to progress serially from one kidney to the other, so the radical removal of involved tissue is not necessary. Laparoscopic approaches have been successful,[131] and a recent case report documents successful treatment with antibiotics alone in a patient with leukemia and a splenic abscess.[132]

Malakoplakia

Renal malakoplakia is a rare granulomatous disease of uncertain etiology that occurs in similar clinical settings to xanthogranulomatous pyelonephritis. The term malakoplakia is derived from the Greek word for soft plaque. Over 200 cases have been reported to date, predominantly in women and the elderly. Many of the clinical and laboratory features of this disease resemble those of xanthogranulomatous pyelonephritis, but most patients have an E. coli rather than a P. mirabilis urinary infection.[133]

The gross lesion is a soft yellow-brown plaque of variable size. Renal tissue is involved in one-fifth of patients and is bilateral in about 50%. The renal pelvis and ureters are involved in an additional one-fifth of patients, and a ureteral stricture may develop. Renal involvement appears frequently to be an ascending progression of bladder malakoplakia. Histologically, the plaques show large histiocytes with a foamy eosinophilic cytoplasm, called von Hansemann macrophages. The cytoplasm contains PAS-positive granules and large renal concentric crystals, named Michaelis-Gutmann bodies, which differentiate malakoplakia from xanthogranulomatous pyelonephritis.[134] These bodies show a typical crystalline structure on electron microscopy and are primarily calcium and iron on chemical analysis. These lesions may be confined to the urinary tract but occasionally are seen on the skin, in the prostate, testes, and the gastrointestinal tract.

The disease is caused by a defect in macrophage function, with impairment of bactericidal activity of monocytes for E. coli, and this organism may play a particular role in its pathogenesis.[134,135] The movement of lysosomes to phagocytic vacuoles is delayed owing to low levels of cyclic guanosine monophosphate. A cholinergic agonist, such as bethanechol, can correct this defect.[136,137] The Michaelis-Gutmann bodies are presumed to result from the abnormal deposition of calcium phosphate and iron in the overloaded phagosomes.[134]

Renal parenchymal malakoplakia usually occurs as an upper tract infection with fever and flank pain or tenderness.[134–136] A palpable flank mass may be present. Imaging reveals enlarged kidneys with multiple filling defects. Renal malakoplakia may progress to renal impairment and failure. The disease occurs more frequently in immunosuppressed patients and has been observed in several patients following renal transplantation.[134,137]

Several patients have been treated successfully with the cholinergic agonist bethanechol chloride and long courses of trimethoprim-sulfamethoxazole or a fluoroquinolone.[134–137] Immunosuppression may have to be modified when the disease occurs in renal transplant recipients.

Urosepsis

The urinary tract is the most common site of origin for gram-negative rod bacteremia, and the development of bacteremia from a urinary focus is termed urosepsis. Urosepsis is one of the most common presentations for bacteremic illness in nursing homes and hospitals. As discussed already, E. coli accounts for almost half of these uroseptic infections, with other enteric gram-negative bacilli and enterococci following in frequency. Interleukin 8 (IL-8), a small chemotactic protein, plays an important role in neutrophil migration during a UTI and increased urinary interleukins occur in urinary tract infections and urosepsis.[138,139] A recent report even suggests that urinary IL-8 can be used for the rapid diagnosis of urosepsis in children.[140] Patients with acute pyelonephritis have higher IL-8 levels in the urine than in the plasma. During urosepsis, this phenomenon stimulates the delivery of neutrophils to the GU system and results in pyuria. Serum IL-1 receptor antagonist, IL-10, and soluble tumor necrosis factors are elevated in urosepsis, suggesting a systemic anti-inflammatory response.[141] Although endotoxin (the bacterial cell wall lipopolysaccharide) may enter the circulation from a well localized focus of gram-negative bacterial infection, the presence of sepsis originating from the urinary tract usually implies bacteremia, which in turn usually results from an infection in the kidney or the renal pelvis.

Clinically, most uroseptic patients present with fever, shaking chills, flank pain, hypotension, cloudy urine, and leukocytosis. However, obtunded patients may not have urinary complaints or clinical signs referable to the urinary tract, and patients with obstructive uropathy might not present with the usual laboratory clues of pyuria and bacteriuria. Bacteremia in a patient with a urinary infection usually implies that the infection originates from the kidney, but in the presence of an indwelling bladder catheter, erosive urethritis or cystitis might be the responsible focus. Also, sepsis may follow the instrumentation or manipulation of the lower urinary tract such as occurs during a percutaneous nephrolithotomy or a ureteroscopy. Staghorn calculi (struvite or apatite) can become embedded with gram-negative bacteria. A recent study identified endotoxins associated with sepsis in stone fragments in a child who died from sepsis syndrome after percutaneous staghorn stone manipulation.[142]

The diagnosis of urosepsis is usually confirmed by blood cultures positive for the same organism cultured from the urine. Despite initial hopes that rapid diagnostic tests for the presence of a circulating endotoxin might speed the diagnosis of bacterial sepsis, no such test is available currently. A careful examination for the presence of bacteria on a drop of unspun urine (under a cover glass, or a gram-stained smear) plus the findings of pyuria in a septic patient point to the urinary tract as the source of the infection in most cases. However, strong clinical suspicion is necessary for less typical patients and at least two and preferably three blood cultures should be obtained to identify the responsible organism.

Treatment requires intravenous fluid support, the maintenance of blood pressure with pressors if necessary, and antibiotics. If the organism is known (as in the case of recently cultured urine in a septic patient), then a single active antibiotic can suffice. If no clues exist as to the identity of the organism, intravenous therapy with an extended-spectrum penicillin (e.g., piperacillin), a penicillin-penicillinase inhibitor combination (e.g., ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam), or a carbapenem (e.g., imipenem, ertapenem, meropenem, doripenem) can be used. Third-generation cephalosporins also can be used, but these agents are not effective against enterococci. Aminoglycosides (gentamicin, tobramycin, or amikacin) may be used in combination with a β-lactam if enterococci or P. aeruginosa are suspected. Combination therapy with a third-generation antipseudomonal cephalosporin such as ceftazidime, or a carbapenem or an extended-spectrum penicillin plus aminoglycoside is suggested if gram-negative rod bacteremia occurs in a patient with granulocytopenia. Intravenous fluoroquinolones (e.g., ciprofloxacin, levofloxacin) also are useful, but resistance is increasing in many centers. Carbapenems have extended activity against gram-negative bacilli, although ertapenem has limited activity against Pseudomonas aeruginosa.[143]

β-Lactamase–mediated carbapenem resistance has been well described in Klebsiella pneumoniae and other Enterobacteriaceae, and these organisms as well as Acinetobacter spp. are widely spread in hospitals.[144,145] Multiple antibiotic resistance is common in these organisms, including resistance to aminoglycosides, cephalosporins, and fluoroquinolones. Some might retain susceptibility to carbapenems, but polymyxin or colistin might be needed to eradicate MDR bacteria.[146] Nephrotoxicity and neurotoxicity warrant caution with these antibiotics.

A new glycylglycine, tigecycline, has antibacterial activity against some MDR bacteria, as well as ESBL-producing Acinetobacter, MRSA, and vancomycin-resistant enterococci. However, tigecycline is unstable in urine and is not used as a first-line agent if gram-negative rod bacteremia originates in the urinary tract.[147,148]

Adjunctive therapy with corticosteroids is not recommended. Considerable research activity has been directed to blocking cytokine activity in sepsis (not limited to urosepsis), but recent trials of antiendotoxin monoclonal antibodies, antitumor necrosis factor antibodies, and IL-1 receptor antagonists have been disappointing.

Others

Tuberculosis (Chapter 27) and renal and perinephric abscesses (Chapter 24) also are discussed elsewhere. Abscesses may rarely develop in the bladder wall. These intramural vesicle abscesses are only rarely reported and are usually caused by coliform bacteria, often in the presence of inflammatory bowel disease, diverticular disease, or a foreign body.

Infections Caused by Unusual or Resistant Organisms

In the face of increasing bacterial resistance to many antibiotics, the treatment of complicated UTIs is less simple given the resistance to fluoroquinolones, TMP-SMX, and β-lactams.[1,149] At least 4 weeks of therapy may be needed and the treatment choice must be based on susceptibility testing. Enterococci are not uncommon causes of UTIs, and GU sites account for the majority of clinical bacteriology laboratory isolates. These organisms are more commonly isolated from nosocomial infections than from the community. Enterococci may be the causative agents in lower UTIs (e.g., cystitis), in catheter-related infections, in infections following urinary tract instrumentation, and in patients with GU anatomic abnormalities.[150,151]

The incidence of enterococcal infection, in general, is increasing at an alarming rate according to the National Nosocomial Infection Surveillance (NNIS) Study; for example, from 1980 to 1989, the incidence of bloodstream infections with enterococci has increased 120%,[149,151,152] and the urinary tract is frequently identified as the source. These infections may originate from the patient's own GU or GI flora or may be nosocomially spread from other patients.

Unfortunately, antimicrobial resistance in enterococci is also increasing dramatically, not unlike the rise in methicillin-resistant S. aureus seen over the past 30 years. A large number of enterococcal strains, especially Enterococcus faecium, show vancomycin resistance. This has been attributed to the almost 160-fold increase in vancomycin usage per 1,000 patient-days in hospitals between 1978 and 1992.[153] Vancomycin resistance is often classified by phenotypic expression of the presence of certain resistance genes such as VanA, which mediates resistance to vancomycin and teicoplanin; VanB with strains susceptible to teicoplanin but resistant to vancomycin; and VanC, which imparts low-level resistance to vancomycin in strains of Enterococcus gallinarum and Enterococcus casseliflavus.[154]

Also, enterococcal strains that were previously susceptible to penicillin and gentamicin have been identified. Even penicillin plus gentamicin therapy may fail to eradicate some of these infecting organisms.[154] Although vancomycin had been used as a mainstay in the therapy of complicated nosocomial enterococcal urinary infections, vancomycin-resistant

E. faecium and E. faecalis threaten the use of this drug. Alternative treatments with drugs such as linezolid or quinupristin-dalfopristin are effective against vancomycin- and penicillin-resistant E. faecium; nitrofurantoin or fosfomycin trometamol may be effective in simple UTIs.[155,156] Vancomycin-resistant E. faecalis may be treated with a penicillin, nitrofurantoin, or fosfomycin. MDR enterococcal infections may be treatable with linezolid, daptomycin, or tigecycline, but the emergence of resistance is possible.[155–158] Daptomycin is also active against MRSA.[159] Recent publications do not recommend the routine treatment of asymptomatic enterococcal bacteriuria.[155] Increasing MDR strains of E. coli causing community-acquired pyelonephritis and other complicated UTIs are being reported, with identified clonal groups and widespread circulation of ESBL-producers responsible for the antimicrobial resistance.[160–161] Some of these organisms might be treatable with carbapenems (imipenem, meropenem, doripenem, ertapenem) or they might require colistin treatment.[146,162]

Hemolytic-uremic syndrome (HUS) associated with enterohemorrhagic E. coli urinary infections has been reported. Hemolytic-uremic syndrome includes a triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal impairment. Thirteen cases of HUS associated with E. coli UTIs have been described. Most of these cases were not associated with diarrhea or a prodrome, which usually occur when HUS occurs as a result of the consumption of fecally contaminated products from cattle or sheep.[163] A few other cases have been reported,[164] but routine screening for shiga toxin–producing E. coli is not recommended.[165]

Atraumatic ruptures of the urinary bladder associated with MRSA have been reported.[166] MRSA UTIs usually require therapy with intravenous vancomycin. Involvement of the upper urinary tract, pyelonephritis, renal abscess, and bacterial endocarditis should be excluded in these patients. Bladder ruptures have been reported as a result of a Candida tropicalis bezoar[167] and secondary to a multiorganism infected urachal cyst.[168]

Anaerobic bacteria are unusual causes of urinary infection, but they are implicated in some patients with genitourinary abscesses, scrotal gangrene, and in patients with urinary diversions.[169,170] Although they are major components of the normal urethral, periurethral, and vaginal flora, their presence in these areas may prevent other, more invasive aerobic or facultative organisms from colonizing these sites and subsequently causing infection. Anaerobic bacteria may be identified in the urine in chronically catheterized patients but this is often short lived and without clinical significance; however, anaerobic bacteriuria is more frequent in patients who have undergone a renal transplantation.[171] Anaerobes that have been implicated in complicated UTIs include Bacteroides fragilis, B. melaninogenicus, Fusobacterium nucleatum, Peptococcus spp., Peptostreptococcus spp., and Clostridium perfringens, among others.[169]

The mechanism by which these organisms cause disease in the bladder, kidney, or prostate depends on their ability to ascend from the periurethral area to the bladder or kidney. This process is accelerated in the presence of obstruction, urinary stasis, calculi, trauma, and catheters or other foreign bodies. Anaerobic bacteria have been documented to cause prostatitis and prostatic abscesses as well as bacteriuria, pyelonephritis, and urosepsis. Some of these organisms (e.g., Bacteroides or Sphaerophorus spp.) have been implicated in urinary or prostate infections following colonic surgery.[169] Clindamycin and metronidazole are usually active against most anaerobic organisms (although resistance is increasing) and cefoxitin or cefotetan, carbapenems, and β-lactams with β-lactamase inhibitor combinations also may be effective. The surgical correction of underlying causes is often required.

CHAPTER

26 Fungal Infections of the Urinary Tract

Carol A. Kauffman

Urinary tract infections due to fungi are much less common than those due to bacteria. Among the fungi, relatively few target the urinary tract (Table 26.1). Candida species are responsible for most urinary tract infections.[1] Other opportunistic yeasts, such as Cryptococcus neoformans, involve the urinary tract usually only when widespread disseminated infection has occurred. Mold infections, such as aspergillosis and mucormycosis, rarely spread to the urinary tract, but have disastrous consequences when they do. Finally, the group of geographically restricted endemic mycoses, histoplasmosis, coccidioidomycosis, and blastomycosis, can cause localized lower urinary tract infections, but rarely cause symptomatic upper tract infection.

Candiduria is not a disease, but is usually the initial event triggering the question as to whether a fungal urinary tract infection is present.[2] Most patients who have Candida in their urine do not have a urinary tract infection, but are merely colonized with these yeasts. Diagnostic tests to define whether candiduria reflects colonization or infection are often not helpful, and localization of the site of infection either to the bladder or the kidneys can be difficult. For this reason, much of the literature on urinary tract involvement with Candida species is actually based on candiduria and much less often on specific infections due to these organisms.

CANDIDA

Epidemiology

Candida species are common members of the microbiota of the perineum but are found in urine in less than 1% of healthy persons.[3,4] In hospitalized patients, especially those in the intensive care unit, candiduria is very common presumably because of the multitude of risk factors that allow ingress of organisms into the bladder and subsequent growth of Candida species in the urine.[5–11] A recent point prevalence survey of positive urine cultures obtained from hospitalized patients in hospitals throughout Europe found that Candida species were the third most common microorganism isolated from urine.[5] Although it has been thought that candiduria could serve as a prelude to candidemia, this appears to be uncommon. Investigation of candiduric and candidemic isolates by molecular genotyping failed to show a relationship between the two sites in over half of the patients in one study.[12] In a large prospective surveillance study only 7 of 530 (1.3%) candiduric patients followed for 10 weeks developed candidemia.[13]

The risk factors for candiduria have been better defined than those for either bladder or kidney infection with Candida. This is due to the fact that firm diagnostic criteria for infection have not been defined, but candiduria is easily and simply defined as the growth of Candida species from a urine culture. Prospective surveillance studies and case-controlled studies have shown that increased age, female sex, antibiotic use, urinary drainage devices, prior surgical procedures, and diabetes mellitus are important risk factors for candiduria[6,8,11,13] (Table 26.2).

In the largest multicenter surveillance study, which assessed 861 hospitalized patients, urinary drainage devices, consisting mostly of indwelling urethral catheters, were present in 83%, diabetes in 39%, and urinary tract abnormalities in 37% of patients who had candiduria. Only 11% of patients with candiduria had no obvious risk factor identified.[13] In a multicenter study from Spain assessing candiduria in patients in an intensive care unit (ICU) setting, the independent risk factors associated with candiduria were age over 65 years, female sex, diabetes mellitus, prior antibiotics, mechanical ventilation, parenteral nutrition, and length of hospital stay before admission to the ICU.[6]

Among children, low-birth-weight neonates who are in an ICU are at the highest risk for candiduria and Candida urinary tract infections.[14–16] Fewer data are available for patients in the community than for hospitalized patients. Risk factors appear to be similar to those in hospitalized patients and include diabetes, indwelling catheters, and the use of antibiotics.[11]

Several studies, especially those focused on the ICU population, have noted increased mortality rates in patients who have candiduria when compared to similar patients without candiduria.[6,9,13,17,18] In all of these studies it appeared that Candida urinary tract involvement was not responsible for death but was most likely a marker for seriously ill patients

26.1 Fungi That Cause Urinary Tract Infection

Yeastlike Fungi
- Candida species[a]
- Cryptococcus neoformans
- Saccharomyces cerevisiae
- Trichosporon asahii

Molds
- Aspergillus species
- Mucorales

Endemic Fungi
- Histoplasma capsulatum
- Blastomyces dermatitidis
- Coccidioides species

[a]The vast majority of fungal urinary tract infections are due to Candida species. All of the other fungi listed only rarely cause urinary tract infections.

who died of their underlying illnesses. Treatment of candiduria did not impact mortality rates.[18]

Pathogenesis

Candida species can cause renal infection by either the hematogenous or ascending routes. In contrast, most bacterial upper tract infections are related to ascending infection from the bladder. It is likely that most kidney involvement with Candida occurs by hematogenous seeding from a distant focus but almost all of these infections cause no urinary tract symptoms. Rather, the patient is ill from candidemia or other foci of infection due to Candida. The pathogenesis of hematogenous seeding of Candida to the kidney has been studied extensively in experimental rodents and rabbits given an intravenous bolus of C. albicans.[19] Multiple microabscesses develop throughout the cortex. As the infection progresses, the yeasts penetrate through the glomeruli into the proximal tubules and are shed into the urine. Healthy animals eventually clear the organisms from the kidney, usually within 2 weeks; however, animals given immunosuppressive drugs cannot clear the infection. In agreement with experimental studies, renal microabscesses have been identified at autopsy in most patients who die of invasive candidiasis.

The pathogenesis of ascending infection with Candida has not been studied as extensively as that of hematogenous spread. Not surprisingly, it has been shown that those Candida strains found in the vagina are genetically related to the strains that cause candiduria in women who have indwelling bladder catheters while in the ICU.[20] There is no animal model that replicates the mode of spread that occurs in humans, which is presumably from the perineum into the bladder and then retrograde to the collecting system of the kidney.[21] Creating the milieu in which Candida persist in the bladder has been difficult in experimental animals. Studies from the 1970s showed that rats made diabetic were unable to clear C. albicans inoculated into the bladder, and also that the presence of a concomitant Escherichia coli urinary tract infection allowed retrograde spread of Candida to the kidney.[19] Unfortunately, these experiments have not been repeated nor has use of this model continued. Another model using bladder tissue explants from rabbits confirmed the essential role of adherence to the epithelial cells in colonization of the explants, but could not further explore the pathogenesis of retrograde spread.[22]

Microbiology

C. albicans is the yeast most commonly isolated from urine, accounting for 50% to 70% of isolates. C. glabrata is the second most common yeast found in urine, accounting for about 20% of isolates.[2,13] However, the proportion of urine isolates that are C. glabrata varies with different risk groups. Older adults frequently have C. glabrata isolated from urine, but neonates rarely are colonized or infected with C. glabrata. In patients who have hematologic malignancies, and in kidney transplant recipients, C. glabrata is more commonly isolated, possibly because of increased use of fluconazole in units that care for these patients. In one series of kidney transplant recipients, over half of all urine isolates were C. glabrata and only one third were C. albicans.[23] A study among hospitalized patients who had indwelling bladder catheters found that independent risk factors for C. glabrata candiduria were diabetes, ICU admission, and prior treatment with antibiotics and with fluconazole.[24]

C. parapsilosis, C. tropicalis, and C. krusei are less commonly found in urine although some centers have reported C. tropicalis more often than C. glabrata.[8] In general, there are no distinguishing characteristics of urinary tract infections due to the different Candida species.

Many laboratories do not identify yeast isolates to species level. This is reasonable because most yeasts that are

26.2 Risk Factors for Candiduria[a]

- Older age
- Female sex
- Diabetes mellitus
- Antibiotic use
- Urinary drainage device
- Urinary tract surgery or instrumentation
- Urinary tract obstruction

[a]Most patients have more than one predisposing factor present.

isolated are merely colonizing the urinary tract. However, knowledge of the species is needed if treatment of infection is required. Almost all isolates of C. albicans, C. tropicalis, and C. parapsilosis are susceptible to fluconazole, the antifungal agent of choice for treating Candida urinary tract infections. However, many isolates of C. glabrata and all isolates of C. krusei are resistant to fluconazole. Additional benefit is obtained when the laboratory performs susceptibility studies for fluconazole by helping the clinician to tailor therapy to the specific infecting organism.

Clinical Manifestations

Most patients with candiduria are asymptomatic, reflecting the fact that most do not have infection. In one large prospective surveillance study of patients with candiduria, fewer than 5% had symptoms suggestive of urinary tract infection.[13] Patients who have had hematogenous spread to the renal parenchyma in the course of candidemia may have fever, hypotension, and other manifestations of sepsis associated with invasive candidiasis. They do not have symptoms suggesting urinary tract infection. In these patients candiduria is a clue to the presence of invasive candidiasis, but the urinary tract is not the primary site of infection or the source of candidemia.

In those patients who do have symptomatic urinary tract infection, symptoms are indistinguishable from those noted with bacterial infections. Cystitis is manifested by dysuria, frequency, urgency, and suprapubic discomfort. Rarely pneumaturia and the passage of particulate matter may be present. Fever is uncommon. Patients who have an indwelling bladder catheter rarely complain of symptoms other than suprapubic discomfort, and if they are in the ICU they often are unable to communicate about symptoms that they might have.

Patients who have pyelonephritis usually have chills, fever, and flank pain. Some patients are afebrile whereas others have predominantly lower tract symptoms, but upper tract infection is noted on imaging studies.[25] Pyelonephritis is more common in diabetics, women, and older adults. Complications of pyelonephritis are uncommon but include emphysematous pyelonephritis, perinephric abscess, and papillary necrosis—all of which are associated with increased morbidity and usually require surgical intervention.[26] Formation of a fungus ball composed of a mass of hyphae and yeast cells in the collecting system is frequently found with pyelonephritis and causes obstruction.[25,27–30] Neonates and infants are especially prone to develop fungus balls.[27,30] If obstruction is present oliguria may occur and candidemia is common. Fungus balls can also form in the bladder and obstruct one or both ureters, causing hydronephrosis.[28]

Diagnosis

The initial task when approaching a patient who has candiduria is to decide if the presence of candiduria represents infection or merely reflects contamination of a urine sample or colonization of the bladder or urinary catheter. Repeating the urine culture to determine if the candiduria disappears tells one that the previous specimen was contaminated and no further diagnostic workup is indicated. If the patient is unable to perform a clean-catch collection of urine, bladder catheterization may be required. In those patients who have an indwelling bladder catheter, the catheter should be replaced and the second urine specimen collected from the newly inserted catheter.

Distinguishing colonization from infection is not simple as there are no standardized criteria that enable one to distinguish the two situations, especially in the setting of an indwelling bladder catheter.[2] Specifically, pyuria and quantitative cultures have not been shown to be definitive markers for the diagnosis of Candida urinary tract infection.[31] In patients who have an indwelling bladder catheter, pyuria is routinely noted and thus is not helpful to differentiate infection from colonization. On the other hand, in patients who do not have an indwelling bladder catheter, the presence of pyuria is helpful. One must be sure that bacteriuria is not present as a cause for pyuria.

Early studies by Wise and colleagues in the 1970s showed broad ranges of colony counts for both colonization and infection.[31,32] For patients who did not have indwelling catheters kidney infection was documented with colony counts in urine as low as 10^4 yeasts per mL. For patients who had indwelling catheters colony counts varied between 2×10^4 to $\geq 10^5$ colony-forming units (CFU) per mL, and the correlation of urine colony counts with biopsy-proved renal infection was poor. In a murine model of renal candidiasis initiated by intravenous inoculation of organisms, urine colony counts varied widely and no specific amount in the urine correlated with the burden of organisms in the kidney.[33]

Identification of casts containing yeasts in the urine is specific for kidney infection.[34] However, the techniques required to evaluate the presence of casts are complicated and time consuming, and this assay is not useful clinically. Finding pseudohyphae in urine may not be indicative of infection, especially because some Candida species, specifically C. glabrata, cannot form pseudohyphae.

Occasionally a patient has symptoms suggesting a urinary tract infection and yeasts are seen on microscopic examination of a urine sample, but the urine culture shows no growth. In this circumstance it is likely the patient has infection with C. glabrata, and the culture plates have not been held long enough for detection of this slowly growing species. Although the standard urine culture techniques used in clinical laboratories detect most Candida species, they can miss C. glabrata strains which may not appear for 48 hours. Asking the lab to culture urine specifically for fungi ensures that plates are kept for at least 5 days, and C. glabrata will then be found.

Imaging procedures including abdominal ultrasound and computed tomography (CT) scan are essential to document obstruction in the bladder, ureters, or renal pelvis.[31] It is important to discover the presence of fungus balls in the bladder or kidneys as surgical intervention is often required

for effective treatment. Perinephric abscess and emphysematous pyelonephritis, although unusual, are serious consequences of upper urinary tract Candida infection and are best detected by CT scan. Cystoscopy is helpful to ascertain the presence and extent of mucosal invasion by Candida.

Treatment

As a general rule asymptomatic patients should not be treated with antifungal agents.[35–38] However, there are two circumstances in which asymptomatic patients should be treated (Table 26.3). One such circumstance is when candiduria likely represents a marker for invasive candidiasis in high-risk patients, especially neutropenics and very low-birth-weight neonates.[35] The other circumstance is when the patient has candiduria and is about to undergo a urologic procedure that is likely to lead to candidemia.[35,39] Asymptomatic candiduria in a kidney transplant recipient does not warrant systemic antifungal treatment unless obstruction is present or the patient develops symptoms suggesting infection.[23]

For many patients simply removing the indwelling bladder catheter will allow the host to clear the candiduria.[2] If catheterization cannot be discontinued, the existing catheter should be removed and a new one inserted. Many times this will eradicate candiduria transiently, but it is highly likely that the organisms will return within a short time period. Relieving obstruction to urine flow in the upper or

26.3 Treatment of *Candida* Fungal Urinary Tract infections

Infection	Preferred Treatment	Comments
Asymptomatic candiduria with no high risk factors	Remove risk factors (bladder catheter, antibiotics)	Antifungal treatment not recommended
Asymptomatic candiduria in low birth weight neonates or neutropenics	Fluconazole, 400 mg (6 mg/kg) daily × 2 weeks	Treat for disseminated candidiasis; for fluconazole-resistant Candida, AmB, 0.5–1.0 mg/kg daily × 2 weeks
Asymptomatic candiduria in patient about to undergo urologic procedure	Fluconazole, 200–400 mg (3–6 mg/kg) daily for a few days periprocedure	For fluconazole-resistant Candida, AmB 0.3–0.6 mg/kg daily for a few days periprocedure
Cystitis	Fluconazole, 200 mg (3 mg/kg) daily × 2 wk	For fluconazole-resistant Candida, AmB, 0.3–0.6 mg/kg daily × 1–7 days OR 5-FC, 25 mg/kg qid × 7–10 days
Pyelonephritis	Fluconazole, 200–400 mg (3–6 mg/kg) daily × 2 wk	For fluconazole-resistant Candida, AmB, 0.5–0.7 mg/kg daily ± 5-FC, 25 mg/kg qid × 2 weeks OR 5-FC alone× 2 weeks
Renal infection—hematogenous spread	Fluconazole, 400 mg (6 mg/kg) daily × 2 wk	Treat for disseminated candidiasis; for fluconazole-resistant Candida, AmB, 0.5–1.0 mg/kg daily × 2 weeks
Prostatitis	Fluconazole, 400 mg (6 mg/kg) daily until resolved	Surgical drainage usually needed in addition to antifungal therapy
Epididymoorchitis	Fluconazole, 400 mg (6 mg/kg) daily until resolved	Surgical drainage usually needed in addition to antifungal therapy
Fungus balls (bladder, ureter, or kidney)	Fluconazole, 200–400 mg (3–6 mg/kg) daily until resolved	Surgical or radiologic intervention almost always required; local instillation of AmB an effective adjunct

AmB, amphotericin B deoxycholate; 5-FC, flucytosine; qid, four times a day.
Modified from Pappa PG, Kauffman CA, Andes D, et al. Clinical practice guidelines for the management of candidiasis: 2009 update by the Infectious Diseases Society of America. Clin Infect Dis. 2009;48:503.

lower urinary tract is essential for the long-term eradication of Candida from the urinary tract. Stopping broad-spectrum antibiotics will help the host clear candiduria without having to resort to antifungal agents.

Patients who have symptoms suggesting cystitis or pyelonephritis, and in whom bacteria as well as Candida are found in the urine culture, should be treated with an antibacterial agent alone to see if this leads to resolution of symptoms. However, many times there is a dual infection and both infections, bacterial and fungal, will require treatment.

Antifungal Agents

When therapy is indicated oral fluconazole is the drug of choice (Table 26.3). A loading dose of 400 mg should be given and then the daily dosage is 200 mg for a total of 14 days.[35,40] Fluconazole achieves high urine levels and effectively treats all Candida species with the exception of those due to C. glabrata, which are relatively or completely fluconazole-resistant, and C. krusei, which are uniformly fluconazole resistant. The dosage of fluconazole is reduced when the creatinine clearance falls to 50 mL per minute (Table 26.4).

26.4 Dosages of Antifungal Agents in Patients with Renal Insufficiency

Antifungal Agent	Creatinine Clearance (mL/min)	Recommended Dosage
Fluconazole	>50	400 mg every 24 hours
	21–50	200 mg every 24 hours
	11–20	200 mg every 48 hours
	Hemodialysis	400 mg after each dialysis
Flucytosine[a]	>50	25 mg/kg every 6 hours
	21–50	25 mg/kg every 12 hours
	11–20	25 mg/kg every 24 hours
	Hemodialysis	25 mg/kg after each dialysis

[a]Flucytosine peak levels should be measured 1–2 hours after dosing and should be <75 ug/mL.

The other available azoles (itraconazole, voriconazole, and posaconazole) and all of the echinocandins (micafungin, anidulafungin, and caspofungin) are not excreted into the urine as active drug, greatly limiting their use for Candida urinary tract infections.[37] It is possible that the tissue concentrations achieved with these agents might be adequate to treat invasive Candida infections of the kidney. However, clinical data are limited and both failures and success have been reported in individual patients.[41–43] It is highly likely that the echinocandins and voriconazole are able to eradicate those Candida organisms that have seeded into the kidney because all of these agents are effective therapy for candidemia and residual infection in the kidney after treatment of candidemia does not seem to be a common problem. However, currently no echinocandins or other azoles are recommended for the treatment of Candida urinary tract infections.

Intravenous amphotericin B deoxycholate has been used for decades as an effective treatment for Candida urinary tract infections.[35] However, because of its well-known toxicity, it is generally reserved for patients who have upper tract infection or documented bladder infection, and not merely colonization with C. glabrata or C. krusei (Table 26.3). The usual dosage is 0.3 to 0.6 mg/kg/d for 5 to 7 days, but even single-dose treatment with 0.3 to 1.0 mg per kg has been shown to be effective.[36,44] Infusion-related side effects that are seen in some patients, even when treated with low dosage amphotericin B deoxycholate, are rigors, fever, nausea, vomiting, and headache. Even a few days of therapy can cause transient renal insufficiency in some patients.

Unfortunately, the lipid formulations of amphotericin B, liposomal amphotericin B, amphotericin B lipid complex, and amphotericin B colloidal dispersion are not effective in treating fungal urinary tract infections.[45] It is postulated that the addition of the lipid component, which decreases nephrotoxicity with these agents, also precludes these drugs from achieving adequate levels in the urinary tract. This has been documented in one patient undergoing nephrectomy.[46]

Oral flucytosine can be used to treat fluconazole-resistant C. glabrata urinary tract infections either in concert with amphotericin B or as the sole agent.[35] Flucytosine is excreted into the urine as active drug in high concentrations. Unfortunately, it is fairly toxic with reversible bone marrow toxicity and hepatotoxicity being common. These adverse effects correlate directly with high serum levels and can be avoided in most patients who have normal renal function by using no more than 25 mg per kg orally every 6 hours for 7 to 10 days. Treatment longer than this is likely to lead to the development of resistance to flucytosine. The risk of toxicity increases greatly with renal dysfunction and the dose must be reduced (Table 26.4).

Local Antifungal Administration

Instillation of amphotericin B into the bladder to treat candiduria is used much less frequently now than previously.[47] Although local instillation will eliminate candiduria the effect is brief and Candida colonization returns in 1 to 2 weeks

in most patients.[48–50] Bladder instillation obviously is not efficacious for patients who have upper tract infection.

The usual daily dosage has been 50 mg amphotericin B deoxycholate per liter of sterile water. An indwelling catheter must be placed for instillation and most often a triple-lumen catheter is used for this purpose. This allows continuous slow infusion of amphotericin B. However, it has been questioned whether this effectively allows the infusate to "wash" the whole bladder or just the local area where the catheter is located. The alternative method for infusing amphotericin B is to administer a bolus of drug several times daily through a standard indwelling catheter, clamp the tube after the administration of drug, and then after about 30 minutes allow the infusate and urine to drain.

Most physicians and patients prefer oral azole therapy rather than bladder instillation, and recent guidelines do not recommend bladder instillation as a therapeutic option.[35] However, there are some specific circumstances in which local administration of amphotericin B can be useful. For example, bladder instillation might be helpful for treating patients who have documented cystitis with C. krusei, or C. glabrata resistant to fluconazole. In some of these patients local infusion of amphotericin B has proved useful.[51] Some have advocated the use of fluconazole bladder infusion (200 mg in 1 liter sterile saline daily) for patients who have renal insufficiency and have failed oral fluconazole therapy and are not candidates for systemic amphotericin B therapy.[52] The other circumstance in which local administration of either fluconazole or amphotericin B is indicated is when a patient has a fungus ball as discussed next.

Treatment of Complications

Patients who have a fungus ball should be treated with systemic antifungal agents, either fluconazole or amphotericin B deoxycholate with or without flucytosine, and surgical or radiologic interventions to relieve obstruction caused by the fungus ball.[35] Nephrostomy tubes placed into the collecting system are usually irrigated with amphotericin B, but fluconazole has also been used in this context.[53] This causes no damage to the kidney but achieves very high local levels of antifungal drug in the fungus ball. Other methods to break up fungus balls include irrigation with saline or streptokinase[54] and debulking the hyphal mass by percutaneous endoscopic disruption.[55,56] Treatment of emphysematous pyelonephritis almost always requires nephrectomy, as is the case with some patients in whom papillary necrosis has occurred following severe Candida pyelonephritis. Perinephric abscess can sometimes be drained without loss of the kidney. For all of these complications of upper tract candidiasis antifungal treatment with either fluconazole or amphotericin B is indicated in concert with surgical management.

Prostatitis

Candida prostatitis presents with symptoms similar to those noted with bacterial prostatitis, but generally patients are not as acutely ill as they can be with bacterial infection. Perineal discomfort, pressure behind the pubis, dysuria, difficulty voiding, and sexual dysfunction are some of the symptoms that may be present.[57–60] The patient may or may not be febrile. Diffuse infection or abscess formation can occur and rarely, emphysematous prostatitis.[61] The prostate is tender on examination and urine obtained after prostatic examination may reveal yeasts. Patients may present with urinary retention, thought to be due to benign prostatic hyperplasia or cancer, only to have Candida infection found on biopsy.

A combination of surgery and antifungal treatment is usually required for effective treatment of Candida prostatitis or prostatic abscess. Fluconazole is recommended as the preferred antifungal agent provided the organism is susceptible.[35] Fluconazole concentrations in prostatic tissue are approximately 30% of serum concentrations.[62] For infections due to C. glabrata or C. krusei that are resistant to fluconazole, amphotericin B is preferred and has been shown to be efficacious.[57] No data are available regarding the penetration of voriconazole, posaconazole, or the echinocandins into prostatic tissue, and their efficacy is unknown.

Epididymoorchitis

Candida epididymoorchitis is uncommon and appears to occur more often in patients who have diabetes and an indwelling catheter or urinary tract instrumentation.[63] A tender scrotal mass usually brings the patient to the physician's attention.[63–66] The presence of candiduria is a clue to the etiology of the epididymoorchitis.[63] Ultrasound or CT scan to assess for abscess formation should be performed. Drainage or orchiectomy is usually required for resolution. Fluconazole, 400 mg daily, is the preferred antifungal agent,[35] but there is experience using amphotericin B with flucytosine.[64,65] Treatment should continue for several weeks and until all signs of infection have resolved.

OTHER YEASTS

Yeasts other than Candida species are an uncommon cause of urinary tract infections. The most common among the non-Candida yeasts is Cryptococcus neoformans, a heavily encapsulated environmental yeast. This fungal infection occurs predominantly in persons who are immunosuppressed but normal hosts also can be infected by C. neoformans. The pathogenesis of infection begins with inhalation of the yeast, which is nonencapsulated in the environment and thus more easily dispersed. The initial infection involves the lungs and usually is asymptomatic. Because of the neurotropism of this organism, meningitis is the most common clinical manifestation.

Widespread disseminated infection, usually with accompanying meningitis, occurs commonly in those who are markedly immunosuppressed, especially patients with AIDS. In autopsy series kidney involvement has been noted in 25% to 50% of AIDS patients, but it is usually asymptomatic.[67] Symptomatic genitourinary tract involvement can occur as one aspect of widely disseminated infection or present as isolated prostatitis or epididymoorchitis.[67–69] Even focal

involvement implies disseminated infection, however, and other sites of infection should always be sought in such patients. The prostate can remain as a reservoir for viable Cryptococcus organisms after other sites of infection are successfully treated leading to subsequent relapse.[70]

The diagnosis of cryptococcosis is established by growth of C. neoformans in culture, by visualization of the encapsulated yeast in tissue sections with special stains, and/or by detection of capsular antigen in serum or body fluids. Treatment is based on whether meningitis is present and on the state of immune suppression in the host. In general, patients who have meningitis and/or disseminated infection should receive initial therapy with amphotericin B and flucytosine and subsequent consolidation and maintenance therapy with fluconazole.[71] In those rare cases that appear to have focal genitourinary tract cryptococcal infection, fluconazole 400 mg daily for at least 6 months is the preferred treatment.[71]

Saccharomyces cerevisiae has been described in a few cases as a cause of urinary tract infection.[72,73] The presentation is the same as that noted with Candida species. If the clinical microbiology laboratory does not identify yeasts isolated from urine to the species level, this organism will not be differentiated from Candida. S. cerevisiae is often resistant to fluconazole, and successful treatment may require amphotericin B.[74]

Trichosporon asahii is an opportunistic yeastlike organism that causes disseminated infection in immunosuppressed hosts, most often in those who have leukemia and are neutropenic. Genitourinary involvement can be related to disseminated infection or in certain settings can occur as an isolated infection. This appears to be the case in kidney transplant recipients who can be merely colonized, develop local fungus ball formation and obstruction, or have progressive invasion of the transplanted kidney without the occurrence of disseminated infection.[75] Treatment of disseminated infection is usually with voriconazole, and treatment of localized infection is voriconazole with surgical relief of obstruction, if present.

ASPERGILLUS AND OTHER MOLDS

Aspergillus and other molds uncommonly involve the urinary tract. In most instances involvement is noted for the first time at autopsy in patients who have widely disseminated infection. However, symptomatic localized urinary tract infections of the kidneys, the prostate, and the epididymis have been reported.[1,76–83] Most commonly these infections are due to Aspergillus species, but infections with the Mucorales, including Rhizopus and Mucor species, and other more rare molds have also been reported.[1] In most cases the patients who have urinary tract mold infections are immunosuppressed due to bone marrow or solid organ transplantation, HIV/AIDS, or neutropenia related to hematologic malignancies.[76,79–83] However, a few patients have been reported who had only diabetes or corticosteroid use as risk factors.[77,78]

The usual pathogenesis in most cases is hematogenous spread to the urinary tract from an initial pulmonary infection. However, primary renal aspergillosis that developed post-lithotripsy in a diabetic patient and localized Aspergillus prostatic abscess related to indwelling bladder catheterization have been reported with no other focus of infection.[77,78]

Kidney involvement is usually manifested by numerous microabscesses and infarcts, and, in some cases, obstruction to the collecting system occurs due to the development of fungus balls.[1] Patients who have obstructing renal lesions present with decreased urine output, flank pain, and fever. Prostatic and epididymal abscesses present with dysuria, frequency, or localized painful scrotal swelling.

Fungus balls or lower tract abscesses can be visualized by CT scan or ultrasound examination. Diagnosis of a mold infection is dependent on tissue biopsy showing invasion by hyphae and culture of the biopsy sample revealing the specific organism. Urine cultures cannot be relied on to yield the organism. Removal of an obstructing fungus ball, and many times nephrectomy, is required to treat mold infections of the kidneys. Surgical drainage of a prostatic abscess and epididymoorchiectomy are usually needed to effectively treat lower tract mold infection. Systemic antifungal therapy, either with amphotericin B or voriconazole for aspergillosis and with amphotericin B for mucormycosis, is necessary in all but exceptional cases in which truly localized infection has been documented. Mortality remains high in patients who have kidney involvement.

ENDEMIC FUNGI

The endemic fungi are those fungi that are restricted to certain geographical areas and that are dimorphic. They exist in the environment as molds, which are the infectious forms. In the body, and in the laboratory at temperatures from 35°C to 37°C, they transform to the yeast phase or in the case of Coccidioides, the spherule phase. The major endemic mycoses are Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis, and Coccidioides posadasii. Paracoccidioides brasiliensis is restricted to South America and Penicillium marneffei to Southeast Asia and will not be discussed further. All of the major endemic mycoses have been reported to infect the genitourinary tract. Infection occurs by the hematogenous route as a sequel to the initial pulmonary infection. There are two major manifestations involving the genitourinary tract. Kidney involvement occurs as one manifestation of widespread disseminated infection with these fungi and is generally asymptomatic, but can be associated with renal insufficiency. The other manifestation is infection of the prostate, epididymis, or testicles presenting either as an isolated finding or as one manifestation of active disseminated infection. In either case, the pathogenesis of infection is via the hematogenous route.

B. dermatitidis has the greatest propensity to cause symptomatic genitourinary tract infection. In patients who have disseminated blastomycosis, involvement of the

genitourinary tract occurs in as many as a third of cases.[1] Kidney involvement is generally asymptomatic and found only at autopsy.[84] In most cases symptomatic infection involves the prostate and less commonly the epididymis or testicles. In some patients, dysuria, hesitancy, and trouble initiating urination are the presenting symptoms of what later is shown to be disseminated blastomycosis.[85] In others, biopsy of a prostatic nodule or a nontender epididymal mass, thought to be cancer, shows granulomas, and B. dermatitidis is seen on histopathologic examination and/or grown from the tissue.[84,86] Every patient who has blastomycosis found to involve the genitourinary tract should have a workup to define the extent of involvement of other organs.

Symptomatic genitourinary tract involvement with histoplasmosis is rare, but autopsy findings document spread to the kidneys not uncommonly in patients who have disseminated histoplasmosis.[87,88] Individual case reports of testicular or prostatic abscesses, epididymitis, and ulcerations of the bladder have been published.[87,89,90] In most of these cases a prostatic nodule or an epididymal or testicular mass, thought to be cancer, is found on biopsy to show granulomas and the small budding yeasts typical of H. capsulatum. In a few cases immune complex glomerulonephritis with H. capsulatum antigen demonstrated in the mesangium has been described.[87,88]

Coccidioidomycosis rarely causes symptomatic urinary tract infection but autopsy series of disseminated coccidioidomycosis have noted kidney involvement in 30% to 40% of cases.[1] Rarely, in the course of severe disseminated coccidioidomycosis, renal insufficiency can be ascribed to kidney involvement. In some patients with disseminated coccidioidomycosis, coccidioiduria can be found with an absence of symptoms. Localized infection, presenting as abscesses or mass lesions of the epididymis, testicles, or prostate, also occurs in patients who have coccidioidomycosis. Sometimes this occurs in the absence of documented disease elsewhere, but in other patients urinary tract involvement is just one manifestation of disseminated infection.[91–93]

Treatment of genitourinary infection due to the endemic mycoses depends on the pathogenesis of the infection. In most cases urinary tract involvement is one manifestation of disseminated disease and systemic therapy with amphotericin B or an azole, as recommended for disseminated infection, is given.[94–96] For those patients who have a focal mass or abscess in the epididymis or testicle, surgical removal has usually been accomplished before the diagnosis is suspected. Although cure has been reported with surgical excision alone,[93] additional treatment with an azole agent is recommended because the pathogenesis of infection is always related to hematogenous dissemination. If biopsy of a prostatic nodule shows infection with one of the endemic mycoses further surgical drainage is generally not necessary, and the infection can be treated successfully with an azole agent.

The specific azole agent to use should be discussed with an infectious diseases consultant. Itraconazole, the azole of choice for histoplasmosis and blastomycosis, does not achieve very high levels in the prostate. However fluconazole, a second-line agent for these infections, achieves excellent prostatic tissue levels.[62] Fluconazole is a first-line agent for coccidioidomycosis and should be used for focal Coccidioides infection of the genitourinary tract. Little is known about the penetration into prostatic tissue by voriconazole or posaconazole, and neither is currently recommended for treatment of the endemic mycoses.

CHAPTER

27 Urinary Tract Tuberculosis

Mark S. Pasternack • Robert H. Rubin

Over a century ago, Osler noted that tuberculosis is the net result of two pathologic processes: "In all tubercles two processes go on: the one—caseation—destructive and dangerous; and the other—sclerosis—conservative and healing. The ultimate result in a given case depends upon the capabilities of the body to restrict and limit the growth of the bacilli."[1]

Perhaps in no other form of tuberculosis are these processes so important in determining the impact of the tubercle bacillus on an organ system as in genitourinary tuberculosis. Progressive destruction and caseating necrosis of the kidney ultimately leading to "autonephrectomy" have long been recognized as possible catastrophic complications of renal tuberculosis. However, progressive ureteral and calyceal scarring seen during healing can result in severe obstructive uropathy and comparable loss of renal function. Therefore, medical and surgical management of genitourinary tuberculosis must focus on both aspects of the tuberculous process, with emphasis on the early diagnosis and prevention of both tissue damage and excessive scarring. Achieving these goals can be challenging because genitourinary tract tuberculosis can be a particularly occult process. This chapter outlines a practical approach to this problem, based on established epidemiologic, pathogenetic, and clinical principles.

ETIOLOGY

Robert Koch first identified the tubercle bacillus in 1882. His classic report defined staining procedures for the direct observation of bacilli in clinical specimens (including the use of aniline dyes for "acid-fastness"), culture techniques on solid medium for the in vitro passage of bacilli isolated from clinical or experimental lesions, and subsequent inoculation of guinea pigs with cultured material to confirm its etiologic role in tuberculosis.[2] Demonstrating an etiologic role for the tubercle bacillus in tuberculosis became the basis of "Koch's postulates," the standard criteria for etiologic research in infectious disease.

Mycobacterium tuberculosis, the human tubercle bacillus, is one of approximately 90 species of higher bacteria with unusual shared structural and tinctorial properties.[3,4] All mycobacteria, members of the genus Mycobacterium, have the ability to take up aniline dyes, such as those contained in carbolfuchsin, and to resist decolorization by washing in alcohol acidified with inorganic acid (e.g., 95% ethanol, 3% HCl). This unique property correlates with the extremely high lipid content of mycobacterial cell walls. Although all mycobacteria are obligate aerobes, they are found in nature in disparate settings: some species are soil and water saprophytes, whereas others are true pathogens of amphibians, reptiles, birds, and various mammals. M. bovis, the bovine tubercle bacillus, has virtually disappeared as a human pathogen in modern societies through tuberculin testing of cattle and pasteurization of dairy products. A variety of mycobacterial species can be pathogenic in humans (e.g., M. avium-intracellulare), whereas others have been characterized as human saprophytes (M. gastri, M. smegmatis). M. tuberculosis is distinguished from the many other "atypical" mycobacteria by its metabolic properties, rate of growth, pigment production, and virulence in experimental infection in guinea pigs, as well as by genomic features that facilitate direct speciation. M. tuberculosis characteristically appears as a small, slender, slightly curved rod 2 to 4 μm in length with a diameter of 0.3 to 0.6 μm. Bacilli can appear singly or in small clusters on clinical specimens. Unlike infected pulmonary secretions where the density of organisms commonly is high, the low density of bacilli in urine samples, as well as their possible confusion with saprophytic mycobacteria, makes urine acid-fast stains impractical for rapid diagnosis. Although M. tuberculosis can grow on simple synthetic media, typically in intertwining aggregates known as serpentine cords, its slow growth rate (15 to 20 hours doubling time) necessitates culture periods of up to 6 to 8 weeks for the appearance of visible colonies. Optimal growth requires high partial pressures of oxygen, as in air, although bacilli can remain viable but metabolically dormant under greatly reduced PO_2. This is particularly relevant for the progression of renal tuberculosis (see later).

The mycobacterial cell wall accounts not only for acid-fast staining, but for some of the important host–parasite

interactions as well. In addition to a peptidoglycan cell wall layer common to conventional bacteria, a second glycan layer encases the organism.[5,6] This arabinogalactan layer is covalently linked to the peptidoglycan layer and also contains esters of mycolic acids, which are very large fatty acids that are unique to mycobacteria. A number of complex glycolipids reside in the outermost layer—"cord factor" (trehalose dimycolate), phosphatides, and sulfatides—but are not covalently linked to the glycan layers.[6] Cord factor is responsible for growth in serpentine cords in vitro and is a virulence factor in vivo.[7] These cell wall moieties (lipoarabinomannan, trehalose dimycolate and its sulfated derivatives) have multiple effects on mycobacterial virulence: they inhibit phagosome maturation and fusion with lysosomes,[6,8] reduce cell surface expression of key host antigen presentation proteins and costimulatory molecules, thus diminishing the presentation of mycobacterial antigens by infected macrophages,[9] and even modulate macrophage survival and apoptosis.[10]

EPIDEMIOLOGY

Tuberculosis and HIV infection are each responsible for approximately 1.8 million deaths worldwide each year (which includes ~400,000 deaths due to dual infections, especially in resource-limited settings).[11] The World Health Organization (WHO) estimates that approximately one third of the world's population is latently infected with M. tuberculosis with approximately 9 million new cases occurring each year. Although more than 90% of cases occur in the developing world with significant overlap among symptomatic HIV infected individuals,[12] 10 to 15 million individuals in the United States are infected with M. tuberculosis, mostly with latent tuberculosis infection.[13,14]

The long-term secular decline in tuberculosis incidence that followed the development of successful antituberculous chemotherapy was disrupted in the 1980s by a decline in the support of tuberculosis control programs, as well as the interrelated challenges of the HIV epidemic, troubling social trends producing growing populations of homeless and incarcerated individuals, and the rising incidence of drug-resistant tuberculosis infections.[15–17] These processes often acted in synergy to produce epidemics of tuberculosis, frequently involving multiply drug-resistant strains, among vulnerable populations in hospitals, correctional facilities, residential care facilities, and homeless shelters.[18,19] The number of reported U.S. tuberculosis cases in 1992 (~26,000) roughly equaled those of 1982, erasing a decade of progress in tuberculosis control. An intensification of tuberculosis control measures, including greater emphasis on intensive initial empiric therapy, sensitivity testing of clinical isolates, and reliance on directly observed therapy, has helped to regain control of the tuberculosis epidemic, and by 2010 only 11,181 new cases were reported.[20]

Tuberculosis in the United States is primarily an urban disease with 75% of the new cases occurring in the 99 metropolitan areas that have populations of more than 500,000. Increasingly, in the United States tuberculosis is found among immigrants and minority groups. Approximately 80% of reported cases in 2010 occurred in Asian, Hispanic/Latino, and African American residents in roughly comparable numbers, whereas whites accounted for only 16% of cases. The nationwide incidence of tuberculosis was 3.6/100,000 overall, with marked variation by ethnicity and immigrant status: the incidence was highest among Asians and Pacific Islanders (22.5/100,000) and was lowest among non-Hispanic whites (0.9/100,000). In 2010 only 40% of cases occurred in native-born individuals, and in many states over 70% of cases occurred among foreign-born individuals. Dual infection with HIV was reported in approximately 10% of cases.[20] In Europe, similar patterns of increased tuberculosis have been seen among immigrants from high tuberculosis incidence countries.[21–23] In addition, relatively high rates of extrapulmonary tuberculosis and drug-resistant tuberculosis have been observed among these immigrant populations.[24,25]

Although the proportion of extrapulmonary disease has nearly tripled from 7.6% to 21% of reported cases of tuberculosis in the United States over the past 40 years, the relative incidence of genitourinary infections among all forms of extrapulmonary tuberculosis has gradually declined.[26] Regional lymph node infections remain the most commonly encountered form of extrapulmonary tuberculosis—genitourinary disease, once common,[27] has declined to 6.5% of extrapulmonary tuberculosis cases in the United States over the past 20 years or so, a frequency roughly comparable to that of tuberculous meningitis.[26] Similar low rates of genitourinary tuberculosis have been reported recently from both low incidence (France)[28] and high incidence countries (Nepal).[29] As outlined later and in Figure 27.1, extrapulmonary tuberculosis is the result of hematogenous spread from a pulmonary site of primary infection. Thus, genitourinary tuberculosis is observed in two clinical settings: commonly, as a late manifestation of earlier clinical or subclinical pulmonary infection and, rarely, as part of the multiorgan infection seen with disseminated (miliary) tuberculosis.

Statistics from the prechemotherapy era indicated that approximately 3% of unselected autopsy patients and 26% of those dying of tuberculosis had evidence of genitourinary tract tuberculosis at autopsy.[30] This high rate of genitourinary disease has declined with effective treatment of pulmonary tuberculosis. Currently, it is estimated that significant genitourinary disease will develop in approximately 4% to 8% of non–HIV-infected individuals with pulmonary tuberculosis if adequate therapy is not instituted.[31]

Traditionally, genitourinary tuberculosis has been a disease of young to middle-aged adults with a slight male predominance.[27,31–34] Although genitourinary tuberculosis has been reported in children,[35–37] it is quite uncommon, and seen today in the rare young child with concomitant miliary disease[37] or in school-age children with somewhat more indolent clinical features similar to those seen in adults.[36] Approximately one quarter of the patients with genitourinary tuberculosis have a history of diagnosed tuberculosis

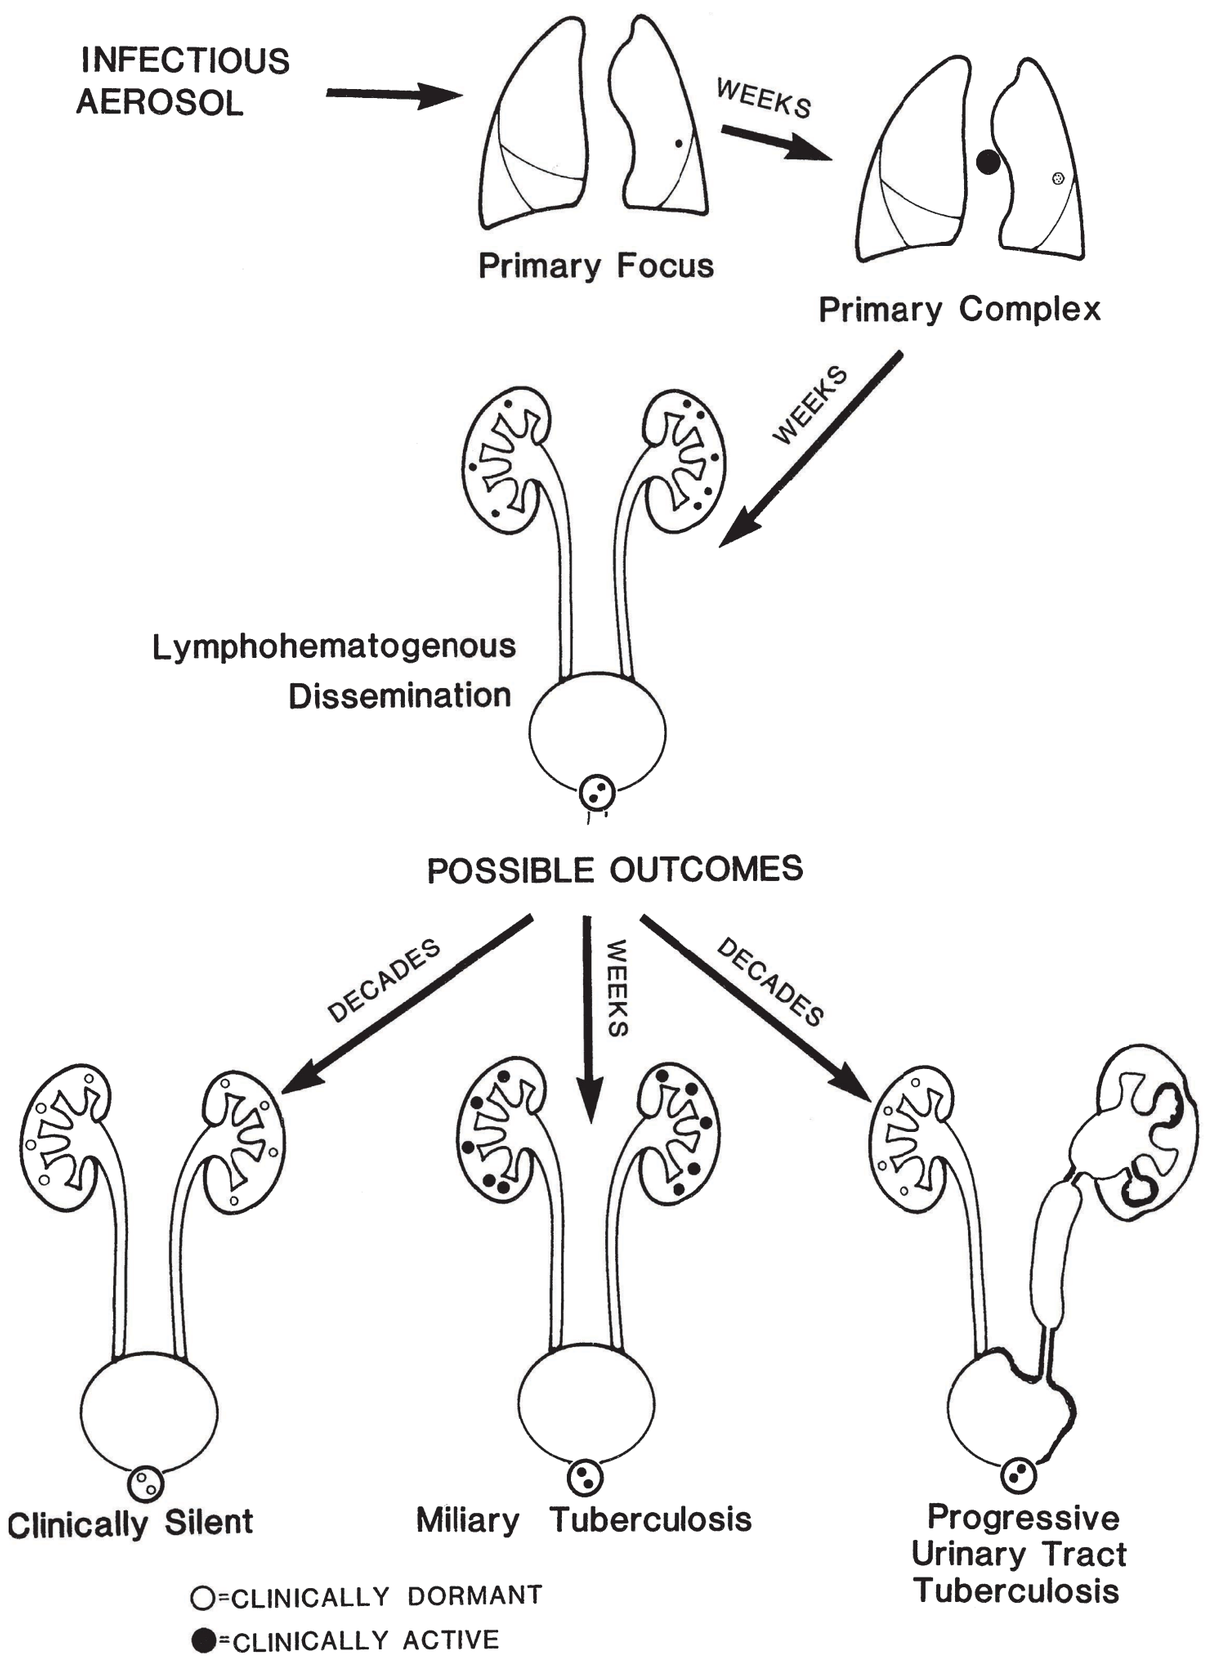

FIGURE 27.1 Schematic representation of the pathogenesis of urinary tract tuberculosis.

(usually of the lung). In an additional 25% to 50% of patients, changes compatible with old pulmonary tuberculosis can be found on chest X-ray films made at the time of diagnosis of genitourinary tract disease.[27,31–33]

Thus, in the non–HIV-infected individual a considerable interval exists between the onset of pulmonary infection and the diagnosis of active genitourinary tuberculosis. Considering patients with early clinical manifestations of primary tuberculous infection (i.e., erythema nodosum, pleurisy, or hilar adenopathy), the time lapse is most commonly 16 to 25 years; intervals exceeding 40 years have been well documented. If one looks at patients with reactivation pulmonary tuberculosis, the time lapse is usually about 4 to 8 years, but still may be as long as several decades.[31,32,38]

There are several epidemiologic implications of these observations. Decreasing the incidence of genitourinary tuberculosis requires the identification and treatment of persons with pulmonary infection prior to the development of extrapulmonary disease. Second, long after the incidence of pulmonary tuberculosis falls, the incidence of genitourinary disease will remain relatively stable, because a reservoir of patients with silent genitourinary tract infection will persist for decades after the incidence of new pulmonary infection falls.[24–26] Thus, the rise in tuberculosis cases that occurred in the late 1980s and early 1990s virtually guarantees an increase in extrapulmonary infections such as genitourinary disease in the next few decades, unless extensive case finding and effective treatment of these individuals are achieved. This task will be rendered particularly difficult because the burden of disease has fallen heavily on those with poorer access to skilled medical care—foreign born, the homeless, the incarcerated, migrant farm workers, and inner city ethnic minority groups.[16,17,20,39] Finally, it is clear that the age of the population with genitourinary tract tuberculosis, and other forms of extrapulmonary tuberculosis, reflects the average age at presentation of active pulmonary tuberculosis—significantly younger among immigrants, urban ethnic minority populations, and the disadvantaged, and over the age of 50 among other groups.[25]

In assessing epidemiologic factors that might predispose to tuberculosis, it is important to emphasize that fewer than 10% of persons with latent tuberculosis infection (reflecting a positive tuberculin skin test or in vitro interferon-γ release assay) ever become ill from this infection.[40] Of this group,

approximately 3% to 5% have manifestations of genitourinary tract disease.[27] In addition to exposure to tuberculosis in high incidence countries, public health factors including crowding, homelessness, poverty, drug addiction, and incarceration, all amplified by the AIDS epidemic,[12] play a significant role in the spread of tuberculosis.

A minimum estimate of clinical tuberculosis in HIV-infected patients is approximately 15% worldwide[11] and 8.6% in the United States,[20] with a somewhat higher incidence (13.8%) in adults 25 to 44 years of age.[41] The annual rate of tuberculosis among tuberculin skin test positive HIV-infected individuals in the United States has been reported to be 35 to 162 cases per 1,000 person years, although in Africa the risk of clinical tuberculosis may be as high as 5% to 10% annually.[42] These variations reflect differences in the prevalence of tuberculosis and immunodeficiency in different population groups. Thus, the rate of tuberculous disease among HIV-infected, tuberculin positive individuals in the United States is roughly 10 times higher than that among comparable HIV-infected, tuberculin negative individuals,[43] and is approximately 80 to 370 times that of the general American population.[44] The continued refinement and availability of antiretroviral therapy combined with antituberculous therapy has altered the natural history of tuberculosis in HIV-infected individuals and, when combined with vigorous public health efforts to identify and monitor treatment, the prognosis of both HIV and tuberculosis in dual-infected patients has improved dramatically.[12,45–47] Dual therapy is often challenging due to drug interactions: for example, rifabutin is required instead of rifampin if a protease inhibitor is used. Fluconazole metabolism is increased in the presence of rifampin[48] and other agents, thus complicating care in these patients. Despite the need for care in constructing the therapeutic regimen, early diagnosis and appropriate therapy of both infections are critical to the patient's survival.[41,44,46,47]

Two epidemiologic patterns of mycobacterial infection are observed in HIV-infected individuals. Individuals from population groups with a low rate of endemic tuberculosis, such as gay men and those with posttransfusion HIV disease, primarily have difficulties with disseminated M. avium-intracellulare infection. In contrast, HIV-infected individuals who either belong to or interact with populations bearing a high rate of endemic tuberculosis (those in developing countries, immigrants from these countries, the homeless, intravenous drug users, prisoners, and, in the United States and other developed countries, the inner city poor) are primarily afflicted with disseminated M. tuberculosis.[44,45] Careful molecular epidemiologic studies have demonstrated that in HIV-infected individuals, outbreaks of tuberculosis resulted in either progressive primary disease or reinfection of individuals whose immunity had been attenuated by the effects of progressive HIV disease.[49,50]

In HIV-infected individuals tuberculosis is often the AIDS-defining illness, not infrequently occurring early in the course of HIV infection. In contrast to other AIDS-related opportunistic infections, the $CD4^+$ count is not a reliable indicator of tuberculosis risk among HIV-infected persons.[44] Extrapulmonary disease, often in conjunction with pulmonary disease, is common,[44] and the time course for the development of disseminated disease may be greatly abbreviated in these individuals. In this setting, genitourinary disease is less commonly seen as an isolated phenomenon, but rather as part of disseminated infection. The incidence of HIV infection among patients with extrapulmonary tuberculosis was significantly elevated in the initial phases of the HIV epidemic,[51] but at present the rate of extrapulmonary tuberculosis in dually infected individuals is comparable to that seen in HIV-uninfected patients.[26] Serial New York City data confirmed aggressive dual therapy led to a reduced rate of extrapulmonary tuberculosis in dually infected individuals.[45]

The coexistence of tuberculosis with HIV infection has already had major public health consequences on the control of tuberculosis. Because HIV infection both increases the burden of infectious tubercle bacilli and obscures the symptoms (owing to the impaired inflammatory response of these immunosuppressed individuals), these people are highly efficient transmitters of tuberculosis. The expected consequence of this is the potential for a marked increase in the occurrence of secondary cases, and even epidemics, in contacts of these individuals, particularly in medical settings, crowded living conditions, prisons, and shelters for the homeless. Those populations most at risk for both HIV infection and tuberculosis, and the coexistence of these two infections, are the same populations with the highest incidence of drug-resistant tuberculosis. The result of this concordance of events is that the tuberculosis that can be amplified by the HIV epidemic includes a high potential for drug-resistant disease, particularly in the former states of the Soviet Union and more generally in resource-limited settings, and can complicate both the management of individual patients and the public health strategies that must be taken to protect the community.[11]

One additional epidemiologic consideration is the possibility that urine from patients with urinary tract tuberculosis could transmit tuberculosis to household members. Vasquez and Lattimer[52] reported a doubling of the incidence of tuberculin positivity among children of parents with active urinary tract tuberculosis without active pulmonary disease. Other observers have been unable to confirm this finding. Our policy has been not to isolate persons with isolated urinary tract tuberculosis but to consider their urine potentially infectious and to maintain contact precautions when handling it.

PATHOGENESIS OF TUBERCULOSIS

Systemic Aspects

The host–pathogen interaction in tuberculosis involving a slowly proliferating pathogen that resists host microbicidal mechanisms stands in stark contrast to conventional bacterial disease, where despite the pathogen's rapid proliferation, the host's resources (complement fixation, opsonization, phagocytosis, and ready lysis within phagocytic cells)

are formidable. The pathogenesis of tuberculosis reflects the balance of intrinsic mycobacterial virulence and the host immunologic response. The classic response in tuberculosis, the formation of granulomas, is ordinarily protective for the host by limiting the proliferation and spread of M. tuberculosis, but may be pathogenic as well, because it may lead directly to tissue injury in the form of caseation.[53–55] Thus, the clinical manifestations of tuberculosis represent not only the consequences of mycobacterial proliferation but also host reparative and destructive responses. In the absence of immunosuppression, the lifetime risk of symptomatic M. tuberculosis infection among latently infected individuals is only ~10%. Similarly, the risk of developing extrapulmonary disease, such as genitourinary tuberculosis, is rather low. An increased understanding of the molecular mechanisms responsible for host defense against mycobacterial infections has led to a growing appreciation that human susceptibility to mycobacterial infection may be attributable in significant measure to host genetic factors, as well as to the intrinsic virulence of M. tuberculosis isolates.[56–58]

Tubercle bacilli are inhaled as small particle aerosols and gain direct access to the alveoli.[53] Presently, ingestion of M. tuberculosis with primary localization of disease in the intestinal tract or oropharynx is rare. The small aerosol inoculum multiplies slowly and is phagocytosed by polymorphonuclear leukocytes, pulmonary macrophages, and dendritic cells. Mycobacteria interact with respiratory epithelium,[59] alveolar surfactant proteins,[60] and both the classic[61] and alternate complement systems,[62] but interactions with macrophage Toll-like receptors (TLRs 2, 4, and 9)[63–65] play a critical role in initiating the host immune response. TLRs are pattern-recognition proteins, expressed on macrophages and dendritic cells, which serve as innate immune receptors.[66] Each TLR binds one or more of a variety of microbial products (endotoxin [lipopolysaccharide], bacterial DNA, flagellin, mycobacterial lipoarabinomannan, etc.) and transduce inflammatory signals culminating in the activation of NF-κB and transcription of tumor necrosis factor α (TNF-α) and interferon-γ.[67] Following opsonization by C3, M. tuberculosis binds to phagocytic cell surface complement receptors and is phagocytosed.[62] Mycobacteria suppress the intracellular calcium flux that normally accompanies phagocytosis and inhibits macrophage activation and phagolysosome maturation.[68,69] M. tuberculosis can also directly adhere to, infect, and translocate across alveolar epithelial cells and endothelial cells,[70–72] facilitating access to lung interstitium and the pulmonary microcirculation, enhancing early dissemination to extrapulmonary foci.

The host response to mycobacterial infection has been called the IL-12–interferon-γ axis.[56,58] Macrophage activation via TLR signaling and other early events is associated with secretion of TNF-α and IL-12 and the related cytokines IL-18 and IL-23[65,73] as well as by activation of NO synthase 2, leading to the synthesis of reactive nitrogen intermediates.[65] The cytokines program resting T lymphocytes toward an inflammatory Th1 response. Activated Th1 lymphocytes secrete as their dominant cytokines interferon-γ as well as TNF-α, and this in turn activates macrophages and enhances their mycobactericidal activity. TNF-α also triggers apoptosis of infected macrophages, which may inhibit mycobacterial replication (see later). The use of TNF-α antagonists (e.g., etanercept, infliximab, and adalimumab) as disease-modifying agents in the treatment of rheumatoid arthritis and other inflammatory diseases confirms a central role for TNF-α in the host response against mycobacterial infection. These therapies have been associated with rapidly progressive tuberculosis, impaired granulomatous reactions in tissue biopsies, and a high rate of extrapulmonary disease.[74]

In the initial stages of primary infection, resting macrophages have a limited ability to lyse mycobacteria, and the bacillary titer rises despite entrapment within macrophage and granulocyte phagosomes and lysophagosomes. Some bacilli can even escape from these organelles and replicate freely within the cytoplasmic compartment.[75] Macrophage-mediated killing of intracellular M. tuberculosis requires the L-arginine-dependent generation of reactive nitrogen intermediates, such as nitric oxide, and this capability is greatly enhanced following macrophage activation by interferon-γ and TNF.[65,76] Thus, infected macrophages program T cells toward a Th1 response which in turn augments macrophage-mediated mycobacterial killing. Foamy macrophages are characteristically seen in caseating granulomata and offer a protected locus of mycobacterial persistence; the disruption of these macrophages helps to recycle M. tuberculosis to the extracellular milieu.[77] T cell-infected macrophage interactions are more complex because several cytolytic T cell effector populations are generated which can lyse infected macrophages.[78,79] In addition to the expansion of conventional peptide-specific $CD4^+$ and $CD8^+$ $\alpha\beta$ T-cell receptor-expressing populations,[79] T cells with a double negative phenotype (CD4-, CD8-) expressing $\gamma\delta$ T-cell receptors recognize mycobacterial phospholipid antigens presented by MHC-like molecules (e.g., CD-1) and lyse infected macrophages via Fas–FasL interaction.[80] These phospholipid antigens are also recognized by $CD8^+$ $\alpha\beta$ T-cell receptor-expressing cytotoxic T lymphocytes, triggering perforin-mediated cytotoxicity, and by natural killer (NK) T cells, which possess NK markers as well as $\alpha\beta$ T-cell receptors.[81] In at least some instances, immune lysis of infected macrophages appears beneficial to the host. Perforin-mediated lysis of infected macrophages reduces M. tuberculosis viability by 50% in vitro,[81] and may be important in vivo in reducing the number of infecting tubercle bacilli. The cytotoxic granules that contain perforin also contain granulysin, a lipid-binding protein that has potent mycobactericidal activity in the presence of perforin.[82] In contrast, Fas-mediated lysis of macrophages does not affect mycobacterial viability, but may be important in reducing antigen presentation and dampening the immune response. The immune lysis of heavily infected macrophages may facilitate the phagocytosis of released mycobacteria by additional activated macrophages. These newly recruited cells have a lower bacillary

burden and may be more effective at killing their intracellular bacilli, or serve as target cells for cytotoxic T lymphocytes.

In addition to their direct cytotoxic activities, the activated lymphocytes secrete a variety of cytokines, including interferon-γ, migration inhibitory factor (MIF), granulocyte-macrophage colony-stimulating factor, TNF-α, IL-12, and inhibitory cytokines such as interleukin-4 (IL-4)[83] and IL-10.[84,85] IL-4 production undermines the host Th1 response, and triggers tissue fibrosis,[86] a characteristic finding in chronic tuberculosis. In HIV-infected individuals coinfected with M. tuberculosis, immunosuppressive cytokines (e.g., IL-10) produced by macrophages/monocytes diminish the T-lymphocyte response in vitro, suggesting that Th2-like activity contributes to uncontrolled, systemic spread in these patients.[87] Macrophages are recruited to infiltrate the area of mycobacterial growth to form granulomas and mature into epithelioid cells by the macrophages' elaboration of TNF[88]; this process requires NK T cells.[89] In spite of macrophage activation, the killing of intracellular mycobacteria by human macrophages is often incomplete.[69]

The outcome of early tuberculous disease covers a spectrum from granuloma formation with efficient containment and healing to slowly progressive disease at the site of the primary pulmonary infection, or to clinically significant systemic spread of disease. Mycobacterial dissemination is actually the rule rather than the exception (Fig. 27.1). Although most bacilli are contained within macrophages initially, their continued proliferation disrupts the macrophages and the bacilli return to the extracellular environment. Most are engulfed again, but some bind to respiratory epithelial cells and ultimately translocate to the microcirculation[71,72] or are carried in the lymphatic drainage and produce regional lymphadenitis. Alternatively, some viable mycobacteria may reach regional lymph nodes while entrapped within dendritic cells or migratory macrophages. Progressive infection within the lymph node contaminates efferent lymph, and when sequential lymph node barriers fail, thoracic duct lymph delivers mycobacteria to the venous blood, seeding the pulmonary bed as well as extrapulmonary sites, such as the skeletal system, lymph nodes, and, most frequently, the kidneys.

Thus, limited hematogenous dissemination due to low grade bacillemia can occur early in the process of granuloma formation when the number of mycobacteria is small, and most organisms are found intracellularly within the macrophages comprising the granuloma. Small granulomas rapidly form at the metastatic foci because mycobacterial immunity is evolving or is already established at the time of dissemination. Although the bacilli may remain viable, the granulomas may remain clinically silent for decades.

Granuloma formation may itself contribute to the pathogenesis of severe tuberculosis.[53] Granulomas are active lesions with continued ingress of immune T lymphocytes and monocytes.[54,90] Shortly after microscopic granulomas become well established, polymorphonuclear leukocytes and monocytes enter the lesion.[91] The resultant phagocytosis is accompanied by exocytosis of lysosomal contents with local tissue destruction. This leads to a characteristic local necrotic process, known as caseation. Macrophage disruption returns the mycobacteria to the extracellular environment, where their proliferation accelerates.[53] Communication of the caseating granuloma with the bronchial tree restores favorable metabolic conditions, and mycobacterial titers can increase by several logarithms. This highly infected material can spread endobronchially to produce additional foci of pulmonary tuberculosis or excavate into a pulmonary vessel, leading to intense bacillemia. Such severe hematogenous dissemination commonly is responsible for miliary tuberculosis rather than limited extrapulmonary disease. In miliary tuberculosis, the systemic features of illness overshadow the asymptomatic renal involvement.

Pathogenesis of Renal Tuberculosis

Local factors play a significant role in the evolution of clinically significant renal tuberculosis. The small silent renal granulomas resulting from silent hematogenous dissemination are typically found bilaterally in the renal cortex and arise from capillaries within and adjacent to glomeruli (Fig. 27.2).[92] A glomerular location is not surprising in view of their high rate of perfusion (increased likelihood of bacillus delivery during sparse bacillemia) and their favorable oxygen tension. Such cortical granulomas usually remain dormant for decades. In some patients, however, bacillary

FIGURE 27.2 Early renal tuberculosis. Three small granulomas are visible in the cortex. The adjacent papillary tip is involved as well. (From Kollins SA, Hartman GW, Carr DT, et al. Roentgenographic findings in urinary tract tuberculosis. *Am J Roengentol Radium Ther Nucl Med.* 1971;121:487, with permission.)

proliferation within the glomerular capillary leads to capillary rupture and delivery of organisms into the proximal tubule. Clinically important renal tuberculosis, therefore, is usually initially localized to the medulla. This is likely caused by entrapment of mycobacteria and infected macrophage debris within the loop of Henle[92] and the known impairment of phagocyte function associated with the hypertonic environment found in the medulla.[93,94]

Analogous to progressive pulmonary disease, granulomas may enlarge in the medulla, leading to caseation and papillary necrosis. Such intraparenchymal granulomas may persist as mass lesions but commonly cavitate into the calyceal system. Despite bilateral hematogenous seeding of the kidneys, clinically significant disease is usually unilateral.[92] Communication of the caseating granuloma with the collecting system usually is responsible for the spread of bacilli to the renal pelvis, ureters, bladder, and accessory genital organs and is analogous to the endobronchial spread of infection seen in cavitary lung disease.[30] Lymphatic spread to contiguous structures also occurs in addition to epithelial infection by a luminal mechanism,[95] and direct hematogenous seeding of pelvic genital organs with clinical sparing of the kidney can occur occasionally.[30] In addition to the direct parenchymal destruction associated with advanced renal lesions, the fibrosis that accompanies the granulomatous process within the collecting system, such as infundibular strictures and renal pelvic kinking, adds an obstructive mechanism that may contribute significantly to progressive renal dysfunction.

PATHOLOGY

The caseating granuloma is the classic microscopic finding in essentially all forms of tuberculosis (Figs. 27.3 and 27.4). Medlar[92] characterized the early pathologic findings in renal tuberculosis by meticulously examining microscopic sections of kidneys from patients who died of pulmonary tuberculosis. Bilateral microscopic renal involvement is the rule, although the extent of involvement usually is asymmetric. Granulomas vary greatly in size, from lesions contained within a single glomerulus to large caseous abscesses, as well as in the apparent density of acid-fast bacilli.

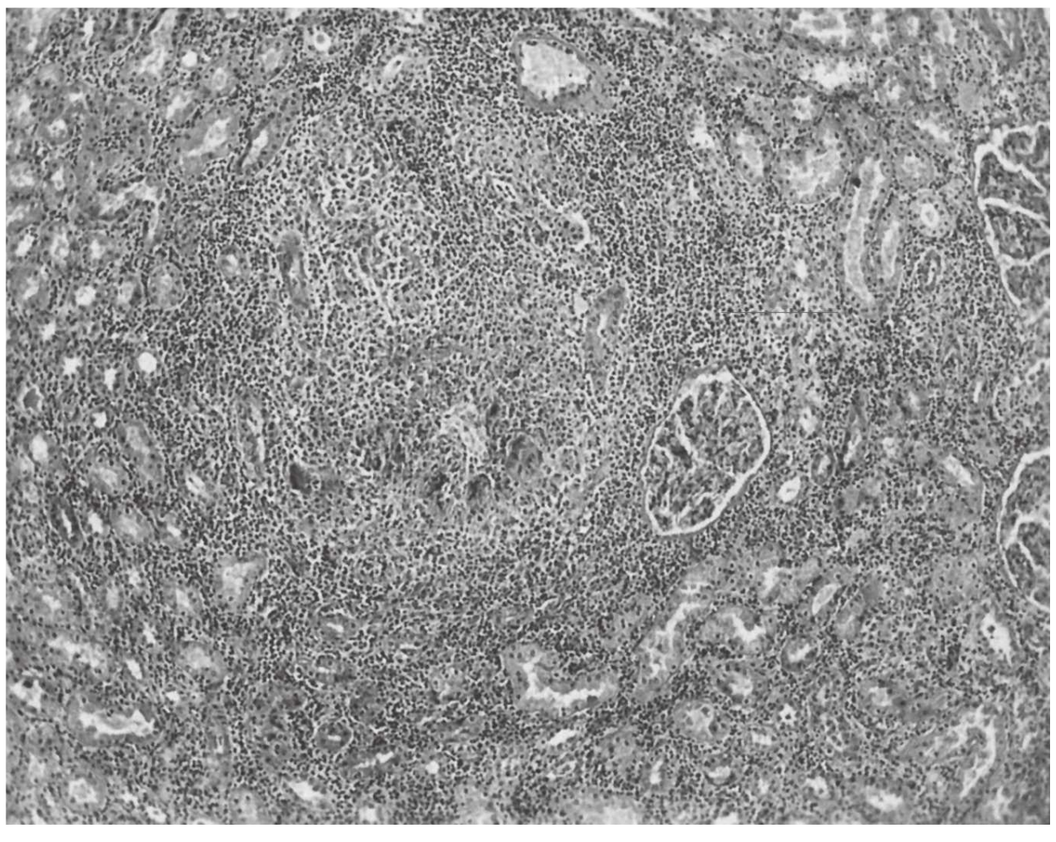

FIGURE 27.3 A caseating granuloma in the renal cortex. In addition to the necrotizing granuloma in the center of the field, a diffuse interstitial infiltrate of lymphocytes is seen. Some tubules are preserved (H&E, magnification ×79).

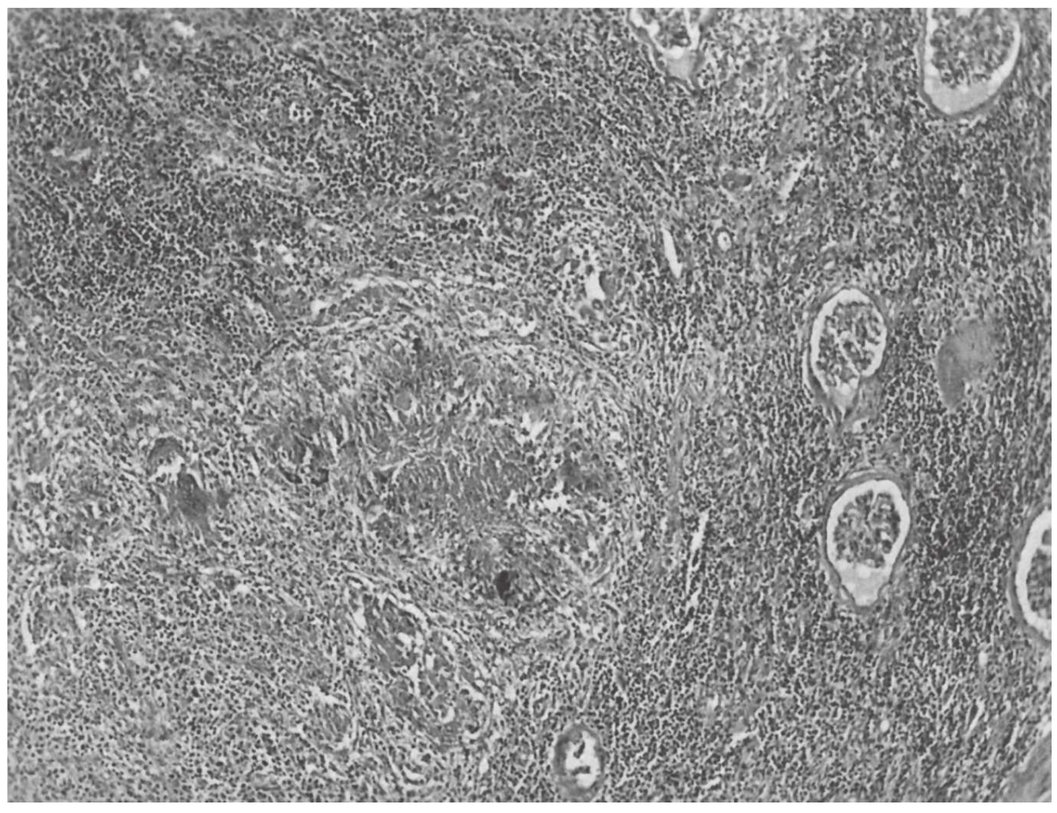

FIGURE 27.4 Renal cortical tissue showing destruction of tubules and a diffuse lymphocytic infiltrate with focal caseating granulomas. The glomeruli are spared (H&E, magnification ×79).

Most renal granulomas originate as vascular lesions in the cortex. Although glomerular lesions predominate, with foci within the capillary tuft, granulomas may develop within capillaries in relation to the convoluted or collecting tubules. Lesions within the collecting system per se are usually at the nadir of the loop of Henle or in the pyramidal collecting tubule, always draining a vascular granuloma (Fig. 27.2), and presumably developing in response to ulceration and discharge of these lesions into the collecting system. Focal sparing of tubules, glomeruli, or both within the granulomas is characteristic of renal tuberculosis (Figs. 27.3 and 27.4).

Clinically significant caseation progresses from the medullary collecting system lesions.[96] The enlarging medullary abscess extends to the papilla and commonly produces papillary necrosis. It may replace the medullary pyramid and persist as a parenchymal cavity, or tuberculoma, or discharge into the draining calyx. Several pyramids may be involved individually with a variable extent of destruction or may coalesce to destroy the bulk of the renal parenchyma (Fig. 27.5). Infection of the calyces, pelvis, and ureter is followed by stricture formation, so that caliectasis[97] and tuberculous pyonephrosis ("caseocavernous renal tuberculosis") are common in advanced disease. The end-stage kidney is nonfunctional ("autonephrectomy") and destroyed by the combined necrotizing and obstructive processes. Calcification in advanced lesions is common and may be focal or generalized, which produces a "putty" or "cement" kidney.

FIGURE 27.5 Renal tuberculosis with replacement of most of the parenchyma by caseous necrosis. There is cavitation of pyramids.

CLINICAL FEATURES

Urinary tract tuberculosis is notorious for its insidious mode of presentation, with approximately 20% of cases diagnosed unexpectedly at operation or autopsy. As many as 20% to 56% of patients with active urinary tract tuberculosis detected on the basis of an abnormal urinalysis or culture deny either constitutional symptoms of tuberculosis or symptoms referable to the urinary tract.[31–34,98,99] One measure of the frequently occult nature of urinary tract tuberculosis comes from Lattimer's classic report[99] wherein 18 of 25 physicians with renal tuberculosis were diagnosed only after developing far-advanced cavitary disease. If physicians with ready access to medical care have renal tuberculosis overlooked, then the problem is only compounded in the highest risk populations—inner city minority groups, immigrants from the developing countries of the world (particularly those undergoing social disruption), and the indigent elderly—all of whom have relatively poor access to medical care.

Roughly 75% or more of patients with urinary tract tuberculosis present with symptoms suggesting urinary tract inflammation. Such symptoms resemble those of conventional bacterial urinary tract infection—dysuria, urgency, frequency, mild or moderately severe back or flank pain, hematuria, nocturia, and pyuria. Renal colic, owing to the passage of clots or stones, may be observed in as many as 10% of patients.[31,32] Severe pain localized to the kidneys is uncommon but has been reported.[100] Epididymal thickening reflecting tuberculous epididymitis should heighten suspicion of upper tract tuberculosis. Noteworthy for their infrequency are the constitutional symptoms usually associated with tuberculosis—fever, weight loss, night sweats, and anorexia. Fewer than 20% of non-HIV infected patients with tuberculosis restricted to the urinary tract have constitutional symptoms, and the presence of such constitutional symptoms should suggest the presence of active tuberculosis in other organs as well.[31–33,98]

As noted previously, the extent of renal dysfunction secondary to tuberculous infection can be quite variable, from small focal areas of infection and scarring unassociated with any functional impairment to gross parenchymatous destruction and complete loss of function. As in any other form of tubulointerstitial nephritis (see Chapter 35), patients with renal tuberculosis may be subject to dehydration because of a concentrating defect, a tendency to lose salt, or both.[101] However, any patient with these findings should be evaluated for possible concomitant tuberculous adrenal disease (Addison disease), particularly when constitutional symptoms are present.[102,103]

Early diagnosis and therapy offers the best hope of limiting renal function loss resulting from parenchymatous infection and destruction. It is also important to identify patients experiencing renal functional loss due to hydronephrosis secondary to obstruction induced by the tuberculous process. Here the second element of the pathologic process induced by tuberculosis, sclerosis, exerts its effects. Strictures, usually either at the ureteropelvic junction or at the lower end of the ureter, can result in hydronephrosis and loss of renal function. Obstruction and hydronephrosis can develop during therapy because such sclerotic strictures are frequently part of the healing process. The clinician must be alert to this possibility, because correction of such obstruction is the best way to preserve renal function in patients with tuberculosis.[31,32,97,104–109]

There are three other major complications of renal tuberculosis: hypertension, superinfection with conventional bacteria, and nephrolithiasis. In 1940, Nesbit and Ratliff[110] reported that hypertension could be cured by the removal of a tuberculous kidney, an observation subsequently confirmed by other authors.[111–114] Subsequent data suggest that this is an uncommon event. First, hypertension may not be more common in patients with renal tuberculosis (<5% of those with tuberculous kidney infection are hypertensive) than in the general population. Second, surgical cure of hypertension in these patients appears to be the exception rather than the rule.[31,32,111] Renal vein renin sampling may be useful in predicting the outcome of surgery for patients with hypertension and renal tuberculosis.[115] Reversible renovascular hypertension due to direct involvement of the renal artery by tuberculous vasculitis has been rarely observed.[116]

Both nephrolithiasis and bacterial superinfection of a urinary tract rendered anatomically abnormal by the tuberculous process are not uncommon. Nephrolithiasis has been

reported in 7% to 18% of patients with renal tuberculosis, and superinfection has been reported in 12% to 50% of patients with urinary tract tuberculosis.[32]

The delivery of large numbers of M. tuberculosis into the urine of patients with renal tuberculosis is the major cause of tuberculous infection of the ureters and bladder. In both loci, scarring and contractures are the major results of tuberculous infection, again the not-so-benign effects of "healing." The result is a small, contracted bladder with greatly thickened walls. There are three functional consequences of this process: a small bladder capacity, incomplete emptying and thus a predisposition to secondary bacterial infection, and, most serious of all, vesicoureteral reflux.[117,118]

The incidence of genital infection in association with urinary tract tuberculosis is very different in the two sexes. In men, such dual involvement is relatively common. Indeed, genital disease may lead to the recognition of extensive urinary tract infection as noted previously. Epididymitis, with or without orchitis, presenting as a scrotal mass or discomfort, is the most common manifestation of male genital tuberculosis. The majority of such patients are free of constitutional complaints.[98,99,119] The importance of this form of tuberculosis is underlined by the report of Ferrie and Rundle[119] that 75% of their patients with tuberculous epididymoorchitis already had evidence on pyelogram of tuberculosis involving the bladder, ureters, kidneys, or all of these organs at the time they presented with their epididymal disease. Epididymitis can present decades after apparently adequate therapy for renal tuberculosis.[120]

Tuberculous prostatitis, an uncommon locus of genitourinary disease, may present with a mass lesion (mimicking prostatic carcinoma), pain, or both, rather than systemic symptoms in most patients and is frequently associated with urinary tract disease (Fig. 27.6). The prostate, like the epididymis and testes, can be infected either by means of the hematogenous route or more directly from infected urine.[121]

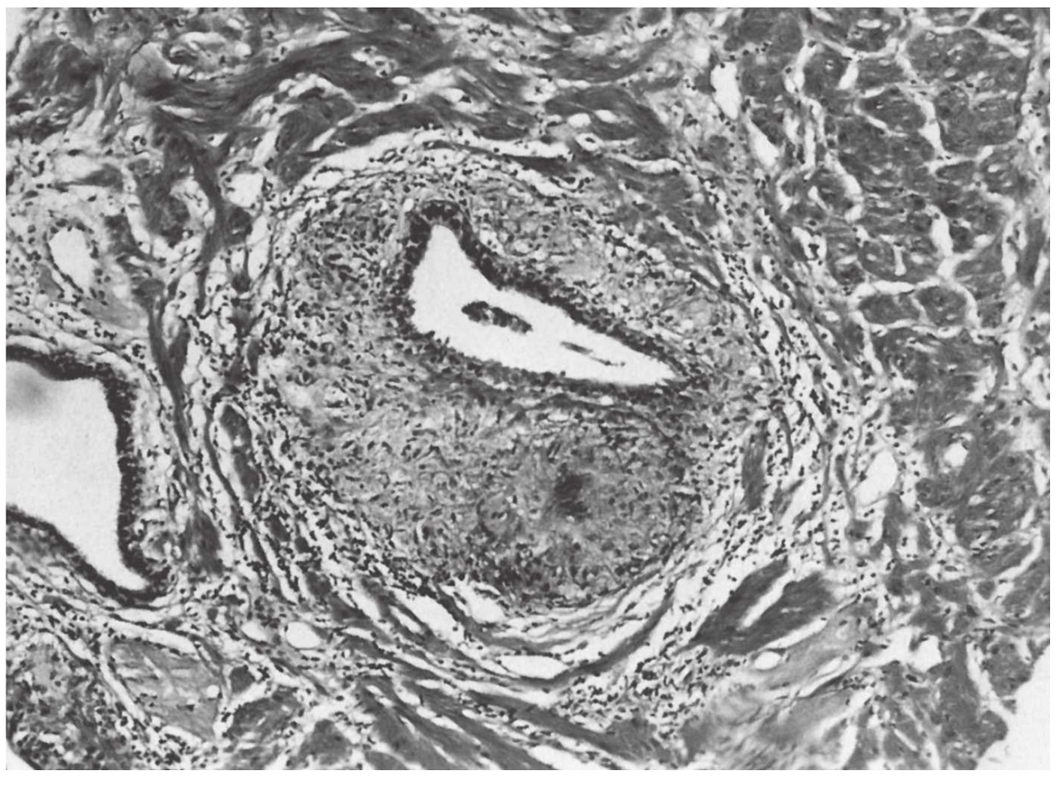

FIGURE 27.6 Prostatic tissue with epithelioid granulomatous reaction surrounding a duct (H&E, magnification ×125).

Viable organisms frequently persist in the prostate long after other parts of the genitourinary system have been sterilized.[31,121] Persistent prostatic infection is presumably related to the same difficulty in delivering effective antimicrobial therapy to the prostate that is responsible for persistent conventional bacterial prostatitis.

Urethral and penile tuberculosis are both quite uncommon but may present with strictures, fistulous tracts, and ulcerating or papulonecrotic skin lesions. Both these forms of tuberculous infection may reflect seeding from infected urine, spread from a contiguous lower genitourinary source such as the prostate, or from direct hematogenous seeding.[104,121] Primary penile tuberculosis has been reported to occur owing to the direct inoculation of M. tuberculosis into a wound following ritual circumcision, after the use of contaminated surgical instruments, sexual contact with women with tuberculosis of the female genital tract, or from contaminated clothing.[104,122,123]

In contrast, tuberculosis of the female reproductive tract is quite distinct from urinary tract tuberculosis. The incidence of renal disease in women with genital tuberculosis is less than 5%, which is little different from that found in patients with pulmonary or skeletal tuberculosis.[124] The explanation for this difference between men and women is clear: Whereas involvement of the male genital tract usually occurs from direct extension or from infected urine, the female genital tract is almost always infected hematogenously, with seeding of the fallopian tubes and then secondary extension from this site. Thus, the major manifestations of female genital tuberculosis—infertility, secondary amenorrhea, vaginal bleeding, and pelvic pain—are quite separate from the manifestations of urinary tract tuberculosis.[31,32 124,125]

Given its insidious nature, routine laboratory studies are quite important in raising the possibility of genitourinary tuberculosis (see later). By far the most useful screening test is urinalysis. As emphasized by Simon and associates,[31] virtually the only time when a urinalysis is normal and a urine culture is positive for M. tuberculosis is in the patient with miliary dissemination, in whom the urinary tract seeding is a recent and perhaps insignificant event. In contrast, essentially every patient with established urinary tract tuberculosis has an abnormal urinalysis with pyuria, hematuria, or both. The old clinical teaching that the asymptomatic patient with pyuria, particularly with an acid urine and a urine culture that fails to reveal conventional bacterial pathogens, must be considered as having tuberculosis until proved otherwise remains true today.[31–33,98,99] Although there are other causes of "sterile pyuria," such as Chlamydia trachomatis or invasive fungal infection, tuberculosis must be excluded in patients with these findings. An abnormal urinalysis should be followed by the placement of an intermediate-strength tuberculin test (5 TU). Virtually every patient with urinary tract tuberculosis who is not receiving systemic steroids, anti-TNF-α therapy, or who has not been rendered anergic by such debilitating conditions as advanced malignancy or HIV infection has a positive tuberculin test. In contrast, fewer

than 20% of patients with urinary tract tuberculosis have abnormalities on tests that measure systemic illness (i.e., anemia, changes in white blood cell count, low serum albumin, etc.).[31,32] Similarly, azotemia at presentation is quite infrequent, because severe bilateral obstructive uropathy is uncommon. Approximately two thirds of patients with urinary tract tuberculosis have evidence of old or current tuberculosis on chest roentgenography.[14,31,32]

ATYPICAL MYCOBACTERIAL INFECTION

Genitourinary infection caused by atypical mycobacterial organisms is quite rare. A Taiwan university hospital recently reported a series of such patients[126]: surprisingly, underlying metabolic disease including chronic renal disease and diabetes mellitus was frequent whereas the incidence of HIV infection or steroid use was quite low. Patients presented with typical refractory lower tract urinary symptoms but had a high rate of systemic symptoms, including fever, and came to medical attention soon after the onset of symptoms, in contrast to patients with M. tuberculosis, who had a low rate of systemic complaints and often presented with persistent symptoms. A variety of nontuberculous mycobacteria was recovered by urine culture. M. avium-intracellulare accounted for 33% and the rapidly growing M. abscessus and M. fortuitum as well as M. gordonae caused another 40% of cases. Destructive and obstructive urinary tract disease, as seen with M. tuberculosis, was common.

In addition, a few cases of prostatic or epididymal infection, or both, owing to M. kansasii have been reported.[127,128] Disseminated disease due to this organism has also been reported in immunocompromised patients, with hematogenous seeding associated with a granulomatous reaction in the kidney and isolation of M. kansasii in the urine.[129] This form of genitourinary infection was more prominent in the early years of the HIV epidemic and currently in resource-limited settings with high rates of advanced HIV-associated immunosuppression.[130]

Diagnosis

The isolation of M. tuberculosis by urine culture is the definitive diagnostic test in renal tuberculosis. Early morning urine specimens are preferred over 24-hour urine samples,[14] because mycobacterial viability falls with prolonged exposure to acid urine.[131] In order to detect the low rate of bacilluria, three to five specimens should be submitted. Samples are routinely decontaminated by limited exposure to acid or alkaline solutions and then concentrated by centrifugation. Neither direct nor amplified nucleic acid hybridization probes are licensed for rapid diagnosis of urinary M. tuberculosis given their borderline sensitivity (~70%) compared to traditional culture,[132] although newer real-time polymerase chain reaction (PCR) methodology may prove as sensitive and specific as culture for the identification of urinary M. tuberculosis.[133]

Cultures are established on standard solid mycobacterial media, either egg-based (Löwenstein-Jensen) or agar-based (Middlebrook 7H10). These media also contain aniline dyes, such as malachite green, to inhibit the growth of bacterial contaminants. The transparent agar medium facilitates early visualization of microcolonies by approximately 1 week. Newer automated liquid based (Middlebrook 7H12) radiometric or colorimetric culture techniques have yields comparable to culture on solid media, with considerably more rapid recovery times.[134]

Microbiologic identification is based on colonial morphology, growth rate and optima (37°C, carbon dioxide-enriched atmosphere), absence of pigment production, accumulation of niacin, reduction of nitrate, and absence of significant catalase activity.[14] Commercial oligonucleotide reagents are available for the rapid speciation of primary isolates by nucleic acid hybridization techniques.

Other rapid diagnostic techniques have been developed but are not licensed yet for routine clinical use. These include high performance liquid chromatography to identify the spectrum of mycolic acids in the bacterial cell (which is useful after 7 to 10 days of culture), enzyme-linked immunosorbent assay (ELISA) techniques to detect mycobacterial protein antigens, and the detection of tuberculostearic acid by gas chromatography and mass spectroscopy.

In retrospective analyses of patients with renal tuberculosis, urine cultures were reported to be positive in ~70% to 90% of cases.[27,31–33] In patients with negative cultures despite optimal processing of multiple samples, the diagnosis is often reached by the recovery of M. tuberculosis from other sites (e.g., sputum or surgical specimens) in the setting of abnormal urinalyses and imaging, together with a positive tuberculin reaction. Some culture-negative patients have enclosed intraparenchymal granulomas which have not yet drained into the collecting system. When tissue specimens are submitted for mycobacterial culture, they are best macerated using sterile sand with a mortar and pestle, because automated homogenization methods may heat samples excessively and kill any mycobacteria present.[131]

Successful mycobacterial isolation provides an opportunity to perform drug susceptibility testing in addition to confirming the diagnosis of genitourinary tuberculosis. Drug susceptibility testing is strongly recommended on initial isolates from all patients, but is critically important in evaluating patients who previously received chemotherapy and in patients epidemiologically linked to known cases of drug-resistant tuberculosis.[14]

Radiology

Radiologic evaluation has long played a central role in the diagnosis and long-term management of patients with renal tuberculosis.[135,136] There is excellent correlation between the pathology of renal tuberculosis and the corresponding abnormalities seen by excretory urography.[137] Even plain films of the abdomen are valuable, as genitourinary

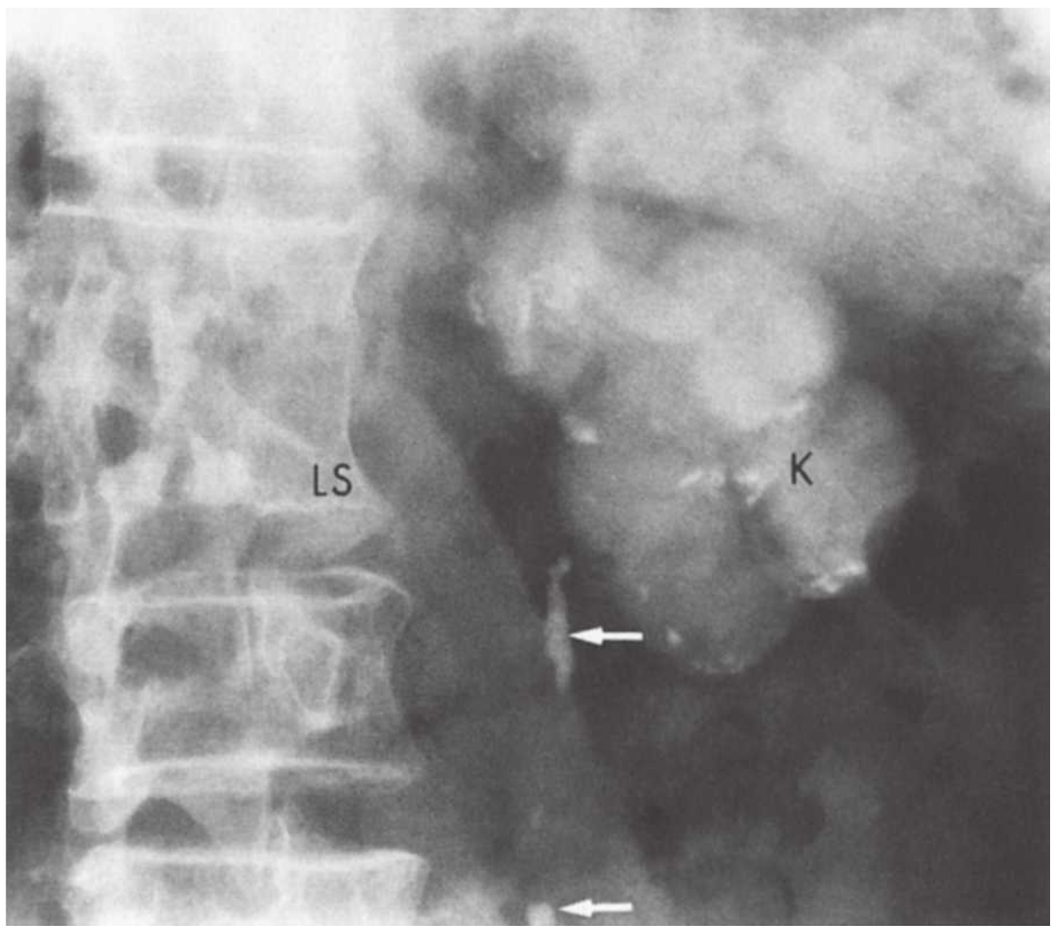

FIGURE 27.7 Plain film of the abdomen shows a left autonephrectomy with calcification of the kidney parenchyma and the left ureter (*arrows*). There is tuberculous involvement of the lumbar spine, resulting in fusion of the intervertebral disc space. *K,* kidney parenchyma; *LS,* lumbar spine.

calcifications (present in up to 50%)[138] as well as other extrapulmonary foci of mycobacterial disease (vertebral, mesenteric lymph node, adrenal glands) may be present (approximately 10%) (Figs. 27.7 and 27.8).[138] Chest radiographs show evidence of tuberculosis in 50% to 75% of patients with active renal disease.[31,32,139] In the remainder, the primary pulmonary granuloma, responsible for hematogenous spread, heals and may no longer be detectable by radiograph, but the metastatic renal granulomas progress to cause local destruction.

Excretory urography including nephrotomography traditionally has been the standard diagnostic imaging technique. In recent years, computed tomography (CT) with contrast, particularly helical CT, has provided increased delineation of renal parenchymal abnormalities, although contrast administration (with risks of allergy and nephrotoxicity) is still required, and the total radiation dose exceeds that of traditional excretory urography. Cross-sectional imaging including CT, magnetic resonance imaging (MRI), and sonography, provide a framework for assessing the renal parenchyma, adrenals, bladder, and genital organs that complements excretory urography.[140,141]

The earliest stage of renal involvement, the cortical granuloma (Fig. 27.2), is associated with positive urine mycobacterial cultures but negative excretory urograms. The spread of infection to the medulla and the evolution of cavitary disease in the papillae represent the earliest changes detectable radiologically (Fig. 27.9). Papillary granulomas caseate and rupture into the collecting system. The resulting small communicating cavities may be single or multiple but

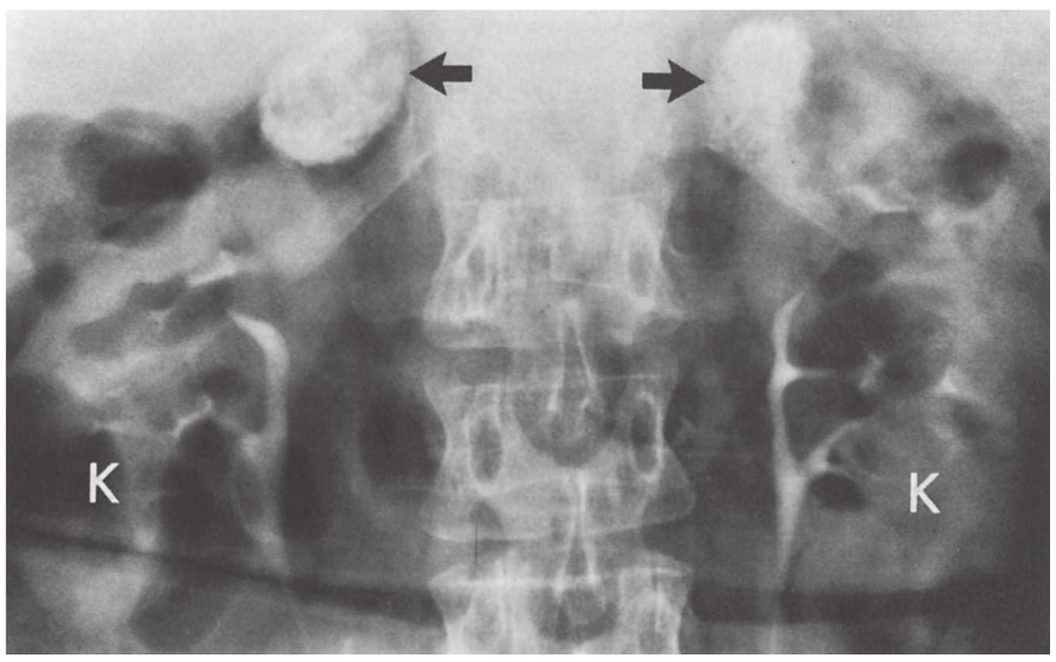

FIGURE 27.8 Tuberculous calcification of both adrenal glands (*arrows*). Intravenous urogram demonstrates the normal kidneys. *K,* normal kidneys.

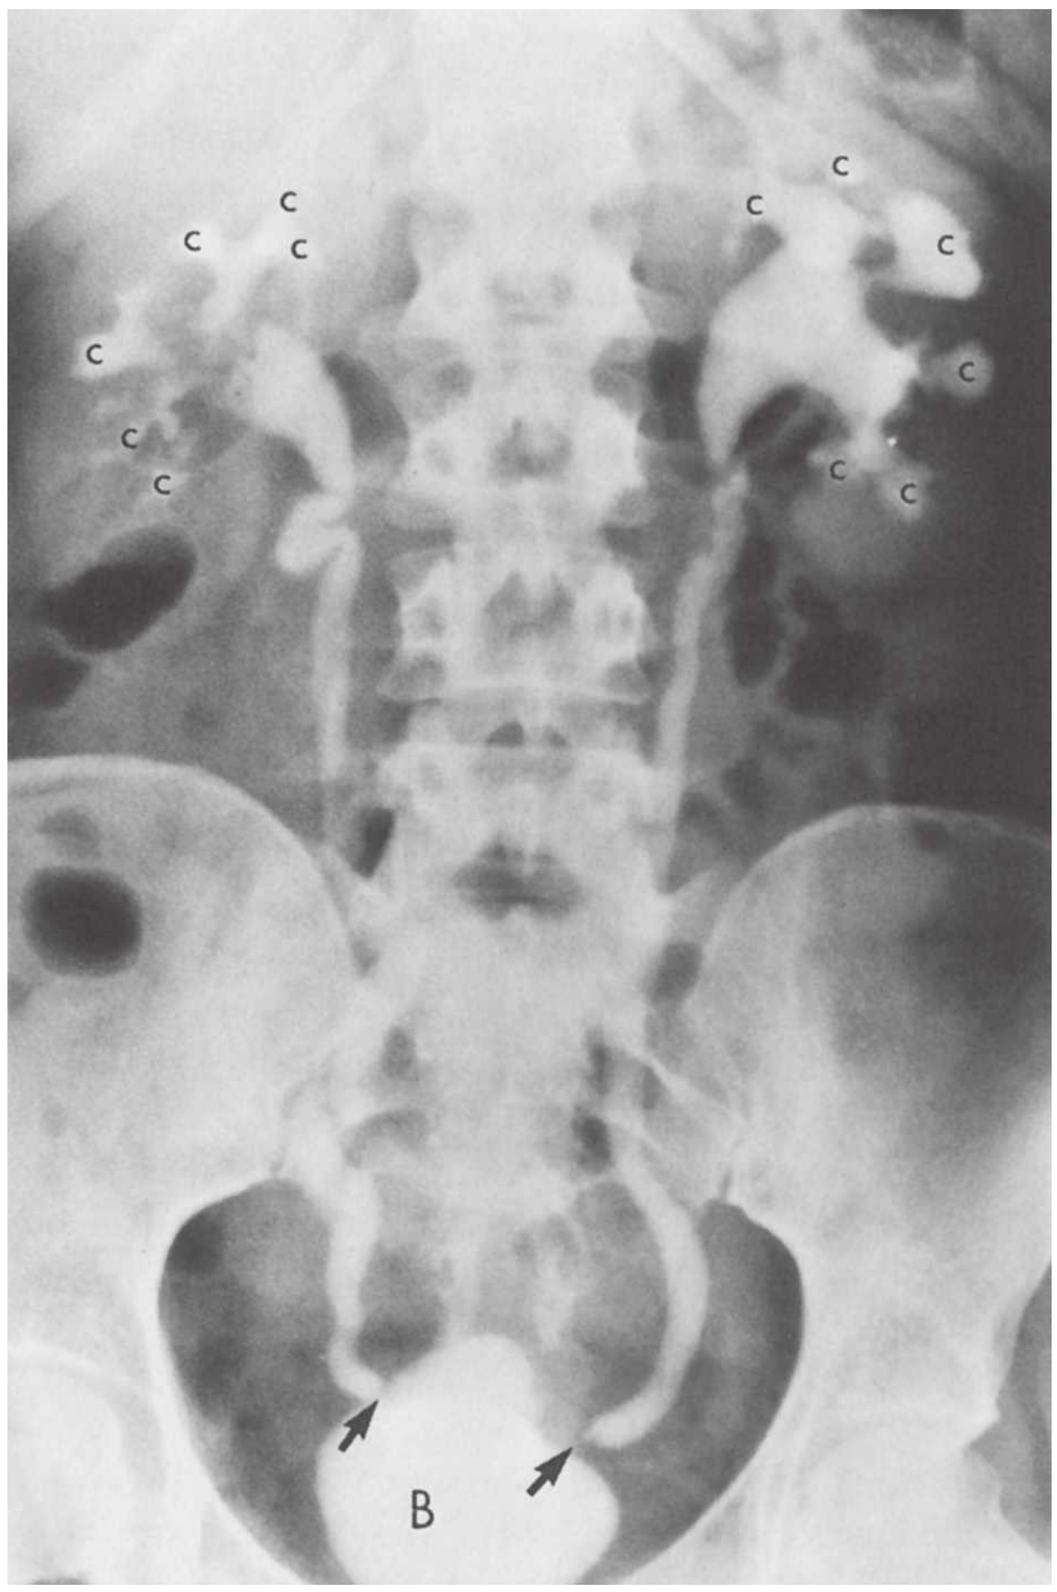

FIGURE 27.9 Intravenous urogram in a patient with active urinary tuberculosis, demonstrating papillary necrosis diffusely involving all the calyces in both kidneys. There is a small irregular bladder and narrowing of both distal ureters (*arrows*). *B,* bladder; *C,* calyces.

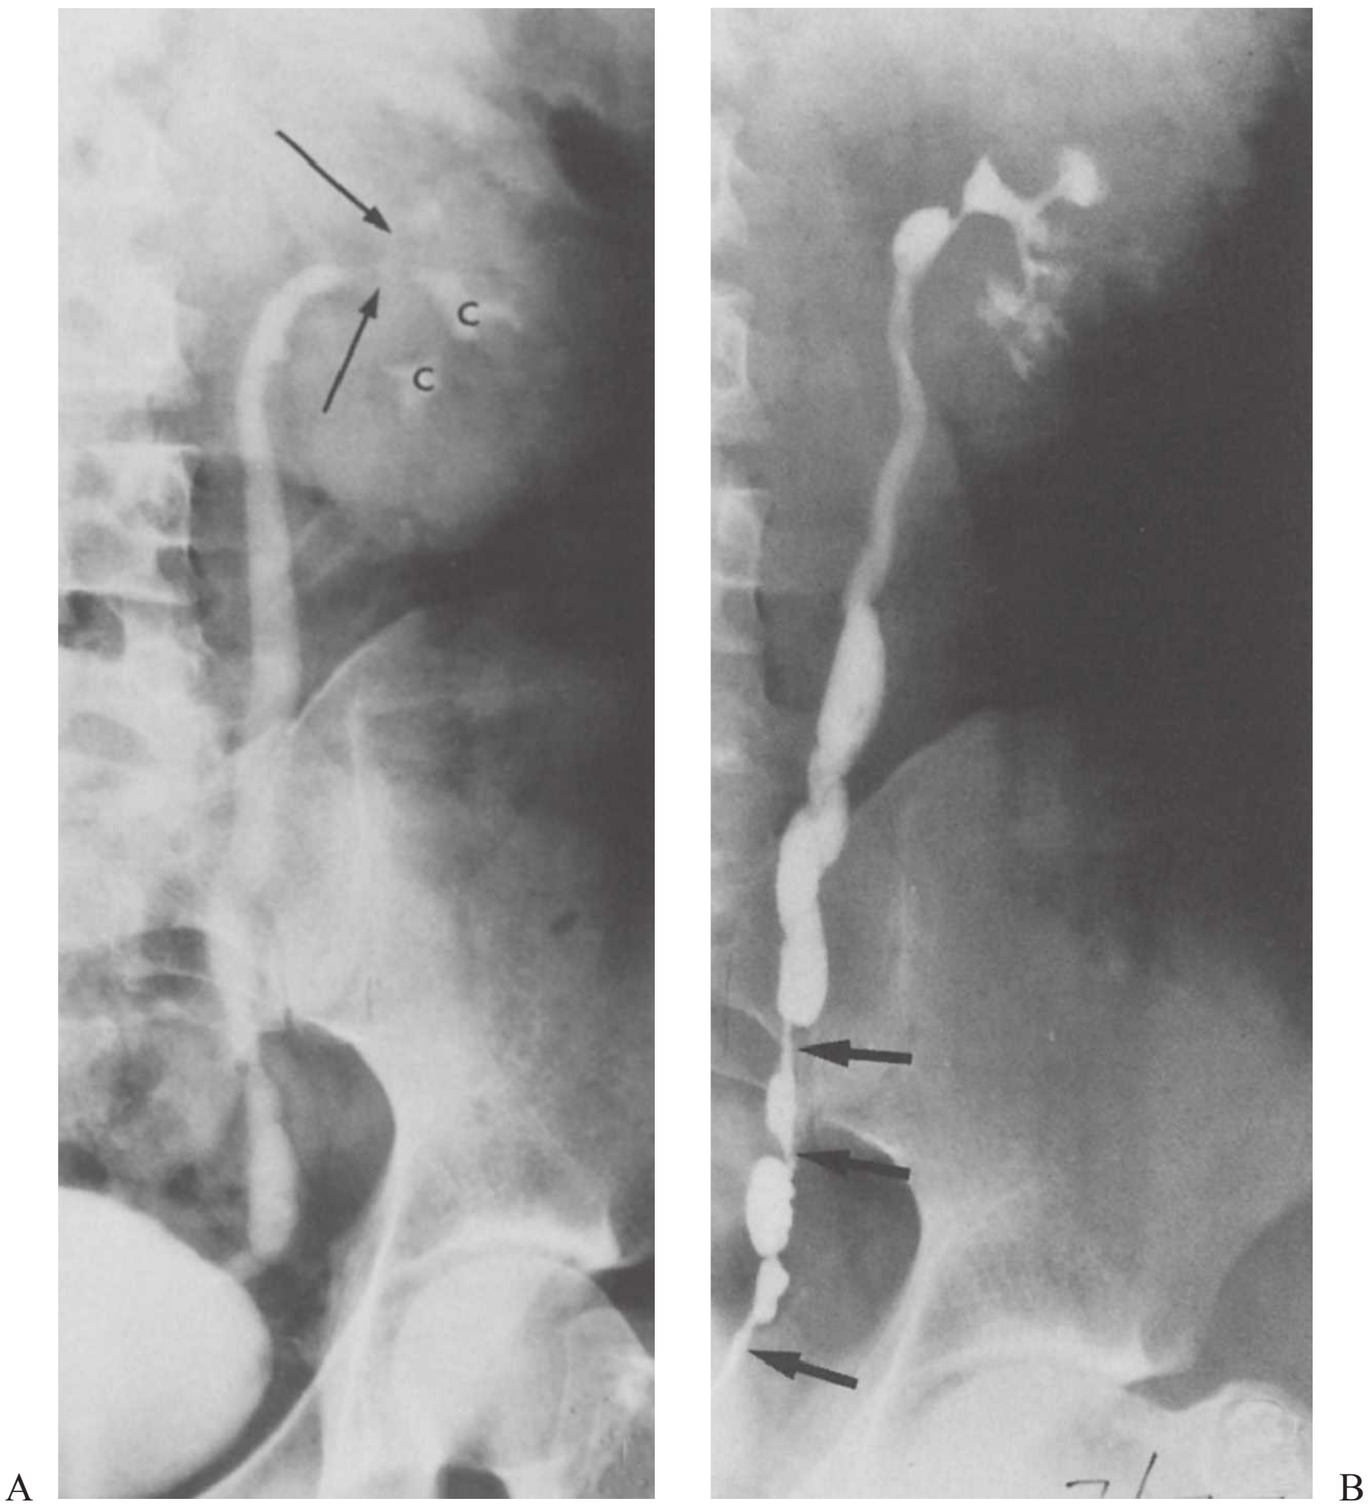

FIGURE 27.10 **A:** Intravenous urogram shows tuberculous narrowing of the left renal pelvis and upper pole infundibulum (*arrows*) and papillary necrosis of the lower pole calyces. The left ureter is moderately dilated and irregular in contour. **B:** Left retrograde pyelogram 6 months later, documenting fibrotic narrowing of the distal ureter (*arrows*) during antituberculous therapy. Tuberculous ureteritis commonly heals by cicatrization and may lead to severe obstruction of the collecting system. *C*, calyces.

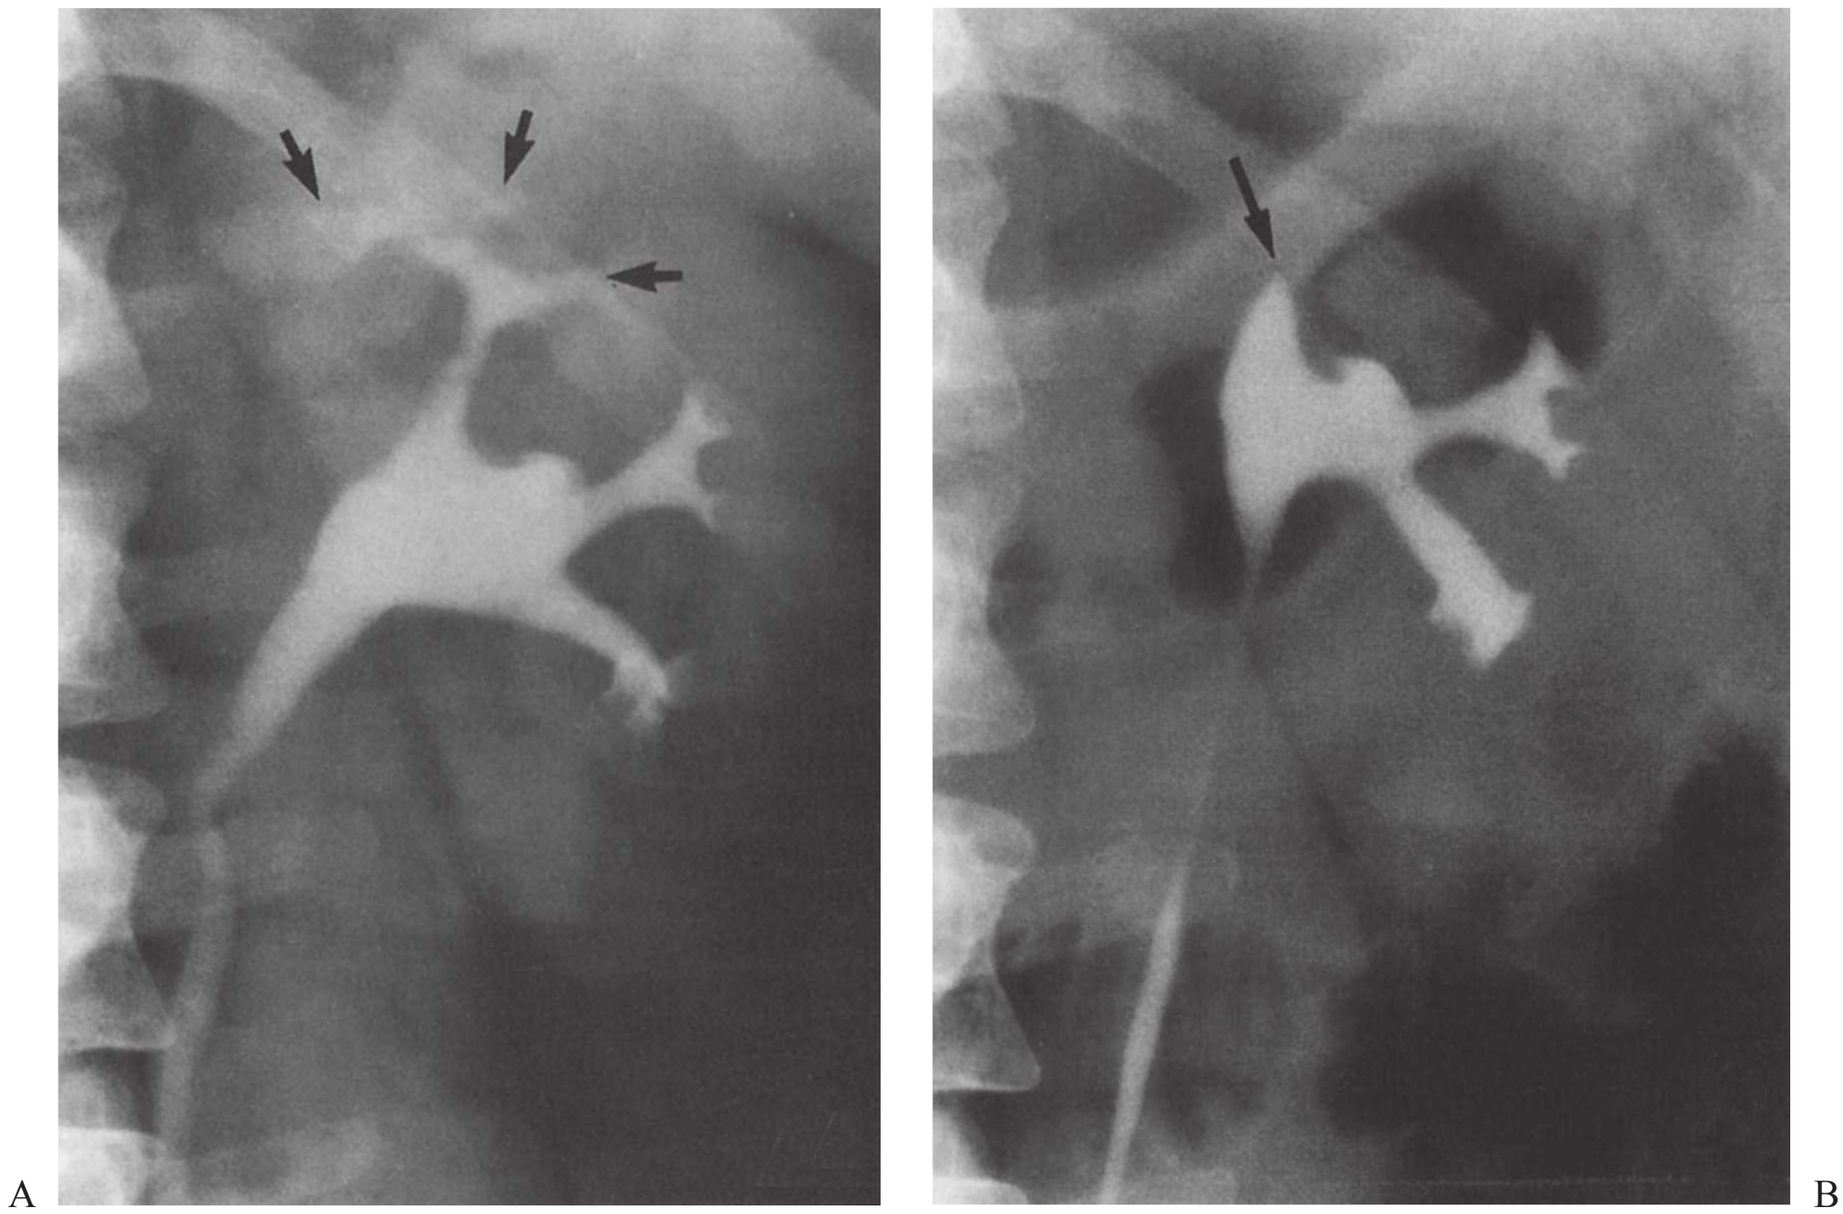
are usually unilateral and may mimic papillary necrosis of other etiologies. With time, they enlarge in an irregular fashion, with shaggy margins, and may progress to involve the entire medullary pyramid. A consequence of papillary cavitation is spread of infection to the uroepithelium and submucosa of the draining calyx. The resulting fibrotic reaction leads to stenosis and even complete stricture of the calyceal infundibulum. Thus a medullary cavity may be excluded from the collecting system and an abscess, or localized tuberculous pyonephrosis, ensues. These lesions may be difficult to distinguish from a truly noncommunicating caseous parenchymal cavity. Advanced medullary disease may lead to renal cortical scarring as well. Amorphous calcification is frequently seen (Fig. 27.7) and may progress to outline the entire granuloma. Both the parenchymal tuberculous granuloma and the noncommunicating pyonephrosis may be confused with primary mass lesions; CT,[140,141] ultrasonography,[141,142] and, in selected cases, magnetic resonance[141,143] or even positron emission tomography (PET)-CT[144] may be helpful by confirming the nonneoplastic, cystic, and avascular properties of the mass.

The discharge of caseous material infects the renal pelvis, ureter, and bladder as well. Renal pelvic involvement is manifested by obstructive changes involving portions of the kidney due to stenosis or kinking of the pelvis or the entire organ due to ureteropelvic junction stenosis (Figs. 27.10 and 27.11). Thus poor visualization by excretory urography may be segmental or involve the entire kidney. Ureteral disease initially presents as mucosal irregularity, together with diffuse dilatation or narrowing due to inflammation or edema (Figs. 27.9 and 27.10).[145] There may be a single focus or multiple areas of ureteral involvement. In addition to an irregular border, the combination of multiple strictures and accompanying segmental dilation leads to a beaded or corkscrew configuration (Fig. 27.10). Unlike nonspecific strictures, tuberculous lesions may extend for several centimeters and are usually present together with ipsilateral renal disease. In some instances, intramural fibrosis leads to a rigid "pipestem" ureter. Calcification and even calculi may be present as well. Ureterovesical junction involvement may produce a stricture responsible for ureteral obstruction or a patulous, rigidly dilated orifice associated with vesicoureteral reflux.

Bladder involvement similarly begins with focal mucosal irregularity and progresses to produce a small, contracted trabeculated bladder with intramural thickening (Figs. 27.9 and 27.12). Occasionally, calcification of the bladder wall may occur.



A B

FIGURE 27.11 Intravenous urograms 14 years apart. **A:** Early change of renal tuberculosis with papillary necrosis of the upper pole calyces (*arrows*). **B:** Fourteen years later, there has been complete stenosis of the left upper pole infundibulum (*arrow*) as the tuberculous process heals by scarring.

The excretory urogram has long been the radiologic standard for evaluating patients with renal tuberculosis because of its capacity to record focal calyceal abnormalities, including cavitation, scarring, and obstruction, and to survey the collecting system in equal detail simultaneously. Sonography cannot record erosive calyceal abnormalities or distinguish advanced caseous disease from focal pyonephrosis. Sonography may, however, play a role in monitoring the possible development of hydronephrosis.[141,142] CT studies, particularly when intravenous contrast reagents are administered, have become the procedure of choice for diagnosing and assessing renal tuberculosis (Fig. 27.13). Thus, in early or focal disease, obstruction of a single major calyx or a group of minor calyces may be observed; tuberculous involvement of the renal pelvis may be visualized as either dilatation owing to ureteropelvic junction obstruction or diffuse pelvic contraction. With advanced disease, small, atrophic kidneys, often with one or more low density areas, are observed.[140] Calcifications of the genitourinary system and extrarenal intra-abdominal disease can likewise be observed at the same time.[140,141,146] Sonographic and CT studies are particularly useful in patients with advanced disease when there is nonvisualization of the affected kidney by excretory urography. Angiography has been used in the past for the rare patient when isolated focal disease caused by obstruction or cavitation has mimicked a primary renal mass,[147] but MRI has largely supplanted the need for arteriography.[141,143] The obliterative arteritis that accompanies progressive caseation is responsible for the avascular appearance of the granulomatous mass with pruning and obliteration of the interlobar arteries.[147] As noted above, tuberculous arteritis of the main renal artery is exceedingly rare.[116]

Clinical Management

The advent of effective chemotherapy has revolutionized the clinical management of urinary tract tuberculosis, although the recent increase in drug-resistant infection, amplified by the AIDS epidemic, threatens this success. Whereas in the prechemotherapeutic era extirpative surgery was the only hope of controlling infection, today medical cure is the rule. There is a continuing need for surgical intervention, but now it is primarily for the correction of anatomic abnormalities caused by scarring rather than for the removal of infected tissues. The two goals, then, in the management of urinary tract tuberculosis are the conservation of tissue and function (both with medical treatment and surgical relief of obstruction resulting from tuberculous scarring) and antimycobacterial cure.

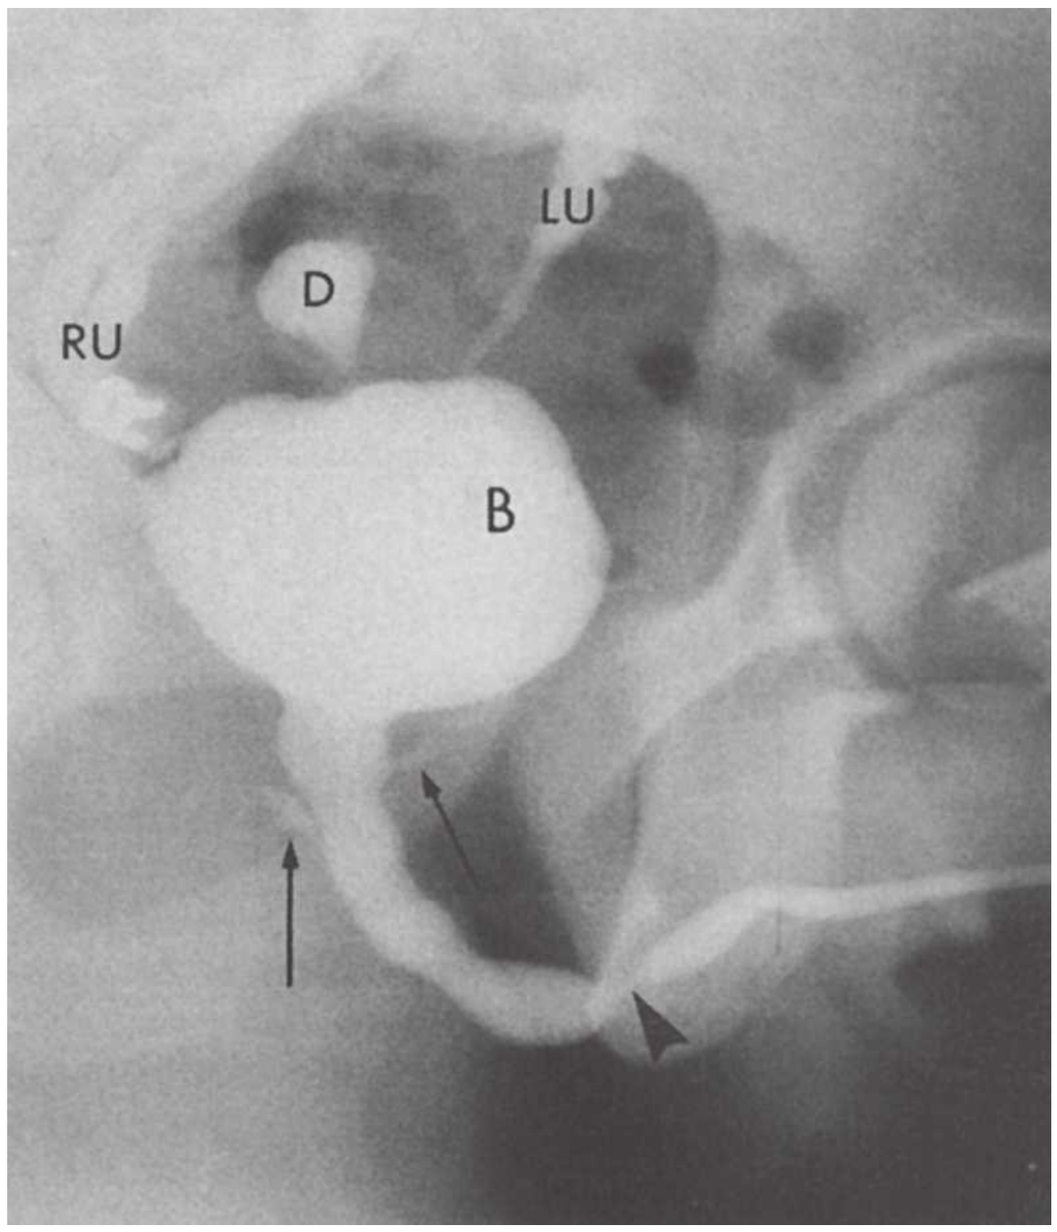


FIGURE 27.12 Voiding cystourethrogram in a young man with left renal tuberculosis, showing reflux into duplicated ureters of a normal right kidney and into an abnormal single left ureter, with a concomitant distal stenosis. The bladder is markedly reduced in volume and there is a diverticulum at the dome. There is reflux of contrast into the prostatic gland (*arrows*) secondary to tuberculous prostatitis. There is a stricture of the midbulbous urethra (*arrowhead*), which is an unusual site for tuberculous involvement. *B,* bladder; *D,* diverticulum; *LU,* left ureter; *RU,* duplicated ureters.

CHEMOTHERAPY OF URINARY TRACT TUBERCULOSIS

The chemotherapeutic approach to tuberculosis is based on the following general principles (Table 27.1).[15,148,149]

1. Mycobacterium tuberculosis may persist in a viable form while multiplying slowly or even intermittently. It is believed that there are three populations of organisms that must be considered when treating patients with active tuberculous infection.[150] The largest number, and fortunately the most easily treated, are those that are extracellular, as within a cavity, where the pH is either neutral or alkaline. Because this group of organisms is actively multiplying, this is the population most easily treated with two or more bactericidal drugs. Also, because it is quantitatively the largest population, drug resistance is most apt to emerge within this population if an inappropriate therapeutic program is employed. A much smaller population of slowly or intermittently multiplying organisms is found at an acid pH within macrophages. Finally, there are a variable number of organisms exhibiting slow or intermittent multiplication at a neutral pH within closed caseous lesions.

   Curative therapy requires eradication of all three populations of organisms. Because of pH constraints, differing abilities to penetrate at different sites, and inherent effects on the tubercle bacillus, each of the available antituberculous drugs is more or less effective for these different populations of M. tuberculosis. Rifampin and related agents (rifabutin and rifapentine) are the only drugs that are bactericidal for all three populations of M. tuberculosis. Isoniazid (INH) is bactericidal both for the actively growing organisms in cavities and for those slowly multiplying within macrophages. Streptomycin and the other injectable aminoglycosides are bactericidal only for the actively replicating extracellular organisms. Pyrazinamide is bactericidal only

for intracellular organisms. All other drugs currently licensed for the treatment of tuberculosis are bacteriostatic. The fluoroquinolones— levofloxacin, moxifloxacin, and gatifloxacin —are bactericidal for M. tuberculosis in vitro (minimum bactericidal concentration of 2 μg/mL, in the setting of peak blood levels >4 μg/mL) and achieve excellent concentrations intracellularly. They are utilized in the treatment of patients who are intolerant of first line agents, or infected with isolates resistant to one or more first line antituberculous agents.[149] The primary role of bacteriostatic antituberculous drugs is to inhibit the development of mutants resistant to simultaneously administered bactericidal agents.

2. The spontaneous development of drug-resistant mutants of M. tuberculosis occurs at a rate of approximately 1×10^{-6}. The probability that a single organism would be resistant to two drugs simultaneously approximates the product of the probabilities of resistance to each drug alone ($1 \times 10^{-6} \times 1 \times 10^{-6} = 1 \times 10^{-12}$). Therefore, a major determinant of the number of drugs necessary to treat tuberculous infection is the number of organisms harbored by the individual. In the case of urinary tract tuberculosis without active infection at other sites, an organism burden of approximately 1×10^{7} is likely. Therefore, a minimum of two drugs to which the patient's isolate is susceptible is required for therapy. Use of only one effective drug, given the rate of mutation to drug resistance and the number of organisms present, would lead to not only clinical failure but also the selection of resistant organisms.
3. The epidemiology of drug-resistant tuberculosis is rather complex and reflects variations in resistance rates among different patient groups based on tuberculosis treatment history, ethnicity, and socioeconomic determinants. The rate of isoniazid monoresistance in the United States was largely unchanged between 1993 (4.1%) and 2005 (4.2%). INH resistance rates were elevated among both U.S. and foreign born Asian/Pacific Islanders, foreign born blacks, and U.S. born Hispanics. Resistance tracked with a history of tuberculosis, failure to complete timely antituberculous therapy, and a history of incarceration.[151] Interestingly, HIV serostatus did not confer an increased risk of INH resistance. Multidrug resistance (MDR-Tbc, INH + rifampin resistance) was identified in 1.3% of isolates in 2010, with rates of 1% in previously untreated patients and ~5% in previously treated individuals. Nearly all MDR-Tb isolates (89.4%) occurred in foreign born individuals.[20]
4. Because of the persistence of drug-resistant tuberculosis in the United States in recent years and the substantial rate of drug resistance in resource-limited settings, drug susceptibility testing should be performed routinely on all patient isolates, rather than just on isolates from high-risk patient groups. Because the most common cause of the development of de novo drug resistance is failure of compliance by the patient, directly observed therapy ("DOT") in which public health workers directly administer the therapy to the patient is often central to successful therapy. Particularly in urban areas, this strategy of enforced antituberculous therapy compliance has proved to be quite successful in blocking the spread of tuberculosis, particularly drug-resistant tuberculosis.[15,149]

The standard of care for urinary tract tuberculosis due to drug-sensitive organisms in a compliant patient is a 6-month regimen, with four-drug initial therapy (INH, rifampin, pyrazinamide, and ethambutol) for 2 months, followed by a 4-month course of INH and rifampin for 4 months[15,149]; ethambutol therapy may be discontinued when sensitivity data becomes available and confirms drug susceptibility. Patients not tolerating pyrazinamide should receive a 7 month continuation phase regimen of INH and rifampin (plus one or more of the other drugs listed until susceptibility testing results are known). More prolonged courses of therapy are indicated for any patient slow to respond to one of the standard regimens, those with miliary or central nervous system disease, those with significant immunosuppression (e.g., AIDS, organ transplant recipients, etc.), and children with multiple sites of involvement (including the skeleton).[148,149] Prolonged therapy for prostatic tuberculosis and advanced renal parenchymal disease is often recommended as well.[152]

HIV-associated tuberculosis is managed similarly to that observed in the HIV-negative population (although our preference is to prolong therapy for an additional 3 to 6 months in those with AIDS), with the following modifications to increase the probability of success: directly observed therapy for all patients with HIV-related tuberculosis; the substitution of rifabutin for rifampin in individuals receiving anti-HIV protease inhibitors because of the risk of drug interactions that affect the efficacy of treatment of both the HIV and the tuberculosis; and monitoring the responses to antituberculosis treatment to individualize the appropriate duration of antituberculosis therapy.[149] HIV-infected individuals initiating antituberculosis therapy soon after starting antiretroviral therapy may experience fever, lymphadenopathy, and exacerbation of symptoms which is now recognized as the immune reconstitution inflammatory syndrome.[149,153] This is seen primarily with advanced immunodeficiency (i.e., low CD4 counts) and can be treated by brief courses of systemic steroid therapy.[149,153]

The management of drug-resistant disease is determined by the results of in vitro susceptibility testing. Three agents including at least one of the front-line bactericidal agents (INH, rifampin, and pyrazinamide) to which the isolate is susceptible, are prescribed. INH resistant isolates may be treated with rifampin, pyrazinamide, and ethambutol, with fluoroquinolone therapy added if there is extensive disease. Rifampin monoresistant isolates are recognized primarily in HIV-infected individuals and require prolonged courses of therapy because rifampin is the cornerstone of highly active

short course antituberculosis regimens: treatment with INH, pyrazinamide, and ethambutol is recommended, with added fluoroquinolone therapy for extensive disease. Dual INH/rifampin resistance requires prolonged multidrug therapy including a fluoroquinolone and an injectable aminoglycoside in addition to two second line agents. The American Thoracic Society guidelines[149] outline treatment requirements for drug-resistant tuberculosis; expert infectious disease consultation should be sought for detailed clinical guidance.

Two types of genitourinary tract tuberculosis are particularly difficult to treat—"the autonephrectomized" kidney destroyed by tuberculosis and now presenting as a nonfunctioning, avascular, calcified, caseous mass, and prostatic tuberculosis. In both these circumstances, delivery of antituberculous therapy to the site of infection is fraught with difficulty. Indeed, as observed in the following, some authorities believe that all end-stage tuberculous kidneys should be removed surgically, and Dutt and Stead[152] noted that tuberculous abscesses must be surgically drained in any patient undergoing short-course therapy. As far as prostatic tuberculosis is concerned, we have observed patients who had been rendered culture negative with 2 years of therapy for urinary tract tuberculosis who, a few years later at the time of an incidental prostatectomy, were shown to harbor living M. tuberculosis at this sequestered site.

SURGICAL MANAGEMENT OF URINARY TRACT TUBERCULOSIS

In the prechemotherapy era, surgical ablation of infected foci was the only therapy available for renal tuberculosis. Without surgery, the 5-year survival rate for patients with renal tuberculosis was 15% to 42%, but with surgery, 10-year survival rates approached 50%.[154] With modern chemotherapy, urinary tract tuberculosis should be routinely curable, but surgical intervention is still required at times.[106–109] Surgical intervention is required for the relief of strictures, particularly ureteral strictures, which can result from the scarring process and may develop in nearly half of patients with renal tuberculosis.[106] Thus, ureteral stenting, sometimes preceded by balloon dilatation, ureteral reimplantations, and, in some cases, relief of intrarenal obstruction to urine flow are important aspects of the modern function-conserving approach to urinary tract tuberculosis.[106–109] Obstruction present at the time of diagnosis is usually addressed several weeks after initiating intensive antituberculous therapy, although percutaneous nephrostomy and stent placement to relieve severe obstruction can be performed acutely. The administration of corticosteroids together with antituberculosis chemotherapy to reduce the risk of progressive ureteral scarring and subsequent surgical intervention has long been discussed[31] but this practice remains unproven. Because ureteral strictures can develop on therapy, the possible need for surgical intervention continues long after cultures for M. tuberculosis turn negative, and close follow-up with periodic radiologic assessment is mandatory (see the previous discussion). Less commonly, patients whose bladders have been badly scarred by the tuberculosis process have such poor bladder function that bladder augmentation or even urinary diversion may be necessary to deal with unbearable urinary frequency, inadequate emptying, or both.[155,156]

Nephrectomy for the nonfunctioning end-stage tuberculous kidney,[152] once considered controversial, has gradually come to be recommended more routinely.[147,149,150] Nephrectomy is indicated for persistent microbiologic failure despite adequate chemotherapy, refractory pain, bacterial superinfection, severe symptomatic stone disease, or definite secondary hypertension. In patients with elevated surgical risk by virtue of age, underlying illness, etc., conservative management may be considered, but more generally nephrectomy is offered in this situation.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the great help of Dr. Isabel Yoder of the Department of Radiology and the late Dr. Robert McCluskey of the Department of Pathology of Massachusetts General Hospital for providing illustrations and for their wisdom in the preparation of this chapter.

CHAPTER 28

Epidemiology, Diagnosis, and Therapy of Acute Kidney Injury

Etienne Macedo • Ravindra L. Mehta

EPIDEMIOLOGY OF ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a complex syndrome associated with several etiologic factors. AKI occurs in a variety of settings with clinical manifestations ranging from a minimal elevation in serum creatinine (SCr) to anuric kidney failure.[1–3] The incidence of AKI with and without need for dialysis has been progressively increasing in the last 15 years[4] (Fig. 28.1) and is more pronounced in older hospitalized patients. Data from the USRDS shows that 1.6% of patients age 66 and older who were continuously enrolled in Medicare inpatient/outpatient had the diagnosis of AKI[4,5] (Fig. 28.2). The increasing incidence can also be explained by the growing awareness by the medical community about AKI as a main risk factor for mortality and an important contributor for chronic kidney disease (CKD).

The reported incidence of AKI is widely variable in different regions of the world (Table 28.1). In the developed world AKI is seldom a community-acquired disease; the condition develops primarily in hospitalized patients. In these regions the incidence of hospital-acquired AKI exceeds that of community-acquired AKI by 5 to 10 times, having an estimated yearly incidence of 0.15% to 7.2%.[6] In the developed world more than 20% of AKI cases occur in the intensive care unit (ICU) setting. On the other hand, in the developing world a number of cases of AKI are found in rural areas. The demographics, etiologies, and outcomes of AKI in rural settings differ from those in more developed areas. In rural regions AKI is caused predominately by snake, spider, caterpillar, or bee envenomations, or by specific infections such as leptospirosis, tetanus, or severe malaria. Those patients are managed by primary caregivers who have limited resources.

The age of AKI patients is another difference between developed and developing countries. Elderly patients predominate in the developed world whereas in the developing world AKI is generally a disease of the young. Children are more often affected in developing countries, constituting more than 15% of patients in some studies. Age differences might partially account for differences in reported survival rates between the developed and developing countries. Paradoxically, patients in developing countries might have a better chance of survival. Here younger patients develop AKI as a result of a single disease (e.g., leptospirosis or malaria) rather than from multiple organ failure, but are more prone to complications secondary to poor nutrition and resource availability (Table 28.1).

The first step for the nephrology community to better understand and quantify the clinical importance of AKI was to develop a uniform definition. Before 2004 acute renal failure (ARF) had no accepted definition resulting in more than 30 different definitions reported in the literature.[7] Consequently, epidemiologic studies used different clinical and physiologic endpoints making it difficult to compare the results between studies (Table 28.1). This lack of a uniform definition yielded discrepancies in AKI incidence, prevalence, and outcomes in various clinical settings. The reported incidence ranged from 1% to 31% and mortality from 28% to 82%.[8–10] The formation of the Acute Dialysis Quality Initiative (ADQI) group in 2000 was the beginning of a process to establish consensus and evidence based guidelines in ARF. In 2004, ADQI formulated the Risk, Injury, Failure, Loss, and End-stage Kidney (RIFLE) classification for ARF.[7] The RIFLE classification system provides three grades of severity for AKI based on the maximal increase in SCr or decrease in urine output from the baseline condition: injury—risk (class R), injury (class I), and failure (class F)—and two outcome classes (loss and end-stage renal disease [ESRD]) (Table 28.2).

The clinical predictive ability of the RIFLE classification has been extensively validated in large general and ICU populations.[8,11–15] In a single center retrospective cohort study, including 5,383 patients admitted during a 1-year period, the incidence of AKI was 67.2%. In that cohort AKI was associated with an increased risk for hospital mortality compared to those who never developed AKI. The higher incidence that might have been considered unusual before the RIFLE era was confirmed in other studies that applied the criteria.[8,11–15]

The ADQI group, associated with representatives of nephrology societies (ASN, ISN, and NKF) and the European

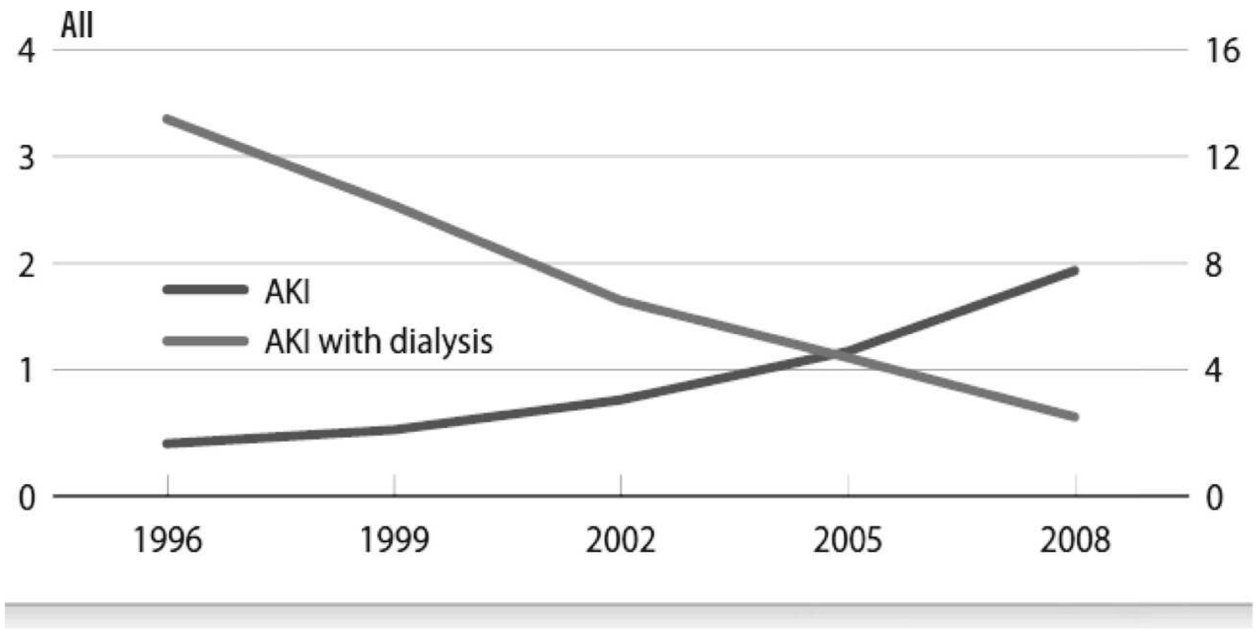

FIGURE 28.1 Hospitalizations for acute kidney injury, with or without dialysis. (Modified from Collins AJ, Foley RN, Herzog C, et al. Excerpts from the US Renal Data System 2009 Annual Data Report. *Am J Kidney Dis.* 2010;55(1 Suppl 1):S1–420, A426–427.)

Society of Intensive Care Medicine, created the Acute Kidney Injury Network (AKIN) as an independent collaborative network intended to facilitate international, interdisciplinary, and intersocietal collaborations.[16] One of the tasks proposed by the AKIN was to further refine the AKI definition. In 2007, a modified version of the RIFLE classification was published, also known as the AKIN classification (Table 28.2).[17] The terms Risk, Injury, and Failure were replaced by stages 1, 2, and 3, respectively. An absolute increase in creatinine of at least 0.3 mg per dL was added to stage 1. Patients starting renal replacement therapy (RRT) are automatically classified as stage 3, regardless of their SCr or urine output. The outcome categories Loss and ESRD were eliminated. Another difference between RIFLE and the AKIN classification is the 48-hour time frame within which the diagnosis of AKI is made, "AKIN criteria . . . change in creatinine should occur within 48h."[17] However, after the diagnosis is established, staging should be applied with no time frame constraint. Additionally, the glomerular filtration rate (GFR) criteria were eliminated.

In the RIFLE and AKIN classification systems patients are classified based on the worst category achieved. This is intended to describe the change or trend in AKI severity over time. Several studies in the ICU population have validated the concept verified in clinical practice that patient outcome progressively worsens with the maximal severity of AKI achieved.[8,12,14,18–20] Over 71,000 patients were included in published studies with the RIFLE classification system; these studies showed a stepwise increase in relative risk (RR) for death going from Risk (RR: 2.40) to Injury (RR: 4.15) to Failure (6.37).[21] Osterman and Chang[22] performed a retrospective analysis of a database of 41,972 patients admitted to ICU. AKI based on RIFLE occurred in 35.8% of patients: 17.2% Risk, 11% Injury, and 7.6% Failure. Patients with Risk, Injury, and Failure had a hospital mortality of 20.9%, 45.6%, and 56.8%, respectively, compared to 8.4% among non-AKI patients. Abosaif et al.[23] retrospectively applied the RIFLE classification in order to evaluate its sensitivity and specificity to predict renal and patient outcomes in 183 critically ill patients with AKI. Mortality rate in the ICU (60 days, 74.4%) and 6-month mortality rate (86%) were significantly greater in the RIFLE-Failure group compared with all groups. Cruz et al.[15] conducted a prospective multicenter study in 19 ICUs in northeastern Italy. Of 2,164 ICU patients who were admitted during the study period, 234 (10.8%) developed AKI whereas 3.3% were treated with RRT. Of the AKI patients, 19% were classified as Risk, 35% as Injury, and 46% as Failure. Overall, ICU mortality was higher among those in RIFLE class Failure (49.5% vs. 20% in R, 29.3% in I).

Hoste and colleagues[14] performed a retrospective single-center study on 5,383 patients admitted during a 1-year period in seven ICUs. AKI occurred in 67% of ICU admissions, and 12% reached a maximum RIFLE class of Risk, 27% Injury, and 28% Failure. Interestingly, among the patients that reached a level of Risk, 56% progressed to either Injury or Failure. Patients with maximum RIFLE class Risk, Injury, and Failure had hospital mortality rates of 8.8%, 11.4%, and

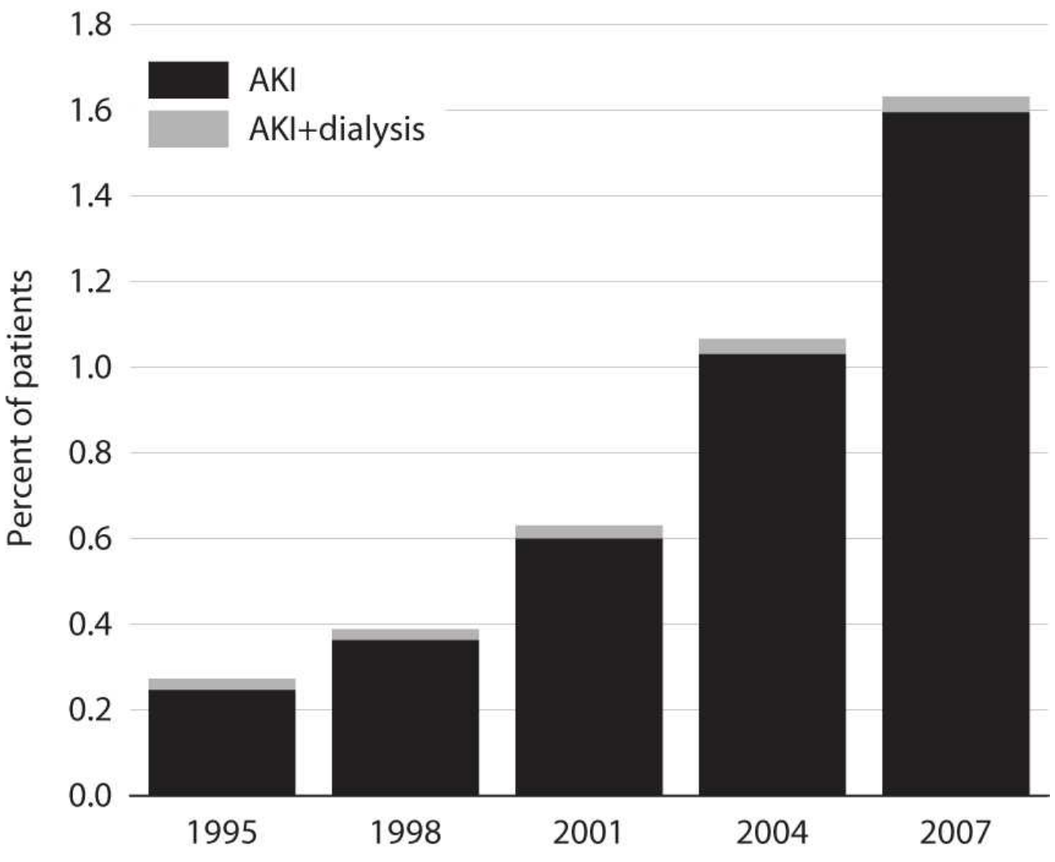

FIGURE 28.2 General Medicare patients age 66 and older continuously enrolled in Medicare inpatient/outpatient, surviving and without end-stage renal disease. (From Collins AJ, Foley RN, Herzog C, et al. United States Renal Data System 2008 Annual Data Report. *Am J Kidney Dis.* 2009;53(1 Suppl):S1–374.)

28.1 Epidemiologic Population Studies of Acute Renal Failure

Country	Definitions of ARF	Incidence (pmp)	Reference
USA	Increase in serum creatinine of 0.5 mg/dL (44.2 mol/L) in patients with baseline serum creatinine <1.9 mg/dL (168.0 mol/L) Increase in serum creatinine >1.0 mg/dL (88.4 mol/L) in patients with baseline serum creatinine 2.0–4.9 mg/dL (176.9– 433.2 mol/L) Increase in serum creatinine of 1.5 mg/dL (132.6 mol/L) in patients with baseline serum creatinine >5 mg/dL (442.0 mol/L)	1% of all hospital admissions All ARF was acquired out of hospital	251
Kuwait	Unknown	95	252
England	Serum creatinine >500 mol/L (5.7 mg/dL) Need for RRT	175 22	253
France	Unknown	104	254
Spain	Sudden increase of serum creatinine >177.0 mol/L (2.0 mg/dL) or sudden increase in serum creatinine >50% when prior renal function was normal or mild CKD was present Need for RRT	209[a] 57	255
Scotland	Serum creatinine 300 mol/L (3.4 mg/dL) Serum creatinine 500 mol/L (5.7 mg/dL) Need for RRT	620 102 50	256
USA (African Americans)	Serum creatinine 2 mg/dL (176.8 mol/L) without renal disease	5/1,000[b] hospital admissions	257
Australia	Need for RRT and mostly critically ill	135	258
England	Serum creatinine 300 mol/L (3.4 mg/dL)	486	259
Scotland	Need for RRT	203	260
South India	Unknown	336	261
Brazil	Increase in serum creatinine of at least 0.5 mg/dL (44.2 mol/L), admission serum creatinine >1.4 mg/dL (123.8 mol/L) for men or >1.3 mg/dL (114.9 mol/L) for women, and a normal serum creatinine level at admission, but presenting an increase during hospitalization	325/3,684 renal evaluations[c]	262
England	Serum creatinine 500 mol/L (5.7 mg/dL) or need for RRT Multiorgan ARF Single-organ ARF	380 125	263

[a]50% of ARF occurred before admission to hospital, 50% developed in hospital.
[b]Represents 79% of all ARF cases per year in one hospital.
[c]53% community-acquired ARF, 47% hospital-acquired ARF.
ARF, acute renal failure; CKD, chronic kidney disease; pmp, per million people; RRT, renal replacement therapy.
From Lameire N, Van Biesen W, Vanholder R. The changing epidemiology of acute renal failure. Nat Clin Pract Nephrol. 2006;2(7):364–377.

28.2 RIFLE and AKIN Classification Systems

Stage	RIFLE	Serum Creatinine Criteria	Urine Output Criteria
1	R	Increase to ≥150%–200% from baseline (AKIN and RIFLE)[a] or increase in serum creatinine >0.3 mg/dL (AKIN)	Less than 0.5 mL/kg/h for more than 6 h
2	I	Increase in serum creatinine >200%–300% from reference	Less than 0.5 mL/kg/h for more than 12 h
3	F	Increase in serum creatinine >300% from reference	Less than 0.3 mL/kg/h for 24 h or anuria for 12 h

[a]Within 48 hours for AKIN criteria, within 7 days for RIFLE criteria.

26.3%, respectively, in contrast to 5.5% in non-AKI patients. RIFLE classes were still associated with hospital mortality after adjusting for multiple covariates (baseline severity of illness, case mix, race, gender, and age). These findings showed that patients with RIFLE-Risk are indeed at significant risk of progression to more severe AKI. Patients with RIFLE class Injury or Failure incur a significantly increased length of stay and an increased risk of in-hospital mortality compared with those who do not progress past Risk or those who never develop AKI.

The increasing severity of illness in critically ill patients with AKI is one of the contributors to the persistently high mortality rate associated with this syndrome. Observational studies suggest that critically ill patients with AKI are increasingly older, have more comorbid diseases, have a higher incidence of septic, and have greater severity of illness and organ failure scores. Two severity of illness scoring systems are widely used: the Acute Physiology and Chronic Health Evaluation (APACHE) score and the Sequential Organ Failure Assessment (SOFA) score.[24,25] Although patients developing AKI have shown a significant decrease in mortality rate in the last decade,[25–27] the persistently high mortality in patients with multiorgan system failure remains a challenge. This emphasizes the need for early assessment and intervention in all cases of AKI. It is apparent that AKI is associated with substantial morbidity, mortality, and cost.

The financial costs of AKI are high. Fischer et al.[28] performed a multicenter analysis in 23 Massachusetts hospitals for a 2-year period (1999 to 2000). They identified 2,252 records of patients hospitalized with uncomplicated ARF. Patients hospitalized with uncomplicated ARF incurred median direct hospital costs of $2,600, median hospital length of stay (LOS) of 5 days, and mortality of 8%. Dialysis was independently associated with significantly greater hospital costs and LOS for patients with uncomplicated ARF ($P < 0.05$) compared to patients with other commom medical diagnoses.[28]

The cost of RRT for patients with AKI is high; however, information on the costs of the three dialytic techniques for AKI is minimal. In a Canadian ICU, the cost of dialysis was $3,486 to $5,117 (Canadian) per week for continuous renal replacement therapy (CRRT).[29] For intermittent hemodialysis (IHD), major costs include the need for supervision by a trained dialysis nurse, which can become an economic issue if IHD is performed on a frequent or daily basis. For CRRT, major costs include disposables and replacement fluids. Most investigators have found that CRRT costs are somewhat greater than IHD.[30,31] An evaluation of total hospital costs[32] showed that from the start of RRT to hospital discharge patients on CRRT total cost was US$57,000 more than that for those on IHD. A recent cost analysis of the of RRT for patients with AKI estimated that mean adjusted total costs were U$1,342/week for IHD compared to U$3,486/week for CRRT[30] and no difference was found in the outcome, renal recovery at hospital discharge. However, there was a nonsignificant statistical trend toward enhanced renal recovery in the CRRT group despite a significantly lower mean arterial pressure and a trend toward higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores. Considering that nonrecovery of renal function would adversely affect quality of life, a modality that enhanced the rate of renal recovery would offer an important advantage, even if there were no difference in survival across modalities.

Parameters for Acute Kidney Injury Diagnosis

Serum Creatinine

Therapeutic interventions are generally based on an evaluation of clinical data and diagnostic information. In AKI the importance of timing of diagnosis was poorly appreciated as therapeutic interventions have generally been lacking, and the small number of studies reported have failed to improve

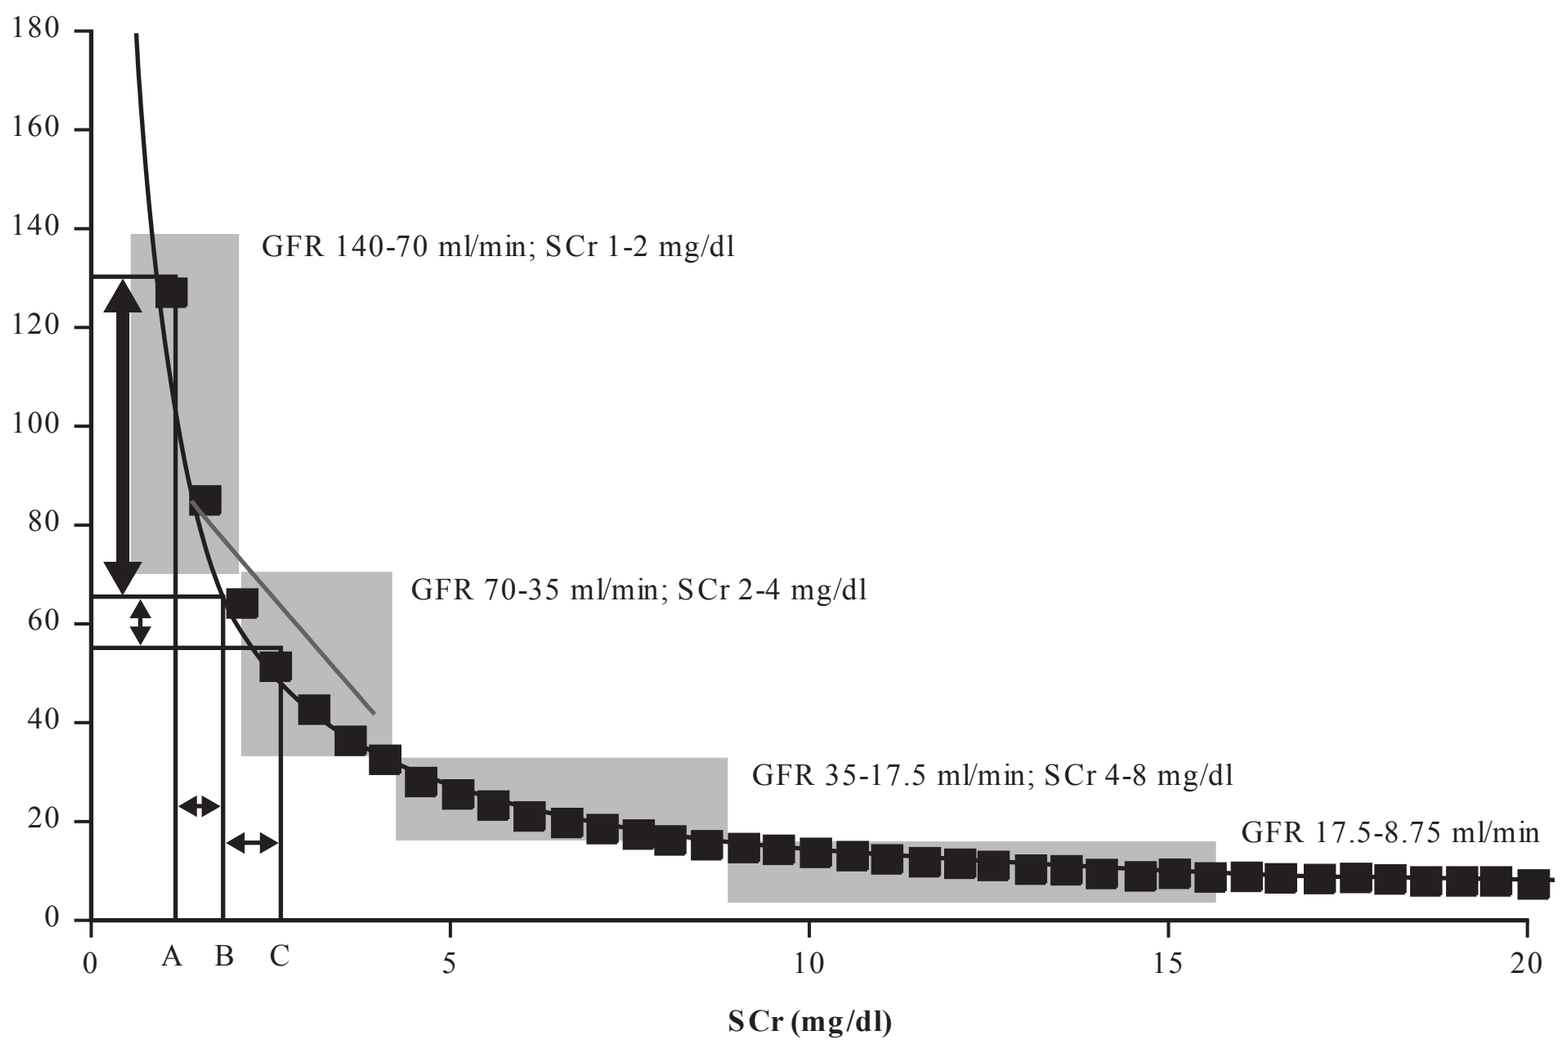
outcomes. In the last decade, the concept of interventions based on "windows of opportunity" coupled with targeted therapy became evident in other ischemic events such as acute chest pain syndromes and stroke. The importance of finding early diagnostic information in AKI has since been highlighted and the development of technology has facilitated the search for new biomarkers of kidney injury.

The current criteria for AKI diagnosis and classification, RIFLE and AKIN, are still based on SCr incremental concentrations and decreased urine output. Many characteristics other than renal function, such as age, muscle mass, catabolic rate, and race, influence SCr concentrations. In addition, SCr levels depend not only on renal elimination but also on creatinine generation and volume of distribution.[33] Given the exponential relation of SCr and GFR, significant decreases in GFR are reflected as small increases in SCr in the early phases of injury (Fig. 28.3).

In a steady state setting a reasonable approximation is that each time the GFR halves, the SCr concentration doubles. Thus, steady state GFRs of 100, 50, 25, 12.5, and 6.25 mL per minute are associated with increasing SCr concentrations ranging from 1 to 16 mg per dL; however, there is wide range depending on the level of extrarenal clearance that is accentuated as kidney function declines and may contribute to up to 40% of total clearance. AKI often occurs in a nonsteady state in which the three determinants of SCr concentration (production, volume of distribution, and renal elimination) fluctuate.[33] Computerized models derived from AKI patients demonstrate that several patterns of change in GFR occur during development and recovery from AKI. These GFR changes are poorly reflected by daily changes in SCr concentration.[33] Moreover, the rise in SCr that occurs in AKI is a post facto finding. In critically ill patients, a nonsteady state condition and the positive cumulative fluid balance enhances the insensitivity of SCr as a parameter of renal dysfunction.[34] Hoste et al. showed that in a group of recently admitted ICU patients with normal SCr the 1-hour urinary creatinine clearance revealed values lower than 80 mL/min/1.73 m^2 in 46.2% of the patients.[35] These data suggest that SCr is not a reliable tool to detect even moderate kidney dysfunction in AKI patients.

Blood Urea Nitrogen

Blood urea nitrogen (BUN) is also used as a parameter to evaluate renal function. However, elevations in BUN level are often, but not always, due to a decrease in GFR. Some factors enhance urea production, such as gastrointestinal bleeding, corticosteroid therapy, and high-protein diet. In conditions of decreased intravascular effective volume like decompensated heart failure, increases in BUN are not proportional to the rise in SCr level and fall in GFR. The usual BUN:SCr ratio is about 10:1 and the BUN and SCr increase by 10 to 15 and 1.0 to 1.5 mg/dL/day, respectively, in the absence of GFR. Increases in the basal metabolic rate that occur with fever or glucocorticoid administration enhance these daily rates. Although an increase in the BUN/



GFR, glomerular filtration rate; SCr, serum creatinine

FIGURE 28.3 Relationship between serum creatinine and glomerular filtration rate (GFR). Changes in serum creatinine represent smaller changes in GFR as renal functions decreases. Creatinine increase from A to B corresponds to a GFR decrease of GFR of 130 to 70 mL per minute, whereas from B to C the same delta creatinine corresponds to a decrease in GFR from 70 to 50 mL per minute. (Modified from Finn WF. The clinical and renal consequences of contrast-induced nephropathy. *Nephrol Dial Transplant*. 2006, 21(6):i2-i10.)

creatinine ratio has been used for many years to help to differentiate between prerenal and renal azotemia, BUN can increase independently from SCr in situations characterized by decreased glomerular perfusion pressure such as heart failure. Some studies have already shown elevations in BUN independently from SCr levels and demonstrated that these two parameters are not only a reflection of the severity of renal dysfunction, but rather the consequence of two distinct pathologic processes.[36–38] The activation of renin–angiotensin–aldosterone system (RAAS) and sympathetic nervous system is responsible for decreasing the glomerular perfusion pressure and GFR. The increment in vasopressin levels upregulates aquaporin-2 and urea transporter expressions and increases water and urea reabsorption. Urea, in contrast to SCr, is not secreted but reabsorbed by the renal tubules. The increased reabsorption of sodium and water, rather than the reduced GFR, enhances reabsorption of urea and increases BUN levels. Thus, BUN levels and BUN/creatinine ratio could be a more effective way to assess circulatory volume than GFR, which is regulated by the pressure difference between glomerular afferent and efferent arterioles.[39] In heart failure and possibly in other settings where underfilling is part of the physiopathologic process, the rise in BUN greater than any fall in GFR is a marker of the neurohumoral axis activation.[40]

In selected circumstances, it may not be clear if an elevated BUN:SCr ratio is due to an acute or chronic process. In this circumstance review of previous records is helpful.

Oliguria

Although the hydration status, osmolar excretion, as well as a large dose of diuretics will influence urine volume, and severe AKI can occur with normal urine output, the urinary flow rate also may provide helpful information about the cause of AKI. Sustained periods of anuria suggest urinary tract obstruction as the cause of AKI. Other rare causes of anuria include rapidly progressive glomerulonephritis, mechanical occlusion of renal blood flow, and diffuse renal cortical necrosis. Nonoliguric varieties of AKI are common, ranging from 25% to 80% of all cases of AKI with 33% nonoliguric at AKI diagnosis.[41–43] The nonoliguric state may be present in all types of AKI including those following surgery, trauma, hypotension, nephrotoxins, and rhabdomyolysis. Several factors may contribute to the devlopment of nonoliguric AKI: use of volume expansion, high-dose potent diuretic agents, high osmolar loads, and renal vasodilators. Another contributory factor is aggressive fluid resuscitation and improved supportive management of critically ill patients. However, nonoliguria may mask the underlying severity of AKI and lead to delayed recognition.

The definition of oliguria changed after the RIFLE and AKIN classification system. The AKIN group proposed the hourly measurement of urine volume, providing an opportunity to treat urine flow as a continuous rather than as an interval physiologic variable, with more time points for the diagnosis of oliguria and detection of AKI. Although fluctuations in this parameter can result from external influences, such as drug administration, the pattern of change can be detected earlier with more frequent observations. Experimental studies conducted in laboratory models of AKI, as well as clinical studies, have clarified the pathophysiologic aspects underlying the variations of urine flow rate in AKI.[44,45] In a study of 25 patients with predominantly renal ischemia-associated AKI, Rahman and Conger found that the urine flow rate strongly correlated with residual GFR.[45] In that study urine flow rate did not correlate with selected aspects of renal tubular function such as urine:SCr or the fractional excretion of sodium.

However, because of the difficulties in measuring and recording the hourly urine output, the AKIN oliguria criterion was evaluated in fewer studies than the SCr criterion. Of the studies evaluating the urine output criterion most were retrospective and used a modified definition of evaluating urine volume in 2 to 12 or 24 hours and shortening the time of observation to the first 24 hours of ICU admission or postoperative period. In a retrospective study Barrantes et al.[46] evaluated the outcomes of hospitalized patients classified by the AKIN criteria, using both the urine output (UO) and SCr criteria in the first 48 hours after ICU admission. Comparing patients that developed AKI using the UO, SCr, or both criteria, they found that UO criterion did not affect the AKI associated mortality. Joannidis et al.,[47] using the SAPS 3 database of ICU patients, assessed 24-hour urine volume for 48 hours. Patients with AKI defined by the lowest urine volume had higher mortality compared to non-AKI patients. In a prospective cohort of cardiac surgery patients, Haase et al.[48] subclassified the AKI patients based exclusively in the UO criterion (over a 48-hour period). Only those patients that reached a RIFLE-F or AKIN stage 3 had significantly longer ICU and hospital lengths of stay and a higher mortality rate (compared to non-AKI patients and those with maximum RIFLE-R/I and AKIN stage 1/2). In a systematic review,[21] the relative risk for death among studies that used both SCr and UO criteria was lower than in those using only the SCr criterion. Hoste and Kellum,[19] in a review including 10 studies, showed that patients in the RIFLE Risk class defined by the SCr criterion were more severely ill than those in the same class defined only by the UO criterion. Hoste et al.[14] also observed that patients in Failure based on the RIFLE GFR criterion had a slightly higher mortality than those in Failure based on the UO criterion. In a study by Cruz et al., RIFLE classes (using creatinine and UO criteria together) were the strongest predictor of ICU mortality in multivariable analysis.[15] In that study, the analysis was based only on the SCr criterion; the RIFLE class was sustained as an independent predictor of ICU mortality but with inferior statistical power. Based only on the UO criterion, RIFLE class did not emerge as an independent predictor.

These clinical observations, and a large body of experimental data, suggest the residual level of GFR is the primary determinant of urine flow in patients with AKI. The higher level of residual GFR in nonoliguric patients is

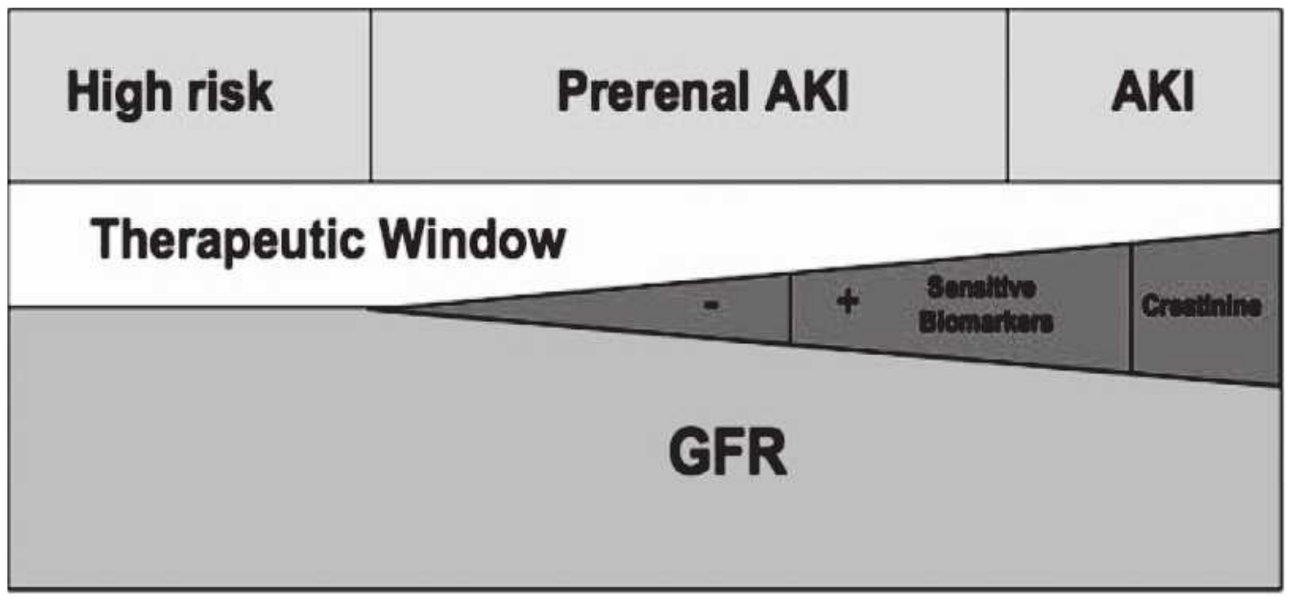


FIGURE 28.4 Time frame association for assessment of risk and early detection of acute kidney injury. Time runs along the *x*-axis, and the figure depicts a closing "therapeutic window" as injury evolves and kidney function worsens. Biomarkers of injury and function will begin to manifest as the condition worsens, but traditional markers of function (e.g., urea nitrogen and creatinine) will lag behind hypothetical "sensitive" markers of kidney injury. Mortality increases as kidney function declines. (From Himmelfarb J, Joannidis M, Molitoris B, et al. Evaluation and initial management of acute kidney injury. *Clin J Am Soc Nephrol.* 2008;3(4):962–967.)

compatible with improved survival and lower morbidity in these patients. However, one needs to be aware that there is a distinction between spontaneous nonoliguria from diuretic induced urine flow with respect to underlying GFR and nonoliguria does not automatically imply a higher GFR.

Biomarkers

The importance of early detection of AKI has been emphasized as an earlier diagnosis would provide a wider window to perform supportive and therapeutic interventions (Fig. 28.4). The recognition of the insensitivity to detect AKI by the most commonly used surrogates of kidney function (SCr and UO) has led to extensive efforts to identify alternative biomarkers for AKI diagnosis, including urine and serum biomarkers. Compared to the use of more sensitive biomarkers of kidney injury, SCr delays the AKI diagnosis by 48 to 72 hours.[49–52] Most of the studies have focused on the ability of these biomarkers to detect AKI earlier than the classical parameters, but biomarkers may be also useful to predict the course and prognosis of AKI (Fig. 28.5). Several promising candidates have emerged, demonstrating reasonable diagnostic performance for AKI up to 48 hours prior to a significant change in SCr.[53,54] Although the commercial platforms are becoming available for research use, the knowledge for the clinical application, utility, and diagnostic value of these early biomarkers remains to be validated. These new candidates are being tested in different AKI clinical scenarios. The different abilities to detect renal injury and estimate GFR are associated with their pathophysiology (Fig. 28.6). AKI biomarkers differ on the basis of how they

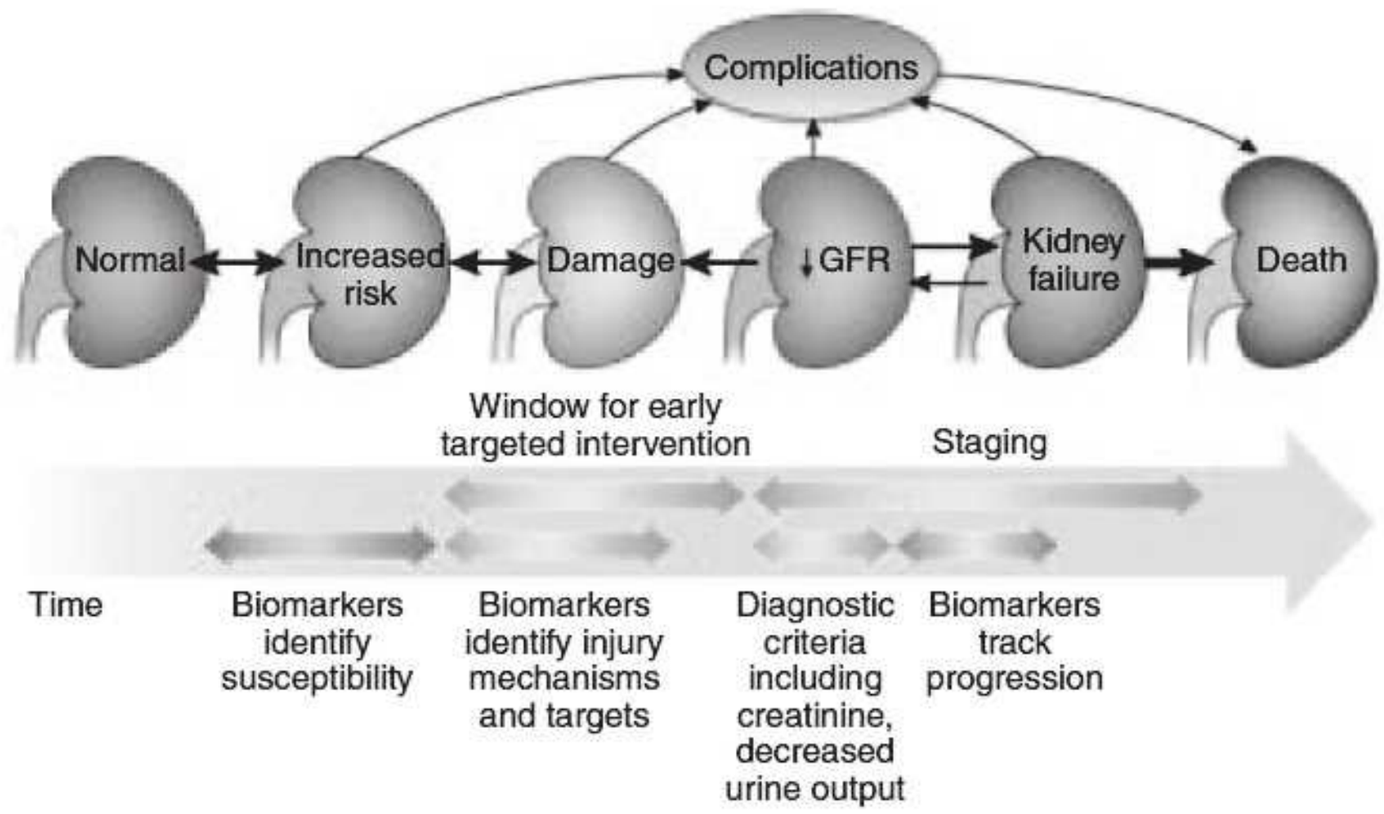

FIGURE 28.5 Conceptual framework for acute kidney injury. Surveillance could be initiated for high-risk individuals on the basis of clinical and biomarker criteria. Sequential assessment of biomarkers may permit identification of a window of opportunity in which kidney injury has been initiated but has not progressed to renal functional change. The duration of this window is inherently dependent on the type and site of injury and the nature and specificity of the biomarkers to determine the targets for intervention. Progression of kidney injury would be determined by development of functional changes staged on the basis of the severity of kidney injury. Biomarkers could further define progression, determine need for additional interventions, and predict prognosis. *GFR*, glomerular filtration rate. (Modified from Mehta RL. Timed and targeted therapy for acute kidney injury: a glimpse of the future. *Kidney Int.* 2010;77(11):947–949.)

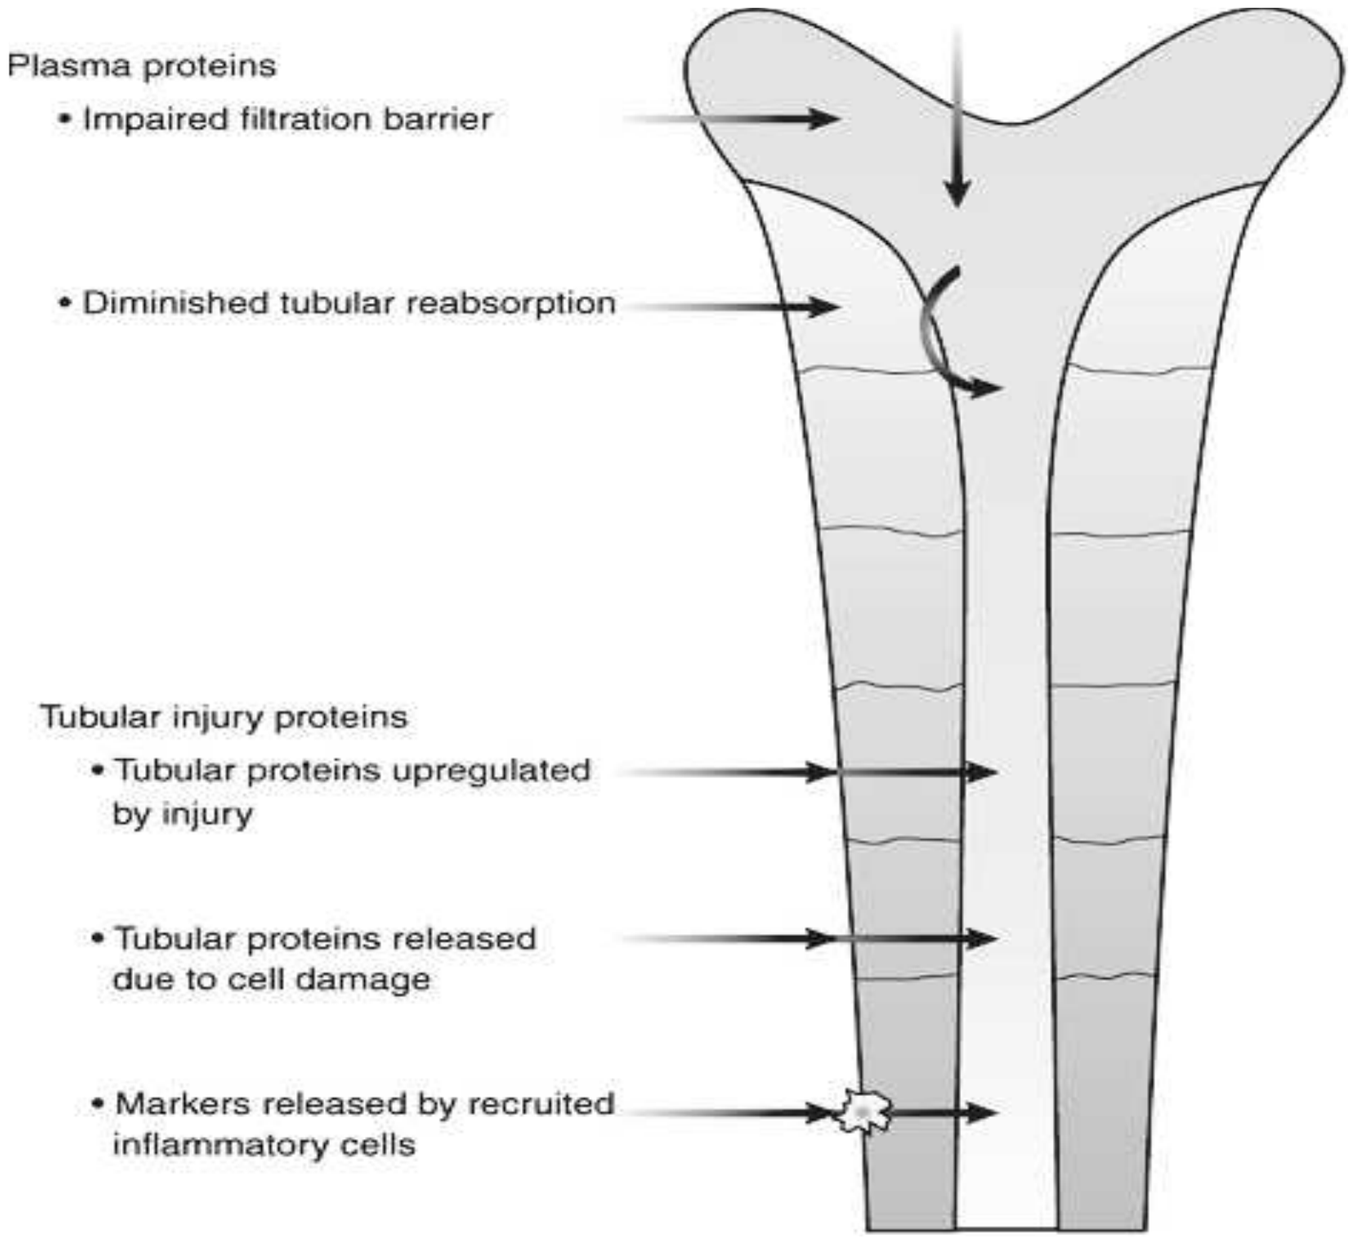

FIGURE 28.6 Pathophysiology of urinary biomarkers. Schematic representation of the mechanisms by which proteins escape into the urine. (Adapted from Briggs JP. The hunt for the perfect biomarker for acute kidney injury: back to gamma-trace? *Kidney Int.* 2008;74(8):987–989.)

enter the urine, either through filtration, upregulation, and secretion or through leakage from damage of a constitutive marker. The time sequence and magnitude of biomarker elevations are unique and may depend on the nature and severity of injury.

In addition to potentially facilitating an earlier diagnosis, these biomarkers will also allow for retesting preventive and therapeutic drugs that have failed in clinical trials that used SCr as a parameter to guide intervention. Another area of possible application for the new biomarkers is assisting in decisions to initiate RRT in patients with AKI. The main biomarkers being tested and some clinical data on their use are summarized below.

Cystatin C

Cystatin C is a low molecular weight protein produced at a constant rate by all nucleated cells. Because of its low molecular weight it is freely filtered at the glomerulus and reabsorbed and catabolized, but not secreted by the renal tubule. Plasma levels correlate with GFR and, unlike creatinine, are not significantly affected by age, gender, race, or muscle mass. In human studies, both pCyC and uCyC have been shown to predict AKI, although its superiority over SCr has not been a universal finding.[55–57] Recently, Herget-Rosenthal et al.[58] compared cystatin C with creatinine for the diagnosis of AKI in a series of 85 patients. Increases in serum levels of cystatin C were detectable 1 to 2 days earlier than comparable changes in SCr. In another study measuring plasma Cr (PCr) and pCyC in 444 adults on ICU admission, of whom 124 already had AKI on entry, pCyC moderately predicted death or RRT (area under curve [AUC] 0.61, 95% confidence interval [CI], 0.53–0.68) and performed similarly as PCr (AUC 0.60, 95% CI, 0.51–0.67).[59] In a cohort of 151 AKI patients from a small multicenter study, Royakkers et al.[60] used the RIFLE classification system to define AKI and compare the performance of sCyC and uCyC as early biomarkers for AKI. Urinary CyC had no diagnostic value during the days prior to AKI diagnosis by SCr (AUC <0.50). In addtion, sCyC and uCyC determined on the first day of AKI diagnosis were poor predictors for the need for RRT (AUC $= 0.66$).[60]

Neutrophil Gelatinase-Associated Lipocalin (NGAL)

Neutrophil gelatinase-associated lipocalin (NGAL) is a 25-kD protein, originally characterized in and secreted by neutrophils, that is bound to gelatinase. The physiologic role of NGAL in the kidney is unknown; however, it is believed to play a role in renal morphogenesis.[61] High throughput functional genomic studies have identified NGAL as one of the most upregulated transcripts in whole kidney tissue very early after acute injury. Downstream proteonomic studies using animal models have also revealed the 25-kD NGAL protein to be one of the earliest and most robustly produced proteins in the kidney after ischemic or nephrotoxic AKI.[62] Several clinical studies have suggested that urine NGAL expression may serve as an early marker of AKI.[63–66] In a clinical trial of 71 children who underwent cardiac surgery, urinary NGAL increased within 2 hours of cardiopulmonary bypass to a level of >50 μg per L in all 20 children who had

an increase in SCr of >50% (RIFLE Risk) and in only one of the 51 children who did not meet the RIFLE definition of AKI.[67] Urinary NGAL also was evaluated in adult patients who underwent cardiac surgery, with far less impressive results.[68] In a cohort of 81 such patients at a single institution, 16 developed AKI, as defined by RIFLE. Preoperative urinary NGAL levels were comparable among patients who did and did not develop AKI and were not significantly different immediately after surgery. However, within 1 hour after surgery, the urinary NGAL concentration began dropping in patients who did not develop AKI but continued to rise in patients with AKI, peaking at 3 hours and remaining elevated for 24 hours.[68] In one study evaluating urinary NGAL levels in emergency room patients, the AUC for NGAL to detect AKI (0.948) did not significantly differ from the curve for SCr (0.921). Nevertheless, there was very little overlap in NGAL values in patients with AKI and prerenal failure, whereas SCr values overlapped significantly in AKI patients and in those that reversed the condition within 48 hours.[64] Urinary NGAL was measured in hospitalized patients with established AKI at study inclusion and after 2 days. Of the 145 patients analyzed, 75 had intrinsic AKI, 32 had prerenal AKI, and 38 patients could not be classified. Urinary NGAL levels effectively discriminated between intrinsic and prerenal AKI (AUC 0.87). An NGAL level over 104 μg per L indicated intrinsic AKI (likelihood ratio 5.97), whereas an NGAL level of 47 μg per L made intrinsic AKI unlikely (likelihood ratio 0.2). A logistic regression analysis showed that NGAL independently predicted a composite outcome (worsening RIFLE severity class within 7 days, need for RRT, and in-hospital mortality) after correcting for demographics, comorbidities, creatinine, and RIFLE class. The authors concluded urinary NGAL was useful in classifying and stratifying patients with established AKI.[69]

Several studies have examined the clinical endpoint of RRT initiation using NGAL.[70] Urine or plasma/serum NGAL have been studied in various clinical settings including children and adults (Table 28.3). In a meta-analysis of studies that evaluated NGAL accuracy for diagnosis and prognosis, 1,948 patients from nine studies were included. The overall incidence of RRT was 4.3%, and the pooled analysis yielded an AUC of 0.782 (95% CI, 0.648–0.917) for discriminating patients who would receive RRT associated with AKI. For a cut-off in NGAL of 278 ng per mL, the sensitivity was 76% and specificity was 80%.[70] However, these studies included diverse patient populations, and the specimens and assays used in obtaining this estimate varied, making it difficult to translate the results to bedside clinical use.

N-acetyl-β-D-glucosaminidase (NAG)

N-acetyl-β-D-glucosaminidase (NAG) is a lysosomal enzyme (>130 kDa) that has been localized to lysosomes in several human cells including the renal tubules. The large molecular weight precludes glomerular filtration implying that urinary

elevations are from tubular origin. Increased activity suggests injury to tubular cells or may reflect increased lysosomal activity. NAG catalyzes the hydrolysis of terminal glucose residues in glycoproteins and is the most active glycosidase found in proximal tubular epithelial cell lysosomes. Urinary NAG activity remains elevated during different kinds of active renal disease.[71] The diagnostic and prognostic ability of nine urinary biomarkers, including NAG, was evaluated in a cross-sectional study with 102 patients with established AKI and compared to 102 subjects without AKI.[72] The non-AKI subjects included healthy controls, ICU patients and subjects who underwent coronary angiography, whereas AKI patients were recruited at initial nephrology consultation. An age-adjusted analysis, using log-transformed biomarker values, showed NAG to be a significant predictor for RRT, mortality, and composite endpoint. The median normalized NAG level in AKI patients who underwent RRT was 0.06 U per mg Cr, versus 0.02 U per mg Cr in those who did not.

In another study including 635 patients presenting to the emergency room, urine NAG was not predictive of a composite outcome of nephrology consultation, ICU admission, RRT initiation, and mortality on multivariable analysis which included SCr and BUN.[64]

Kidney Injury Molecule-1 (KIM-1)

Kidney injury molecule-1 (KIM-1) is a type I transmembrane glycoprotein with a cleavable ectodomain localized in the apical membrane of dilated tubules in acute and chronic injury. KIM-1 and its soluble ectodomain in urine (90 kDa) are believed to play a role in the regeneration processes after epithelial injury. It is undetectable in normal kidney tissue but expressed at very high levels in proximal tubule epithelial cells in human and rodent kidneys after ischemic or toxic injury.[73] A small study in six patients with confirmed acute tubular necrosis (ATN) showed KIM-1 expression via immunohistochemistry on kidney biopsy. The same investigators subsequently examined urinary KIM-1 in 40 patients and found KIM-1 levels elevated to a higher degree in patients with ischemic acute tubular necrosis (ATN) compared to patients with contrast nephropathy, other forms of AKI, CKD patients, and normal controls.[74] In a cohort of adults undergoing coronary artery bypass graft (CABG), urinary KIM-1 levels were predictive of subsequent AKI (sensitivity 0.74, specificity 0.9, AUC 0.83) at 12 hours postsurgery. Other studies also suggest that urinary KIM-1 may be useful in identifying ischemic ATN.[49,75,76]

In a study by Liangos et al., the AUC for prediction of RRT or death for KIM-1 was 0.61 (95% CI, 0.53–0.61), comparable to that of SCr and UO.[77] On adjusted analysis, patients in the highest KIM-1 quartile had a 3.2-fold higher odds (95% CI, 1.4–7.4) for a composite outcome compared to patients with the lowest quartile. However, the result was no longer significant when adjusted for multiple factors. In another study by the same authors, KIM-1 was not a significant predictor for RRT, but was a significant predictor for mortality.[72]

Interleukin-18

Interleukin (IL)-18 also has been considered as a candidate biomarker for acute renal injury. IL-18 is a pro-inflammatory cytokine generated by caspase-1-mediated cleavage in injured proximal tubules and released into the urine.[78] It can also enter the urine by glomerular filtration. In animal models, IL-18 has been shown to exacerbate tubular necrosis, and neutralizing antibodies to IL-18 reduced renal ischemic injury in mice.[78] In humans urinary IL-18 levels were measured in 72 individuals, 14 with ATN, 8 with prerenal failure, 5 with urinary tract infections, 12 with CKD, 22 who received a kidney transplant, and 11 healthy control subjects. Patients with ATN had significantly higher urinary IL-18 levels as compared with control subjects and patients with other forms of kidney disease.[66] Similarly, patients who underwent transplantation and had delayed graft function had higher urinary IL-18 levels than patients with prompt graft function. Using samples collected on days 0, 1, and 3 of the Acute Respiratory Distress Syndrome (ARDS) Network trial, urine IL-18 levels of >100 pg per mL were associated with a 6.5-fold increased risk for development of AKI, defined by RIFLE.[52]

Many other factors beside GFR determine biomarker elevation: heterogeneity of clinical settings, underlying patient characteristics, severity of illness, and potential reasons for decreased renal function. It is more likely that a panel of biomarkers will provide a better understanding about the timing, nature, and the severity of an acute renal insult. Further work is clearly needed to inform the time course and performance of AKI biomarkers in various situations, to identify the pathways involved, to define clinical endpoints, including prerenal states, and to improve adjudication of biomarker data with respect to functional changes.[79]

DETERMINING REVERSIBILITY

Although epidemiologic studies have shown that even small increases in SCr are predictive of nonrenal outcomes, SCr remains an insensitive and delayed marker of AKI. A key unanswered question is whether reversible AKI or prerenal AKI is also associated with increased complications and worse outcomes. For decades the differentiation from intrinsic AKI and prerenal AKI was based on urine analysis and microscopy parameters, but could only be confirmed retrospectively by the reversibility of creatinine increase or improvent of urine output. In the era of the new biomarkers new paradigms may arise to answer this question.

Physiology of Reversibility

The traditional classification of AKI includes causes associated with a decrease in renal blood flow (Table 28.4), intrinsic renal parenchymal diseases (Table 28.5), or obstruction of urine flow (Table 28.6). Although obstructive AKI is usually easier to diagnose, prerenal and intrinsic renal causes can be difficult to distinguish in the clinical setting. Another

28.4 Causes of Reversible Acute Kidney Injury

Decreased Intravascular Fluid Volume
- Extracellular fluid loss—burns, diarrhea, vomiting, diuretics, salt-wasting renal disease, primary adrenal insufficiency, gastrointestinal hemorrhage
- Extracellular fluid sequestration—pancreatitis, burns, crush injury, nephrotic syndrome, malnutrition, advanced liver disease

Decreased Cardiac Output
- Myocardial dysfunction—myocardial infarction, arrhythmias, ischemic heart disease, cardiomyopathies, valvular disease, hypertensive disease, severe cor pulmonale

Peripheral Vasodilation
- Drugs—antihypertensive agents
- Sepsis
- Miscellaneous—adrenal cortical insufficiency, hypermagnesemia, hypercapnia, hypoxia

Severe Renal Vasoconstriction
- Sepsis
- Drugs—nonsteroidal anti-inflammatory agents, β-adrenergic agonists
- Hepatorenal syndrome

Mechanical Occlusion of Renal Arteries
- Thrombotic occlusion
- Miscellaneous (emboli, trauma [e.g. angioplasty])

28.5 Renal Causes of Acute Renal Failure

Renal Vascular Disorders
- Vasculitis
- Malignant hypertension
- Scleroderma
- Thrombotic thrombocytopenic purpura
- Hemolytic–uremic syndrome
- Disseminated intravascular coagulation
- Mechanical renal artery occlusion (surgery, emboli, thrombotic occlusion)
- Renal vein thrombosis

Glomerulonephritis
- Postinfectious
- Membranoproliferative
- Rapidly progressive glomerulonephritis (idiopathic, polyarteritis nodosa, systemic lupus erythematosus, Wegener syndrome, microscopic polyarteritis, Goodpasture syndrome, Henoch-Schönlein purpura)
- Drugs

Interstitial Nephritis
- Drugs (penicillin, sulfonamide, rifampin, ciprofloxacin, phenindiones, cimetidine, proton pump inhibitors [omeprazole, lansoprazole], azathioprine, phenytoin, captopril, thiazides, furosemide, bumetanide, allopurinol, nonsteroidal anti-inflammatory drugs including selective cyclooxygenase-2 inhibitors, 5-aminosalicylates)
- Hypercalcemia

Infections
- Nonspecific due to frank septicemia or systemic anti-inflammatory response syndrome
- Specific organisms (Legionella, Leptospira, Rickettsia, Hantavirus, Candida, malaria)
- Specific organ involvement (bacterial endocarditis, visceral abscess, pyelonephritis)

Infiltration
- Sarcoid
- Lymphoma
- Leukemia

Connective Tissue Disease

Tubular Necrosis
- Renal ischemia (prolonged prerenal)
- Nephrotoxins (aminoglycosides, radiocontrast agents, heavy metals, organic solvents, other antimicrobials)
- Pigmenturia (myoglobinuria, hemoglobinuria)
- Miscellaneous

way to approach AKI classification is to ascertain the possibility of reversibility.

Prerenal AKI has been accepted as a reversible form of renal dysfunction, caused by factors that compromise renal perfusion. The term has been used as part of a dynamic process that begins with a reversible condition, the prerenal state, and can progress to an established disease, ATN. Experimental models have largely informed our current understanding of the physiology of the kidney injury associated with prerenal failure. Before the onset of clinically evident prerenal azotemia, the kidney passes through a phase of remarkable compensation called pre-prerenal azotemia.[80] Three main steps are involved in this compensatory mechanism: (1) the cardiac output fraction that reaches the kidney; (2) plasma filtration by the glomerulus (filtration fraction); and (3) proportion of the glomerular filtrate that is reabsorbed by the tubules. Renal blood flow (RBF) depends on the tone of renal vascular resistance (RVR) in relation to systemic vascular resistance (SVR): if the RVR increases in relation to the SVR, the RBF decreases. At reduced levels

28.6 Causes of Postrenal Acute Kidney Injury

Intrarenal (Intratubular)
- Crystal deposition—uric acid, oxalic acid, methotrexate, acyclovir, triamterene, sulfonamides, indinavir, tenofovir
- Protein deposition—light chains, myoglobin, hemoglobin

Extrarenal
- Ureteral/pelvic
- Intrinsic obstruction—tumor, stone, clot, pus, fungal ball, papilla
- Extrinsic obstruction—retroperitoneal and pelvic malignancy, fibrosis, ligation, abdominal aortic aneurysm

Bladder
- Prostate hypertrophy/malignancy
- Stones
- Clots
- Tumor
- Neurogenic
- Medication

Urethral
- Stricture
- Phimosis

of cardiac output, intrarenal factors are triggered, increasing renal arterial vascular tone and, consequently, decreasing the RBF. In order to maintain the intraglomerular pressure, efferent arteriolar resistance increases, preserving the filtration pressure even when the pressure in the afferent arteriolar decreases to levels low enough to cease filtration. Augmented activity of the sympathetic nervous system, RAAS, and vasopressin secretion increases the amount of filtered fluid and Na^+ that are reabsorbed.

These three mechanisms, control of blood flow to the kidney, the filtration fraction, and amount of fluid and solutes reabsorbed by the kidney, are the components responsible for the kidney reserve. However, the efficiency of these mechanisms has limits imposed by structural changes and the severity of the insult. The reserve is diminished by the presence of underlying arterial and intrinsic renal diseases that interfere with the control of renal blood flow, filtration fraction, and reabsorbtion functions, as well as by drugs that interfere with the vascular or neural humoral control of these mechanisms. When these compensatory mechanisms are overwhelmed, a prerenal state is discernible.

The frequency of prerenal azotemia as a cause of AKI varies with the clinical setting. A prospective study by Hou et al.[81] found prerenal azotemia to be the single most common cause of AKI in a general medical-surgical hospital. Liano found that prerenal causes of AKI among the elderly accounted for 48% of community-acquired AKI and 58% of hospital-acquired AKI (Fig. 28.7).[82,83] Brivet observed that in critically ill patients, prerenal causes accounted for 17% of cases of AKI.[84] Prerenal forms of AKI also appear to be common causes of community-acquired AKI and constituted 70% of all such cases as reported by Kaufman and associates.[85]

The terms "reversible AKI" or "prerenal failure" refer to all these different conditions that vary considerably in pathophysiology and course, including intravascular volume depletion, relative hypotension, compromised cardiac output, or hepatorenal syndrome (HRS). Although these terms are usually defined as an elevation of SCr or a reduction of UO that is easily reversible with improved renal perfusion

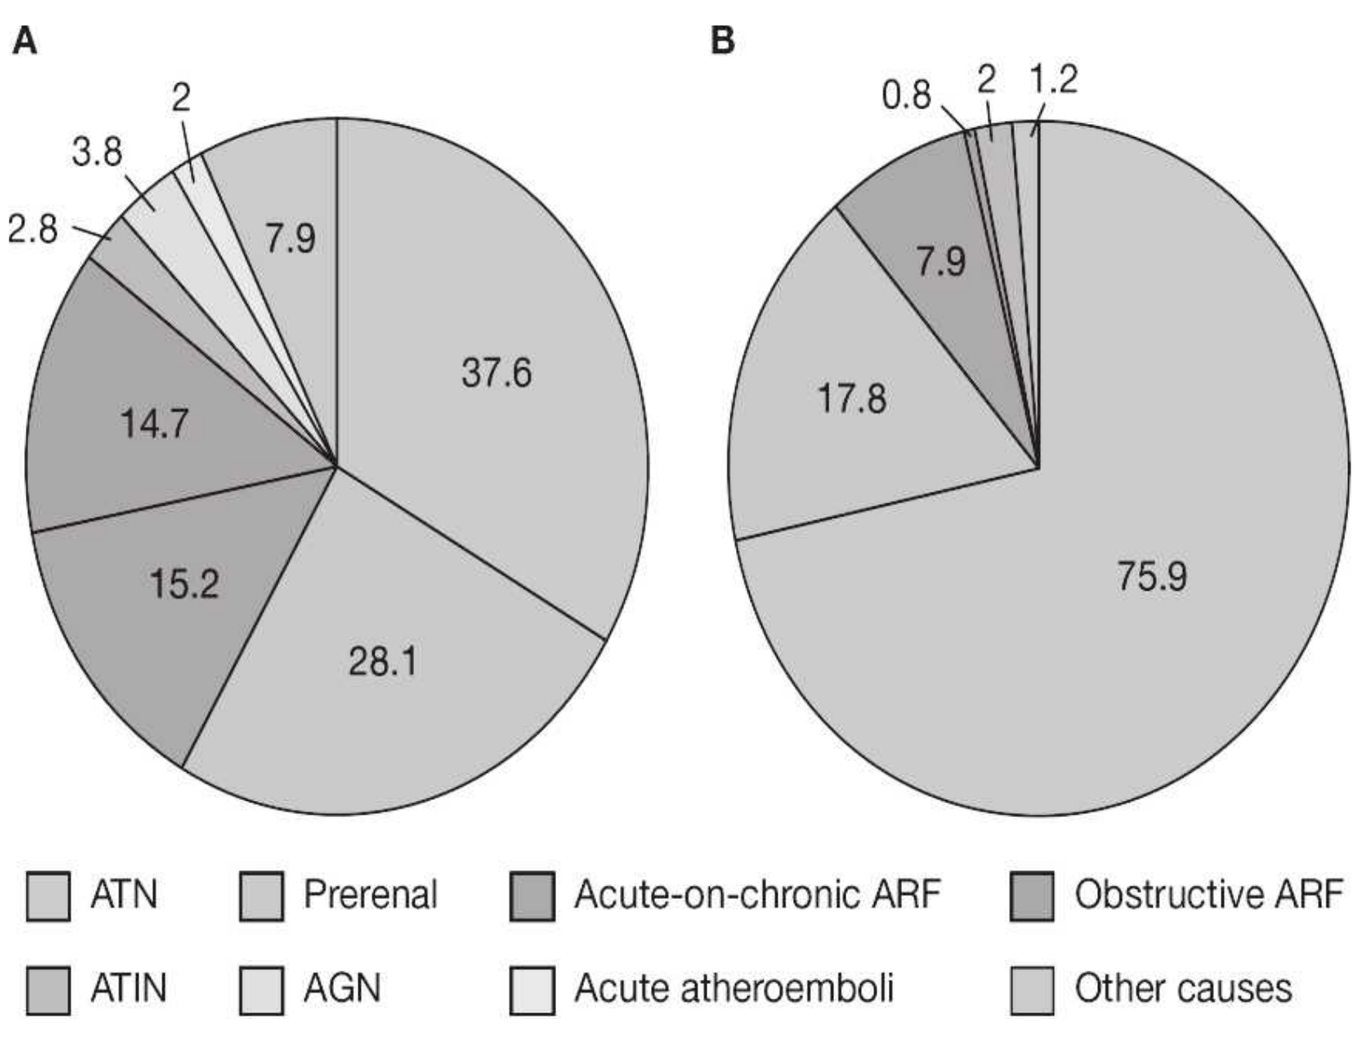

FIGURE 28.7 Percentage distribution of causes of acute renal failure in **(A)** non–intensive care unit (ICU) and **(B)** ICU settings. ICU patients are generally younger, less frequently afflicted by acute-on-chronic renal failure, and have significantly more acute tubular necrosis than the non-ICU group. *AGN*, acute glomerulonephritis; *ARF*, acute renal failure; *ATIN*, acute tubulointerstitial nephropathy; *ATN*, acute tubular necrosis; *ICU*, intensive care unit. pressure, there is no agreement on the amount, nature, and duration of fluid resuscitation needed to eliminate a prerenal state. In most cases, the effect of fluid expansion or hemodynamic effect on renal function is retrospective and frequently evaluated by trial and error. The return of renal function to the previous baseline within 24 to 72 hours is considered to represent a prerenal or reversible condition. Diagnostic strategies have usually been based on demonstrating a fluid responsive change in renal function. The AKIN group recommended the "exclusion of urinary tract obstructions or . . . easily reversible causes of decreased urine output" and application of the diagnostic criteria "following adequate resuscitation when applicable."[17] This modification in the criteria was intended to exclude transient changes in creatinine or UO due to volume depletion or other easily reversible causes of renal hypoperfusion. Although ideally created for prospective application, most studies seeking to validate the criteria were retrospective. In those studies, the exclusion of urinary tract obstruction and prerenal failure are impossible to verify. One small retrospective study attempted to evaluate the outcome of patients that met the adequate resuscitation criteria in comparison to those patients in which data on fluid challenge was not available.[86] Detailed fluid challenge information was available in 123 patients who met AKI criteria. They found that the association of AKI with in-hospital mortality was still significant even when the appropriate fluid challenge requirement was discarded.

Several clinical scenarios are often associated with a potentially reversible or prerenal form of AKI. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with volume depletion, hypoalbuminemia, an edematous disorder, advancing age, underlying chronic renal failure, or recent diuretic use are all contributing factors for prerenal AKI.[87] A similar reversible form of AKI can complicate angiotensin-converting enzyme (ACE) therapy in the presence of decreased RBF from severe bilateral renal artery stenosis, renal artery stenosis in a solitary kidney, and other high-renin, high-angiotensin II states (i.e., edematous states and volume depletion disorders). In these cases ACE inhibition, with a resultant decrease in both renal perfusion pressure and efferent arteriolar constriction, can precipitously decrease GFR. About one third of patients with severe congestive heart failure experience an abrupt rise in SCr concentration following ACE inhibitor therapy.[88] In the setting of heart failure, this increase in SCr following ACE inhibition tends to be mild and readily reversible on discontinuation of the drug.

Although laboratory tests to distinguish reversible prerenal conditions from ATN have been used, these diagnostic parameters present frequent exceptions and the distinction between prerenal and renal causes are frequently not accurate (Fig. 28.8). The plasma (P) urea/creatinine ratio, urine (U) osmolality, U/P osmolality, U/P creatinine ratio, urinary Na level, and fractional excretions of Na (FE_{Na}) are the most frequently used tests. Serum U/P creatinine ratio

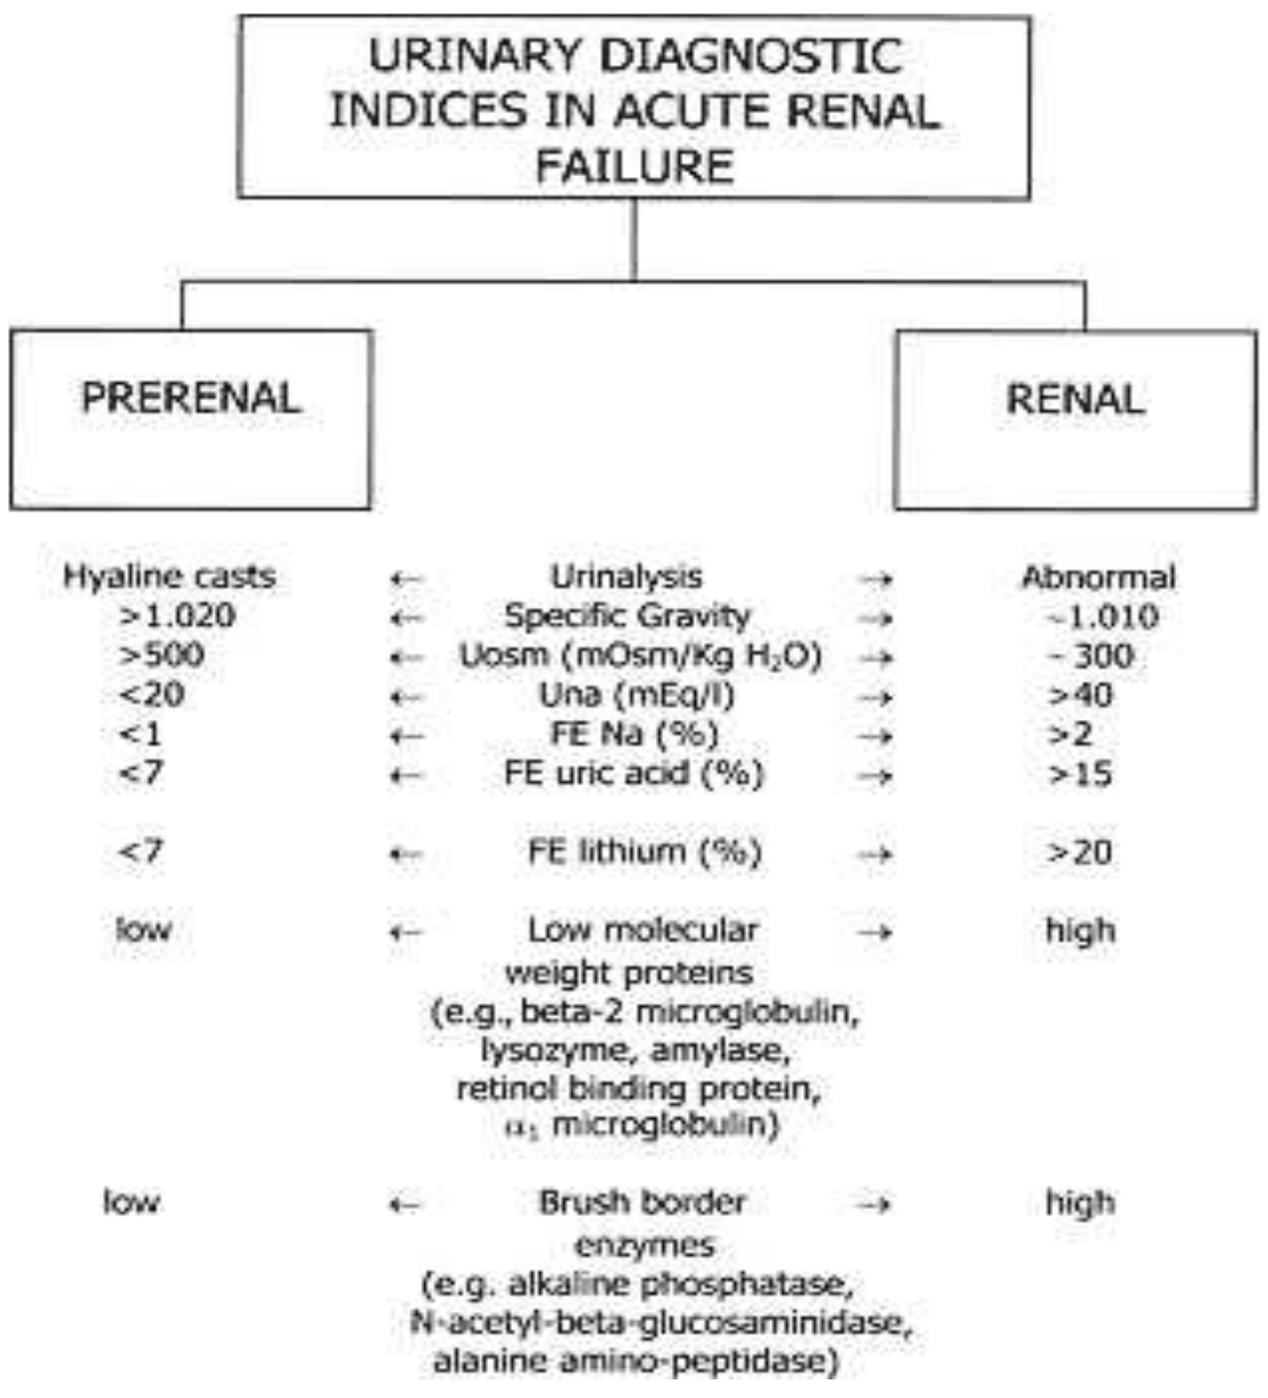

FIGURE 28.8 Urinary diagnostic indices to differentiate between prerenal and renal causes of acute kidney injury.

helps to identify whether the oliguria is a result of water reabsorption (U/PCr > 20) or loss of tubular function (U/PCr <20). In reversible states the reabsorption of sodium is increased, not only from the increase in proximal tubular reabsorption of water, but also by the increase in aldosterone level secondary to hypovolemia. The frequent use of diuretic therapy limits the value of FE_{Na}. The fractional excretion of urea (FE_{UN}) can be helpful in these cases. FE_{UN} relates inversely to the proximal reabsorption of water; urea reabsorption leads to a decrease in FE_{UN} and an increase in the BUN/creatinine ratio. Carvounis et al.[89] found that FE_{UN} has a high sensitivity (85%), a high specificity (92%), and a high positive predictive value; in that study a FE_{UN} less than 35% was associated with a 98% chance of reversible failure. Still, there are limitations for the use of FE_{UN}. In osmotic diuresis and with the use of mannitol or acetazolamide, the proximal tubular reabsorption of salt and water is impaired, so there can be an increase in FE_{UN} even in states of hypoperfusion. The same can occur when a patient is given a high protein diet or presents with excessive catabolism. Urinary osmolality is also used to evaluate the urinary concentration ability, a function that becomes impaired in the early process of tubular dysfunction. A value greater than 500 mOsm per kg indicates that tubular function is still intact, although there are also some considerations about this index; a low protein diet or low protein absorption by intestinal edema can impair the concentration ability of the urine and show a low osmolality even in reversible states.

There are some promising new biomarkers for AKI that may be helpful in distinguishing between reversible and established AKI.[64,69,90] During the reversible state, the persistent vasoconstriction associated with metabolic changes and inflammation promotes the release of cell functional markers that can be detected in the blood and urine. However, at the current time, there are no specific markers representing reversible conditions.

Obstruction to Urine Flow

Obstruction of urine flow is generally considered a less common cause of AKI. In several series, obstructive uropathy is encountered in 2% to 10% of all cases in AKI.[83,84] However, obstructive uropathy is more common in selected patient populations, such as the very young or older men with prostatic disease, and patients with a single kidney or intra-abdominal cancer, particularly pelvic cancer. Obstructive uropathy is most frequently encountered in community- and hospital-associated AKI and is less common in ICU-related AKI.[82,83] For example, obstructive uropathy constitutes 20% to 40% of all community-acquired AKI. Finally, the cause of obstructive uropathy is often amenable to therapy. Thus, obstructive uropathy should be considered in each case of AKI.

Obstruction of urinary flow can occur anywhere from the kidneys to the urethral meatus. Certain points along this path are more susceptible to obstruction. The three points of narrowing along the ureter include the ureteropelvic junction, the crossing of the ureter over the area of the pelvic brim, and the ureterovesical junction. The cause of obstruction of urine flow can be classified as intrarenal or extrarenal (Table 28.6). Intratubular deposition of either crystalline or proteinaceous material can increase intratubular pressure, thereby decreasing effective glomerular filtration pressure. For example, intratubular precipitation of uric acid can cause tubule obstruction and AKI. Acute uric acid nephropathy is most often seen following chemotherapy for leukemias and lymphomas. In this setting, the liver converts the purine load generated by cytolysis into uric acid. The high filtered load of uric acid and tubular reabsorption combine to produce high tubular concentrations of soluble urate and uric acid. Acidification of tubular fluid converts urate to uric acid, which can crystalize and occlude tubular lumens.

Abrupt exposure of the kidneys to high filtered loads of other insoluble crystalline substances can also cause an intrarenal form of obstructive uropathy. For example, AKI associated with calcium oxalate crystalluria can accompany ethylene glycol ingestion, administration of the anesthetic agent methoxyflurane, chronic pancreatitis, and use of gastrointestinal lipase inhibitors.[91–94] Administration of high doses of methotrexate can be associated with AKI, possibly owing to intratubular precipitation of the insoluble 7-hydroxy metabolite of methotrexate.[95] Other crystalline substances that can potentially precipitate within renal tubules and lead to AKI include acyclovir, triamterene, sulfonamides, and protease inhibitors such as indinavir.[96]

Another cause of intratubular obstruction is the deposition of immunoglobulin light chains in plasma cell dyscrasias. Immunoglobulin light chains are low molecular weight proteins that are filtered through the glomerulus and reabsorbed into the proximal tubular epithelium by initially binding to a heteromeric receptor complex composed of megalin and cubilin.[97] Saturation of this receptor-mediated endocytotic process results in the presence of free light chains in the distal nephron and urine. Nephrotoxicity of the metabolism of monoclonal light chains causes tubulointerstitial nephritis and cast nephropathy (also known as "myeloma kidney"), resulting in AKI and progressive CKD from tubular obstruction.[97]

Extrarenal lesions are the most common cause of postrenal AKI and are listed in Table 28.6. Several factors determine renal response to extrarenal obstruction. The site, degree, and rapidity of onset of obstruction are all important. Without a complicating infection, substantial improvement in renal function can follow decompression of the urinary tract after several days of complete obstruction. In men, prostatic obstruction is by far the most common cause of postrenal AKI because of its critical location at the bladder outlet. Obstruction of the upper urinary tract is a less common cause of AKI because it requires simultaneous obstructions of both ureters or unilateral ureteric obstruction with either absence of or severe disease in the contralateral kidney. Intraureteric obstruction can be due to stone, released necrotic papillae, tumor, pus, blood clots, and fungal balls. Papillary necrosis can occur in the

setting of sickle cell disorders, chronic urinary tract infections, analgesic abuse, and obstructive uropathy. Extraureteric lesions producing obstruction include retroperitoneal fibrosis, adenopathy, and tumors. Retroperitoneal fibrosis is often idiopathic but may be encountered in response to retroperitoneal neoplasia as well as in the setting of some pharmacologic agents (methysergide, methyldopa, β-blockers), prolonged peritoneal dialysis, and some connective tissue diseases. It has been reported that a high frequency of AKI occurs because of prostatic carcinoma in males and pelvic carcinoma (predominantly cancer of the cervix) in females causing ureteric occlusion. Less commonly encountered causes of extrinsic ureteric obstruction include inflammatory bowel disease (predominantly right-sided obstruction), an inflammatory reaction resulting from a leaking abdominal aortic aneurysm, and the late stages of pregnancy.

Acute obstruction can also be related to use of pharmacologic agents with potential anticholinergic effects (e.g., tricyclic antidepressants, phenothiazines, antihistamines) and cold remedies containing α-adrenergic agents (e.g., phenylpropanolamine) often precipitate acute urinary retention by impairing detrusor function and enhancing bladder sphincter tone, respectively.

PROLONGED OR SUSTAINED ACUTE KIDNEY INJURY

A variety of renal disorders can lead to a prolonged or sustained AKI (Table 28.5). In hospitalized adults in whom reversible and obstructive causes have been excluded, AKI is often caused by ATN. By contrast, in an outpatient setting in which reversible and obstructive causes have been excluded, other renal parenchymal diseases more often cause AKI.

Three major categories of insults are associated with ATN: prolonged renal ischemia, nephrotoxins, and pigmenturia (myoglobinuria and hemoglobinuria). Patients with ATN frequently present with more than one insult and several experimental studies in animal models of AKI demonstrate that multiple renal insults such as fever, bacteremia, endotoxemia, relative hypotension, and aminoglycoside exposure contribute to decrements in renal function with resulting AKI. This is referred to as multifactorial AKI.

The most common predisposing factor in the development of ATN appears to be renal ischemia resulting from a functional or structural reduction in renal perfusion.[10,83,98] Sepsis, and particularly septic shock, has assumed an ever-increasing role as a major predisposing factor in the occurrence of ATN.[10,99] Nephrotoxins are involved in about 20% of all cases of ATN.[10,83,98] Contemporary nephrotoxins commonly encountered include the aminoglycoside antimicrobial agents, radiographic contrast materials, NSAIDs, and antineoplasic drugs (Table 28.7). A high proportion of patients with AIDS develop nephrotoxicity from drugs used to manage HIV.

28.7 Factors Predisposing the Kidney to Nephrotoxicity

Drug-Related	Patient-Related
Concentration of the drug through reabsorptive and secretive processes	Preexisting renal dysfunction
High number of transporters result in high intracellular concentrations	Dehydration
Large luminal membrane surface area	Diabetes mellitus
Large biotransformation capacity	Exposure to multiple nephrotoxins

Diagnostic Approach

There are numerous causes of AKI, some of which are amenable to specific therapeutic interventions. For these interventions to be effective they must be applied early in the course of the disease process, preventing further deterioration of the renal function as mortality and complications of AKI appear to be proportional to its severity.[19] For example, Chertow et al. showed a 6.5-fold increase in the odds of death for patients with a 0.5 mg per dL increase in SCr.[100] In pediatric patients with acute decompensated heart failure, Goldstein et al. found that a rise in SCr of 0.3 mg per dL or more was associated with a sevenfold increased risk of in-hospital death.[101] Additionally, several studies have shown that the change in severity stage of AKI (AKIN from RIFLE) is associated with an incremental risk for mortality.[14,19,21,102] An early diagnosis and accurate assessment of AKI severity is essential to develop approaches for earlier intervention, correct reversible factors, and mitigate the downstream effects of AKI.

Chart Review, History, and Physical Examination

Meticulous chart analysis to determine recent clinical events possibly associated with the development of AKI is fundamental (Fig. 28.9). A history with regard to prescription drugs, over-the-counter agents, and herbal preparations, as well as possible environmental exposure, is critical as nephrotoxins are frequently contributing factors to the development of AKI. The relationship between medication exposure and AKI may not be readily apparent in some cases, thus a detailed history should always be performed. The presence of signs and symptoms of sepsis or heart failure, and symptoms related to the genitourinary tract (urine

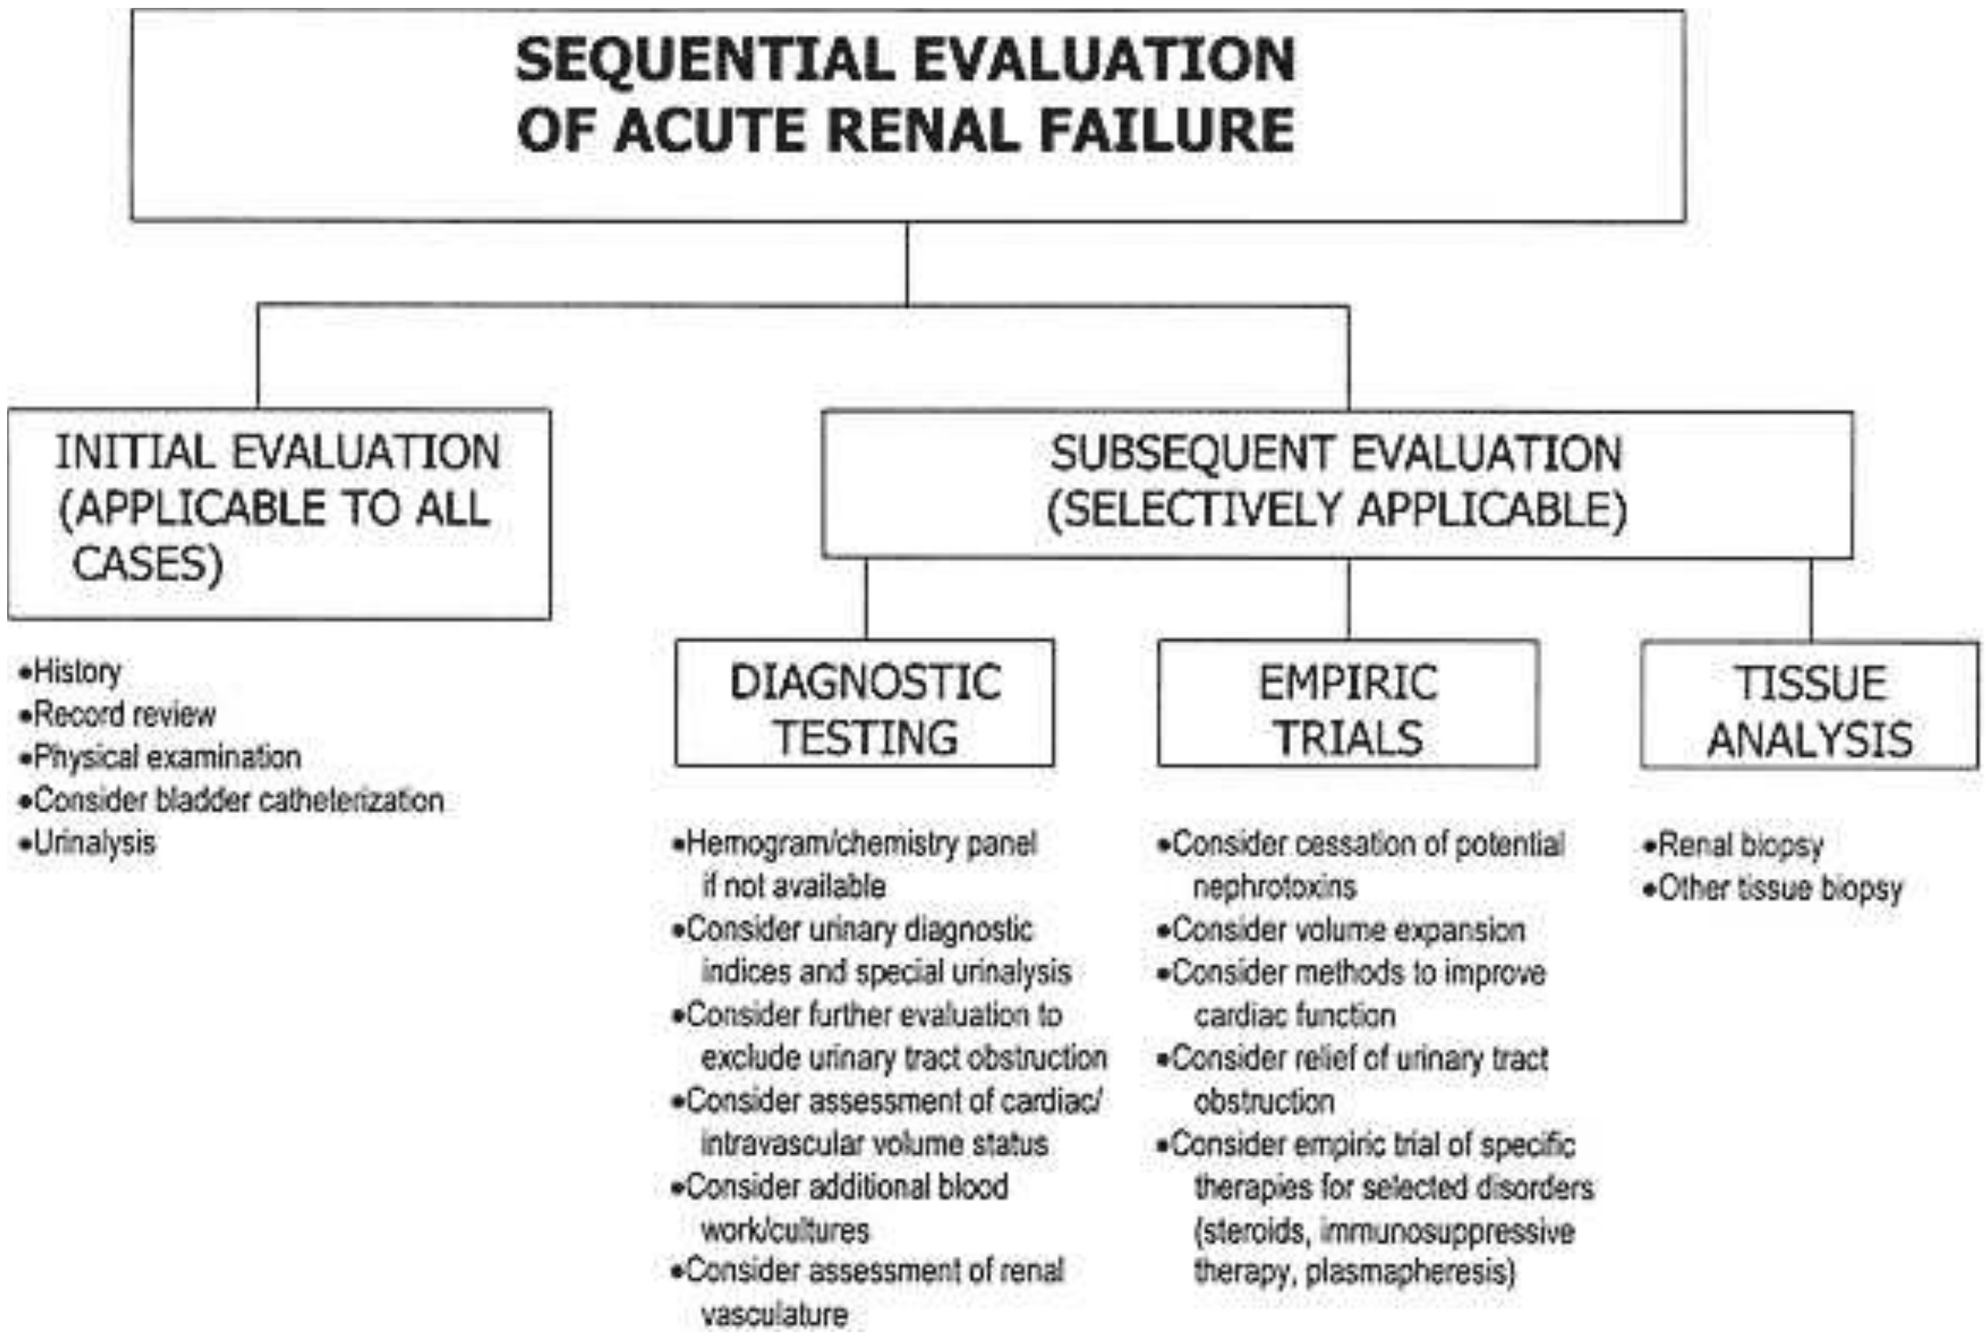

FIGURE 28.9 Suggested sequential diagnostic evaluation to determine the cause of acute kidney injury.

output, pyuria, dysuria, hematuria, and flank or abdominal pain) can provide helpful diagnostic information. Intense thirst, salt craving, orthostatic syncope, and muscle cramps often are symptoms of extracellular fluid volume depletion. Examination of serial vital signs, hemodynamic data, intake and output, and daily weight can provide important data regarding the cause of AKI. A weight change of greater than 0.25 to 0.50 kg per day indicates gain or loss of salt and/or water. Recording of serial renal functional data and correlation of any deterioration in renal function with clinical events such as those altering systemic hemodynamics and use of potential nephrotoxins often are of great diagnostic value. Physical examination can be of value in determining the presence or absence of prerenal and postrenal causes of AKI, as well as the presence of a systemic disorder that could result in a renal cause of AKI. The effect of either loss or sequestration of extracellular fluid volume on systemic hemodynamic responses depends on several variables, including the composition and rate of fluid loss and the underlying health state of the patient.

Physical examination must also include palpation for determining the state of peripheral circulation, renal size, and the possibility of abdominal aortic aneurysms. Palpation or percussion of the suprapubic area is necessary to detect bladder distention, and rectal and pelvic examinations are needed to detect prostatic and pelvic disorders. Examination of the skin may reveal palpable purpura suggestive of vasculitis; lower extremity evaluation may reveal livedo reticularis and evidence of emboli, suggesting atheroembolic disease. It is beyond the scope of this chapter to detail all the physical findings that can be associated with causes of AKI; however, the presence of neurologic or pulmonary disease, fever, skin lesions, joint abnormalities, or diffuse lymphadenopathy suggests the presence of a systemic disorder associated with AKI.

Laboratory

Blood Urea Nitrogen

Elevations in BUN are dependent on the nitrogen intake, the degree of renal impairment, and the degree of protein catabolism. In the noncatabolic patient with mild renal impairment, daily BUN usually increases <10 to 15 mg per dL per day and SCr <1.5 mg per dL per day. High catabolic states and high-protein diets are associated with greater urea nitrogen production that can exceed 50 mg per dL.

Another condition associated with a BUN increase not proportional to the rise in SCr level and fall in GFR is the presence of decreased intravascular effective volume. Normally, the usual BUN:SCr ratio is about 15:1 and the BUN and SCr increases by 10 to 15 and 1.0 to 1.5 mg/dL/day, respectively, in the absence of GFR. In situations characterized by decreased glomerular perfusion pressure, such as heart failure, BUN can increase independently from SCr. Elevations

in BUN are independent from SCr levels, and these two parameters are a reflection of the severity of renal dysfunction, and actually a consequence of two distinct pathologic processes.[36–38] The activation of RAAS and the sympathetic nervous system are responsible for decreasing the glomerular perfusion pressure and GFR. The increment in vasopressin levels upregulates aquaporin-2 expression and increases water reabsorption. Urea, in contrast to SCr, is not secreted but reabsorbed by the renal tubules. The increased reabsorption of sodium and water, rather than the reduced GFR, enhances reabsorption of urea and increases BUN levels. Thus, BUN levels and BUN/creatinine ratio could be a more effective way to assess circulatory volume than GFR, which is regulated by the pressure difference between glomerular afferent and efferent arterioles.[39] In heart failure, and possibly in other settings where underfilling is part of the pathophysiologic process, the rise in BUN greater than any fall in GFR is a marker of the neurohumoral axis activation.[40]

In selected circumstances it may not be clear if an elevated BUN:SCr ratio is due to an acute or chronic process. In these settings, a review of previous records is helpful. Although the test is not widely avilable, measurement of carbamylated hemoglobin can be helpful. Hemoglobin potentially undergoes nonenzymatic carbamylation of its terminal valine. Thus, similar to the hemoglobin A1C value as an index of blood sugar control, the level of carbamylated hemoglobin is an indicator of the degree and duration of elevated BUN.[103,104] A carbamylated hemoglobin level greater than 80 to 100 μg carbamyl valine per gram hemoglobin suggests the diagnosis of chronic rather than ARF.[105,106]

Serum Creatinine

Clinicians usually follow daily SCr concentrations to assess whether GFR is increasing, decreasing, or constant in patients with AKI. The SCr concentration, however, is dependent on creatinine production, volume of distribution, and renal elimination. However, in patients with AKI, changes in GFR often correlate poorly with changes in SCr concentration. In AKI, three main factors influence the estimation of kidney function: the actual GFR, fluctuations in creatinine production, and fluid balance.[33] Moran and Myers[107] demonstrated this in several patterns of AKI (abrupt and large, slow and progressive, and stepwise). They developed a simple, computerized model of creatinine kinetics in patients with postischemic AKI to calculate GFR based on SCr concentration corrected for changes in creatinine volume of distribution. They suggested that changes in GFR are difficult to evaluate using SCr concentration alone in the setting of AKI.[33]

Jelliffe developed an equation to estimate GFR in patients with unstable (nonsteady state) kidney function that considered fluctuations in kidney function and creatinine production without requiring timed urine collection.[108] The Jelliffe equation is based on the concept that daily changes in SCr depend on the difference between creatinine production and excretion. Bouchard et al. demonstrated that the GFR by Jelliffe correlated best with urinary creatinine clearances.[109] In an ICU cohort the eGFR by Cockcroft–Gault, Modification of Diet in Renal Disease, and Jelliffe overestimated urinary creatinine clearance in 80%, 33%, and 10%, respectively. The relative overestimation of GFR in AKI with both Cockcroft–Gault and MDRD was more prominent when baseline GFR was higher.

Fluid administration is a common and required component of the management of critically ill patients and has recently focused on goal-directed resuscitation with early volume expansion in the ICU course. These strategies frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body weight in a short period of time.[110] The fluid accumulation increases the extracellular fluid (ECF), altering the volume of distribution of SCr, and resulting in potential overestimation of the level of kidney function.[34] The masking of AKI severity by volume expansion may be especially problematic in settings where the SCr is rising relatively slowly owing either to lower creatinine generation (e.g., as might be expected in the elderly or patients with less muscle bulk) or to more modest overall injury.

Urine Microscopy

Urinary microscopy (UM) is an integral part of the clinical evaluation of patients with kidney disorders and is frequently utilized to differentiate some clinical conditions (e.g., nephrotic syndrome, urinary tract infection, nephritic syndrome). Drug toxicity has also been assessed by UM, as in the case of indinavir, acyclovir, and amoxicillin, associated with variable degrees of leukocyturia, crystalluria, and cellular casts.[96,111–113]

In the case of AKI, UM has traditionally been used as a tool to differentiate prerenal AKI and ATN. Sediment containing few formed elements or only hyaline casts strongly suggests prerenal azotemia or obstructive uropathy. With ATN, brownish-pigmented cellular casts and many renal tubular epithelial cells are observed in more than 75% of patients. Sufficient red blood cells to cause microscopic hematuria are traditionally thought to be incompatible with a diagnosis of ATN and usually result from glomerulonephritis or structural renal disorders (stones, tumor, infection, or trauma). Red blood cell casts suggest the presence of glomerular or vascular inflammatory diseases of the kidney and rarely, if ever, occur with ATN. Red blood cell casts, however, can be seen rarely in acute interstitial nephritis. The presence of large numbers of polymorphonuclear leukocytes, singly or in clumps, suggests acute diffuse pyelonephritis or papillary necrosis. In allergic tubular-interstitial nephritis eosinophilic casts on Hansel's stain of urine sediment may be diagnostically helpful.[114–116] Eosinophiluria may be also present in some forms of glomerulonephritis and in atheroembolic renal disease but is rarely encountered in ATN.[117] The combination of brownish-pigmented granular casts and positive occult blood tests on urine in the absence of hematuria indicates either hemoglobinuria or myoglobinuria. In AKI, the finding of large numbers of "football-shaped" uric acid

crystals in fresh, warm urine may suggest a diagnosis of acute uric acid nephropathy, whereas the finding of large numbers of "back-of-envelope–shaped" oxalic acid suggests ethylene glycol toxicity.[118] Other agents (e.g., indinavir, sulfadiazine, acyclovir, and methotrexate) also can induce AKI with characteristic crystal appearance on urinalysis.[112,118] The presence of broad casts (defined as more than three white blood cells in diameter) suggests chronic renal disease.

Recently, two different groups have revised the clinical value of performing UM.[119,120] In a pilot study, Chawla et al. developed an AKI cast-scoring index to standardize urine-sediment. The score precision was evaluated in 30 patients with a clinical syndrome compatible with ATN with an interobserver index of 99.8 ± 0.29%, and a coefficient of variation of 1.24%. Urine-sediment was further correlated with outcomes in 18 patients with ATN. The authors found that renal recovery was worse in those patients with a higher cast scoring index (2.55 ± 0.9 vs. 1.7 ± 0.79; P = .04), and area under the ROC curve of the cast scoring system to predict nonrenal recovery was 0.79. In another study, Perazella et al. proposed a different scoring system for differentiating ATN from prerenal AKI (Table 28.8).[120] Using the final AKI diagnosis at discharge as a gold standard, UM at the day of nephrology consultation was highly predictive of ATN. The odds ratio for ATN incrementally increased with a higher score. In patients with initial diagnosis of ATN, any granular casts (GCs) or renal epithelial tubular cells (RETCs) (score 2) resulted in a PPV of 100% and a NPV of 44%. The lack of RTECs or GCs in patients with initial diagnosis of prerenal AKI had a sensitivity of 0.73 and specificity of 0.75 for the final diagnosis of

ATN. A scoring point system of UM findings was used to predict adverse outcomes.[121] Correlation of the urinary-sediment score and AKIN stage at nephrology consultation was demonstrated, and the score was associated with a higher risk of worsening AKI in a dose-dependent manner.

Urinary Chemical Indices

Since the 1940, the concentrations of sodium (U_{Na}) and chloride (U_{Cl}) in the urine have been known to be high during established phases of ATN. Although the accuracy of U_{Na} alone in determining the cause of AKI was limited, the renal failure index ($U_{Na} \div$ U/P creatinine) or the fractional excretion of sodium (FE_{Na} or $U/P_{Na} \div$ U/P creatinine $\times$ 100) was found to have a high degree of accuracy in differentiating between reversible prerenal azotemia and ATN. However, there are several caveats when using spot urine chemistries as a diagnostic tool to evaluate the cause of AKI. Despite widespread, routine use, no study has demonstrated that knowledge of these indices either changes management or improves outcome of AKI.

Nearly all studies of spot chemistries have been performed at a single time point often relatively late in the course of AKI. The lack of serial data is important because AKI is a dynamic process. During the early phases of AKI, renal tubular function is intact. Later, cell injury may result in loss of tubular cell polarity. The resulting urine chemistries, therefore, are dependent on the phase of the course in which they were obtained. This may limit the sensitivity and specificity of urine chemical indices. For example, the early course of AKI occurring in the setting of sepsis,

radiocontrast exposure, rhabdomyolysis, and NSAID use is often associated with renal vasoconstriction, hypoperfusion of the kidney, and low FE_{Na}.[122] Later in the course, the FE_{Na} often increases, if tubular necrosis occurs.

Two other points deserve emphasis with regard to use of urine chemistries as an AKI diagnostic tool. Early in the course of urinary tract obstruction, in some patients with nonoliguric ATN, and in some vascular/glomerular disorders (acute glomerulonephritis, vasculitis, thrombotic thrombocytopenic purpura) urinary chemical indices can be indistinguishable from those seen with prerenal AKI. Conversely, several acute renal parenchymal disorders (e.g., interstitial nephritis, severe ischemic nephropathy, and exacerbations of chronic renal failure) can be associated with urine chemical parameters indistinguishable from ATN, suggesting a lack of specificity. Finally, it is important to acknowledge that potentially reversible prerenal AKI with an $FE_{Na} > 1\%$ occurs in selected settings such as recent diuretic use, bicarbonaturia, salt-wasting nephropathy, glycosuria, and mineralocorticoid deficiency. In the setting of prerenal AKI associated with bicarbonaturia, the urinary chloride concentration is low, confirming a prerenal state.[123] In the setting of prerenal AKI associated with diuretic use, the fractional excretion of trace lithium, urea nitrogen, or uric acid continues to be low.[124] Although urine chemical indices are most often used as diagnostic adjuncts in patients with AKI, they may also provide prognostic information. Some studies suggested that in oliguric patients with AKI lower values for FE_{Na} and higher values for U/P osmolality can predict a high likelihood of a response to diuretics.[125]

Miscellaneous Tests

In some circumstances the cause of AKI may not be evident after chart review, history, physical examination, and urinalysis. In some cases a review of the hemogram may be helpful. A peripheral blood smear that reveals rouleaux formation may suggest the presence of a plasma cell dyscrasia. Eosinophilia is compatible with allergic interstitial nephritis, atheroembolic disease, and polyarteritis nodosa. A microangiopathic picture with thrombocytopenia suggests vasculitis, malignant hypertension, the HELLP syndrome, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. The presence of coagulopathy can suggest either disseminated intravascular coagulation or an antiphospholipid antibody syndrome as the cause of AKI. If glomerulonephritis is a diagnostic possibility, then the presence of antineutrophilic cytoplasmic antibodies may suggest a diagnosis of either Wegener granulomatosis (primarily a cytoplasmic pattern) or pauci-immune glomerulonephritis (primarily a perinuclear pattern). Antibodies to glomerular basement membrane are strongly suggestive of Goodpasture syndrome, whereas antinuclear antibodies and antibodies against DNA suggest the presence of systemic lupus erythematosus. The presence of cryoglobulins may point to the presence of circulating immune complexes, a plasma cell disorder, or primary cryoglobulinemia.

Imaging

Ultrasonographic evaluation of the kidney can also help in the diagnosis of AKI. Ultrasound is an excellent modality for structural imaging as it is possible to detect renal parenchyma size, scarring, fibrosis, and polycystic kidneys. The presence of small kidney size strongly supports a diagnosis of chronic renal disease and may also help to differentiate acute from chronic renal failure. The echogenicity of the cortex can be assessed with a hyperechoic cortex (normal cortex is hypoechoic to liver), present in most cases of chronic renal failure, adult polycystic kidney disease being the notable exception. Noncontrast computed tomographic (CT) and magnetic resonance imaging (MRI) scans analyze renal structure and renal artery calcification. Other functional studies, such as mercaptoacetyltriglycine (MAG3) and diethylene triamine pentaacetic acid (DTPA), evaluate renal perfusion, uptake, and excretion of a tracer.

A further role of imaging is to determine the number of present and functioning kidneys. For ARF to occur in previously normal kidneys, the underlying cause must be a bilateral process, or a single functioning kidney must be compromised.

Kidney ultrasonography is most commonly ordered in the setting of AKI to rule out urinary tract obstruction. Although renal ultrasonography is a safe and noninvasive test, because obstruction is a relatively uncommon cause of hospital-acquired AKI, the majority of ultrasonography results obtained are negative. In fact, hydronephrosis (HN), the evidence of obstruction on imaging, is only identified on renal ultrasound in 1% to 10% of patients with AKI.[10,126] Licurse et al.[127] sought to create a stratification system that would help clinicians ascertain the risk of renal obstruction among those with AKI. The idea was to improve the probability of a positive finding on renal ultrasound. The authors identified multiple risk factors for hydronephrosis: history of hydronephrosis, history of abdominal or pelvic cancer, prior pelvic surgery, or a single functioning kidney. Patients with a history of heart failure, granular casts on urinalysis, elevated leukocyte count, documented hypotension, or exposure to aspirin, diuretics, or vancomycin during hospitalization were less likely to have hydronephrosis.[127] Patients in the ICU also have a lower incidence of obstruction.

Obstructed kidneys are typically normal sized with dilated ureters, renal pelvis, and calyceal systems. The urine-filled structures appear as anechoic areas with posterior acoustic enhancement. Ureter and renal pelvis can be dilated without being obstructed, mainly after previous obstruction that leaves a residual dilated collecting system, or as an anatomic variant (enlarged extrarenal pelvis). False negatives can occur in the hyperacute setting if the renal collecting system has not had time to dilate, or if associated with retroperitoneal fibrosis. Noncontrast CT scan is the gold standard for detecting ureteric calculi. The ureters can usually be traced between the kidney and bladder, and a hyperdense stone can be seen at the distal site of hydroureter. More than

99% of renal calculi are radiopaque on CT scan; however, xanthine calculi may be radiolucent and stones associated with indinavir are radiolucent. The obstructed kidney is typically edematous (i.e., swollen) with perirenal stranding. A noncontrast study can usually detect many extrinsic compressing masses, such as retroperitoneal tumors or cervical or colon carcinomas, that may produce bilateral obstruction. Scintigraphic imaging with either Tc-99m-MAG3 or Tc-99m-DTPA can detect ureteric obstruction and the negative predictive value of nuclear medicine scanning is extremely high.

In ATN, ultrasounds will usually show enlarged kidneys with a smooth contour caused by interstitial edema. The cortex can present normal echogenicity with either a normal or hypoechoic medulla. The renal arteries can also be evaluated for the renal index (RI), which is an objective measure of the resistance to renal perfusion. RI is defined as (systolic velocity minus diastolic velocity) divided by systolic velocity, and has been heavily investigated to determine whether elevation in RI can differentiate ATN from renal hypoperfusion not yet complicated by ATN. Unfortunately, RI has inadequate specificity for routine clinical use. The examination of choice in suspected ATN is a MAG3 nuclear medicine study. Scintigraphic imaging examinations in ATN using Tc-99m-MAG3 demonstrate relatively well-preserved on-time renal perfusion and delayed tracer uptake, often with a continuing activity accumulation curve. Excretion of tracer into the collecting system is delayed and reduced, but there is no obstruction to drainage of the collecting systems.

In suspected glomerulonephritis or acute interstitial nephritis, the "gold standard" diagnostic test is a renal biopsy. The main role of imaging is to detect structural signs of chronic renal disease and to exclude other causes of ARF. MAG3 studies will show poorly functioning kidneys, but will not show accumulation pattern or obstruction to drainage. Edema can sometimes be demonstrated with ultrasound, manifesting as hypoechoic large kidneys.

Renal Biopsy

A renal biopsy is rarely undertaken but should be considered in the setting of AKI in the presence of: (1) no obvious cause of AKI, (2) either extrarenal clinical evidence or a history of systemic disease, (3) heavy proteinuria and persistent hematuria, (4) marked hypertension in the absence of volume expansion, (5) prolonged (>2 to 3 weeks) oliguria, and (6) anuria in the absence of obstructive uropathy. In clinical practice, most nephrologists choose to biopsy when they are not confident of the cause of the AKI or when the renal injury has an obscure etiology. In a significant proportion of patients diagnosed with AKI, the clinical context suggests the etiology with a reasonable degree of certainty. In other less clear cases the lack of efficient therapeutic options coupled with the risks of a biopsy decreases the likelihood that the clinician will perform the procedure. However, the development of AKI is often multifactorial, and some other causes of AKI may be misclassified as ATN.

Several studies have examined the clinical utility of renal biopsy in the setting of AKI.[128,129] Rivera et al. obtained data from 9,378 cases with native biopsy-proven renal diseases between 1994 and 2001, investigating clinicopathologic correlations. Acute renal failure was an important cause for performing a kidney biopsy: 12% in that cohort. The majority of the biopsies were in adults and elderly patients, predominantly with the suspicion of vasculitis and crescentic glomerulonephritis (GN).[129] In an Italian survey similar results were found: 34.1% frequency of vasculitis and crescentic GN in 1,059 renal biopsies of patients with AKI.[130] In Baltimore, 259 renal biopsies of adults older than 60 years with ARF showed similar results: 35.2% of the diagnoses were crescentic GN.[131] However, these studies included mostly patients with active urinary sediment, a selection bias resulting from clinical practice of biopsy indication in AKI. In most AKI patients, clinical evaluation eliminates prerenal and postrenal causes of AKI, and the results of the biopsies show what we would find when performing biopsy in AKI patients who are thought not to have ATN.[132] Another issue is determining the number of patients clinically diagnosed with ATN who actually have another disease other than AKI. Most importantly, it is necessary to determine the number of patients with treatable forms of AKI that are not being identified.

Several studies have suggested significant discordance between prebiopsy and postbiopsy diagnoses in the setting of AKI. Haas et al. studied the elderly and found the clinical diagnosis to be incorrect in 34% of cases biopsied, many of them involving potentially treatable entities.[131] Among elderly patients with rapidly progressive renal injury, Uezono et al. found 71% of the patients with crescentic GN and 17% with interstitial nephritis. Prebiopsy and histopathologic diagnoses differed in 15% of patients, and both groups benefited from therapeutic intervention.[133]

These data emphasize the value of renal biopsy in the management of AKI of uncertain origin, irrespective of the age of the patient. Accurate diagnosis is important to direct the appropriate treatment, especially in vasculitis and crescentic GN, in which the delay in diagnosis may affect outcome. Given the safety of the ultrasound tomographic-guided renal biopsy, unclear causes of AKI deserve renal biopsy consideration.

Primary Prevention

The development of AKI contributes to dysfunction of other organs, such as heart, lung, brain, and liver.[134–136] Even small changes in GFR are associated with increased mortality.[21] Consequently, primary prevention and early diagnosis of AKI is of central clinical importance. As shown in the conceptual model of AKI illustrated in Figure 28.5, the first step in preventing AKI is an adequate risk assessment. The prevention of AKI should start with assessment of the risk to develop AKI; identification of comorbidities, nephrotoxic medications in use, and early recognition of acute reversible risk factors

associated with AKI. A surveillance approach, applying close monitoring in patients at risk to develop AKI, is a fundamental key to AKI prevention.[137] General preventive strategies are outlined in Table 28.9. A contemporary study has illustrated the potential value of a computerized surveillance system with electronic notification of clinicians to attenuate nephrotoxin-induced AKI.[138] In this study e-mail messages were sent to clinicians to notify them whenever mild increases in SCr occurred in their patients receiving a nephrotoxic drug.[138] This notification led to earlier discontinuation of the offending agent compared to when clinicians were not notified. Earlier notification and cessation of the offending agent decreased the frequency of development of severe AKI from 7.5% to 3.4%. This study confirms that earlier identification of patients with higher risk allows the physician to apply preventive measurements, adjust or suspend nephrotoxic drugs, and, when possible, delay or avoid progression of renal injury. However, recommendations to prevent AKI are not uniformly followed. Weisbord and associates reviewed the medical records of "at risk" patients who underwent radiologic investigations using radiocontrast.[139] They found that of 144 patients eligible for intravenous volume expansion, 16% failed to receive any intravenous fluids. NSAIDs and COX-2 inhibitors were prescribed for 8% of patients.[139] These results validate the effort to bring to light the importance of surveillance, the continuation of the search for earlier markers of AKI, along with providing education to the medical community to valorize small changes in renal function.

28.9 Prevention of Acute Kidney Injury

Avoidance of Nephrotoxicity
- Recognition of agents with nephrotoxic potential
- Recognition of high-risk populations
- Avoidance of concomitant use of more than one nephrotoxin
- Consideration of alternative therapies
- Use of smallest dose and briefest duration
- Formulation/dosing modification
- Monitoring of blood levels if available
- Frequent measurement of renal function
- Surveillance systems to alert clinicians to changes in renal function
- Hydration

Minimization of Nosocomial Infection
- Meticulous handwashing
- Conservative use and rapid removal of intravascular and intravesicular catheters
- Cautious use of antibiotics based on culture data with automatic stop orders to ensure periodic reassessment
- Aspiration pneumonia precautions (elevate head of bed, attention to gastric residual volume, conservative use of sedatives/hypnotics)

Selected Application of Pharmacologic Intervention
- Extracellular fluid expansion
- Maintenance of high urine flow
- Maintenance of cardiac index and mean arterial pressure
- Renal vasodilators
- Intravenous albumin
- Growth factors
- Calcium channel blockers
- Miscellaneous agents

Selected Application of Nonpharmacologic Interventions
- Preoperative optimization
- Maintenance of high oxygen delivery
- Minimization of artificial ventilation
- Supranormal optimization of cardiovascular hemodynamics
- Prophylactic hemofiltration

Risk Assessment

Although AKI associated with one specific cause is common outside the ICU, most critically ill patients have several etiologic factors associated with the development of AKI. AKI acquired in the hospital is often due to a combination of insults. The most common associated causes are failure of renal autoregulation, direct nephrotoxicity, ischemia reperfusion, and inflammatory states. As multiple factors directly influence renal function, the nature and timing of the inciting event is commonly unknown. Accurate identification of AKI risk factors is a fundamental first step in achieving early diagnosis and implementing preventive strategies.

In the ICU population two large prospective observational studies have provided a better understanding of the risk factors associated with AKI in this setting: BEST and PICARD.[10,98] Both BEST and PICARD found sepsis to be the most common contributing factor to ICU-related AKI. A significant percentage of patients developing severe AKI had baseline CKD. In the BEST study in 47.5% of patients ARF was associated with septic shock. Thirty-four percent of ARF was associated with major surgery, 27% was related to cardiogenic shock, 26% was related to hypovolemia, and 19% of ARF was potentially drug-related.[10]

Volume depletion is one of the most common and important risk factors for AKI. In addition to hypovolemia, renal hypoperfusion may be caused by decreased cardiac output, decreased plasma oncotic pressure, hypotension, and decreased renal prostaglandin synthesis. Preexisting renal disease and advanced age, which is often associated with some degree of decreased renal function, are also common risk factors associated with AKI. Administration of a potentially nephrotoxic agent, or drugs that may enhance

nephrotoxicity, obviously increases the risk of AKI. For example, the concurrent use of furosemide and intravenous contrast agents may increase the risk of AKI.[140] Sepsis, congestive heart failure, nephrotic syndrome, and hepatic disease are common conditions associated with AKI.[10]

Although several individual risk factors are associated with the development of AKI, the combination of risk factors and the development of risk stratification scores could provide better tools to predict AKI in specific patient populations (e.g., after cardiac surgery, contrast exposure, hospital-acquired, general surgery, and high-risk surgery).[141–143] Few models have examined the clinical risk factors for the development of AKI among the ICU population.[144,145] Risk profiling can also be used to establish appropriate criteria for surveillance for AKI in hospitalized patients.[146] The use of models to predict the risk of AKI can help clinicians to identify patients with high risk of developing AKI, improve care, and provide better patient counseling.[50]

Volume Expansion

Regardless of the nature of the insult, hemodynamic stabilization with optimization of the cardiac output and blood pressure are key factors in preventing the initiation or worsening of AKI. The general aim is to optimize volume status based on physiologic measurements, maintain adequate hemodynamic status and cardiac output to ensure renal perfusion, and avoid further insults (e.g., hypotension and hypovolemia). Therefore, fluid management is an important intervention for patients in the initiation or extension phase of AKI. However, once the injury is initiated and the extension phase starts, the impact of volume expansion with intravenous fluids on clinical outcomes has not been well described and needs to be balanced with the unwanted consequence of fluid accumulation and overload.

Although there are no specific guidelines for optimizing hemodynamic and fluid status for renal function preservation, extrapolation of data from clinical settings associated with AKI can be instructive. To improve the evaluation of volume status, international guidelines for management of sepsis from the Surviving Sepsis Campaign recommends invasive monitoring with measurements of central venous pressure and venous oxygen saturation (superior vena cava or mixed) based on the early goal-directed therapy approach.[147] The Rivers study randomized patients with severe sepsis or septic shock to receive 6 hours of standard therapy, or 6 hours of early goal-directed therapy, before admission to the intensive care unit. The protocol ensured that all patients had a central venous pressure of between 8 and 12 mm Hg, a mean arterial pressure of >65 mm Hg, and a urine output of >0.5 mL/kg/min, by the administration of 500-mL boluses of crystalloid or colloid and vasopressor agents as necessary. Early goal-directed therapy patients received a central venous catheter capable of measuring $ScvO_2$, and they had to achieve a $ScvO_2$ of >70%, pursued by red blood cell (RBC) transfusion for anemic patients (hematocrit, <30%) and dobutamine therapy for patients above that threshold. This initial approach, applied for 6 hours, reduced the mortality rate, need of mechanical ventilation and vasopressors, and length of hospital stay.[147]

A number of studies have since established the benefits of adequate fluid expansion and earlier vasopressor administration for rapid shock reversal.[148] However, data from recent studies have shown that fluid expansion should be stopped when patients are no longer fluid responsive.[149] Late and prolonged aggressive resuscitation in critically ill patients is associated with fluid overload and worse outcomes. Data from the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network indicate that after initial resuscitation, a conservative approach to fluid administration was associated with faster weaning from mechanical ventilation and decreased length of ICU stay, without any deterioration of kidney function or worse kidney outcomes.[149] A liberal fluid approach as part of early goal-directed therapy appears to be beneficial during the first 6 hours of shock, and a conservative approach should be followed after shock resolution. In AKI patients, in the absence of shock, it is still unknown if these same principles apply. The potential risks of fluid accumulation and volume overload in the setting of AKI need to be considered.[110,150]

Another issue in critically ill patients is determining the optimal fluid to use for resuscitation. The recent Saline versus Albumin Fluid Evaluation (SAFE) trial in 6,997 patients found that fluid resuscitation with saline or albumin resulted in similar relative risks of death in critically ill patients.[151] There were also no significant differences in the proportion of patients with new single-organ and multiple-organ failure, length of ICU stay, length of hospital stay, days of mechanical ventilation, or days of renal replacement therapy.[151] In patients with cirrhosis and spontaneous bacterial peritonitis, intravenous albumin (1.5 g per kg at diagnosis followed by 1 g per kg on day 3) decreased the frequency of AKI (defined as a 50% greater increase in pretreatment BUN or serum creatinine to levels >30 and 1.5 mg per dL, respectively) from 33% to 10% ($P = .002$).[152]

Hydroxyethylstarches (HESs) are the most used nonprotein intravascular volume expanders. In addition to their efficiency in fluid management they have anti-inflammatory properties and reduced cost compared with albumin. However, the physicochemical characteristics and the electrolyte composition of the solvent make these coumponds a potential risk to alter coagulation and platelet function. Another concern with the use of HES is the development of AKI. There is a risk of urine hyperviscosity and consequent tubular lumen obstruction, leading to a tubular lesion called "osmotic nephrosis." The HES solutions have different nephrotoxicty potential depending on the degree of substitution at carbons 2 and 6 in the glucose ring in combination with the molecular weight and molar substitution. They are identified by three numbers which indicate the concentration of the solution; the mean MW (kDa); and, most significantly, the molar substitution (e.g., 10% HES 200/0.5). More recent data using a third generation of HES, 130/0.4, have reported no adverse

effects on renal function in patients who are considered to be at higher risk—for example, those with mild to severe renal dysfunction, advanced age, or on high-dose therapy. In patients at risk for AKI, renal function should be closely monitored when these agents are utilized, and the newer generation of isooncotic HES (130/0.4, 6%) should be preferred.

Prevention of Contrast Medium Nephropathy

Common among the various protocols is the need to establish and maintain an adequate hydration status. To prevent contrast medium nephropathy (CIN) low-risk patients should increase their oral fluid intake and high-risk patients should receive intravenous hydration. Hydration with isotonic saline starting the morning of the procedure, or immediately before in cases of emergency interventions, is superior to half-isotonic (0.45%) saline.[153] A randomized, controlled trial (RCT) compared isotonic saline with isotonic sodium bicarbonate (154 mmol per L $NaHCO_3$ in 5% dextrose) at 3 mL/kg/hr starting 1 hour preprocedure followed by 1 mL/kg/hr for the 6 hours after the procedure. CIN was significantly lower in the bicarbonate group, 2% versus 14% in the saline solution group.[154] The mechanism for the superiority of isotonic bicarbonate over isotonic saline is unclear. Animal studies have shown that bicarbonate is capable of scavenging reactive oxygen species, and the increased pH in the proximal tubule and the renal medulla associated with bicarbonate administration could reduce generation of superoxide. In addition, isotonic saline contains high amounts of chloride with a potential vasoconstrictor effect on renal vasculature. Considering that most hydration studies using isotonic bicarbonate use shorter infusion protocols (only 1 hour) than those using isotonic saline (usually 12 to 24 hours), hydration with bicarbonate is also an attractive alternative in the setting of emergency procedures.

Joannidis et al.[155]conducted a meta-analysis to address discordant results of trials evaluating the efficacy of bicarbonate. Although they confirmed that bicarbonate therapy is more effective in preventing contrast media-induced nephropathy, the study's heterogeneity and publication bias were substantial, preventing clear and definitive conclusions.

Iodinated contrast medium (CM) can be categorized according to osmolality into high-osmolal CM (HOCM; ~2,000 mOsm/kg), low-osmolal CM (LOCM; 600–800 mOsm/kg), and iso-osmolal CM (IOCM; 290 mOsm/kg). Evidence to date suggests that the iso-osmolal, nonionic CM are the least nephrotoxic and should therefore be used in patients at high risk for CIN.

The volume of contrast administered is also a crucial risk factor and an independent predictor of CIN. Based on the volume of contrast given [V] and the creatinine clearance [CrCl], a V/CrCl ratio >3.7 was a significant and independent predictor of CIN in the general population. Administration of contrast more than once in a short period of time is another risk factor, and contrast studies should be postponed at least 48 hours after the last infusion of contrast if possible.

Acetylcysteine

N-acetylcysteine (NAC) is a tripeptide analogous to glutathione able to cross cellular membranes. NAC may reduce vasoconstriction and oxygen free radical generation following contrast administration. Because an increased production of free radicals by the kidneys is partly responsible for their cellular damage in postischemic and nephrotoxic AKI, several clinical studies have attempted to use NAC to prevent or attenuate AKI.

In the first study NAC, a dose of 600 mg orally twice daily the day before and the day of the procedure prevented AKI following radiocontrast administration. Since then there has been ongoing debate as to whether NAC is effective for preventing CIN. Marenzi et al. confirmed the preventive and the dose-dependent effect of NAC in CIN prevention in a large single-center RCT.[156] However, in a large randomized study assessing the efficacy of NAC in preventing CIN (487 patients), intravenous NAC 500 mg did not provide renal protection in patients with impaired renal function compared with placebo.[157] Recent meta-analyses concluded that NAC, compared to periprocedural hydration alone, could lower the risk of CIN in high-risk patients. Therefore, NAC use is recommended based on its potential benefit, low cost, and excellent side effect profile. However, NAC should never replace IV fluids which have a more substantial benefit. In practice, we combine both hydration and NAC in patients at risk for CIN.

Prevention of Drug- and Nephrotoxin-Induced Acute Kidney Injury

Amphotericin B

Amphotericin B (AmB) associated nephrotoxicity can occur in as many as one third of treated patients and the risk of AKI increases with higher cumulative doses. Lipid formulations seem to cause less nephrotoxicity compared with the standard formulation, AmB deoxycholate. Amphotericin lipid complex, liposomal AmB, and AmB colloidal dispersion are significantly less nephrotoxic than amphotericin B deoxycholate; however, there are no conclusions in the comparison of AmB colloidal dispersion nephrotoxicity to other lipid formulations. The use of these formulations can help to preserve renal function in patients with systemic fungal infections; still, they are significantly more expensive. Recently, alternative antifungal agents such as itraconazole, voriconazole, and caspofungin have been more commonly used in patients at high-risk for AKI.

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Nonsteriodal Anti-inflammatory Drugs

ACE inhibitors and angiotensin receptor blockers (ARBs) cause vasodilatation of the efferent glomerular arteriole, further reducing intraglomerular pressure already compromised by the blood pressure lowering effect of these agents.

In patients with renal dysfunction they can contribute to reducing the GFR. In patients with an increase in SCr higher than 30% after the initiation of ACE inhibitor and ARB treatment, bilateral renal artery stenosis, stenosis of the renal artery in a solitary kidney, or diffuse intrarenal small vessel disease should be suspected and these drugs should be discontinued. Although there is very limited information it is generaly advisable to discontinue ACE/ARB during an AKI episode. However, these decisions need to be individualized and ACE/ARB may be restarted when there is recovery of renal function in order to support other organ function (e.g., heart failure).

NSAIDs or COX-2 inhibitors should be used with caution in patients with atherosclerotic cardiovascular diseases, CKD, liver disease, and intravascular volume depletion. As NSAIDs cause acute inhibition of cyclo-oxygenase (COX, type I or II), they can reduce GFR and renal blood flow. In critically ill patients, renal hypoperfusion due to decreased effective arterial volume is relatively common, and inhibition of prostaglandin-induced vasodilation by these agents may further compromise renal blood flow and exacerbate ischemic injury.

Aminoglycosides

Clinical evidence of AKI due to aminoglycoside nephrotoxicity usually occurs 5 to 10 days after initiation of the treatment, is typically nonoliguric, and is associated with decreased urine concentrating ability and urinary magnesium wasting. With multiple daily dosing schedules, elevated aminoglycoside peak levels appear to correlate with nephrotoxicity. Because aminoglycoside uptake by proximal tubular cells is a saturable process, once-daily dosing can decrease tubular cell toxicity by reducing the amount of drug taken up by proximal tubular cells. In the general population extended intervals between doses maintains the target dose while decreasing the risk of nephrotoxicity compared with multiple daily dosing. However, intensive care patients have different volumes of distribution and variable clearance, thereby making it difficult to maintain correct serum levels with longer intervals. As these drugs are entirely excreted by glomerular filtration, patients with compromised renal function are at increased risk for nephrotoxicity. In these patients the administration of a large single dose can be associated with a decreased uptake and lower antimicrobial effect.[158] Therefore, to treat serious infections in critically ill patients, dosing with maximum concentration (C_{max}), monitoring, and minimal inhibitory concentration (MIC) evaluation of the pathogen are necessary.[158]

Uric Acid Nephropathy and Tumor Lysis Syndrome

Acute uric acid nephropathy is caused by deposition of uric acid crystals in the interstitium and tubules associated with tumor lysis syndrome (TLS). The early recognition of patients at high risk for TLS is the first step to prevent the development of AKI. In patients with high-grade hematologic malignancies, risk factors for TLS are large tumor burden, lactate dehydrogenase levels above 1,500 IU, extensive bone marrow involvement, and high tumor sensitivity to chemotherapeutic agents. In patients with low or intermediate risk of TLS, allopurinol can be used as a hypouricemic agent and should be started 2 days before chemotherapy. Aggressive hydration with isotonic saline is initiated 2 days before the chemotherapy to maintain a high urinary output, allowing the elimination of uric acid and phosphate. If urinary output decreases despite adequate fluid intakes, a loop diuretic should be added, but renal replacement therapy will be required if oliguria persists.[159] The use of urine alkalinization to promote elimination of urates is not recommended as it can induce calcium phosphate deposition and therefore aggravate TLS. In addition to the hydration, recombinant urate oxidase can reduce uric acid levels and the risk of uric acid deposition nephropathy.[160] Recombinant urate oxidase should be initiated in high-risk patients or for established TLS.

MANAGEMENT OF ACUTE KIDNEY INJURY

After the kidney insult has occurred measures should be directed to avoid further injury, facilitate repair and recovery, and prevent AKI complications (Fig. 28.10). The timing of interventions is crucial to their effectiveness. Various approaches have been applied but are best appreciated in the context of specific scenarios. Initial management includes careful assessment of the etiology of kidney dysfunction and patient volume status. The main goals are maintenance of adequate hemodynamic status to ensure renal perfusion and avoidance of further kidney injury. Appropriate therapeutic interventions to reduce kidney function loss, prevention, and treatment of the associated complications of AKI need to be instituted concurrently. Any potentially nephrotoxic agents should be avoided, including intravascular radiocontrast. Antimicrobial agents such as aminoglycosides, amphotericin, acyclovir, and pentamidine should be avoided or their doses adjusted to avoid further insult.

Fluid and Electrolyte Management

Although early and vigorous resuscitation with crystalloid solutions and aggressive infection control can reduce the incidence of AKI (see previous), the role of fluid resuscitation in established AKI is less clear. Volume status is one of the most difficult parameters to assess and fluid resuscitation should target a predefined preload, stroke volume, or cardiac output rather than a set mean arterial pressure. Many clinical studies have demonstrated the poor value of right atrial pressure and pulmonary artery occlusion pressure in predicting volume expansion efficacy. Other bedside indicators of preload, such as the right ventricular end-diastolic volume (evaluated by thermodilution) and the left ventricular end-diastolic area (measured by echocardiography), have also been shown to be ineffective in differentiating volume

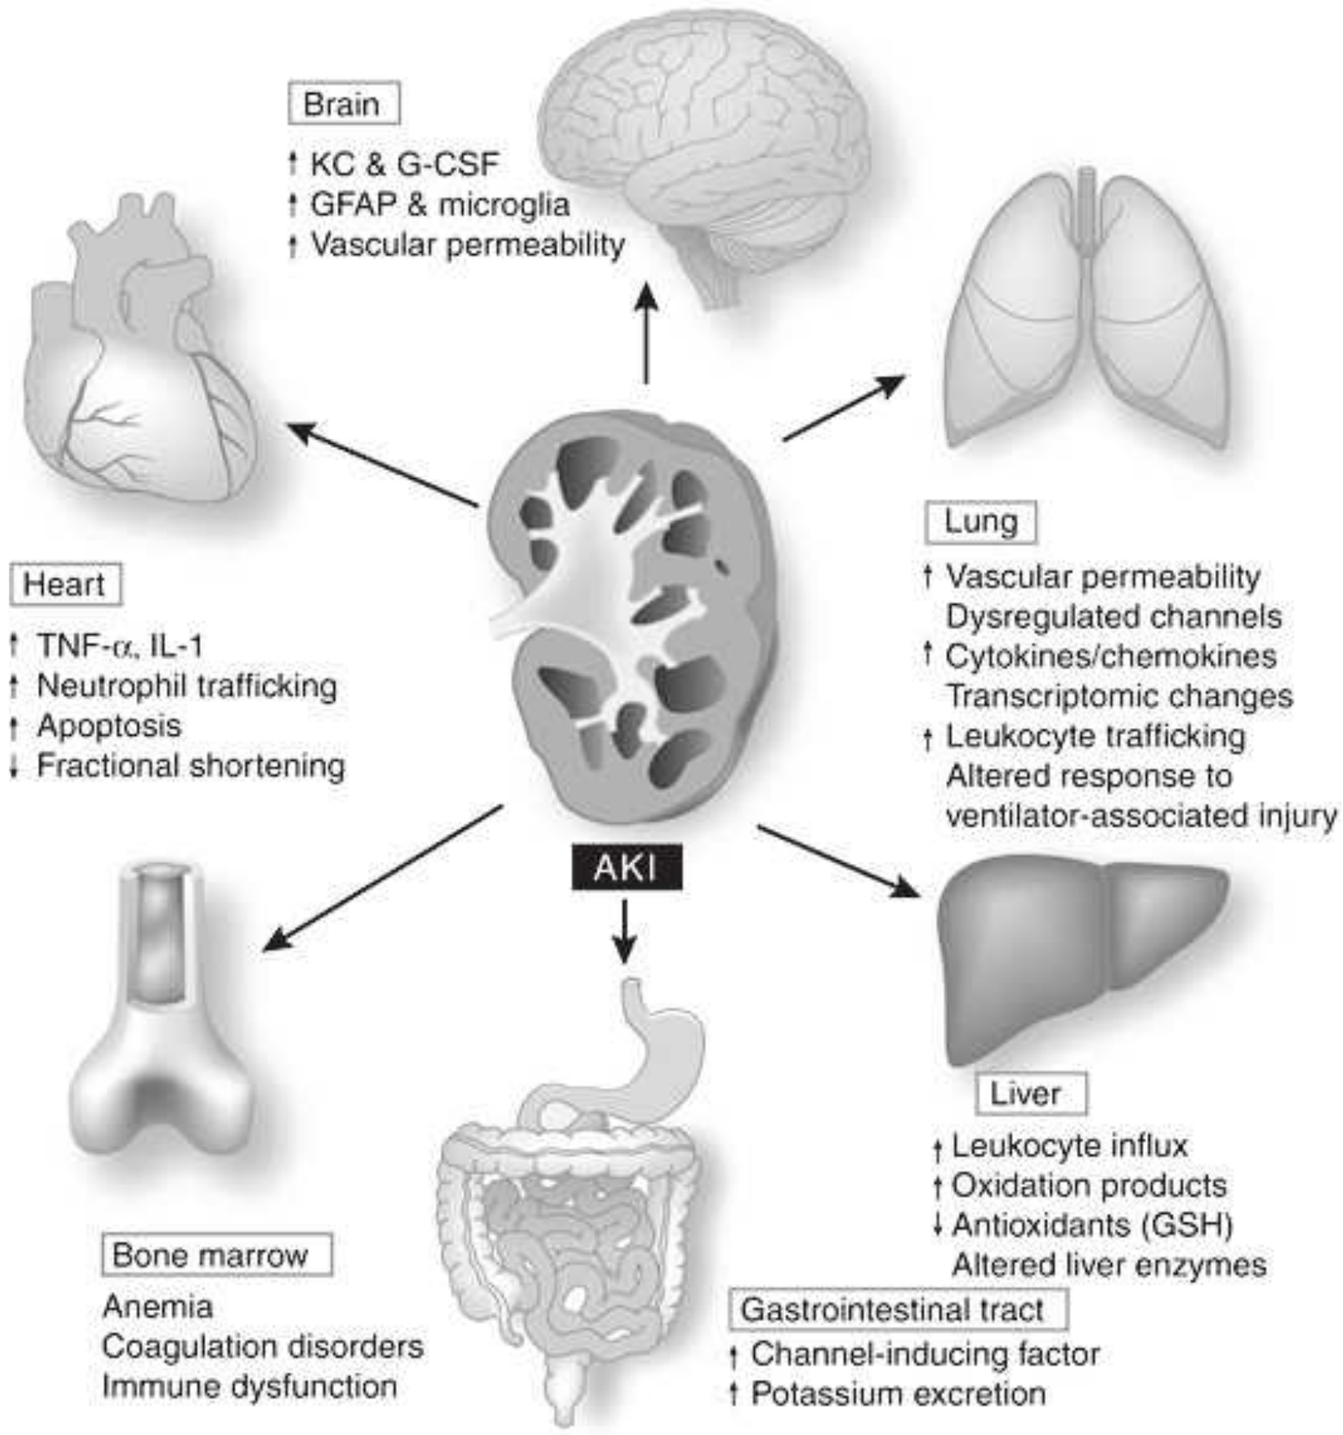

FIGURE 28.10 Acute kidney injury (AKI)-induced distant organ effects. AKI leads to changes in distant organs, including brain, lungs, heart, liver, gastrointestinal tract, and bone marrow. Changes have been described in organ function, microvascular inflammation and coagulation, cell apoptosis, transporter activity, oxidative stress, and transcriptional responses. *AKI*, acute kidney injury; *G-CSF*, granular colony-stimulating factor; *GFAP*, glial fibrillary acidic protein; *GSH*, glutathione; *IL-1*, interleukin-1; *KC*, keratinocyte-derived chemokine; *TNF-α*, tumor necrosis factor-α. (From Scheel PJ, Liu M, Rabb H. Uremic lung: new insights into a forgotten condition. *Kidney Int*. 2008;74(7):849–851.)

responder from nonresponder patients.[161] In critically ill patients receiving mechanical ventilation, respiratory changes in left ventricular stroke volume can predict fluid responsiveness. In hypovolemic patients, positive-pressure ventilation may induce a fall in the venous return and, consequently, in cardiac output. Based on the positive relationship between ventricular end-diastolic volume and stroke volume, the expected hemodynamic response to volume expansion is an increase in right ventricular end-diastolic volume, left ventricular end-diastolic volume, stroke volume, and cardiac output. Because a decrease in ventricular contractility decreases the slope of the relationship between end-diastolic volume and stroke volume, the increase in stroke volume as a result of end-diastolic volume increase depends on ventricular function.

Volume expansion in critically ill patients can frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body water in a short period of time. Some recent studies have demonstrated the role of fluid accumulation on adverse outcomes showing the association between fluid accumulation and mortality and the benefits of restrictive fluid management strategies in acute respiratory distress syndrome (ARDS). A prospective multicenter observational study (PICARD) found that patients with fluid overload, defined as increase in body weight relative to baseline >10%, had significantly higher mortality at 60 days (46% vs. 32%).[110] In addition, increases in the total body water alter the volume of distribution of creatinine resulting in underestimation of serum values.[34] The resulting underestimation of the severity of renal dysfunction may delay recognition and adequate treatment of AKI. In AKI patients presenting with fluid overload the evaluation of kidney function should consider the effect of fluid balance in order to prevent underestimation of AKI severity, correctly modify drug dosing, and avoid use of nephrotoxic agents.

In patients with positive fluid balance, large fluid intakes, and inadequate urine output, loop diuretic therapy can be initiated in conjunction with measures to optimize systemic and kidney perfusion. Although administration of furosemide facilitates fluid management, concerns of possible harm from loop diuretics in AKI surfaced after studies showed that associated diuretic use had an increased adjusted risk of death and nonrecovery of renal function. In urgent situations, morphine and nitrates can be used to alleviate the respiratory symptoms. Morphine reduces patient anxiety and decreases the work of breathing; it can be administered intravenously at an initial dose of 2 to 4 mg over a 3-minute period and can be repeated if necessary at 5- to 15-minute intervals. Nitrates are the most commonly used vasodilators in pulmonary edema. Nitroglycerin reduces left ventricular filling pressure via venodilation and an initial dose of 5 μg per minute of intravenous nitroglycerin is commonly used

in addition to diuretic therapy. When fluid overload cannot be quickly treated with medical management, positive ventilation pressure may need to be initiated with or without endotracheal intubation, and dialysis depends on the clinical situation.

Loop Diuretics and Natriuretics

Although loop diuretics are often prescribed in established AKI,[162] a recent meta-analysis confirmed that their use is not associated with reduced mortality or better kidney recovery.[163] Two prospective cohort studies evaluating diuretic use in AKI and mortality yielded controversial results with one study showing an increase[164] and the other study showing no effect.[165] However, an association between diuretic use and a shorter duration of dialysis was found in this meta-analysis.[163] Still, two other meta-analyses have shown that loop diuretics do not affect mortality, need for dialysis, or number of dialysis sessions required.[166] In regard to morbidity, diuretics are associated with an increased risk of ototoxicity.[166] Concomitant prescription of aminoglycosides and diuretics should be avoided due to an increased risk of ototoxicity. Well-designed trials of diuretics are required to assess their benefits and potential side effects in AKI. In the meantime, we suggest that a trial of diuretics may be utilized to enhance urine output; however, if this approach is not successful, escalating doses of diuretics should be avoided.

Atrial natriuretic peptide (ANP) has been studied as a treatment for AKI in four RCTs.[45,167–169] ANP was shown to reduce need for dialysis but did not reduce mortality.[45] In the largest study published so far, ANP improved overall dialysis-free survival in the subgroup of oliguric patients.[167] A subsequent trial, including 222 oliguric patients, did not confirm that ANP reduces mortality or dialysis-free survival.[169] The most recent study evaluated the use of ANP treatment for a mean of 5.3 ± 0.8 days in 61 patients who underwent cardiac surgery. The use of ANP decreased the probability of dialysis and improved dialysis-free survival.[168] Larger studies are required to confirm the benefits of ANP in AKI.

Nesiritide, a B-type natriuretic peptide, is currently approved by the FDA for the treatment of heart failure. Nesiritide induces vasodilation and indirectly increases cardiac output, having no inotropic or heart rate effect. In some individuals, a resultant decrease in the neurohormonal activation can result in natriuresis and diuresis. In adults with acute decompensated heart failure, nesiritide reduces pulmonary capillary wedge pressure, reduces right atrial pressure and systemic vascular resistance, decreases symptoms of heart failure, and enhances clinical status. However, questions regarding the risks of nesiritide therapy have recently been raised. The most frequently reported adverse effect is dose-related hypotension and an acute increase in SCr concentration. This effect in kidney function has not been shown to negatively affect mortality and reviews of large, observational, registry databases do not suggest an adverse inpatient mortality effect compared with other vasodilator therapies.[170]

Vasoactive Agents

"Renal-dose" dopamine (0.5 to 3 μg/kg/min), given as a specific vasodilatator to increase renal blood flow and prevent AKI, does increase urine output but does not affect AKI outcome or mortality.[171] Dopexamine, a synthetic dopamine analogue, is a dopamine 1 and less potent dopamine 2 receptor agonist. Small studies performed in patients undergoing liver transplant surgery have not found a beneficial effect of dopexamine in preventing AKI.

No RCTs have assessed the effect of norepinephrine on prevention of AKI. In a meta-analysis, fenoldopam, a dopamine receptor-1 agonist increasing blood flow to the renal cortex and outer medulla, was shown to reduce the risk of AKI in postoperative or critically ill patients (odds ratio, 0.43).[172] A large RCT will need to be performed to confirm these findings. Intrarenal administration of fenoldopam allows the use of a substantial dose of fenoldopam mesylate while avoiding systemic adverse effects such as hypotension. In a registry of 268 patients treated with intrarenal fenoldopam, infused for at least 1 hour, the incidence of CIN was less than 1%, compared to 27% based on historic rates in that population. Although we are still waiting for additional studies to confirm these results, it may be a promising preventive measurement for patients at high risk of CIN.

Vasopressors are often considered to be detrimental for organ perfusion. However, experimental and clinical data suggest a beneficial effect of norepinephrine on the urine output in sepsis. A small prospective study including 14 patients in septic shock showed that norepinephrine improved SCr and creatinine clearance when mean arterial pressure was raised above 70 mm Hg.[173] However, in a small RCT including 28 patients, increasing mean arterial pressure from 65 to 85 mm Hg with norepinephrine did not improve renal function.[174]

Fenoldopam has shown improved outcomes in some studies. In a recent meta-analysis, fenoldopam decreased the need for dialysis (7% vs. 10%) and in-hospital mortality (15 vs. 19%) in ICU patients.[172] However, this meta-analysis had limitations, such as no standardized criteria for initiation of dialysis, heterogeneity of populations and AKI definitions, dosage and duration of treatments, and the absence of independent measure of GFR. An adverse effect of fenoldopam is hypotensive episodes, and it may be more frequent and deleterious outside RCTs.[172,175] These results show that, although widely promoted, the use of fenoldopam needs to be confirmed with an adequately powered trial.

Avoidance of Hyperglycemia

Effective management of hyperglycemia in critically ill patients has been a major topic of discussion since a landmark study demonstrated a significant reduction in mortality and morbidity in surgical patients who were treated with an intensive regimen to control blood glucose. Subsequent studies have highlighted the importance of hyperglycemia for adverse outcomes in various populations and proposed algorithms

for glycemic control. A systematic review of intensive insulin therapy in critically ill patients found a 38% reduction in the incidence of AKI, whereas other negative trials showed no benefit and an increased risk of hypoglycemia.[8]

In critical illness membrane expression of GLUT-1, GLUT-2, and GLUT-3 proteins is upregulated and allows glucose to enter cells more in proportion to extracellular glucose levels. This contributes to glucose overload in several tissues, including brain neurons, hepatocytes, endothelial cells, and renal tubules. These events are associated with various cytokines (tumor necrosis factor α [TNF-α] and interleukin 6 [IL-6]), hormones (cortisol, catecholamines, and growth hormone), and other molecules (vascular endothelial growth factor and transforming growth factor [TGF]) that are also upregulated in renal failure.

The kidney plays an important role in glucose homeostasis. In humans renal glucose production contributes approximately 25% to systemic glucose production, whereas renal glucose uptake accounts for 20% of systemic glucose removal. Because glucose homeostasis in the kidney is regulated by insulin, loss of kidney metabolic function could account for a component of insulin resistance as a result of loss of a major target organ for insulin action. Uremia is also associated with decreased hepatic and peripheral glucose uptake and a reduction in peripheral tissue glucose transporters. The kidney also metabolizes insulin and reduced renal function prolongs the half-life of insulin and can contribute to hypoglycemic events. One of the major risk factors for development of hypoglycemia in the ICU is the presence of preexisting renal dysfunction and the need for kidney replacement therapy.

Some studies have shown that maintaining blood glucose levels around 110 mg per dL reduced the onset of acute kidney injury from 12.3% to 9% ($P = .04$) and need for dialysis by 41%. Whereas the lowered blood glucose level was related to reduced mortality and other complications, the insulin dosage was an independent determinant for prevention of AKI.[176] Two large intervention studies in medical and surgical ICU patients confirmed a similar association and found that the development of newly acquired AKI decreased by 75% and 45%, respectively.[177] In a large observational study, patients who did and did not have diabetes and required glycemic control had more infections, anemia, and AKI (11% and 7% versus 4%; $P < 0.001$) compared with control subjects.[178] Additional observational studies from different populations suggest a linkage of hyperglycemia and the metabolic syndrome with the development of AKI. Most of these studies used a doubling of creatinine or a creatinine level >2.5 mg per dL as a criterion for AKI; however, a more sensitive criterion (0.5 mg per dL creatinine change) would likely increase the incidence of AKI. Whether these associations are simply a consequence of the deranged metabolic milieu that accompanies critical illness or there is a direct effect of hyperglycemia and insulin resistance on the kidney still needs more evaluation.

Although several pieces of the puzzle linking hyperglycemia and kidney function are still missing, there is enough evidence now to suggest that the kidneys are active in the process and a target for new injury. On the basis of these conclusions hyperglycemia should be considered a major risk factor for AKI in the ICU and should prompt specific measures. Clinicians should seek out a history of hyperglycemia as part of the evaluation of critically ill patients who are at risk or develop AKI and institute preventive and therapeutic measures.

However, achieving glycemic control is not easy and hypoglycemic events are commom in AKI patients. In a recent large, international, randomized trial in critically ill patients (NICE sugar study), intensive glucose control increased the absolute risk of death to 90 days compared to conventional glucose control. Severe hypoglycemia was significantly more common with intensive glucose control. In a meta-analysis including 26 trials, a total of 13,567 patients, and data from the NICE sugar study, the relative risk (RR) of death with intensive insulin therapy compared with conventional therapy was 0.93. Patients in surgical ICUs presented a benefit from intensive insulin therapy (RR 0.63), whereas patients in medical ICU did not (RR 1.0).

Based on these recent studies it appears that intensive insulin therapy significantly increased the risk of hypoglycemia and is not associated with a benefit in mortality among critically ill patients. Whether there is a benefit in preventing or ameliorating AKI is still unclear. We would recommend maintaining appropriate control of blood glucose in the 120 to 140 mg per dL range.

Protective Mechanical Ventilation

Mechanical ventilation is associated with the disruption of pulmonary epithelium and endothelium, lung inflammation, atelectasis, hypoxemia, and the release of inflammatory mediators.[179,180] These inflammatory mediators can cause injury to lungs and other organs.[181] Traditional approaches to mechanical ventilation use tidal volumes of 10 to 15 mL per kg of body weight and may cause stretch-induced lung injury in patients with acute lung injury.[182,183] Treatment with a ventilation approach designed to protect the lungs from excessive stretch resulted in improvements in several important clinical outcomes in patients with acute lung injury and ARDS.[183] Thus, in mechanically ventilated patients an important preventive measure is to avoid excessive lung stretch during adjustments to mechanical ventilation, and a lower tidal volume protocol should be used in patients with acute lung injury and ARDS.

Mechanical ventilation has been shown to be an important independent factor for mortality in AKI patients, and the time on mechanical ventilation is also associated with increased mortality.[10] In addition, AKI is a risk factor for prolonged mechanical ventilation.[184] Patients with prolonged mechanical ventilation are predisposed to pulmonary infections, and infection is the leading cause of death in patients with AKI.

In patients in need for renal support, removal of fluid with ultrafiltration can improve pulmonary edema resulting in better oxygenation.[122] However, in these patients, remov-

ing fluid faster than interstitial fluid can be mobilized into the circulation can induce hypotension and contribute to prolonged AKI. A judicious rate of fluid removal should be individualized to the clinical status of the patient in order to avoid this vicious cycle.

Pharmacologic Approaches

A variety of drugs are effective in altering the course of experimental models of ATN. However, only a few have consistently shown benefits in preventing or attenuating established AKI (Table 28.10).

Statins

Statins induce downregulation of angiotensin receptors, decrease endothelin synthesis, decrease inflammation and improve endothelial function by inhibiting nuclear factor κB, decrease expression of endothelial adhesion molecules, increase nitric oxide bioavailability, attenuate production of reactive oxygen species, and protect against complement-mediated injury. All of these mechanisms may be involved in the protective effect against CIN. A number of publications support the potential for kidney protection with statin administration.[185] A recent prospective study evaluated the effect of statins to decrease the incidence of CIN during percutaneous coronary intervention. Patients receiving statins prior to the procedure had a significant decrease of CIN (3% vs. 27%).[186] However, in a retrospective cohort study evaluating patients undergoing major vascular procedures,[187] perioperative statin administration did not improve renal function, reduce length of stay, or reduce mortality. No benefit was observed in patients with a preexisting creatinine clearance <40 mL per min. Currently, there is no basis to recommend the initiation of statin therapy specifically for the pericontrast period to prevent CIN. Patients who are already on statin therapy, or need it for other indications, should be maintained on statins through contrast procedures.

Calcium Channel Blockers

Calcium antagonists have been shown to reverse the afferent arteriolar vasoconstriction induced by a variety of stimuli and also have an independent natriuretic effect.[188] These drugs were exhaustively evaluated in the prevention of AKI, especially in the context of transplant-associated nephropathy. If administered prophylactically calcium blockers protected against posttransplantation delayed graft failure in some studies. However, a large multicenter RCT evalu-

28.10 Drugs Tested in Clinical Studies for Prevention or Treatment of Acute Kidney Injury

Drugs	Results
Prevention	
Dopamine	No effect on kidney function
Fenoldopam	Controversy: no effect on kidney function or beneficial effect on kidney function
Loop diuretics	No effect on kidney function
N-acetylcysteine	Variable beneficial effect in contrast-induced nephropathy
Statins	Beneficial effect on kidney function
Calcium channel blockers	No effect on kidney function
Adenosine antagonists	Controversial effect on kidney function
Multipotent stem cells	Beneficial effect on kidney function in Phase 1 studies
Erythropoietin	Uncertain based on a large Phase 2/3 trial in intensive care unit patients
Small interfering ribonucleic acid	Beneficial effect on kidney function, undergoing Phase 2/3 trials
Treatment	
Loop diuretics	No effect
Atrial natriuretic peptide	Possible beneficial effect on survival and kidney function
Dopamine	No effect on mortality or kidney function
Norepinephrine	Possible beneficial effect on kidney function
Fenoldopam	Controversy: No effect on mortality or kidney function Beneficial effect on mortality and need for dialysis
Insulin	Controversial effect
Mesenchymal stem cells	Beneficial effect on kidney function
Erythropoietin	Beneficial effect on kidney function
Alkaline phosphatase	Beneficial effect on kidney function

ating the effect of isradipine on renal function, incidence and severity of delayed graft function, and acute rejection after kidney transplantation did not find any benefit.[189] A systematic review evaluated the benefits and harms of using calcium channel blockers in the peritransplant period in patients at risk of ATN after cadaveric kidney transplantation.[190] The authors suggested calcium channel blockers given in the perioperative period reduced the incidence of ATN posttransplantation. However, the heterogeneity of the trials makes the comparison of studies difficult. The use of calcium channel blockers during renal transplant surgery may be of benefit in extended donor criteria transplants (e.g., donors older than 60 years, predonation SCr level higher than 1.5 mg per dL, cerebrovascular disease as the cause of death), or those with prolonged ischemia times.

Adenosine Antagonists

Small clinical studies evaluating the role of theophylline, an adenosine antagonist, in the prevention of contrast nephropathies have shown discordant results. A recent study, including seven RCTs, concluded that the prophylactic administration of theophylline or aminophylline appeared to protect against CIN.[191] However, this meta-analysis included studies that did not control for hydration status. A recent RCT adding theophylline to NAC showed a reduced incidence of CIN. Additional selective blocker agents, such as rolofylline, have maintained renal function in patients with decompensated heart failure, although they have not been assessed for prevention of AKI. At the moment it remains unclear if theophylline as a solo agent might be useful in preventing contrast nephropathy. Further studies are necessary prior to its routine use.

Disorders of Electrolyte and Uric Acid Metabolism

Hyperkalemia, hyponatremia, metabolic acidosis, and hyperuricemia often occur in AKI.

Potassium

A rise in plasma potassium concentrations to >5.5 mEq per L is a frequent complication seen in 50% of patients with AKI. Hyperkalemia is due to continued potassium release from cells, or dietary potassium, in the face of impaired renal potassium elimination. The potassium concentration of intracellular water is about 155 mEq per L in skeletal muscle. Thus, in conditions such as tumor lysis syndrome and rhabdomyolysis, dangerous levels of hyperkalemia can occur quickly. In patients with rhabdomyolysis induced by extensive traumatic muscle crush injury, plasma potassium concentrations can rapidly increase from normal to life-threatening levels. Other factors including a cellular shift of potassium due to academia; hyperosmolality or potassium loads from exogenous sources such as blood, dietary intake, potassium salts (e.g., salt substitutes); or large doses of penicillin G can also contribute to hyperkalemia. AKI induced by NSAIDs can also be associated with marked hyperkalemia. The effect of these agents in suppressing renin and aldosterone secretion may be responsible in part.

The primary risk of hyperkalemia is on cardiac conduction where it may cause bradycardia or asystole. If echocardiogram (ECG) changes are present, the administration of intravenous calcium is urgent. Concomitantly, sources of oral or intravenous potassium should be identified and removed, including drugs with effect on potassium handling such as beta-adrenergic antagonists, potassium-sparing diuretics, ACE inhibitors, ARBs, and other drugs that inhibit renal potassium excretion.

The next step is to enhance the shift of potassium to the intracellular space using parenteral glucose and insulin infusions. The onset of action is within 20 to 30 minutes, and the effect lasts for 2 to 6 hours. Continuous infusions of insulin and glucose-containing intravenous fluids can be used to prolong their effect. Sodium bicarbonate also promotes shift of K^+ into the intracellular space, the effect occurs in less than 15 minutes, and has 1 to 2 hours' duration. This therapy can be started if there is no concern of fluid overload (44.6 mEq intravenously over 5 minutes); however, the potassium-lowering effect of sodium bicarbonate is most prominent in patients with metabolic acidosis. Beta-adrenergic agonists given as aerosols are also effective but more likely to produce side effects and so are not often prescribed to treat hyperkalemia.

Potassium excretion should be increased by the administration of loop diuretics and cation exchange resins, such as Kayexalate or calcium resonium. The resins can be administered orally or rectally, as a retention enema. In case of hyperkalemic emergencies, rectal administration is preferred, as the colon is the major site of action of this drug. If hyperkalemia is unresponsive to conservative measures, or occurs in patients with ESRD, emergency hemodialysis is the treatment of choice. As it may take some time to initiate RRT, medical management should always be used while waiting for dialysis to be started. Monitoring for potassium levels should continue following conservative or dialytic management to prevent and treat rebound hyperkalemia from the underlying process.

Acid-Base Disorders

In AKI, metabolic acidosis is the most common acid-base abnormality. The metabolic acidosis results from continued production of nonvolatile acid and decreased renal ability to excrete acid. In severe catabolic states, the usual daily production of 1 mEq per L of nonvolatile acid can be markedly increased. Accumulation of phosphate and unexcreted unmeasured anions—such as sulfate, urate, hippurate, hydroxypropionate, furanpropionate, and oxalate—are contributory. Hypoalbuminemia can attenuate this acidification process, and it is exacerbated by lactic acidosis. Despite retention of unmeasured anions, the anion gap remains within

normal limits in 50% of patients. Although metabolic acidosis is frequent, triple acid-base disturbances can also occur.

The approach to acid-base disturbances in AKI needs to be adjusted to the underlying causes. There is controversy surrounding the optimal treatment of acute metabolic acidosis. When metabolic acidosis is simply a complication of AKI, sodium bicarbonate can be administered if the serum bicarbonate concentrations fall below 15 to 18 mmol per L. Bicarbonate administration in lactic acidosis due to an underlying shock is controversial given the possibility of an increase in CO_2 generation, worsening of the intracellular acidosis, and volume overload. Rapid improvement in the metabolic status may also enhance hypocalcemia, which may lower cardiac output. Therefore, since the benefit of bicarbonate in patients with lactic acidosis due to an underlying shock seems limited, most physicians would restrict the administration of sodium bicarbonate to patients with severe metabolic acidosis (arterial pH below 7.10 to 7.15) to maintain the pH above 7.15 to 7.20 until the primary process can be reversed. Alternative forms of base treatment have not been studied extensively in patients with AKI. Tris(hydroxymethyl)aminomethane (THAM) is excreted in the urine and its clinical efficacy compared to sodium bicarbonate remains unproven.[192] We do not recommend its use in patients with AKI, especially in patients with hyperkalemia, because THAM does not decrease potassium levels in contrast to bicarbonate and can even cause hyperkalemia. Restriction of protein intake has also been suggested as a method of acidosis control since protein breakdown has been associated with worsening acidosis.

Sodium

Hyponatremia is a common complication of AKI and is caused by an absolute or relative increase in solute-free water intake. Rare associations with hyponatremia and AKI include toxin ingestion,[193,194] rhabdomyolysis, infection,[195] and hypothyroidism.[19] The treatment consists of water restriction to below the level of output. Salt restriction is usually necessary to treat fluid overload and/or edema. In cases of true volume depletion with associated prerenal AKI, isotonic saline will need to be administered to correct both disorders.

Intensive care patients with hypernatremia are more prone to AKI. In most cases, treatment of the underlying cause will be necessary and water deficit will need to be estimated. Water should be administered orally or intravenously as dextrose in water to correct serum sodium at a maximum rate of 10 mmol/L/day. Dialysis and continuous RRT, in particular, may be required to optimally correct sodium disorders in AKI.

Renal Replacement Therapy

The issues regarding RRT in AKI are currently the source of much debate and investigation. The areas of debate include when to initiate, what modality to use, and the dose of therapy to deliver.

Dialysis Initiation

Whether or not to provide dialytic support, and when to initiate, are two of the fundamental questions facing nephrologists and other intensivists in most cases of severe AKI. The optimal timing of dialysis for AKI is not defined. The association of early initiation of dialysis with survival benefit was first suggested by case series with historical controls conducted in the 1960s and 1970s.[197–199] However, the relevance of these studies to current practice is questionable, given that BUN concentrations at the start of dialysis in the "early" treatment groups in these previous studies are considered high by modern standards. In the modern dialysis era, few studies have examined the association of the timing of initiation of dialysis in AKI with mortality. Moreover, changes in illness severity, especially in later years, make comparisons of studies extremely difficult. Single-center studies that were restricted to AKI after trauma[200] and coronary artery bypass surgery[201,202] suggested a benefit to dialysis initiation at lower BUN concentrations. In a broader population, Bouman et al.[203] randomized 106 critically ill patients with AKI to early versus late initiation of dialysis. The early initiation group started dialysis within 12 hours of low urine output, less than 30 mL per hour for 6 hours, not responding to diuretics or hemodynamic optimization, or creatinine clearance less than 20 mL per minute. The late initiation group started dialysis when classic indications were met. The study did not find differences in ICU or hospital mortality between the groups of early and late initiation, or in renal recovery among survivors. A prospective multicenter observational cohort study[204] performed by the Program to Improve Care in Acute Renal Disease (PICARD) analyzed dialysis initiation—as inferred by BUN concentration in 243 patients from five geographically and ethnically diverse clinical sites. Survival rates were slightly lower for patients who started dialysis at higher BUN concentrations, despite a lesser burden of organ system failure. Adjusting for age, hepatic failure, sepsis, thrombocytopenia, and serum creatinine and stratified by site and initial dialysis modality, initiation of dialysis at higher BUN was associated with an increased relative risk for death (95% CI, 1.16 to 2.96).

Although the maintenance of BUN concentrations below arbitrarily set levels is usually a reference for starting dialysis treatment, BUN reflects factors not directly associated with kidney function such as catabolic rate and volume status. SCr is influenced by age, race, muscle mass, catabolic rate, and its volume of distribution varies on fluid overload patients. Thus, neither creatinine nor BUN should be used to absolutely determine when to initiate dialysis. In a prospective multicenter observational study conducted at 54 intensive care units (ICUs) in 23 countries,[205] timing of RRT was stratified into "early" or "late" by median urea at the time RRT started and also categorized temporally from ICU admission into early (less than 2 days), delayed (between 2

and 5 days), or late (more than 5 days). Timing by serum urea showed no significant difference in mortality (63.4% for urea ≤24.2 mmol per L vs. 61.4% for urea >24.2 mmol per L). However, when timing was analyzed in relation to ICU admission, late RRT was associated with greater crude mortality (72.8% late vs. 62.3% delayed vs. 59% early, P = .001) and covariate-adjusted mortality (OR, 1.95; 95% CI, 1.30–2.92; P = .001). Overall, late RRT was associated with a longer duration of RRT and stay in hospital and higher rate of dialysis dependence.

There are potential safety concerns regarding earlier initiation of dialysis, including increased risk for infection from an indwelling dialysis catheter, hypotension, delayed renal recovery, and leukocyte activation from contact with dialysis membranes.[206,207] The concept that dialysis initiation would prolong the course of AKI was supported by experimental data showing renal lesions consistent with fresh ischemia in dialyzed animals without systemic hypotension, long after their initial renal injury. In the presence of ischemia, the vasculature of normal kidneys responds with vasodilation as part of the autoregulatory response to maintain renal blood flow and GFR. In ATN, autoregulation is impaired; as a result, recurrent ischemic tubular injury is more likely to occur, thereby delaying the restoration of function. However, it is difficult to document that earlier initiation of dialysis is harmful because patients with more severe forms of renal injury may develop indications for dialysis earlier in their ICU course and may be more likely to develop irreversible disease independent of therapy. Several factors can influence the survival and recovery of renal function in dialytic AKI patients. Whether these risks outweigh the potential benefits of earlier initiation of dialysis is still unclear.[207]

In current practice the decision to dialyze is based most often on clinical features of volume overload and biochemical features of solute imbalance (e.g., azotemia, hyperkalemia). Data from an RCT comparing IHD to CRRT suggest that the indication for dialysis is an important determinant of outcome.[208] In that study patients dialyzed predominantly for solute control experienced better outcomes than those dialyzed predominantly for volume overload. Patients dialyzed for control of both azotemia and volume overload experienced the worst outcome. Volume resuscitation is a common strategy used in the treatment of multiorgan failure, particularly when accompanied by sepsis syndrome and hypotension. It is often applied indiscriminately in the setting of oliguric AKI, where it is assumed that providing additional volume will improve renal perfusion, prompting correction of renal dysfunction. Although this may be of great benefit to patients with prerenal azotemia, excessive volume administration can lead to pulmonary edema, compromising oxygenation and ventilation, and hastening the need for dialysis. In critically ill patients, especially in the postoperative period and in septic patients after volume expansion, the increase in total body water can reach more than 10 L within 7 days.[149,209] Mukau et al.[210] found that 95% of their patients with postoperative AKI had fluid excess of more than 10 L at the time of dialysis.

Despite recent evidence suggesting positive fluid balance as possibly harmful for ICU patients, the association between fluid balance and outcomes in AKI patients is not completely defined. These patients are expected to present higher positive fluid balance; however, the impact in the prognosis is poorly understood. Payen et al.[211] analyzed data from the Sepsis Occurrence in Acutely Ill patients (SOAP) study, a multicenter observational cohort study including 198 ICUs. In AKI patients, mean daily fluid balance was significantly more positive among nonsurvivors than survivors (0.98 ± 1.5 versus 0.15 ± 1.06 L per 24 hours, P <0.001). Bouchard et al.[150] found that fluid overload, defined as a >10% increase in body weight relative to baseline, was associated with significantly higher mortality rates at 60 days (46% vs. 32%; P = .006). The adjusted odds ratio for death associated with fluid overload at dialysis initiation was 2.07 (95% CI, 1.27–3.37). In that study, among the dialyzed patients, survivors had lower fluid accumulation at dialysis initiation compared with nonsurvivors (8.8% vs. 14.2% of baseline body weight) (Fig. 28.11).

These factors collectively suggest the need to develop evidence-based, patient-specific, and nonbiased indications for the initiation of dialysis in AKI (Table 28.11). Timing of RRT, a potentially modifiable factor, might exert an important influence on patient survival. However, it largely depended on its definition. We favor utilizing an approach that recognizes that the strategy in treating AKI is to minimize and avoid uremic and volume overload complications. Thus, it is not necessary (and arguably harmful) to wait for progressive uremia to initiate dialytic support. The indications for dialysis should include a consideration of the need for renal support (as well as renal replacement), and the timing of dialysis should be based on the goals to be achieved.

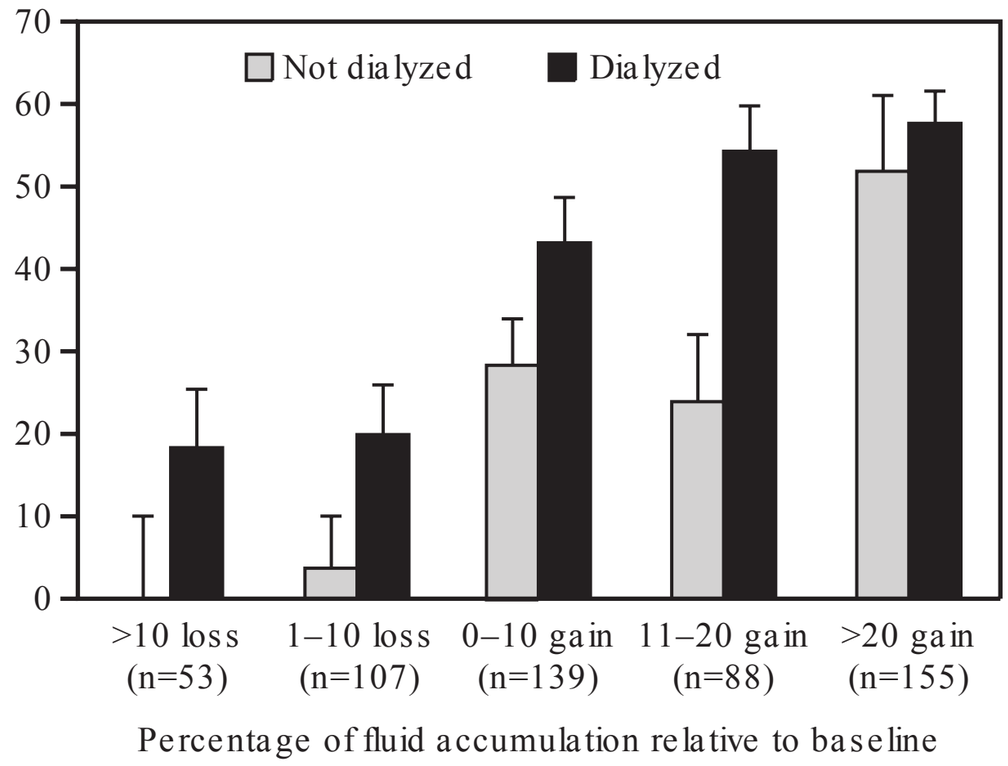

FIGURE 28.11 Mortality rate by final fluid accumulation relative to baseline weight and stratified by dialysis status. (From Bouchard J, Mehta RL. Fluid accumulation and acute kidney injury: consequence or cause. *Curr Opin Crit Care*. 2009;15(6):509–513.)

28.11 Prognostic Factors in Acute Kidney Injury

Severity of Renal Dysfunction
- Magnitude of rise in serum creatinine concentration
- Urinalysis
- Fractional excretion of sodium
- Presence of oliguria or anuria
- Requirement for renal replacement therapy
- Duration of renal dysfunction

Underlying Health of the Patient
- Age
- Presence of chronic kidney disease
- Presence, severity, and reversibility of underlying disease

Clinical Circumstances
- Cause of the renal failure
- Severity and reversibility of acute process(es)
- Number and type of other organ systems failed
- Development of sepsis and other complications

Intermittent Versus Continuous

The choice of intermittent or continuous therapy is currently based on the experience of the nephrology team and the availability of therapies. When both therapies are available, the indication of CRRT or IHD is based on the patient's neurologic, hemodynamic, and catabolic status. Ideally, the therapy should be tailored to the patient's demands, which changes daily in the critically ill. It is now accepted that more than one therapy will be utilized for managing patients during the course of AKI. Transitions from CRRT to IHD are common and reflect the changing needs of patients during their AKI course. For instance, patients in the ICU may initially start on CRRT when they are hemodynamically unstable, transition to SLED-EDD when they improve, and leave the ICU on IHD. In the recent ATN trial, 57% of the patients had more than one therapy whereas 23% and 20% had IHD and CRRT alone.[212] We recommend that all therapies should be utilized as indicated to best support patient needs through their course.

The comparison of the operating characteristics of the two therapies will help to recognize the strengths and weaknesses of each modality. Fluid removal is a desirable component of any renal replacement therapy and is a major goal of renal replacement for AKI.[213] Fluid removal and, hence, fluid balance, is limited to the period of dialysis. If the patient is hemodynamically unstable during this period, it may be difficult to remove any fluid. Fluid removal is slower and hypotension is uncommon with peritoneal dialysis and CRRT. It has been suggested that the latter modality may be associated with an improved outcome, due perhaps to more stable hemodynamics; however, this has not been rigorously demonstrated.[207] The high efficacy of these therapies in continuous fluid removal allows for use in situations other than renal failure, such as heart failure.[214] Pediatric patients are better suited for PD and CRRT, and these modalities have been used successfully in the management of AKI in neonates.[215,216]

The continuous removal of fluid permits the delivery of optimal nutrition as fluid load becomes a nonlimiting factor. Two other factors influence the overall nutritional balance of the patient in dialysis: the composition of the dialysate and hemofiltrate solutions. Although lactate-based dialysate and hemofiltrate solutions can rarely result in hyperlactatemia and worsening of acid-base status, they can cause higher urea generation rates compared to bicarbonate solutions.[217,218] The content of glucose in dialysate solutions results in glucose absorption during the dialysis procedure, which contributes to the caloric load. This glucose content is also associated with an increase in endogenous insulin secretion in most patients, and some patients may require exogenous insulin.[219] The use of a lower dextrose concentration-based dialysate in CRRT usually prevents this complication. Another nutritional factor is the dialysance of amino acids, vitamins, and trace elements across the filter. Losses appear to depend more on the serum levels than on the underlying clinical status of the patient.[220] To avoid potential harm, vitamin supplementation should be provided for all patients on CRRT regardless of dialysis dose, and pharmacists should be consulted to optimize drug dose adjustments.[221] With the massive expansion of therapeutic alternatives in critical care (especially antibiotics), much more research is required to understand optimal drug during CRRT.

The effect of the dialysis modality on outcome is still a major question to be answered. In four prospective cohort studies,[222–225] none suggest differences in mortality between modalities. A recent systematic review[226] identified nine RCTs that compared CRRT versus intermittent methods.[227–234] The relative risk of death associated with CRRT was not significantly different than with intermittent hemodialysis (RR 1.10; 95% CI, 0.99–1.23). The last Cochrane Review comparing dialysis modalities concluded that, in hemodynamically stable patients, modality does not appear to influence outcomes. In hemodynamically unstable patients, CRRT may be preferable as patients on CRRT maintain higher mean arterial pressure and show a trend toward lesser need for escalation of vasopressor therapy and arrhythmias.[235]

Dose of Dialysis

Until recently, dialysis dose was considered to play a pivotal role in improving outcomes in critically ill patients requiring CRRT. The relationship between treatment dose and patient outcome in AKI was first investigated prospectively in a single-center study where 425 subjects were randomized to 45, 35, and 20 mL/kg/h of postdilution continuous venous-venous hemofiltration (CVVH). Subjects receiving doses of

45 and 35 mL/kg/h experienced lower mortality rates compared to subjects receiving 20 mL/kg/h, 42% and 43% versus 59%, respectively ($P < 0.005$). After this study was published, three other RCTs showed contradictory results. Bouman et al.[203] found no difference in mortality among subjects who received higher hemofiltration volumes—48.2 mL/kg/h versus 19.5 mL/kg/h. Tolwani et al.[236] randomized 200 patients for CVVHDF using two different ultrafiltration volumes. The intensive group received 29 mL/kg/h against 17 mL/kg/h for those in the standard group. There was no significant difference in the mortality rate between groups: 64% versus 60% ($P = .56$). Adding a diffusive component (18 mL/kg/h of dialysate) in 206 patients submitted to hemofiltration (25 mL/kg/h of replacement fluid), Saudan et al.[237] showed a significant decrease in mortality—46% versus 61% ($P = .0005$). In this study, subjects in the hemodiafiltration group received substantially more overall solute clearance than subjects in the hemofiltration group, making it difficult to determine if the reduction in mortality was attributable to the higher dose or the addition of diffusive clearance.

Schiffl et al.[238] conducted an RCT comparing conventional alternate day dialysis to daily dialysis among 160 patients with AKI, assessing 14-day survival. The groups were similar with respect to baseline characteristics and illness severity and were analyzed by intention to treat. In the daily group, the weekly delivered Kt/V was 5.8 ± 0.4, and in the conventional group it was 3.0 ± 0.6. The duration of therapy was 3.3 hours per session in the daily group and 3.4 hours per session in the conventional group. The daily HD group had improved survival (28% vs. 46%, $P = .01$) and recovered kidney function more quickly (9 ± 2 days vs. 16 ± 6 days, $P = .001$). Factors significantly associated with an increased odds of death included alternate day HD (vs. DHD) (OR 3.92, 95% CI, 1.68–9.18, $P = .002$), higher APACHE III scores (OR 1.06, 95% CI, 1.01–1.12 per point increase, $P = .02$), oliguria (OR 3.02, 95% CI, 1.35–6.77, $P = .007$), and sepsis (OR 3.27, 95% CI, 1.43–7.50, $P = .005$).[238] The Schiffl study was the first randomized trial suggesting that patients with AKI benefited from more frequent HD and, consequently, a higher weekly Kt/V.[238]

Two recent large multicenter RCTs did not find benefit of intensive dose of dialysis over a standard dose.[212,239] The ATN trial was a randomized multicenter study including 1,124 critically ill AKI patients with sepsis or at least one nonrenal organ dysfunction. This trial aimed to provide a definitive conclusion on the benefits of intensive versus less-intensive dialysis dosage.[212] Intensive dosage was defined as CRRT with an effluent rate of 35 mL/kg/h, IHD or SLED six times per week, and less-intensive dosage as CRRT with an effluent rate of 20 mL/kg/h, and IHD or SLED three times per week. Each IHD or SLED treatment was aimed to achieve a single-pool Kt/V_{urea} of 1.2 to 1.4. The mean delivered dosages (5.4 treatments per week vs. 3 treatments per week at Kt/V of 1.3 or effluent rate of 35.8 vs. 22.0 mL/kg/h) were almost identical to the prescribed dosages. Subjects were switched from one modality to another according to their Sequential Organ Failure Assessment (SOFA) cardiovascular score (IHD when the score was 0 to 2 and CRRT or SLED when the score was 3 or 4). Baseline characteristics were similar between the groups. There were no differences in the primary endpoint, mortality at 60 days, in the duration of renal replacement therapy, or rate of recovery of kidney function or nonrenal organ failure between the groups. In contrast to the Bouman and Tolwani studies,[203,236] the sample size of the ATN study was sufficiently large so that there was adequate power to detect modest differences in mortality.

In the RENAL study 1,508 critically ill adults meeting predetermined criteria for the initiation of RRT were randomly assigned to postdilution CVVHDF with an effluent flow of 40 mL/kg/h or 25 mL/kg/h.[239] All patients received CRRT as their first mode of RRT and only 7% of patients received IHD later in their ICU stay. Thus, the RENAL study constitutes a more direct measure of the relationship between intensity of CRRT and survival.

The design of the ATN or the RENAL studies did not include predetermined strategies for some parameters that may have influenced the results, such as the timing of initiation of therapy, fluid balance, and site of delivery of replacement fluids (pre- vs. postdilution). It is important to note that subjects in the less intensive group received more renal replacement therapy than most patients in routine clinical practice. Therefore, practitioners should not conclude that dose is unimportant. In AKI there is a marked discrepancy between prescribed and delivered dose of dialysis. The delivered Kt/V in AKI patients have been shown to be 30% lower than prescribed,[238,240] resulting from hypotension, dialyzer clotting, and vascular access recirculation.[241]

The ideal dialysis prescription for AKI should incorporate an assessment of the dose of dialysis delivered. Unfortunately, there are no standard methods for assessing the dose of dialysis in AKI. In ESRD, the dose of dialysis prescribed and delivered is usually based on an assessment of the amount of urea removed, using urea kinetic modeling either via direct dialysis quantification or by using regression formulas incorporating fractional urea reduction.[242] A key feature of these methods is the assumption that patients with ESRD are in steady state with respect to urea generation, volume status, and renal and extrarenal clearance. However, dialysis dosing in AKI needs to account for highly variable body water volumes and varying urea generation rates, as well as different methods of dialysis and changes in renal and extrarenal clearance. Unfortunately, these issues have not been accurately quantified or adequately studied in prospective cohort studies or clinical trials conducted to date.

In general, the dose of dialysis is based on modality-specific criteria (e.g., membrane choice, operational characteristics, and the duration of each dialysis session). For patients treated with IHD, the frequency of dialysis is another determinant of the overall dose of dialysis delivered. Table 28.3 shows a comparison of the factors affecting dose of dialysis for IHD and CRRT. Several investigators have attempted to quantify the dose of dialysis delivered in AKI

using methods used for patients with ESRD. Clark et al.[243] compared IHD to CRRT techniques using a computer model to derive the required IHD frequency (per week) or required CRRT for a given patient weight for desired BUN values of 60, 80, and 100 mg per dL. For the attainment of intensive IHD metabolic control (BUN = 60 mg per dL) at steady state, a required treatment frequency of 4.4 dialyses per week was predicted for a 50-kg patient. However, the model predicted that the same degree of metabolic control could not be achieved even with daily IHD therapy in patients 90 kg or more. On the other hand, for the attainment of intensive CRRT metabolic control (BUN = 60 mg per dL), required urea clearance rates of approximately 900 mL per hour and 1,900 mL per hour were predicted for 50 and 100 kg patients, respectively. These data suggest that, for many patients, rigorous control of azotemia equivalent to that readily attainable with most CRRT programs can be achieved with intensive (nearly daily) IHD regimens only. In practice, the frequency of dialysis usually depends on the patient's clinical and biochemical status. It is noteworthy that reimbursement policies in the United States currently do not support the practice of daily IHD.

Other promising concepts should also be prospectively tested to improve our current understanding of the pathophysiology of AKI and help to better define dialysis dosage requirements. To improve the definition of dialysis dosage, other dialysis parameters, such as fluid balance, need to be assessed. In CRRT the effluent volume per se may not accurately reflect clearance as clotting of filter is associated with declining efficacy in effluent saturation. Although current RRT substitute small solute and volume clearances, the later parameter has never been included in randomized studies on dialysis dosage in AKI.[211,212,239] More importantly, fluid excess has been shown to be independently associated with increased mortality in one adult and several pediatric observational studies in AKI.[101,211,215] Fluid excess was usually defined as a proportion of initial hospital admission weight. In the largest pediatric study, the percentage fluid excess at dialysis initiation was significantly lower in survivors versus nonsurvivors (14.2 ± 15.9% vs. 25.4 ± 32.9%; $P < .03$) even after adjustment for severity of illness.[101] Therefore, fluid excess may contribute to imbalances between groups and should be better characterized in future studies. Results from the ongoing RENAL trial, a multicenter trial comparing an augmented versus a normal CRRT regimen, may add additional insight into the question of dialysis dose and outcome (Fig. 28.12).

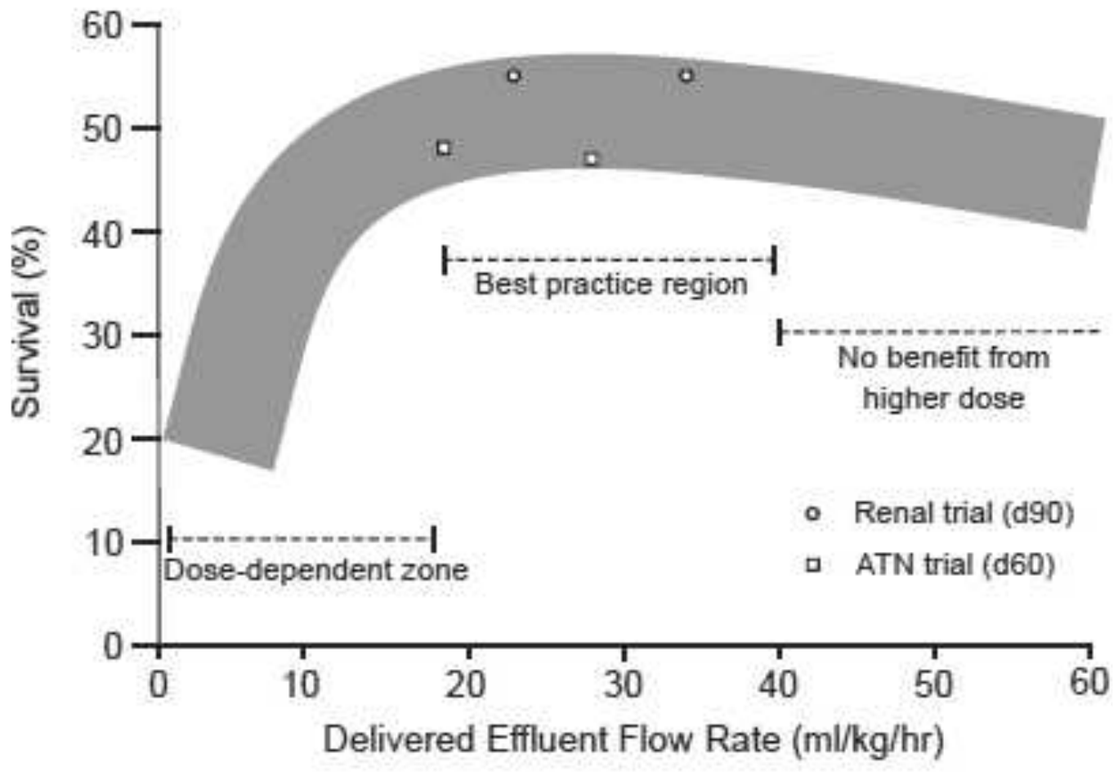

FIGURE 28.12 Possible relationship between delivered dose of continuous renal replacement therapy and survival, with results from the ATN and RENAL. These studies indicate a plateau response at the dose ranges examined. Acute tubular necrosis (ATN) doses are corrected for predilution. To reproduce these results, clinicians will need to prescribe continuous renal replacement therapy doses above the lower target dose in the trial protocols (20 or 25 mL/kg/min) as larger periods of filter downtime can be expected outside a clinical trial environment. Below this best-practice region, survival is likely to be dose-dependent; however, the exact nature of this relationship has not been formally determined. Doses above the best-practice region are unlikely to be beneficial to unselected patients and could potentially be harmful. *ATN*, Veterans Affairs/National Institutes of Health Acute Renal Failure Trial Network; *RENAL*, Randomized Evaluation of Normal versus Augmented Level. (Adapted from Prowle JR, Schneider A, Bellomo R. Clinical review: Optimal dose of continuous renal replacement therapy in acute kidney injury. *Crit Care*. 2011;15(2):207.)

Nutritional Considerations

AKI patients present an increased risk of protein–energy malnutrition due to poor nutrient intakes and high catabolic rates. Nutritional support should be directed to ensure adequate nutrition, prevent protein–energy wasting with its concomitant metabolic complications, promote wound healing and tissue repair, support immune system function, accelerate recovery, and reduce mortality.

In critically ill patients, the metabolic response to stress causes increased production of some cytokines (IL-1, IL-6, TNF-α), counterregulatory hormones (catecholamines, cortisol, glucagon), and immune mediators (thromboxane A2, prostaglandin F2a, prostaglandin E2).[244] The activation of stress-mediated response causes skeletal muscle breakdown, impairs amino acid transport into skeletal muscles, suppresses insulin-mediated protein synthesis, depletes body energy reserves and constitutive proteins, and increases urea production and peripheral insulin resistance.[245] As a result, critically ill patients have loss of body energy reserves (glycogen, protein, and fat stores), hypertriglyceridemia, hyperglycemia, and negative nitrogen balance.

Severe malnutrition occurs in up to 42% of patients with AKI. Severely malnourished patients have a significantly increased in-hospital length of stay, increased risk for comorbidities (sepsis, septic shock, hemorrhage, intestinal occlusion, cardiac dysrhythmia, cardiogenic shock, acute respiratory failure), and increased in-hospital mortality.[246] Nutritional assessment is difficult, especially in AKI patients

presenting higher metabolic demands. Subjective Global Assessment (SGA) accesses nutritional status, requires no additional laboratory testing, and is highly predictive of outcome.[247]

Patients with AKI should receive a basic intake of at least 1.5 g/kg/day of protein and an energy intake of no more than 30 kcal nonprotein calories or 1.3 × BEE (Basal Energy Expenditure) calculated by the Harris–Benedict equation. Thirty to 35% of calories should come from lipid, as lipid emulsions. Monitoring of nitrogen balance to assess the effectiveness of supplemental nutritional therapy is determined by measuring protein intake over 12 or 24 hours and urinary excretion of urea nitrogen over the same time interval. A positive or negative protein balance is used to determine the adequacy of protein intake of the patient. It is calculated as follows:

$$\text{Nitrogen balance} = (\text{protein intake}/6.25) - (\text{UUN} + 4),$$

Protein intake and urinary urea nitrogen (UUN) are each expressed in grams.

The enteral route should be the first choice for nutritional support if the gastrointestinal tract is functioning, whereas parenteral nutrition should be reserved when the gastrointestinal tract cannot be used, or when the enteral route appears inadequate to reach nutrient intake goals.[248] AKI itself and other factors commonly present in critically ill patients, such as medications, hyperglycemia, and electrolyte disorders, can impair gastrointestinal motility.

CHAPTER

29 Pathophysiology of Ischemic Acute Kidney Injury

Charles L. Edelstein • Robert W. Schrier

INTRODUCTION

Acute kidney injury (AKI) is defined as a sudden decrease in the glomerular filtration rate (GFR) occurring over a period of hours to days. The Acute Dialysis Quality Initiative (ADQI) has developed the RIFLE classification of AKI that divides AKI into the following stages: (1) risk, (2) injury, (3) failure, (4) loss of function, and (5) end-stage kidney disease.[1–3] The RIFLE criteria have been validated in multiple studies (i.e., as the RIFLE class increases so does mortality).[1–3] The term AKI, in general, replaces the term acute renal failure (ARF) and ARF is restricted to patients that have AKI and need renal replacement therapy. AKI has also replaced the term acute tubular necrosis (ATN). The term ATN emerged from the early observation on renal biopsy that necrosis of some renal tubular epithelial cells may occur in humans with acute renal injury.[4] Tubular epithelial casts (muddy brown casts) are excreted in the urine of these patients. However, it is now known that the tubular necrosis is quite patchy and alone could not account for GFR less than 10 mL/min/1.73m^2, the functional hallmark of clinically significant AKI.[4] Moreover, a percentage, ranging from 30% to 70%, of the urinary tubular epithelial cells has been shown to be viable by culture and the exclusion of vital dyes.[5,6] This observation is somewhat surprising because, generally, cells, which are separated from their extracellular matrix, undergo apoptosis.[7–10] Emerging results suggest that adhesion molecules (e.g., cadherins and integrins) may allow a cell-to-cell or a cell-to-matrix adhesion that not only avoids apoptosis, but also may contribute to intratubular obstruction.[11–14] Intraluminal tubular casts on a renal biopsy are a hallmark of clinical AKI, and earlier nephron dissection studies by Jean Oliver demonstrated a preferential location of these casts in the medullary collecting duct.[15] This location is of particular relevance to the overall low GFR in AKI because thousands of nephrons drain into a single medullary collecting duct.

There is debate about whether the pathophysiology of clinical AKI is primarily tubular or vascular. In fact, initial rat micropuncture studies were unable to consistently detect an elevation in tubular pressures in experimental ARF and thus the term vasomotor nephropathy replaced the ATN term for the clinical syndrome.[16–18] Experimental results have emerged that both vascular and tubular factors are involved in the pathogenesis of clinical AKI. Most recently, the role of endothelial injury and dysfunction[19] in promoting an inflammatory response in AKI[20] has received prominence. Thus, this chapter will discuss the potential tubular and vascular factors, as well as inflammatory processes, involved in the pathogenesis of ischemic AKI (Fig. 29.1). Toxic AKI will be discussed in another chapter. However, it must be emphasized that AKI in humans is frequently multifactorial. Both ischemic and toxic insults combine in a synergistic fashion to cause clinical AKI.

The understanding of the pathogenesis of ischemic AKI is of considerable importance for several reasons. First, this clinical syndrome is quite frequent, occurring in 5% to 10% of hospitalized patients and in 30% to 40% of intensive care unit (ICU) patients.[21–23] The incidence is likely to increase in the future because of the use of newer nephrotoxic drugs and the performance of more complex procedures in older patients.[24] Second, ischemic AKI has a very high mortality particularly when requiring dialysis to treat the resultant uremic syndrome. Overall mortality averages from 40% to 50%; however, the patient in the ICU with ischemic AKI may have a mortality in excess of 80%, particularly if the patient has multiorgan failure.[25–30] It is widely quoted that the mortality of AKI has only improved slightly in the last 40 years.[31] However, a study[32] suggests there has been improvement in AKI mortality between the late 1970s and the early 1990s. Third, there is considerable evidence that a functional component of the renal failure exists. Specifically, a histologic examination of the kidney from patients with clinical AKI exhibits normal glomeruli, occasional tubular necrosis, some intraluminal casts, and modest interstitial edema.[4] There is virtually no evidence for irreversible tissue damage and the morphologic changes alone fail to support the presence of a GFR less than 10 mL/min/1.73m^2.

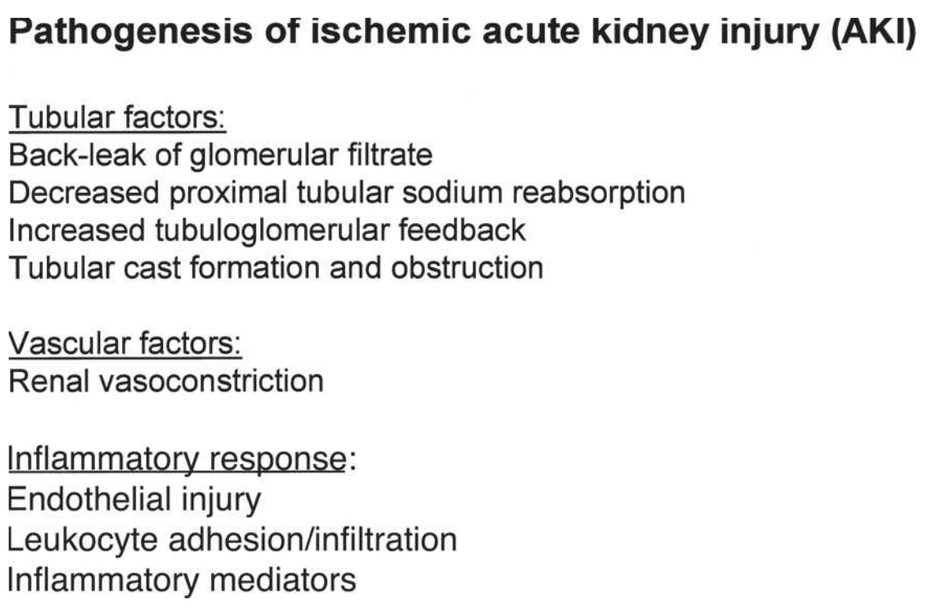

FIGURE 29.1 Vascular and tubular factors and inflammatory processes are involved in the pathophysiology of ischemic acute kidney injury.

EXPERIMENTAL MODELS OF ACUTE KIDNEY INJURY

Available models to study the pathophysiology of renal cell ischemia are listed in Table 29.1.[33] An understanding of these models will allow a better interpretation of the multiple studies discussed in this chapter.

Proximal and distal tubular cells in culture have been widely used to study tubular injury. These cells change from their normal dependence on oxidative mitochondrial metabolism to glycolysis under culture conditions.[34] As a result, these cultured tubules become less susceptible to oxygen deprivation. Thus, exposure to drugs like antimycin-A, ionomycin, or a combination to induce "chemical" ATP depletion and subsequent necrosis or apoptosis is used. Cultured cells also undergo considerable structural change, which includes simplification of both their apical and basolateral compartments.[35] The presence of necrosis rather than apoptosis in these cells may be related to the level of ATP depletion. In cultured mouse proximal tubules subjected to ATP depletion below 15% of control values, the cells died of necrosis; whereas in ATP depletion to 25% to 70% of control values all the cells died of apoptosis.[36] Therefore, although cultured tubule cells are the least complex model and allow for an understanding of the mechanisms involved, the therapeutic implications for in vivo AKI are limited.

Freshly isolated rat or rabbit proximal tubules in suspension are also widely used to study proximal tubular injury.[37–45] The method of isolation of tubules is by collagenase digestion and Percoll centrifugation. Hypoxia is achieved by gassing the suspension with 95%N_2/5%CO_2 for up to 15 minutes, thereby reducing the pO_2 to approximately 30 mm Hg. Lactic dehydrogenase (LDH) release into the suspension medium is measured as an index of lethal membrane injury.[46,47] The tubules are preincubated with cytoprotective agents and enzyme inhibitors before the induction of hypoxia, and the effect of these agents on cell membrane injury can be determined. The presence of necrosis rather than apoptosis during short periods of hypoxia (15 to 30 minutes) in this model was demonstrated using DNA-specific dyes, such as Hoechst 33342 and propidium iodide.[48] Another study has also demonstrated that during hypoxia there is endonuclease activation without morphologic features of apoptosis in the same model of rat proximal tubules.[49] Freshly isolated tubules are valuable for both structural and metabolic investigations because they retain the biochemical properties of the in vivo state and a high degree of structural integrity, and are highly polarized and fully differentiated.[33] However, the tubules are highly sensitive to ATP depletion, and severe hypoxia or anoxia results in necrosis of more than 50% of the cells after 30 minutes. Isolation methods also expose the tubules to repeated 4°C exposure and collagenase.

In whole animal studies—usually rats, rabbits, or mice—a clamp model of ischemic AKI is used.[50–52] Ischemic AKI is generally induced by (1) clamping of both the right and left renal pedicles or renal arteries or (2) unilateral renal pedicle or artery clamp preceded by contralateral nephrectomy. The renal vessels are clamped for varying periods of time, generally from 30 to 60 minutes, followed by varying periods of reperfusion. This results in a reversible model of AKI in which the blood urea nitrogen (BUN) and serum creatinine reach a peak at 24 to 48 hours reperfusion and

29.1 Available Models to Study the Pathophysiology of Renal Cell Ischemia (Increasing Order of Complexity)

Model	Origin
Cultured tubular cells	Primary culture of human, rat, and mouse; Madin-Darby canine kidney (MDCK) cells (distal); porcine renal epithelial (LLC-PK1) cells (proximal); opossum kidney (OK) cells; human kidney (HK) cells
Freshly isolated proximal tubules in suspension	Rabbits, rats, mice
Isolated perfused kidney	Rats
Whole animals	Rabbits, rats, mice, dogs (not much used anymore)
Human patients	Renal biopsy studies; urine and serum biomarkers of acute kidney injury

Adapted from Reference 33.

then gradually normalize over the next 7 days.[50–53] However, renal vessel clamping in rats results in extensive necrosis of proximal tubules. This necrosis is much more extensive than is seen in humans with ischemic AKI. Nevertheless, although animal models of ischemic AKI are complex with many experimental limitations, they provide important leads for future therapeutic clinical interventions.

In the isolated perfused kidney model, the kidney is removed from the animal. The perfusate usually consists of a Krebs-Henseleit buffer with albumin. Urine is collected by cannulation of the ureter. This model allows for the study of factors independent of changes in systemic hemodynamics and neural activity. Further advantages include the study of specific circulatory factors or pharmacologic agents that are added to the perfusate. These agents are thus delivered directly to the kidney. The disadvantages of the model are (1) the absence of red blood cells in the perfusate impairs oxygen delivery to the medullary thick ascending limb (mTAL) and (2) perfusate flow greatly exceeds normal in vivo values. The isolated perfused kidney is regarded as a model of selective hypoxia to the medullary thick ascending limb.[54]

Studies in patients with AKI, although having important experimental limitations, have the most direct therapeutic value. An analysis of urine cytology represents a noninvasive method for potentially defining the cause of AKI.[4] Meyers and colleagues[55–57] have examined patients with ischemic AKI postrenal transplantation by obtaining biopsies of these allografts at the time of transplantation. Biomarkers of kidney injury would greatly facilitate the early detection and the precise diagnosis of AKI.

BIOMARKERS OF ACUTE KIDNEY INJURY

AKI is usually diagnosed by recording increases in serum creatinine and decreased urine output over several days. However, serum creatinine is not a good marker of renal function in AKI because its concentration can be affected by factors not related to renal function such as the volume of distribution, muscle mass, and creatinine secretion.[28] When the kidney is injured and the true GFR suddenly drops, but there is a slow increase in serum creatinine over days. This new steady state, which may take up to 7 days, is reached when creatinine generation equals creatinine excretion. In contrast to serum troponin in myocardial infarction, an increase in serum creatinine lags and may not be directly related to tubular injury in AKI. Recent studies have examined urine and serum biomarkers of kidney injury that have the potential to facilitate the diagnosis of AKI.

Recently described molecules such as the cytokine interleukin (IL)-18,[58] kidney injury molecule-1 (KIM-1),[59] cysteine-rich protein 61 (Cry61),[60] neutrophil gelatinase–associated lipocalin (NGAL),[61] and sodium/hydrogen exchanger isoform 3 (NHE3)[62] have demonstrated compelling results as markers of AKI at the preclinical level. Studies have been initiated to explore these molecules in human AKI.

Because of the crucial importance of early therapy in the management of AKI, markers are being explored for early diagnosis. NGAL was investigated as an early biomarker for AKI following cardiopulmonary bypass in 45 patients.[63] Urine and serum were collected at baseline and at frequent intervals for 5 days following a cardiopulmonary bypass. All patients who developed AKI (defined as a 50% increase in serum creatinine) displayed a significant increase in serum and urine NGAL very early after the cardiopulmonary bypass compared to patients without AKI. These results show that NGAL may be a sensitive, early urinary, and serum biomarker for AKI.

In a nested case-control study within the adult respiratory distress syndrome (ARDS) network trial, urinary IL-18 was investigated as an early marker of AKI.[64] Median urine IL-18 levels were significantly higher in AKI cases (defined as a 50% increase in serum creatinine) as compared to controls. On multivariable analysis, urine IL-18 values predicted the development of AKI 24 and 48 hours later after adjusting for demographics, sepsis, acute physiology and chronic health evaluation (APACHE) III score, serum creatinine, and urine output. After controlling for other parameters, a rise in urine IL-18 by 25 pg per milliliter was associated with an increased odds ratio of AKI by 19% for the next 24 hours. Urine IL-18 performed as a diagnostic test with an area under the receiver operator characteristic curve of 73%. The conclusion of this study is that urinary IL-18 levels can be used for the early diagnosis of AKI.

A recent study demonstrated that serum cystatin C appears to increase 24 to 48 hours before serum creatinine in patients with AKI.[65] However, cystatin C is a marker of GFR, or a functional marker, and is not a structural or biochemical marker of renal tubular injury.

There are multiple promising serum and urinary biomarkers (eg, IL-18, neutrophil-gelatinase-associated lipocalin [NGAL], kidney injury molecule-1 [KIM-1], cystatin C, liver fatty acid-binding protein [L-FABP]), which detect AKI before the rise in serum creatinine and predict outcomes in patients with AKI.[66] Prospective studies to determine the use of these biomarkers in larger populations have been initiated. In this regard, a National Institutes of Health (NIH)-funded clinical consortium consisting of investigators from nine academic centers called TRIBE-AKI (Translational Research Investigating Biomarkers in Early Acute Kidney Injury) has been established. Currently, the consortium is performing a prospective multicenter observational cohort study of 1,800 patients receiving cardiac surgery to determine whether urine IL-18, urine NGAL, and serum cystatin C are biomarkers for the early diagnosis and long-term outcomes of AKI. Ultimately, disease control studies to determine the impact of a biomarker screening on AKI morbidity and mortality are desirable. In this regard, a prospective study in over 500 ICU patients in New Zealand determined whether erythropoietin therapy decreases the incidence of AKI, as determined by serum creatinine and serum cystatin C, and lowers levels of urinary IL-18, NGAL, and KIM-1.[67] In this

study, early intervention with erythropoietin based on urine biomarker levels did not affect the outcome of AKI.[67]

BACK-LEAK OF GLOMERULAR FILTRATE POSTRENAL ISCHEMIA

It has been proposed that GFR in ischemic AKI is really not as low as measured because glomerular filtrate leaks across the damaged epithelial monolayer and/or the tubular basement membranes. In some toxic experimental models of ischemic AKI, diffuse tubular necrosis and basement membrane damage has been associated with evidence for back-leak of glomerular filtrate. The term "back-leak" of glomerular filtrate refers to the unregulated passage of salt and water from the tubular lumen into the interstitium and later back into the renal venous capillaries and renal veins.[68] However, the level of epithelial and basement membrane damage with these experimental toxic models (e.g., cisplatin, mercuric chloride) is virtually never observed in human AKI. Myers et al.[69] have performed human studies using solute sieving curves in search of tubular back-leak of glomerular filtrate. They found dextran sieving curves could sometimes exceed inulin sieving curves, thus providing evidence in support of the back-leak of solutes (i.e., dextran), which are normally unable to cross intact tubular epithelial basement membranes. However, even when accepting the validity of this method for documenting tubular back-leak of filtrate, the calculated amount would only account for a decrease in renal function of 8% to 10%. Thus, although tubular back-leak of glomerular filtrate might occasionally occur in patients with severe ischemic AKI, it is unlikely to be a dominant pathogenic factor.

The tight junction of polarized tubular epithelial cells is the most apical component of the junctional complex and serves as an important permeability barrier.[70] Tight junctions also control cell polarity.[71] However, the tight junction in the proximal tubule is relatively "leaky" with as much as one-third of proximal sodium reabsorption occurring via the paracellular route. The tight junctional complex is a dynamic and regulated structure. Some of its protein components have been identified and include the transmembrane protein occludin. Nontransmembrane proteins on the cytosolic leaflet include zona occludens (ZO)-1, ZO-2, cingulin, 7H6, and several unidentified phosphoproteins. Interactions of some of these proteins with the actin cytoskeleton is a major determinant of the tight junction structure and may also play a role in the regulation of tight junction assembly.[70] The integrity of the tight junction is disrupted during ischemic injury and must be reestablished for recovery.[72] There is in vitro experimental evidence in cell culture studies for an impaired tight junction between tubular epithelial cells undergoing chemical anoxia.[73] Ruthenium red, which normally is impermeable to tight junctions, has been shown to enter the ZO after chemical hypoxia and renal ischemia.[73,74] Energy depletion abolishes the gate function of the tight junction, as determined by the dramatic decrease in transepithelial resistance, but it leaves the fence function intact, as determined by the maintenance of lipid polarity.[75] In an ATP depletion–repletion model in Madin-Darby canine kidney cells, tight junction proteins such as ZO-1 reversibly form large complexes and associate with cytoskeletal proteins.[76] A model has been proposed in which a key, potentially regulated step in the generation of the ischemic epithelial cell phenotype is the interaction between tight junction proteins and fodrin and/or other cytoskeletal proteins.[76] Intracellular calcium plays a role in tight junction reassembly after ATP depletion.[72] In this study, the role of intracellular calcium in tight junction reassembly after ATP depletion–repletion was studied using the cell-permeable calcium chelator 1,2-bis(2-aminophenoxy)ethane-N,N,N',N'-tetra-acetic acid-AM (BAPTA-AM). Lowering intracellular calcium during ATP depletion was associated with a significant inhibition of the reestablishment of the permeability barrier following ATP repletion as measured by transepithelial electrical resistance and mannitol flux, marked alterations in the subcellular localization of occludin by immunofluorescent analysis, and decreased solubility of ZO-1, and other tight junction proteins by the Triton X-100 extraction assay. This suggested that lowering intracellular calcium potentiates the interaction of tight junction proteins with the cytoskeleton.

Studies have also shown the importance of small GTPases (Rho, Rac, Cdc-42) in the integrity of the ZO.[77] ATP depletion with chemical hypoxia has been demonstrated to inactivate these GTPases and thereby contribute to increased paracellular back-leak of filtrate.[71,78] Expression of constitutively active ras homolog gene family, member A (RhoA) GTPase in ATP-depleted Madin Darby canine kidney (MDCK) cells prevents tight junction disassembly.[71] Cyanide-induced chemical hypoxia increases the kinase activity of c-Src and causes its translocation to cell–cell junctions where it binds to and phosphorylates β-catenin and p120, suggesting that this may contribute to the loss of epithelial barrier function.[79] It is likely that the effects on tight junction integrity seen in ATP depletion are due, at least in part, to the inhibition of Na-K-ATPase.[80] The relevance of these cell culture observations to clinical ischemic AKI in patients remains to be proven.

DECREASED TUBULAR SODIUM REABSORPTION

Proximal tubular injury, whether it be sublethal reversible dysfunction, necrosis, or apoptosis, has been extensively studied. Mechanisms of proximal tubular injury that will be discussed in this section are outlined in Table 29.2. The study of proximal tubular injury is of special relevance in order to explain the decreased tubular sodium reabsorption that occurs with a postrenal ischemia.

In the normal kidney, Na^+ is vectorially transported from the proximal tubule lumen across the apical membrane microvilli into the tubular epithelial cells and then across the basolateral membrane into the interstitium and the peritubular circulation.[81] Na^+ influx into the polarized proximal tubular epithelial cells across the apical membrane is passive

29.2 Mechanisms of Hypoxic/Ischemic Proximal Tubular Injury

Sublethal Reversible Injury
- Cytoskeletal disruption and loss of polarity
- Loss of tight junction function
- Loss of cell-matrix adhesion
- Abnormal gene expression

Necrosis
- Severe ATP depletion (15% of normal)
- Calcium influx
- Calcium-dependent phospholipase A_2 ($cPLA_2$)
- Calcium-dependent cysteine proteases (e.g., calpain)
- Calcium-independent PLA_2
- Caspase-1
- Interleukin-18 (IL-18)
- Metalloproteases
- Oxygen radicals
- Lipid peroxidation
- Deficiency of glycine
- Nitric oxide (generated by iNOS)
- Endonuclease activation
- Deficient heat stress response
- Potassium efflux
- Klotho deficiency

Apoptosis
- Mild ATP depletion (25%–50% of normal)
- Caspase-3
- Caspase-1
- Caspase-6
- Endonuclease activation
- Serine proteases
- Insulinlike growth factor I receptor deficiency
- Deficient heat stress response
- Erythropoietin
- NGAL
- Ghrelin
- Bcl-2 proteins
- Mitochondrial fragmentation

iNOS, inducible nitric oxide; NGAL, neutrophil gelatinase–associated lipocalin.

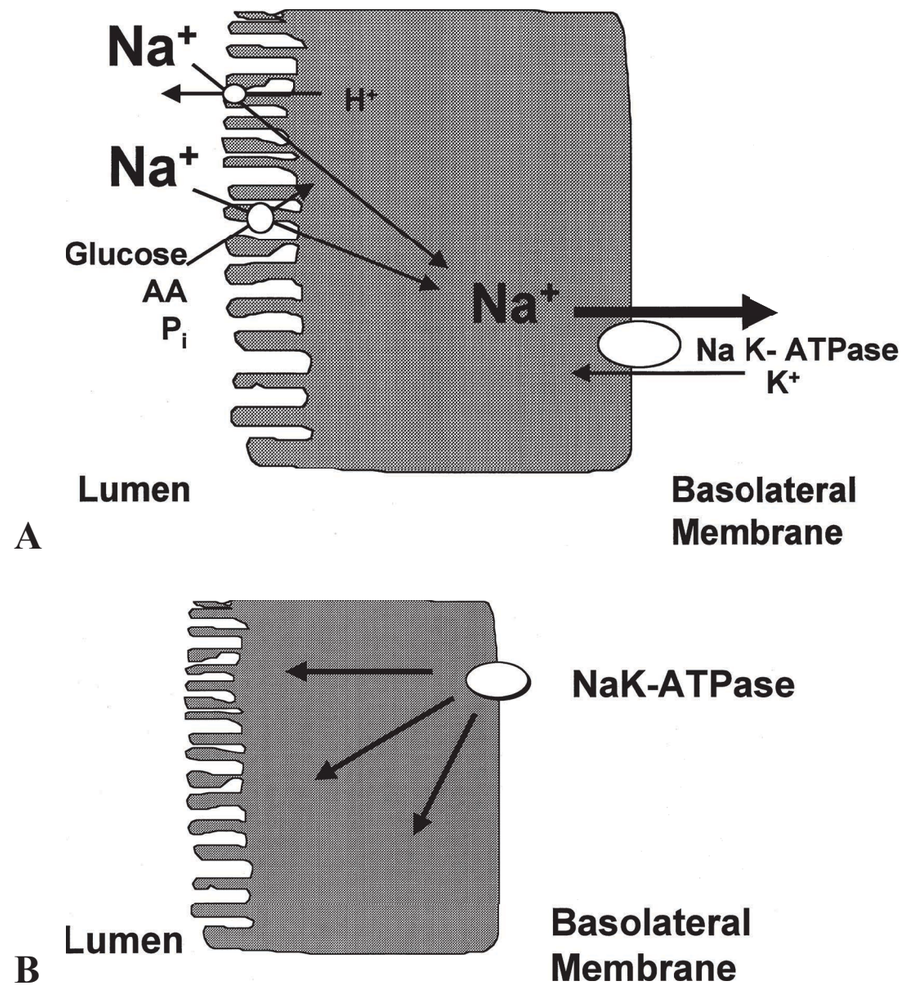

FIGURE 29.2 **A:** Normal reabsorption of sodium in the proximal tubule. The NaK-ATPase pump is located on the basolateral surface of the proximal tubule. **B:** Translocation of the Na-K-ATPase pump away from the basolateral proximal tubule membrane during hypoxia/ischemia. The loss of polarity of proximal tubule cells during chemical anoxia and ischemia results in a translocation of the Na-K-ATPase. During ATP depletion in cultured cells, the Na-K-ATPase translocates to the apical membrane. In human kidney allografts with delayed function, the Na-K-ATPase translocates to the cytoplasm. The translocated Na-K-ATPase remains functional.

down the Na^+ gradient via the H^+/Na^+ exchanger and various Na^+ cotransporters. The Na^+ gradient is maintained by an active transport via the Na^+/K^+-ATPase at the basolateral membrane of the proximal tubular cells (Fig. 29.2A).

The earliest signs of clinical AKI are urinary muddy brown casts and an increased fractional excretion of sodium (FE_{Na}).[82,83] The proximal tubule is the most frequent morphologic site of injury in ischemic AKI in both humans and animals.[84] The S_3 segment of the proximal tubule is particularly prone to ischemic injury, perhaps because of its location in the outer medulla, which is relatively hypoxic compared to the renal cortex.[84] The proximal tubule nephron site is also associated with impaired vectorial sodium transport. The earliest morphologic changes with ischemic injury include invagination and sloughing of the brush border membrane into the lumen, an abnormality that is compatible with impairment and a loss of apical sodium antiporters and cotransporters responsible for sodium entry into the proximal tubular epithelium.[85–87] The tubules lose their polarity.[83] In vitro studies have shown that ATP depletion leads to dephosphorylation and inactivation of the actin binding protein, ezrin, and activation of the actin depolarizing protein in the proximal tubule membrane.[88,89] This leads to a disruption of the microvillar actin and a loss of the brush border membrane.[90] A loss of polarity of the proximal tubule cells during chemical anoxia and ischemia has also been shown with the translocation of the Na-K-ATPase to the apical membrane (Fig. 29.2B).[91–93] The translocated Na-K-ATPase remains functional.[94] In MDCK cells exposed to ATP depletion, there is a loss of polarity of Na-K-ATPase and a dissociation of the membrane–cytoskeleton complex at the spectrin–ankyrin interface.[95] Thus, sodium transport back

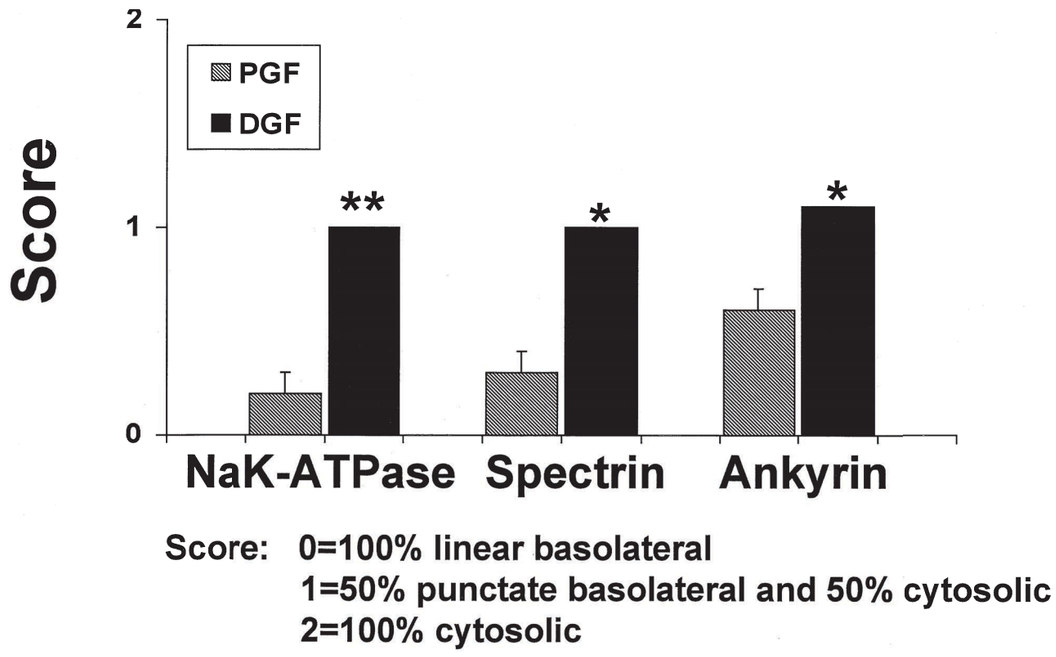

FIGURE 29.3 The cellular location on immunohistochemistry of the actin binding proteins, ankyrin and spectrin, and Na-K-ATPase in cadaveric transplanted kidneys with prompt graft function (PGF) and delayed graft function (DGF) was compared. In those kidneys with DGF, approximately 50% of the ankyrin, spectrin, and Na-K-ATPase was translocated from the basolateral membrane to the cytoplasm. Whereas those kidneys with a PGF had only minimal translocation of these proteins from the basolateral membrane. * $P < .01$ versus PGF; ** $P < .05$ versus PGF. Adapted from Alejandro et al.[55]

across the apical membrane and into the proximal lumen, as well as decreased proximal tubular sodium reabsorption, has been proposed in response to hypoxia and ischemia.

Studies in cadaveric transplanted kidneys with both prompt and delayed graft functions have been compared relative to the cellular location of the actin binding proteins, ankyrin and spectrin, and Na-K-ATPase using selective antibodies. In kidneys with delayed graft function, approximately 50% of the ankyrin, spectrin, and Na-K-ATPase were translocated from the basolateral membrane to the cytoplasm (Fig. 29.3). Those kidneys with prompt graft function had only minimal translocation of these proteins from the basolateral membrane (Fig. 29.3).[55] These observations therefore have contributed to our understanding of reversible and sublethal tubular dysfunction in ischemic kidneys in vivo (Fig. 29.3).

Because proximal tubular cells in a culture convert from primarily oxidative to glycolytic metabolism and alter their phenotype,[34,35] confirmation of experimental results in other systems is advisable. The use of freshly isolated proximal tubules to study the response to hypoxia has also been enlightening. These tubules, in general, maintain their phenotype and oxidative metabolism but are more sensitive to hypoxia, as assessed by LDH release, than in vivo tubules.[96–99] Hypoxia for 15 to 30 minutes causes a reproducible release of LDH, and the cells die by necrosis.[48,49] The central role of intracellular calcium and various protective maneuvers against hypoxic injury have been demonstrated in these isolated proximal tubules. However, before discussing the role of intracellular calcium in proximal tubular injury, we shall briefly consider adenine nucleotides. It is unquestioned that the first effect of ischemia, hypoxia, or mitochondrial inhibition in most in vitro and in vivo models is to compromise adenine nucleotide metabolism. A decreased production of ATP precedes the increase in intracellular calcium.

Adenine Nucleotides

The removal of oxygen from renal cells or whole kidneys results in prompt decreases in the cellular ATP pool. Initially, adenosine diphosphate (ADP) and adenosine monophosphate (AMP) concentrations increase,[52] and further catabolism of AMP to adenosine and then to hypoxanthine and, in some species to xanthine, occurs as the ischemic period is prolonged.[100,101] The provision of exogenous ATP-$MgCl_2$ to ischemic rat kidneys protects against ischemic injury.[102] Mechanisms whereby a loss of ATP results in cellular injury include the loss of purine nucleosides themselves (in some species, the generation of oxygen free radicals during reperfusion), and the loss of many metabolic functions (e.g., phosphorylation of important enzymes, ion channels, and the functions of ion transporters that are dependent on adequate ATP levels).

Ischemic preconditioning protects the heart, and in some studies the kidneys, from subsequent ischemia–reperfusion injury. Ischemic preconditioning appears to be mediated via the activation of adenosine receptors, specifically the A_1 adenosine receptors. In support of this are studies that the exogenous administration of adenosine or A_1 adenosine agonists mimic ischemic preconditioning in cardiac muscle.[103] It was recently demonstrated that rat kidneys can be preconditioned to attenuate ischemic–reperfusion injury. In this study, adenosine infusion before the ischemic insult protects renal function via A_1 adenosine receptor activation, and adenosine A_1 antagonism blocks adenosine-induced protection. In a more recent study, acute and delayed protection against renal ischemia was seen with an A_1 adenosine receptor agonist.[104] In addition, adenosine A_3 receptor activation before the ischemia worsens the renal ischemia–reperfusion injury and A_3 receptor antagonism protects renal function.[103] A_2A adenosine receptors mediate the inhibition of ischemic AKI in rats due to an inhibitory effect on neutrophil adhesion.[105,106] A combined infusion of an A_{2A} adenosine receptor agonist and a type IV phosphodiesterase (PDE 4) inhibitor leads to enhanced protection against ischemia–reperfusion injury in mice.[107] Protection against renal ischemia–reperfusion injury by A_2A receptor agonists or endogenous adenosine requires the activation of receptors expressed on bone marrow–derived cells.[108] The A_2A adenosine receptor may be a novel therapeutic target in renal ischemia–reperfusion injury.[109,110]

Intracellular Calcium

The normal regulation of epithelial cell calcium is demonstrated in Figure 29.4A. Calcium exists in the cell as cytosolic free calcium, which is the smallest pool, but the most critical for regulation of intracellular events. Calcium is also bound to proteins and anions in the cytosol and to membrane

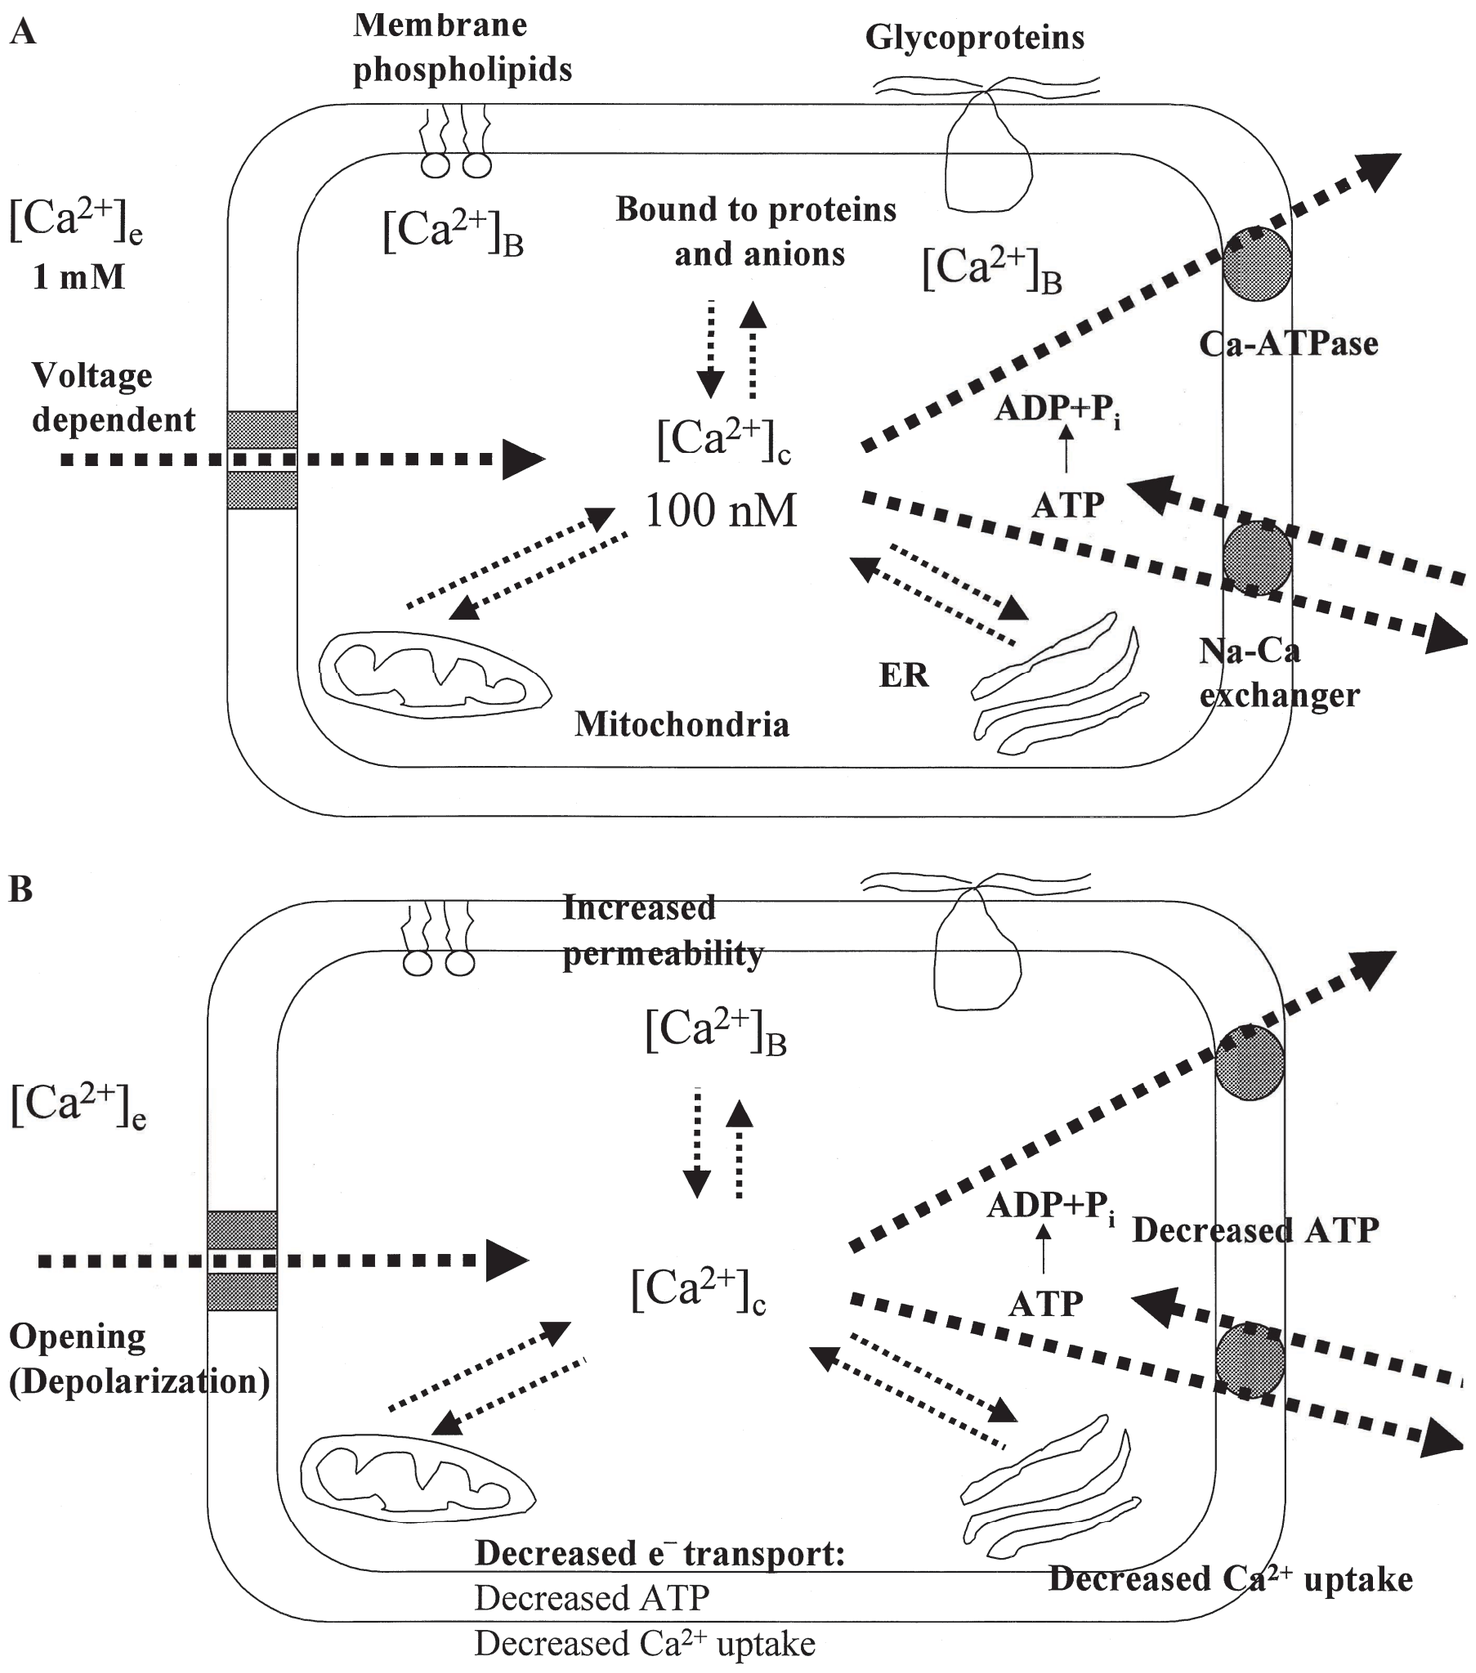

FIGURE 29.4 **A:** The normal regulation of epithelial cell calcium. The cytosolic free calcium $[Ca^{2+}]_c$ is the smallest amount, but the most critical for the regulation of intracellular events. The concentration of calcium in the cytosol is about 100 nM, which is 1/10,000 of the extracellular calcium, which is in a micromolar concentration of $[Ca^{2+}]_e$. Calcium is also bound to proteins and anions in the cytosol and to membrane phospholipids and glycoproteins $[Ca^{2+}]_b$. The largest pool of intracellular calcium is in the mitochondria and the endoplasmic reticulum. The large electrochemical gradient is maintained by binding calcium to intracellular components and by apical and basolateral transport systems. Transport systems, which maintain the large electrochemical gradient between intracellular and extracellular Ca^{2+}, may be voltage dependent or ATP dependent like the $Ca2^{+}$ ATPase pump and the $Na^{+}/Ca2^{+}$ exchanger. During cell injury, active mitochondrial sequestration appears to be quantitatively the most important process for buffering elevations in cytosolic calcium. **B:** During epithelial cell injury, several factors favor increases in cytosolic free calcium. There is (1) depolarization or an opening of voltage-dependent channels; (2) increased membrane permeability; and (3) decreased mitochondrial electron transport leading to decreased ATP levels. The decreased ATP leads to decreased calcium uptake by mitochondria and the endoplasmic reticulum, and a decreased ability to pump calcium out of the cell.

phospholipids and glycoproteins. The largest pools of intracellular calcium are in mitochondria and the endoplasmic reticulum.[111,112] The concentration of calcium in the cytosol is about 100 nM, which is 1/10,000 of extracellular calcium concentrations.[111] The large electrochemical gradient between intracellular and extracellular calcium is maintained by the binding of calcium to intracellular components and by apical and basolateral transport systems. Transport systems may be voltage dependent or ATP dependent. Calcium efflux is mediated in basolateral membranes by both calcium ATPase, which is ATP dependent, and by a Na^{+}/Ca^{2+} exchanger on the basolateral membrane, which is ATP independent.[113] Normally, the cell membrane is impermeable to calcium and maintains the steep calcium gradient between cytosolic free calcium and the extracellular space.[112] However, when cytosolic calcium increases in response to either increased cellular membrane permeability or decreased calcium efflux, or both, the mitochondria and the endoplasmic reticulum (ER)

actively increase their calcium uptake. Mitochondrial uptake and retention of calcium becomes substantial only when cytosolic levels exceed 400 to 500 nM, as occurs with cell injury.[111] Mitochondrial uptake is regulated by a calcium uniporter in the mitochondrial inner membrane. Thus, during cell injury, active mitochondrial sequestration appears to be quantitatively the most important process for buffering elevations in cytosolic calcium.

During epithelial cell injury, several factors favor increases in cytosolic free calcium (Fig. 29.4B). This includes (1) decreased mitochondrial electron transport leading to decreased ATP levels, (2) increased membrane permeability, and (3) depolarization or opening of voltage-dependent channels. The decreased ATP leads to a decreased calcium uptake by mitochondria and ER and a decreased ability to pump calcium out of the cell.

With this background on the normal regulation of cell calcium, we shall now consider the role of intracellular calcium in tubular injury. In 1981, it was proposed that calcium ions were important participants in the functional, biochemical, and morphologic disturbances that characterize AKI.[114,115] Numerous studies over the past 15 years in different injury models and cell types have demonstrated an increase in cytosolic calcium in renal epithelial cell injury. These studies are summarized in Table 29.3.

The crucial questions to implicate calcium as a primary factor in cell injury are (1) whether the increase in cytosolic calcium precedes the injury and (2) whether preventing the rise in cytosolic calcium attenuates the injury.[116,117] To investigate whether hypoxia is associated with an increase in free cytosolic calcium in proximal tubular cells, which precedes any evidence of membrane damage, a video imaging technique was developed in which free intracellular calcium could be measured simultaneously with staining of nuclei with the membrane impermeable indicator, propidium iodide, as an index of hypoxia-induced membrane damage.[118] Propidium iodide enters the cell through the damaged plasma membrane and stains the cell nucleus. The percent of nuclei that stain with propidium iodide is quantitated and is an index of plasma membrane damage. Hypoxia in rat proximal tubules is associated with a significant rise in cytosolic calcium, which antecedes evidence of membrane damage as assessed by propidium iodide staining.[99] Cytosolic calcium increased from 170 to 390 nM during 5 minutes of hypoxia. The increase in cytosolic calcium preceded propidium iodide–detectable cell injury (Fig. 29.5). The increase in cytosolic calcium that preceded the hypoxic membrane damage was promptly reversible with reoxygenation after 8 minutes of hypoxia. This is important because if cytosolic calcium is increased only after lethal cell membrane damage, reoxygenation should not have

29.3 Increases in Cytosolic Calcium in Renal Epithelial Cell Injury

Injury Model	Cell Type	Reference
Calcium ionophore	Rabbit proximal tubules	Mandel and Murphy, 1984[467]
Anoxia	LLCMK2 cells	Snowdowne et al., 1985[468]

normalized cytosolic calcium. The 10 minutes of cytosolic calcium rise correlated significantly with subsequent cell damage observed at the 20 minute mark. The pivotal role of the rise in cytosolic calcium during hypoxia was further demonstrated by using the intracellular Ca^{2+} chelator BAPTA to prevent the rise in cytosolic calcium; this approach resulted in marked cytoprotection against hypoxic tubular injury.

What are the mechanisms whereby increases in cytosolic free calcium could lead to cell membrane injury? Potential calcium-dependent mechanisms include changes in the actin cytoskeleton of proximal tubule microvilli,[119] activation of calcium-dependent PLA_2,[40] and activation of the calcium-dependent cysteine protease, calpain.[116,117,120,121]

Calcium-Dependent Changes in the Actin Cytoskeleton

The role of calcium in pathophysiologic alterations of the proximal tubule microvillus actin cytoskeleton was studied in freshly isolated tubules.[119] Precisely defined medium calcium levels were defined using a combination of the metabolic inhibitor, antimycin, and the ionophore, ionomycin, in the presence of glycine to prevent lethal membrane damage. Increases of intracellular calcium to 10 μM were sufficient to initiate concurrent actin depolymerization, fragmentation of F-actin into forms requiring high-speed centrifugation for recovery, redistribution of villin to sedimentable fractions, and structural microvillar damage consisting of severe swelling and fragmentation of actin cores. However, during ATP depletion induced by antimycin alone or hypoxia alone, initial microvillar damage was calcium independent. This study suggests that both ATP depletion-dependent but Ca^{2+}-independent, as well as Ca^{2+}-mediated processes, can disrupt the actin cytoskeleton during acute proximal tubule cell injury; that both types of change occur, despite protection afforded by glycine and reduced pH against lethal membrane damage; and that Ca^{2+}-independent processes primarily account for prelethal actin cytoskeletal alterations during simple ATP depletion of proximal tubule cells.

In normal proximal tubule cells, actin is concentrated in apical brush border microvilli, along with the actin-binding protein, villin. Villin plays an important role in actin bundling and in microvillar assembly but can also act as an actin-fragmenting protein at higher calcium concentrations. The effects of ischemic injury and reperfusion on the distribution of villin and actin in the proximal tubule cells of rat kidneys were examined.[122] This study demonstrated that villin may be involved in the initial disruption of the actin cytoskeleton during reperfusion injury and that its migration back to the apical domain of these cells accompanies the reestablishment of a normal actin distribution in the brush border.

ATP depletion results in the conversion of monomeric G-actin to polymeric F-actin during tissue ischemia.[123] This conversion results from altering the ratio of ATP-G actin and ADP-G actin, causing a net decrease in the concentration of thymosin actin complexes as a cosequence of the differential affinity of thymosin beta 4 for ATP and ADP-G actin.[124] Recent studies suggest that the actin-binding protein tropomyosin binds to and stabilizes the apical actin microvilli under physiologic conditions in proximal tubules.[125]

Activation of Phospholipase A_2

Phospholipase A_2 (PLA_2) enzymes are important regulators of prostaglandin and leukotriene synthesis and can directly modify the composition of cellular membranes.[126] PLA_2 enzymes are also potent regulators of inflammation. The cytosolic form, $cPLA_2$, preferentially releases arachidonic acid from phospholipids and is regulated by changes in intracellular calcium concentration.[127]

PLA_2 enzymatic activity was measured in cell-free extracts prepared from rat renal proximal tubules.[40] Both soluble and membrane-associated PLA_2 activity were detected. All PLA_2 activity detected during normoxia was calcium dependent. The fractionation of cytosolic extracts by gel filtration revealed three peaks of PLA_2 activity. Exposure of tubules to hypoxia resulted in stable activation of soluble PLA_2 activity, which correlated with the disappearance of the highest molecular mass form (>100 kDa) and the appearance of a low–molecular-mass form (approximately 15 kDa) of PLA_2. Hypoxia also resulted in the release of a low–molecular-mass form of PLA_2 into the extracellular medium. Pretreatment of tubules with glycine before hypoxia blocked this release of PLA_2 but not the activation of soluble PLA_2 activity. This study provides direct evidence for calcium-dependent PLA_2 activation during hypoxia. However, calcium-independent forms of PLA_2 have also been found to play a role in hypoxic proximal tubular injury.[128]

The mechanism of PLA_2-induced cell membrane damage is interesting. Membrane phospholipid breakdown has been observed to occur in a number of tissues during ischemia.[129] In proximal tubules, hypoxia has been shown to

cause an increase in free fatty acids, which was initially believed to contribute to cell injury.[130] However, a study from our laboratory has shown that unsaturated free fatty acids protect against hypoxic injury in proximal tubules and that this protection may be mediated by a negative feedback inhibition of PLA_2 activity.[41] This protective effect of unsaturated free fatty acids has been confirmed by Zager et al.[131] The injurious effect of PLA_2 could be related to a direct disruption of cell membrane integrity by attacking the phospholipid component of cell membranes or through the accumulation of lysophospholipids, which have been shown to disrupt cell membranes and cause cytotoxicity.[132]

Activation of Calpain

The cysteine proteases are a group of intracellular proteases that have a cysteine residue at their active site. The cysteine proteases consist of three major groups: cathepsins, calpains, and the newly discovered caspases. The major groups of cysteine proteases are shown in Table 29.4. The cathepsins are non–calcium-dependent lysosomal proteases that do not appear to play a role in lethal cell injury.[133–135] Calpain is a calcium-activated neutral protease (CANP).[136] It has absolute dependence on calcium. There are two major ubiquitous or conventional isoforms of calpain, the low calcium sensitive μ-calpain and the high calcium sensitive m-calpain.[137,138] The isoenzymes have the same substrate specificity but differ in affinity for Ca^{2+}. μ-Calpain is activated by micromolar concentrations of Ca^{2+}, and m-calpain is activated by millimolar concentrations of Ca^{2+}. The millimolar concentrations of intracellular calcium needed for the activation of m-calpain are not seen in normal cells, and phosphatidylinositol is thought to lower the calcium concentration required for half the maximal autolysis of m-calpain.[139] Procalpain exists in the cytoplasm as an inactive proenzyme and becomes active proteolytically only after it has become autolysed at the cell membrane. Activity of the autolysed calpain is subject to a final regulation by calpastatin.[140,141] Calpastatin is a specific endogenous inhibitor of calpain. It is as widely distributed in nature as the enzyme itself. Calcium is required for calpastatin to bind to calpain and thus for the inhibitory effect of calpastatin on calpain.

Postulated functions of calpain include platelet activation and aggregation, cytoskeleton and cell-membrane organization,[142] and the regulation of cell growth.[143–146]

The calcium-dependent calpains have been shown to be mediators of hypoxic/ischemic injury to the brain, liver, and the heart.[147–150] The role of the calcium-dependent cytosolic protease, calpain, in hypoxia-induced renal proximal tubular injury has also been demonstrated.[43] Tubular calpain activity increased significantly by 7.5 minutes of hypoxia, before there was significant LDH release, and further increased during 20 minutes of hypoxia. Chemically dissimilar cysteine protease inhibitors markedly decreased LDH release after 20 minutes of hypoxia and completely prevented the rise in calpain activity during hypoxia. This role of calpain in proximal tubule injury has subsequently been confirmed by other groups.[151,152] This increased calpain activity has subsequently been shown to be associated with a breakdown of the cytoskeletal protein, spectrin, both in vitro[45] and in vivo,[153] as well as increasing Na-K-ATPase into the cytoplasmic fraction of the cell.

Recent studies have demonstrated that calpain mediates progressive plasma membrane permeability and the proteolysis of cytoskeleton-associated paxillin, talin, and vinculin during antimycin A or hypoxia-induced proximal tubular cell death.[154] Novel nonpeptide calpain inhibitors are protective against antimycin A–induced calcium influx and hypoxia/reoxygenation-induced proximal tubular cell death.[155] In novel in vivo studies, calpastatin transgenic mice that had a decreased activation of calpain in the kidney

29.4 The Major Groups of Cysteine Proteases

	Cathepsins	Calpains	Caspases

were generated.[156] In an anti-glomerular basement membrane (GBM) model, calpastatin-transgenic mice had less severe glomerular injury and a reduction in nuclear factor kappa-B (NF-κB) activation, suggesting a role for calpain in inflammation.

Caspases

Caspases are another group of intracellular cysteine proteases. Caspases participate in two distinct signaling pathways: (1) the activation of proinflammatory cytokines and (2) the promotion of apoptotic cell death.[9,157–162] Caspases 3 and 7 are the major mediators of apoptosis. The term "caspase" embodies two properties of these cysteine proteases in which "c" refers to "cysteine" and "aspase" refers to their specific ability to cleave substrates after an aspartate residue. The members of the caspase family are divided into subfamilies based on substrate specificity and function.[163] Caspase-1 (previously known as IL-1–converting enzyme [ICE]) plays a major role in the activation of proinflammatory cytokines. For many years it was not known how caspase-1 was activated. It has recently been discovered that procaspase-1 is activated in a complex called the inflammasome.[164,165] The inflammasome is a protein scaffold that contains NALP (NACHT, LRR, and pyrin domain–containing) proteins, an adaptor protein called ASC (apoptosis-associated specklike protein containing a caspase-recruiting domain [CARD]), procaspase-1, and caspase-5. The interaction of the CARD of procaspase-1 is mediated by the CARD of ASC and the CARD present in the C-terminus of NALP-1. Active caspase-1 in the inflammasome is a regulator of the unconventional protein secretion of leaderless proteins like IL-1α and fibroblast growth factor (FGF)-2.[166] In a recent study, the inflammasome components NLRP3 and ASC were highly expressed in the renal tubular epithelium of humans and mice.[167] The absence of Nlrp3, but not ASC, protected against ischemic AKI.[167] Activation of caspases-1, 8, 9, and 3 have been described in hypoxic renal epithelial cells[168–170] and cerebral ischemia.[171] Although cells contain many caspases, the targeted disruption of specific caspase genes in mice has provided much insight into the functions of individual caspases during cell death.[172]

Although caspases play a crucial and extensively studied role in apoptosis, there is now considerable evidence that the caspase pathway may also be involved in necrotic cell death.[173] The inhibition of caspases protects against necrotic cell death induced by the mitochondrial inhibitor, antimycin A, in PC12 cells, Hep G2 cells, and renal tubules in a culture.[174,175] Caspases are also involved in hypoxic and reperfusion injury in cultured endothelial cells.[176] Rat kidneys subjected to ischemia demonstrate an increase in both caspase-1 and caspase-3 mRNA and protein expression.[177] Caspases play a role in hypoxia-induced necrotic injury of isolated rat renal proximal tubules.[48] In this study, caspase activity was increased in association with cell membrane damage as assessed by LDH release. A specific caspase inhibitor attenuated the increase in caspase activity and markedly protected against cell membrane damage. To specifically identify the caspase involved in proximal tubular injury, proximal tubules were isolated from capsase-1 knockout mice and exposed to hypoxia.[178] Proximal tubules from caspase-1 knockout mice were protected against hypoxic injury, demonstrating the role of caspase-1 in directly causing cell membrane damage in proximal tubules.[178]

A study[179] investigated the role of caspase inhibition and apoptosis in ischemic AKI in mice in vivo. A relationship between apoptosis and subsequent inflammation was found. At the time of reperfusion, administration of the antiapoptotic agents insulin-like growth factor 1 (IGF-1) and ZVAD-fmk (a caspase inactivator) prevented the early onset of not only renal apoptosis, but also inflammation and tissue injury. Conversely, when the antiapoptotic agents were administered after the onset of apoptosis, these protective effects were completely abrogated.

There appears to be an interaction between caspases and calpain during hypoxia-induced injury in the proximal tubule, because caspase inhibition was shown to decrease calpain activity during hypoxia.[48,121] Recent in vivo studies[153] suggest that caspase-mediated degradation of the endogenous inhibitor of calpain, calpastatin, is a mechanism whereby the calcium-mediated activity of calpain is increased.

Caspases in Cold Ischemia

Preservation injury, also known as cold ischemia, is an important clinical problem in kidney transplantation. Significant damage to the kidney may occur during harvest, cold storage, and transport. An ongoing area of interest is identifying methods to reduce organ injury during this process. The primary consequence of cold ischemic injury is delayed graft function (DGF) in kidney transplants.[180–182] These consequences have both short-term and long-term effects. In a kidney transplant, for example, DGF increases patient morbidity in the short term because the hospital stay is longer and dialysis may be required. In the long term, DGF independently predicts reduced 1- and 5-year graft survival.[183]

Both human and animal studies suggest that the adverse impact of cold ischemia may be associated with apoptosis. In human kidney transplant biopsies performed after 1 hour of reperfusion, apoptosis of tubular cells correlated significantly with cold ischemic time.[184] Biopsies of human donor kidneys, which subsequently developed postoperative AKI, demonstrated increased renal tubular epithelial cell apoptosis.[185] Prolonged cold ischemia has also been shown to increase apoptotic cell death in rat kidney allografts at 24 weeks posttransplant.[186] Mitochondria undergo significant changes during ischemia and may contribute to preservation injury.[187]

Caspases have been studied in cold ischemic kidneys.[188] Kidneys were stored for 48 hours at 4°C to produce cold ischemia. Caspase-3 activity was massively increased (100-fold) in cold ischemic kidneys compared to controls. On immunoblot analysis, the processed form of caspase-3

was increased in cold ischemic kidneys compared to controls. The increase in caspase-3 was associated with significantly more renal tubular apoptosis and brush border injury. The pan-caspase inhibitor prevented the formation of the processed form of caspase-3 and the increase in caspase activity, and reduced apoptosis and brush border injury. The results of this study suggest that caspase inhibition may prove useful in kidney preservation.

In a pig model of cold ischemia in which the heart was stopped to mimic donation after cardiac death (DCD), there was a massive increase in apoptosis, caspase-3/7 activity, and caspase-3 protein expression.[189] Apoptosis was compared in DCD kidneys subjected to static versus pulsatile perfusion for 24 hours. Pulsatile perfusion significantly reduced proximal tubular apoptosis and was associated with increased Bcl-2 and hypoxia-inducible transcription factor-1α in the kidney.

The relevance of these studies to organ preservation and the subsequent risk of graft dysfunction is substantial. Caspase inhibitors are a particularly attractive approach to reduce the incidence of DGF in kidney transplantation.

Caspase-1 and IL-18

Caspase-1 is a proinflammatory caspase that cleaves precursor IL-1β and precursor IL-18. Caspase-1-/- mice developed less ischemic AKI as judged by renal function and renal histology (Fig. 29.6A).[190] IL-1β receptor knockout mice or mice treated with IL-1β receptor antagonist (IL-1Ra) are not protected against ischemic AKI.[30] Because caspase-1 also activates IL-18, lack of the mature form of IL-18 in these caspase-1-/- mice was investigated as a possible mechanism of this protection against AKI. Kidney IL-18 was more than 100% increased in wild-type AKI as compared to sham-operated controls. On an immunoblot analysis, there was

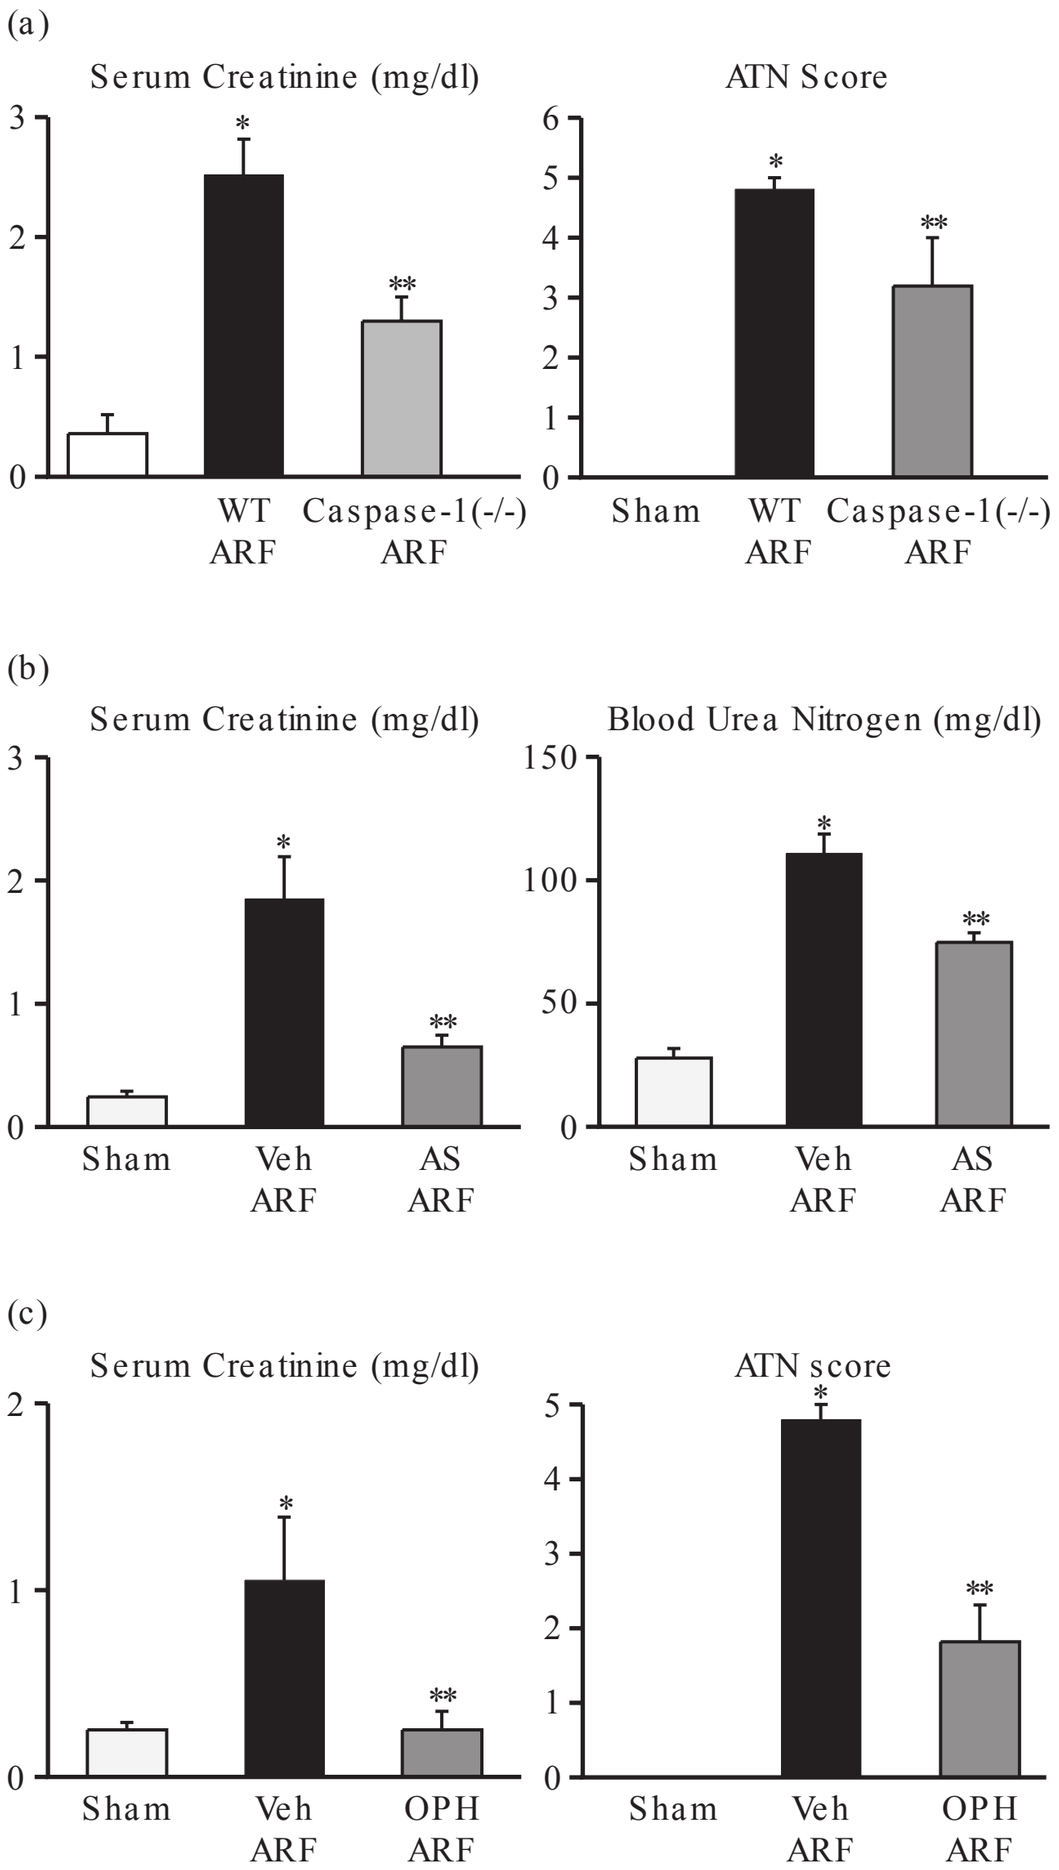

FIGURE 29.6 Caspases and interleukin (IL)-18 in ischemic acute kidney injury (AKI). **A:** Caspase-1-/- mice are protected against ischemic AKI. Caspase-1-/- mice developed less severe AKI, as determined by the serum creatinine and AKI scores compared with wild-type (WT) mice with AKI. * $P < .001$ versus sham; ** $P < .01$ versus WT AKI. **B:** Caspase-1 converts the pro to mature IL-18. Mice treated with IL-18 antiserum (AS) are functionally protected against ischemic AKI. In vehicle-treated mice with ischemic AKI (Veh AKI), serum creatinine and blood urea nitrogen (BUN) levels were significantly increased at 24 hours compared with sham-operated controls. In mice treated with neutralizing IL-18 AS, the serum creatinine and BUN levels were significantly reduced. * $P < .01$ versus sham, ** $P < .01$ versus vehicle-treated mice with Veh AKI. **C:** Mice treated with the pan-caspase inhibitor OPH-001 are protected against ischemic AKI. In vehicle-treated mice with ischemic AKI, the serum creatinine and AKI scores were significantly increased at 24 hours of postischemic reperfusion compared with sham-operated controls. In mice treated with OPH-001 (OPH) before the induction of ischemic AKI, the serum creatinine and AKI scores were significantly decreased compared with sham-operated controls. * $P < .001$ versus sham; ** $P < .01$ versus vehicle-treated mice with Veh AKI; not significant versus sham. a conversion of the precursor to the mature form of IL-18 in AKI wild-type mice, but not in the caspase-1-/- AKI mice and sham-operated controls. To further analyze the role of IL-18, wild-type mice were injected with rabbit antimurine IL-18 neutralizing antiserum prior to the ischemic insult. These mice were protected against AKI to a similar degree as caspase-1-/- mice (Fig. 29.6B).

Caspase-deficient mice have provided extensive information on the role of individual caspases in disease processes. The study of caspase inhibitors is an important step toward the possible therapeutic effect of caspase inhibition in ischemic AKI. Mice with ischemic AKI treated with newly developed caspase inhibitor, Q-VD-(Ome)-OPH (OPH-001) had a marked reduction (100%) in BUN and serum creatinine and a highly significant reduction in the morphologic AKI score compared with vehicle-treated mice (Fig. 29.6C).[191] OPH-001 significantly reduced the increase in caspase-1 activity and IL-18 and prevented neutrophil infiltration in the kidney during ischemic AKI. To further investigate whether this lack of neutrophil infiltration was contributing to the protection against ischemic AKI, a model of neutrophil depletion was developed. Neutrophil-depleted mice had a small (18%) reduction in serum creatinine during ischemic AKI but no reduction in the AKI score despite a lack of neutrophil infiltration in the kidney. Remarkably, caspase-1 activity and IL-18 were still significantly increased in the kidney in neutrophil-depleted mice with AKI. Thus, to investigate the role of IL-18 in ischemic AKI in the absence of neutrophils, neutrophil-depleted mice were treated with an IL-18–neutralizing antiserum. IL-18-antiserum–treated neutrophil-depleted mice with ischemic AKI had a significant reduction (75%) in serum creatinine and a significant reduction in the AKI score compared to vehicle-treated neutrophil-depleted mice. These results suggest a novel neutrophil-independent mechanism of IL-18–mediated ischemic AKI.

In other studies, it was determined whether IL-18–binding protein transgenic (IL-18BP Tg) mice are protected against ischemic AKI.[192] IL-18 function is neutralized in IL-18BP Tg mice. IL-18BP Tg mice with AKI had significantly lower BUN, serum creatinine, and ATN score than wild-type mice. The number of macrophages in the kidney was significantly reduced in IL-18BP Tg compared with wild-type mice. The proinflammatory chemokine, CXCL1 (also known as KC or IL-8), was significantly reduced in the kidneys of IL-18BP Tg mice compared to wild-type mice. This study demonstrates that protection against ischemic AKI in IL-18BP Tg mice is associated with less macrophage infiltration and less production of CXCL1 in the kidney.

The effects of different caspase inhibitors on ischemic AKI in the rat kidney have been studied.[193] A caspase-1 inhibitor significantly reduced functional and histologic evidence of ischemic AKI compared to a caspase-3 inhibitor. Another group of investigators found that caspase-1–deficient mice were not protected against renal ischemia.[194] In this study, the model of renal ischemia was 45 minutes of unilateral renal pedicle clamping with contralateral nephrectomy. This model produces a milder form of functional injury than bilateral clamping. At 24 hours, BUN and creatinine were lower in the caspase-1-/- mice than in the wild-type, but the decrease was not statistically significant.

Matrix Metalloproteinases

Matrix metalloproteinases are a large family of zinc-dependent matrix-degrading enzymes that include interstitial collagenases, stromelysins, gelatinases, elastases, as well as membrane-type matrix metalloproteinases. They play a crucial role in remodeling the extracellular matrix, which is an important physiologic feature of normal growth and development. In the kidney, interstitial sclerosis and glomerulosclerosis have been associated with an imbalance of extracellular matrix synthesis and degradation.[195] Alterations in renal tubular basement membrane matrix proteins, laminin and fibronectin, occur after renal ischemia-reperfusion injury.[196] The role of matrix metalloproteinases in this process has been studied.

In endothelial cells isolated from ischemic kidneys, the proteolytic activity of proMMP-2, proMMP-9, and MMP-9 was increased. Occludin, an in vivo MMP-9 substrate, was partly degraded in the endothelial fractions during ischemia, suggesting that the upregulation of MMP-9 had a functional effect to degrade occluding. These data suggest that AKI leads to the degradation of the vascular basement membrane and to increased permeability related to the increase of MMP-9.[197] In renal cells, in vitro cleavage of cadherins in normal rat kidney (NRK) cells requires active membrane-type (MT)1-MMP (MT1-MMP), also known as MMP-14.[198] The disruption of cadherin/catenin complexes in AKI may be associated with the transtubular back-leak of glomerular filtrate. In contrast to the potential injurious role of some MMPs, MMP9 protects the S3 segment of the proximal tubule and the intercalated cells of the collecting duct from apoptosis in AKI, most likely by releasing soluble stem cell factor (sSCF), an MMP9 substrate.[199]

Meprin A is a zinc-dependent metalloendopeptidase that is present in the brush border membrane of renal proximal tubular epithelial cells. The redistribution of this metalloendopeptidase to the basolateral membrane domain during AKI results in degradation of the extracellular matrix and damage to adjacent peritubular structures. The effect of meprin A, the major matrix degrading metalloproteinase in rat kidney, on the laminin–nidogen complex was examined. Nidogen-1 (entactin) acts as a bridge between the extracellular matrix molecules, laminin-1 and type IV collagen, and thus participates in the assembly of basement membranes. Following ischemic injury, meprin A undergoes redistribution and/or adherence to the tubular basement membrane. Nidogen breakdown products are produced as the result of partial degradation of tubular basement membrane by meprin A following renal tubular ischemia–reperfusion injury.[200]

The susceptibility of inbred strains of mice to ischemic and nephrotoxic acute renal failure was studied in mice with normal and low meprin A activity.[201] The strains of mice with normal meprin A developed more severe renal functional and structural injury following renal ischemia or the injection of hypertonic glycerol compared to the two low meprin A strains. These findings suggest that meprin A plays a role in the pathophysiology of AKI following ischemic and nephrotoxic acute renal failure insults to the kidney.[201] A recent study[202] demonstrated that meprin inhibition protects against ischemic AKI in vivo in rats.

Nitric Oxide

NO is a lipophilic, highly reactive free radical gas with diverse biomessenger functions.[203] NO mediates diverse functions including vasodilatation, platelet aggregation inhibition, neurotransmission, inflammation, antimicrobial and antitumor actions, and apoptosis.[203] Whether the net effects of NO are beneficial or deleterious is determined by the cell type, the concentration of NO, the duration of production, and the composition of the surrounding microenvironment.[203] There are three major nitric oxide synthase (NOS) isoforms in the kidney: neuronal NOS or nNOS (also known as NOS1), inducible NOS (iNOS, also known as NOS2), and endothelial NOS or eNOS (also known as NOS3) (Table 29.5).[204] The macula densa is the principal site of nNOS expression in the kidney.[205,206] In situ hybridization studies in the NRK demonstrate iNOS mRNA in the S3 segment of the proximal tubule, the cortical and medullary thick ascending limb, the distal convoluted tubule, and the cortical collecting duct and the inner medullary collecting duct.[207] eNOS mRNA has been detected in glomeruli, preglomerular vasculature, and proximal and distal tubules.[208] eNOS protein is mainly present in the endothelium of intrarenal, afferent, efferent, and glomerular arterioles and the medullary vas recta.[205] Expression of eNOS protein in tubules has not yet been reported.[204] nNOS and eNOS are continuously present, are activated by calcium, and are also termed constitutive NOS (cNOS).[209,210] In contrast, iNOS is induced when the cells have been stimulated by certain cytokines, microbes, and microbial products, and thus is called iNOS.[211,212] The time course of both calcium-dependent and -independent NOS activity in the rat renal cortex and medulla has been studied.[213] Calcium-dependent NOS activity in the cortex and the medulla decreased in the early phase of AKI and then increased in the recovery phase in the cortex. iNOS activity increased in the early phase of AKI in both the cortex and the medulla and was maintained at higher levels in the medulla. However, in another study, L-arginine improved the deficiency of constitutive NOS activity and improved the recovery phase of ischemic AKI in rats.[214]

Studies in freshly isolated proximal tubules from knockout mice have also revealed the role of NO in hypoxic/ischemic tubular injury. Hypoxia-induced proximal tubule damage, as assessed by LDH release, was no different between wild-type and mice in which eNOS and nNOS had been knocked out. However, proximal tubules from iNOS knockout mice demonstrated resistance to the same degree of hypoxia.[42] The iNOS knockout mice also had less renal failure and better survival than the wild-type mice after renal artery clamping.[215] An induction of heat shock protein was also observed in the iNOS knockout mice as a potential con-

29.5 Nitric Oxide Synthase (NOS) Isoforms

	Tissue Distribution		
Isoform	**Body**	**Renal**	**Phenotype of Knockout Mouse**
nNOS (Type 1)	Neurons, skeletal muscle, penis	Macula densa	Protection against cerebral ischemia[478,479]
iNOS (Type 2)	Constitutive: ileum, uterus, skeletal muscle. Induced: macrophage, VSMC	Constitutive: mTAL, proximal tubule	Less hypotensive response to LPS[480] Increased mortality in polymicrobial sepsis[481] No protection against LPS-induced AKI[375] Protection against ischemic AKI[215]
eNOS (Type 3)	Endothelium	Glomerular vessels, intrarenal arteries	Hypertension[482] Increased susceptibility to stroke[483] and myocardial ischemia[484]

nNOS, neuronal nitric oxide synthase; iNOS, inducible nitric oxide synthase; eNOS, endothelial nitric oxide synthase; VSMC, vascular smooth muscle cell; mTAL, medullary thick ascending limb; LPS, lipopolysaccharide; AKI, acute kidney injury.

tributor to the protection. Chiao et al.[216] produced further results in a renal artery clamp model in mice in which alpha melanocyte-stimulating hormone (αMSH) was shown to block the induction of iNOS, decrease neutrophil infiltration, and afford functional protection. A subsequent study examined the relative importance of αMSH on the neutrophil pathway by examining the effects of αMSH in ICAM-1 knockout mice and neutrophil-poor isolated perfused kidneys where neutrophil effects are minimal or absent.[217,218] In this study, it was found that αMSH decreases renal injury when neutrophil effects are minimal or absent, indicating that αMSH inhibits neutrophil-independent pathways of renal injury.

Hypoxia was found to increase NO release from freshly isolated proximal tubules and this effect was blocked by L-NAME, a nonspecific NOS inhibitor, but not by the inactive D-NAME compound.[39,219] The NO release during hypoxia was accompanied by LDH release and was reversed by L-NAME administration. Interestingly, however, the administration of L-NAME, the nonspecific NOS inhibitor, to the rat kidney clamp model actually worsened the renal failure.[220] This result was interpreted as an overriding blocking effect of eNOS activity with the nonspecific effects of L-NAME.[68] This would worsen the renal vasoconstriction and the resultant injury, thus obscuring any salutary effect at the level of the proximal tubule.[221] Thus, opposing abnormalities in NO production within the endothelial and tubular compartments of the kidney may contribute to renal injury.[68] Reduced eNOS-derived NO production causes vasoconstriction and worsens ischemia; increased iNOS-derived NO production by tubular cells adds to the injurious effects of ischemia on these cells. Therapeutic interventions to modulate NO production in ischemic AKI may require the selective modulation of different NOS isoforms in the tubular and vascular compartments of the kidney.[222] On this background, Noiri and colleagues[220] performed studies using a specific antisense oligonucleotide to iNOS. The ischemia-induced upregulation of iNOS and nitrite production were both blocked by the antisense oligonucleotide. Most importantly, the BUN and serum creatinine did not rise after the renal ischemic insult in the animals treated with the antisense oligonucleotide against iNOS.

Noiri and colleagues also studied the relationship between NO and osteopontin during ischemic AKI. Osteopontin is a negatively charged glycosylated phosphoprotein that is expressed in many tissues, including the renal epithelial cells. Osteopontin serves both a cell attachment function and a cell signaling function via the alpha-v beta-3 integrin. Effects on gene expression include suppression of the induction of NOS by inflammatory mediators. Osteopontin may play an important role in the pathophysiology of AKI. Osteopontin knockout mice subjected to renal ischemia developed worse renal failure and more structural damage than wild-type controls.[223] This was associated with the augmented expression of inducible NOS and the prevalence of nitrotyrosine residues in kidneys from osteopontin knockout mice versus wild-type counterparts. This study[220] provides strong evidence of the renoprotective action of osteopontin in acute renal ischemia.

The protective effect of 17 β-estradiol against ischemic AKI in rats is due to the activation of the PI3K/Akt pathway followed by increased eNOS phosphorylation.[224]

The microvillar actin and cellular integrins are potential substrates of NO action, which could contribute to the ischemia-mediated sloughing of the brush border membrane and the detachment of the proximal tubule epithelial cells from their extracellular matrix.[11,225–227] Such an effect would not only result in impaired tubular sodium reabsorption, but would also provide intraluminal cellular debris as a component of tubular cast formation.

Heat Shock Proteins

The stress response is a highly conserved homeostatic mechanism that allows cells to survive a variety of different stresses.[228] Stresses that trigger the heat shock response include hyperthermia, hypothermia, the generation of oxygen radicals, hypoxia/ischemia, and toxins.[229] On a molecular level, their function is to protect cells from environmental stress damage by binding to partially denatured proteins, dissociating protein aggregates, regulating the correct folding, and cooperating in transporting newly synthesized polypeptides to the target organelles.

The proteins induced by these stresses belong to a family of proteins called heat shock proteins (HSP). The proteins are identified by their molecular weight. The most important families include proteins of 90, 70, 60, and 27 kDa.[229] HSP 90 is essential for cell viability. It is associated with the steroid hormone receptor and is a general chaperone with ATPaselike activity. In stressed cells, it associates with the cytoskeletal protein, actin. The HSP 70 family includes proteins that are both constitutively expressed and induced by stress. They are the most highly induced proteins by stress and function as chaperones, binding to unfolded or misfolded proteins. The HSP family is restricted to the mitochondrial matrix where it functions as an unfoldase. The HSP 27 family has functions similar to HSP 70. Ubiquitin is a stress protein that binds denatured proteins and targets them for proteolysis by the proteasome.

Renal ischemia results in both a profound fall in cellular ATP and a rapid induction of the 70 kD heat shock protein family, HSP-70.[230,231] The relationship between cellular ATP and the induction of the stress response in the renal cortex during renal ischemia has been studied. Van Why et al.[232] demonstrated that a 50% reduction in cellular ATP in the renal cortex must occur before the stress response is detectable, that a reduction of ATP below 25% of control levels produces a more vigorous response, and that reperfusion is not required for the initiation of a heat shock response in the kidney.[232]

Ischemic AKI also induces differential expression of small HSPs. In sham-operated kidneys, HSP 25 localized to glomeruli, vessels, and collecting ducts, whereas another

stress protein, αB-crystallin, localized primarily in medullary thin limbs and collecting ducts. After ischemia, HSP 25 accumulated in proximal tubules in the cortex and the outer medulla, whereas αB-crystallin labeling became nonhomogeneous in the outer medulla, and increased in the Bowman capsule. This study demonstrates that there is striking differential expression of HSP 25 and αB-crystallin in various renal compartments.[233]

In vitro studies have demonstrated that HSP induction protects cultured renal epithelial cells from injury. It has been determined that prior heat stress protects opossum kidney (OK) cells, a cultured renal epithelial cell line, from injury mediated by ATP depletion.[234] Also, HSP 70 overexpression is sufficient to protect cultured proximal tubule (LLC-PK1) cells from hyperthermia but is not sufficient to protect against hypoxia.[235]

During ischemic AKI, the question of whether prior HSP induction by hyperthermia is protective is controversial. One study[236] found that prior heat shock protected kidneys against warm ischemia. Another study[237] investigated the protective effect of heat shock proteins on ischemic injury to renal cells in two different experimental models: ischemia-reflow in intact rats and medullary hypoxic injury as seen in the isolated perfused rat kidney. The prior induction of HSP by hyperthermia was not protective against the functional and morphologic parameters of ischemic AKI in either of these models.[237] These variable results may be explained by the complexity of the intact animal compared to cultured cells; the degree, duration, and timing of the hyperthermic stimulus; and the differential response of mature and immature kidneys.[24,238]

Pharmacologic agents have been used to increase stress protein expression. In a recent study, the induction of HSP 70, a potent antiapoptotic agent, inhibited ischemic renal injury in mice.[239] Recently, inhibitors of the proteasome have been identified that can block the rapid degradation of abnormal cytosolic and ER-associated proteins. The hypothesis that proteasome inhibitors, by causing the accumulation of abnormal proteins, might stimulate the expression of cytosolic heat shock proteins and/or ER molecular chaperones and thereby induce thermotolerance was tested in Madin-Darby canine kidney cell cultures.[240] The inhibition of proteasome function induced heat shock proteins and ER chaperones and conferred thermotolerance in these cells. Thus, these agents may have applications in protecting against cell injury.[240] Another study[241] determined that proteasome inhibition protects against the morphologic and functional abnormalities in ischemic AKI in rats.[241] However, the effect of proteasome inhibition on HSP induction during ischemic AKI was not determined in this study.

The mechanism of HSP protection against ischemic AKI is interesting. It has been suggested that HSPs participate in the postischemic restructuring of the cytoskeleton of proximal tubules.[242] It was found that HSP 72 complexes with aggregated cellular proteins in an ATP-dependent manner, suggesting that enhancing the HSP 72 function after an ischemic renal injury assists refolding and stabilization of Na(+)-K(+)-ATPase or aggregated elements of the cytoskeleton, allowing reassembly into a more organized state.[243] Another study examined the temporal and spatial patterns of HSP 25 induction in relation to the actin cytoskeleton.[244] This study suggested that there are specific interactions between HSP 25 and actin during the early postischemic reorganization of the cytoskeleton. In another study,[245] the Brown Norway rat was resistant to renal failure and AKI compared to the Sprague-Dawley rat. The Brown Norway rat had no distribution of Na-K-ATPase into detergent soluble cortical extracts, and the immunohistochemistry showed that baseline HSP 72 and 25 expression was increased in proximal tubules of the Brown Norway rats compared to the Sprague-Dawley rats.

Another potential mechanism of HSP protection against proximal tubular injury is the inhibition of apoptosis. OK proximal tubule cells exposed to ATP depletion develop apoptosis by morphologic and biochemical criteria. Prior heat stress reduced the number of apoptotic-appearing cells, significantly decreased DNA fragmentation, and improved cell survival compared with controls.[246] This study demonstrated that novel interactions between HSP 72 and the antiapoptotic protein Bcl2 may be responsible, at least in part, for the protection afforded by prior heat stress against ATP depletion injury.

Altered Gene Expression

During renal ischemia in vivo, the reaction of the renal epithelial cells is heterogeneous.[247] Some cells, especially those of the proximal tubule, undergo necrosis. Other cells undergo apoptosis, and still others survive the ischemic injury intact. In addition, injured tubules are relined with new cells actively engaged in DNA repair and synthesis. Thus, surviving tubular cells can reenter the cell cycle and replicate. These cells may undergo partial dedifferentiation that allows them to undergo mitosis.[248] The complex events that mediate this heterogeneous response of tubular cells are being studied. This response of tubular cells may involve the early immediate gene response.

Immediate early genes and proto-oncogenes are induced during the early reperfusion period after renal ischemia.[249] There is c-Fos and c-Jun activation as well as an increase in DNA synthesis.[250] There is an accumulation of early growth response factor 1 (Egr-1) and c-Fos mRNAs in the mouse kidney after occlusion of the renal artery and reperfusion.[251,252] Transient expression of the genes c-Fos and Egr-1 may code for DNA binding transcription factors and initiate the transcription of other genes necessary for cell division.[253] JE and KC, growth-factor–responsive genes with cytokinelike properties that play a role in inflammation, are also expressed during early renal ischemia.[254] These genes may code for proteins with chemotactic effects that can attract monocytes and neutrophils into areas of injury.[252] Studies demonstrate that c-Fos and c-Jun are expressed following renal ischemia as a typical immediate

early gene response, but they are expressed in cells that do not enter the cell cycle.[248,255] The failure of the cells to enter the cell cycle may depend on the coexpression of other genes.

DNA synthesis occurs in the proximal tubule, whereas the induction of the early gene response is restricted to cells of the thick ascending limb and collecting duct.[252] Thus, the immediate early gene response does not always occur in cells that undergo DNA synthesis, suggesting that the role of the early gene response is not necessarily proliferative in this setting. The role of the stress response during renal ischemia and the fate of the cells undergoing it are unknown. This immediate early gene response may play a role in the protection of tubular cells against injury. Alternatively, it may be important in mounting a response that will later help the regeneration of other tubular cells because the products of some of these genes are localized to cells that do not undergo cell death from apoptosis or necrosis.[256] The immediate early gene response may be the response to sublethal injury, allowing the cell to dedifferentiate.[253]

The pathways that lead to the early gene response are interesting. At least two quite different pathways lead to the activation of c-Jun.[257–259] Growth factors activate c-Jun via the mitogen-activated protein kinases (MAPKs), which include extracellular-regulated kinases (ERKs) 1 and 2. This pathway is proliferative in nature. In contrast, the stress-activated protein kinase (SAPK) pathway is separate from the MAPK pathway. These kinases include c-Jun N-terminal kinase (JNK) 1 and 2. Activation and the effect on cell fate of the SAPK pathway is very different from the MAPK pathway. The SAPK pathway is essentially antiproliferative and can lead to either cell survival or cell death. During renal ischemia, SAPKs are activated, and the inhibition of SAPK after ischemia protects against renal failure.[260,261] Thus, it is possible that manipulation of this pathway could lead to therapies that may ameliorate AKI.

Numerous recent studies have analyzed gene expression during ischemic AKI. Cell communication, apoptosis, and inflammation genes distinguish primary allograft function in human kidney transplantation.[262] In renal ischemia–reperfusion in mice, there was an increase in genes involved in cell structure, extracellular matrix, intracellular calcium binding, and cell division/differentiation.[263] In another study in mice, there were consistent patterns of altered gene expression in the first 24 hours of postischemic reperfusion.[264] These genes included transcription factors, growth factors, signal transduction molecules, and apoptotic factors. In ischemia–reperfusion in the rat, alterations in the expression of 18 genes were identified by microarray analysis.[265] Nine genes were upregulated (ADAM2, HO-1, UCP-2, and thymosin β4 in the early phase, and clusterin, vanin1, fibronectin, heat-responsive protein 12, and FK506-binding protein in the established phase). Nine genes were downregulated (glutamine synthetase, cytochrome p450 IId6, and cyp 2d9 in the early phase, and cyp 4a14, Xist gene, peroxisome proliferator-activated receptor gamma (PPARγ), α-albumin, uromodulin, and ADH B2 in the established phase). Changes in the gene expression of ADAM2, cyp2d6, fibronectin, HO-1, and PPARγ were confirmed by quantitative real-time polymerase chain reaction (PCR). One of the problems with microarray analysis in the whole kidney during ischemic AKI in vivo is identifying which of the numerous cell types in the kidney is the source of the gene alteration. Laser capture microdissection of immunofluorescently defined cells (IF-LCM) can isolate pure populations of targeted cells from a sea of surrounding cells with excellent preservation of mRNA.[266] This technique has been used to label and isolate thick ascending limb cells in the kidney for mRNA analysis.[266]

In ischemic AKI in mice, 24,600 genes were tested by transcriptional analysis.[267] At days 3, 10, and 28 after ischemic AKI, 242, 146, and 46 genes were upregulated, respectively, and 85, 35, and zero genes were downregulated, respectively. Gene expression changes were primarily related to immune and inflammatory pathways both early and late after AKI. The most highly upregulated genes late after AKI were hepatitis A virus cellular receptor 1 (Havcr1) and lipocalin 2 (Lcn2), which code for KIM-1 and NGAL, respectively.

The PPARs are a group of nuclear receptor proteins that function as transcription factors regulating the expression of genes. PPARs play crucial roles in the regulation of cellular differentiation, development, and metabolism and tumorigenesis. Increased expression of PPARα[268] or PPARβ/δ[269] protects aginst ischemic AKI. Maintenance of free fatty acid oxidation in the proximal tubule may be the mechanism of the protection against ischemic AKI.[270]

Apoptosis

Apoptosis was first described by Kerr et al.[271] The term comes from the ancient Greek word that means "the dropping off as of leaves from a tree." The term stresses the facts that apoptosis is a physiologic form of cell death, occurs in the individual cell (or leaf) in a programmed pattern, and can be triggered according to a program regulated by external stimuli (autumn).[7] Thus, apoptosis is the name given to the process of physiologic or programmed cell death. Apoptotic cells undergo a series of morphologically identifiable changes in their pathway to cell death.[272] The morphologic, biochemical, and molecular characteristics of apoptosis versus necrosis are very different (Table 29.6). Autophagy has been proposed as a third mode of cell death.[273] Autophagy is a process in which cells generate energy and metabolites by digesting their own organelles and macromolecules. Autophagy permits a starving cell, or a cell that is deprived of growth factors, to survive. There are differences in the mode of death and different morphologic, biochemical, and molecular attributes between apoptosis, necrosis, and autophagy.[273]

The triggers of apoptosis include (1) cell injury (e.g., ischemia, hypoxia, oxidant injury, nitric oxide, cisplatin); (2) loss of survival factors (e.g., deficiency of renal growth factors, impaired cell-to-cell or cell-to-matrix adhesion);

29.6 Morphologic, Biochemical, and Molecular Differences Between Apoptosis and Necrosis

Apoptosis	Necrosis
Individual cells shrink and detach from other cells	Multiple cells swell but remain attached
Plasma membranes remain intact	Plasma membrane disruption
Cell excludes DNA-specific dye, propidium iodide	Propidium iodide enters cell and stains nucleus
Nuclear condensation, fragmentation, and pyknosis	Nuclear swelling and autolysis
Apoptotic bodies	No apoptotic bodies
Nuclear DNA fragmentation	Nuclear DNA fragmentation
Programmed by gene activation	No gene activation
Phagocytosis of cellular fragments	Cellular lysis
No inflammation	Inflammation

Autophagy has been proposed as a third mode of cell death.[273] Autophagy is a process in which cells generate energy and metabolites by digesting their own organelles and macromolecules, permitting a starving cell or a cell that is deprived of growth factors to survive.

and (3) receptor-mediated apoptosis (e.g., Fas [CD 95] and transforming growth factor [TGF]β).[274]

The two major pathways of apoptosis involve Fas and p53.[9,10,275] In the tumor necrosis factor (TNF) receptor superfamily, Fas antigen (CD 295) is the most important factor. Engagement of Fas by its ligand (FasL) results in apoptosis. The tumor suppressor gene, p53, mediates apoptosis in cells in which the DNA has been damaged. The cascades involving Fas and p53, which are centrally important in cell death, are shown in Figure 29.7.

Caspases are the major mediators of the cell death in apoptosis and also play a role in necrotic cell death. The central role of caspases in cell death is supported by caspase-8, 9, and 3 knockout mice that have strong phenotypes based on apoptotic cell death defects, developmental defects, and usually fetal/perinatal mortality.[162] Caspase-7, like caspase-3, is an executioner caspase and is downstream of the initiators, caspase-8 and 9. Both the intrinsic and extrinsic pathways activate caspase-7. Caspase-3 and 7 exhibit very similar substrate specificities in peptide hydrolysis assays in vitro.[276] However, the role of caspase-7 during the execution phase of apoptosis is obscure.[277] Caspase-7 is unable to cleave the well-known caspase-3 substrates including fodrin, gelsolin, DNA fragmentation factor 45 (DFF45), inhibitor of apoptosis proteins (IAP), and signal transducer and activator of transcription 1 (STAT-1).[277] Also, caspase-7 is unable to activate caspases that would normally be activated by caspase-3.[278] It is known that caspase-3 and 7 can act independently as executioners of apoptosis. Both caspase-3 and caspase-7 deficient mice are perinatally lethal due to a lack of apoptosis.[279] Caspase-7 may play a more specialized role in apoptosis than caspase-3.[277] Both caspase-3 and 7 are critical mediators of mitochondrial events of apoptosis.[280] Caspases have been described in detail earlier in this chapter.

Caspase-dependent or independent endogenous endonuclease activation, resulting in DNA fragmentation, is considered a characteristic biochemical marker for apoptosis.[49] However, DNA fragmentation also occurs in cellular necrosis.[49,281,282] The differentiation of apoptosis from necrosis in tubular cells, therefore, is still difficult[283] and requires both the demonstration of DNA fragmentation, usually using a histochemical technique based on terminal deoxynucleotidyl transferase (TdT) reactivity with DNA breaks, as well as morphologic evidence of apoptosis by light and electron microscopy. Pathways usually associated with apoptosis (e.g., endonuclease activation, increased mitochondrial permeability) may also be associated with necrosis, suggesting that apoptotic and necrotic cell death may share the same pathways.[284] Both apoptosis and necrosis can occur in tissues exposed to ischemia–reperfusion or cultured cells exposed to hypoxia.[285]

The number of in vitro and in vivo studies where apoptosis is described in renal tubules is increasing. These studies are summarized in Tables 29.7 and 29.8. A feature of in vitro prolonged ATP depletion leads to necrosis, whereas milder and shorter ATP depletion leads to apoptotic cell death. A similar pattern has emerged from the in vivo studies (Table 29.8) (i.e., the same insult in a mild form can lead to apoptosis and, when severe, can lead to necrosis).

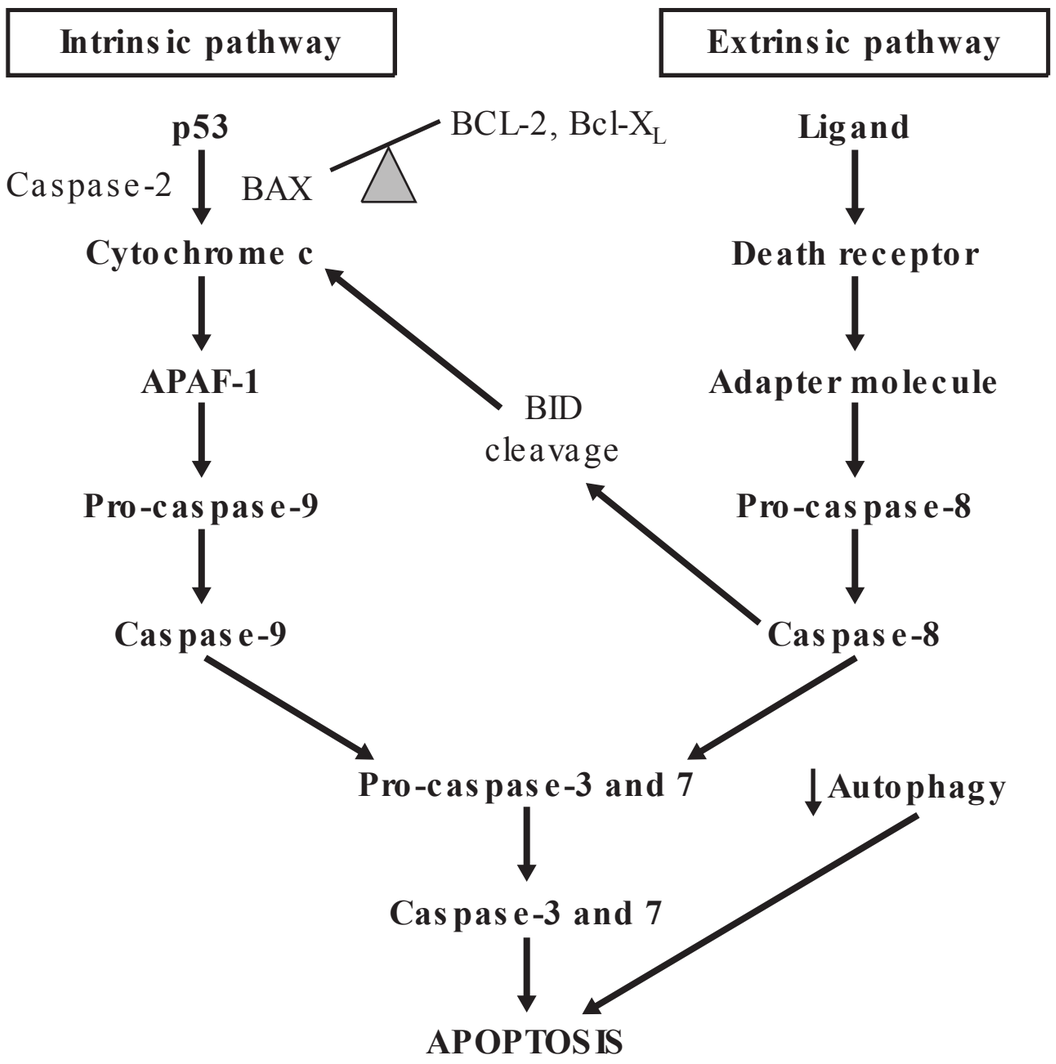

FIGURE 29.7 The major pathways of apoptosis. There are two major pathways of caspase-mediated apoptosis.[461] In the mitochondrial or intrinsic pathway, stress-induced signals (e.g., p53) act via Bcl-2 proteins to cause cytochrome c release from mitochondria. In the intrinsic pathway, there is the binding of a ligand (e.g., Fas ligand) to its death receptor (e.g., Fas) that recruits an adaptor protein. In the intrinsic pathway, the death receptors are a subset of the tumor necrosis factor (TNF) receptor family of cell surface molecules. Cytochrome c binds to a protein called apoptotic protease activating factor-1 (APAF-1). This binding allows APAF-1 to activate caspase-9, an initiator caspase, which then activates caspase-3 and -7. The presence of an excess of the antiapoptotic protein Bcl-2 on mitochondria inhibits cytochrome c release. Caspase-2 is a recently discovered caspase that is a critical initiator of the mitochondrial apoptosis pathway.[463] The activation and increased activity of caspase-2 is required for the permeabilization of mitochondria and the release of cytochrome c.[463] In the extrinsic pathway, the death receptors (CD95/Fas/APO-1, TNFR1, DR3/WSL-1/TRAMP, DR4/TRAIL-R1, DR5/TRAIL-R2, and DR6) are a subset of the TNF/NGF receptor family of cell surface molecules that possess a common motif within their cytoplasmic tails, called the death domain. The death domains of these receptors recruit adapter molecules that, in turn, recruit caspases to the receptor complex. For example, Fas antigen (CD 95) is engaged by its ligand (FasL) resulting in apoptosis. The activation of procaspase-8 requires association with its cofactor Fas-associated death domain (FADD). The pathways may be linked because caspase-8 may cleave a member of the Bcl-2 family, BH3-interacting domain death agonist (BID), which can release cytochrome c. Apoptosis mediated by both pathways has been described during renal ischemia–reperfusion in rats.[464,465] Both caspase-3 and -7 play a crucial and extensively studied role in the promotion of all forms of apoptotic cell death.[160] Caspase-7, like caspase-3, is an executioner caspase and is downstream of the initiators caspase-8 and -9. In general, cells may be more sensitive to apoptosis if autophagy is inhibited.[273] Bax, Bcl-2-associated X protein.

Numerous recent studies have demonstrated that erythropoietin (EPO) protects against ischemic AKI by affecting apoptotic cell death.[286–288] A single dose of EPO either pre-ischemia or just before reperfusion improves renal function and tubular injury; prevents the activation of caspase-3, 8, and 9; and reduces apoptotic tubular cell death.[286] EPO also protects against hypoxia-induced apoptosis in human proximal tubule cells.[287] In the same study, EPO functionally protected against ischemic AKI in rats in vivo and reduced outer medullary thick ascending limb apoptosis while potentiating tubular mitosis and proliferation.[287] In another study in rats with ischemic AKI, EPO decreased serum creatinine, decreased tubular apoptosis and necrosis, decreased tubular cell proliferation, increased antiapoptotic Bcl-2 protein expression, decreased caspase-3 activity, and increased heat shock protein 70 (HSP70) expression.[288] In a model of endotoxemia-induced AKI in mice, EPO significantly decreased renal superoxide dismutase and attenuated the renal dysfunction as assessed by inulin-GFR.[289] EPO receptors are expressed on mesenchymal stem cells (MSCs).[290] EPO results in an expansion of MSCs in bone marrow and the spleen that may mediate protection against ischemic AKI.[290] Thus, EPO may be a potential new therapy for AKI in humans.

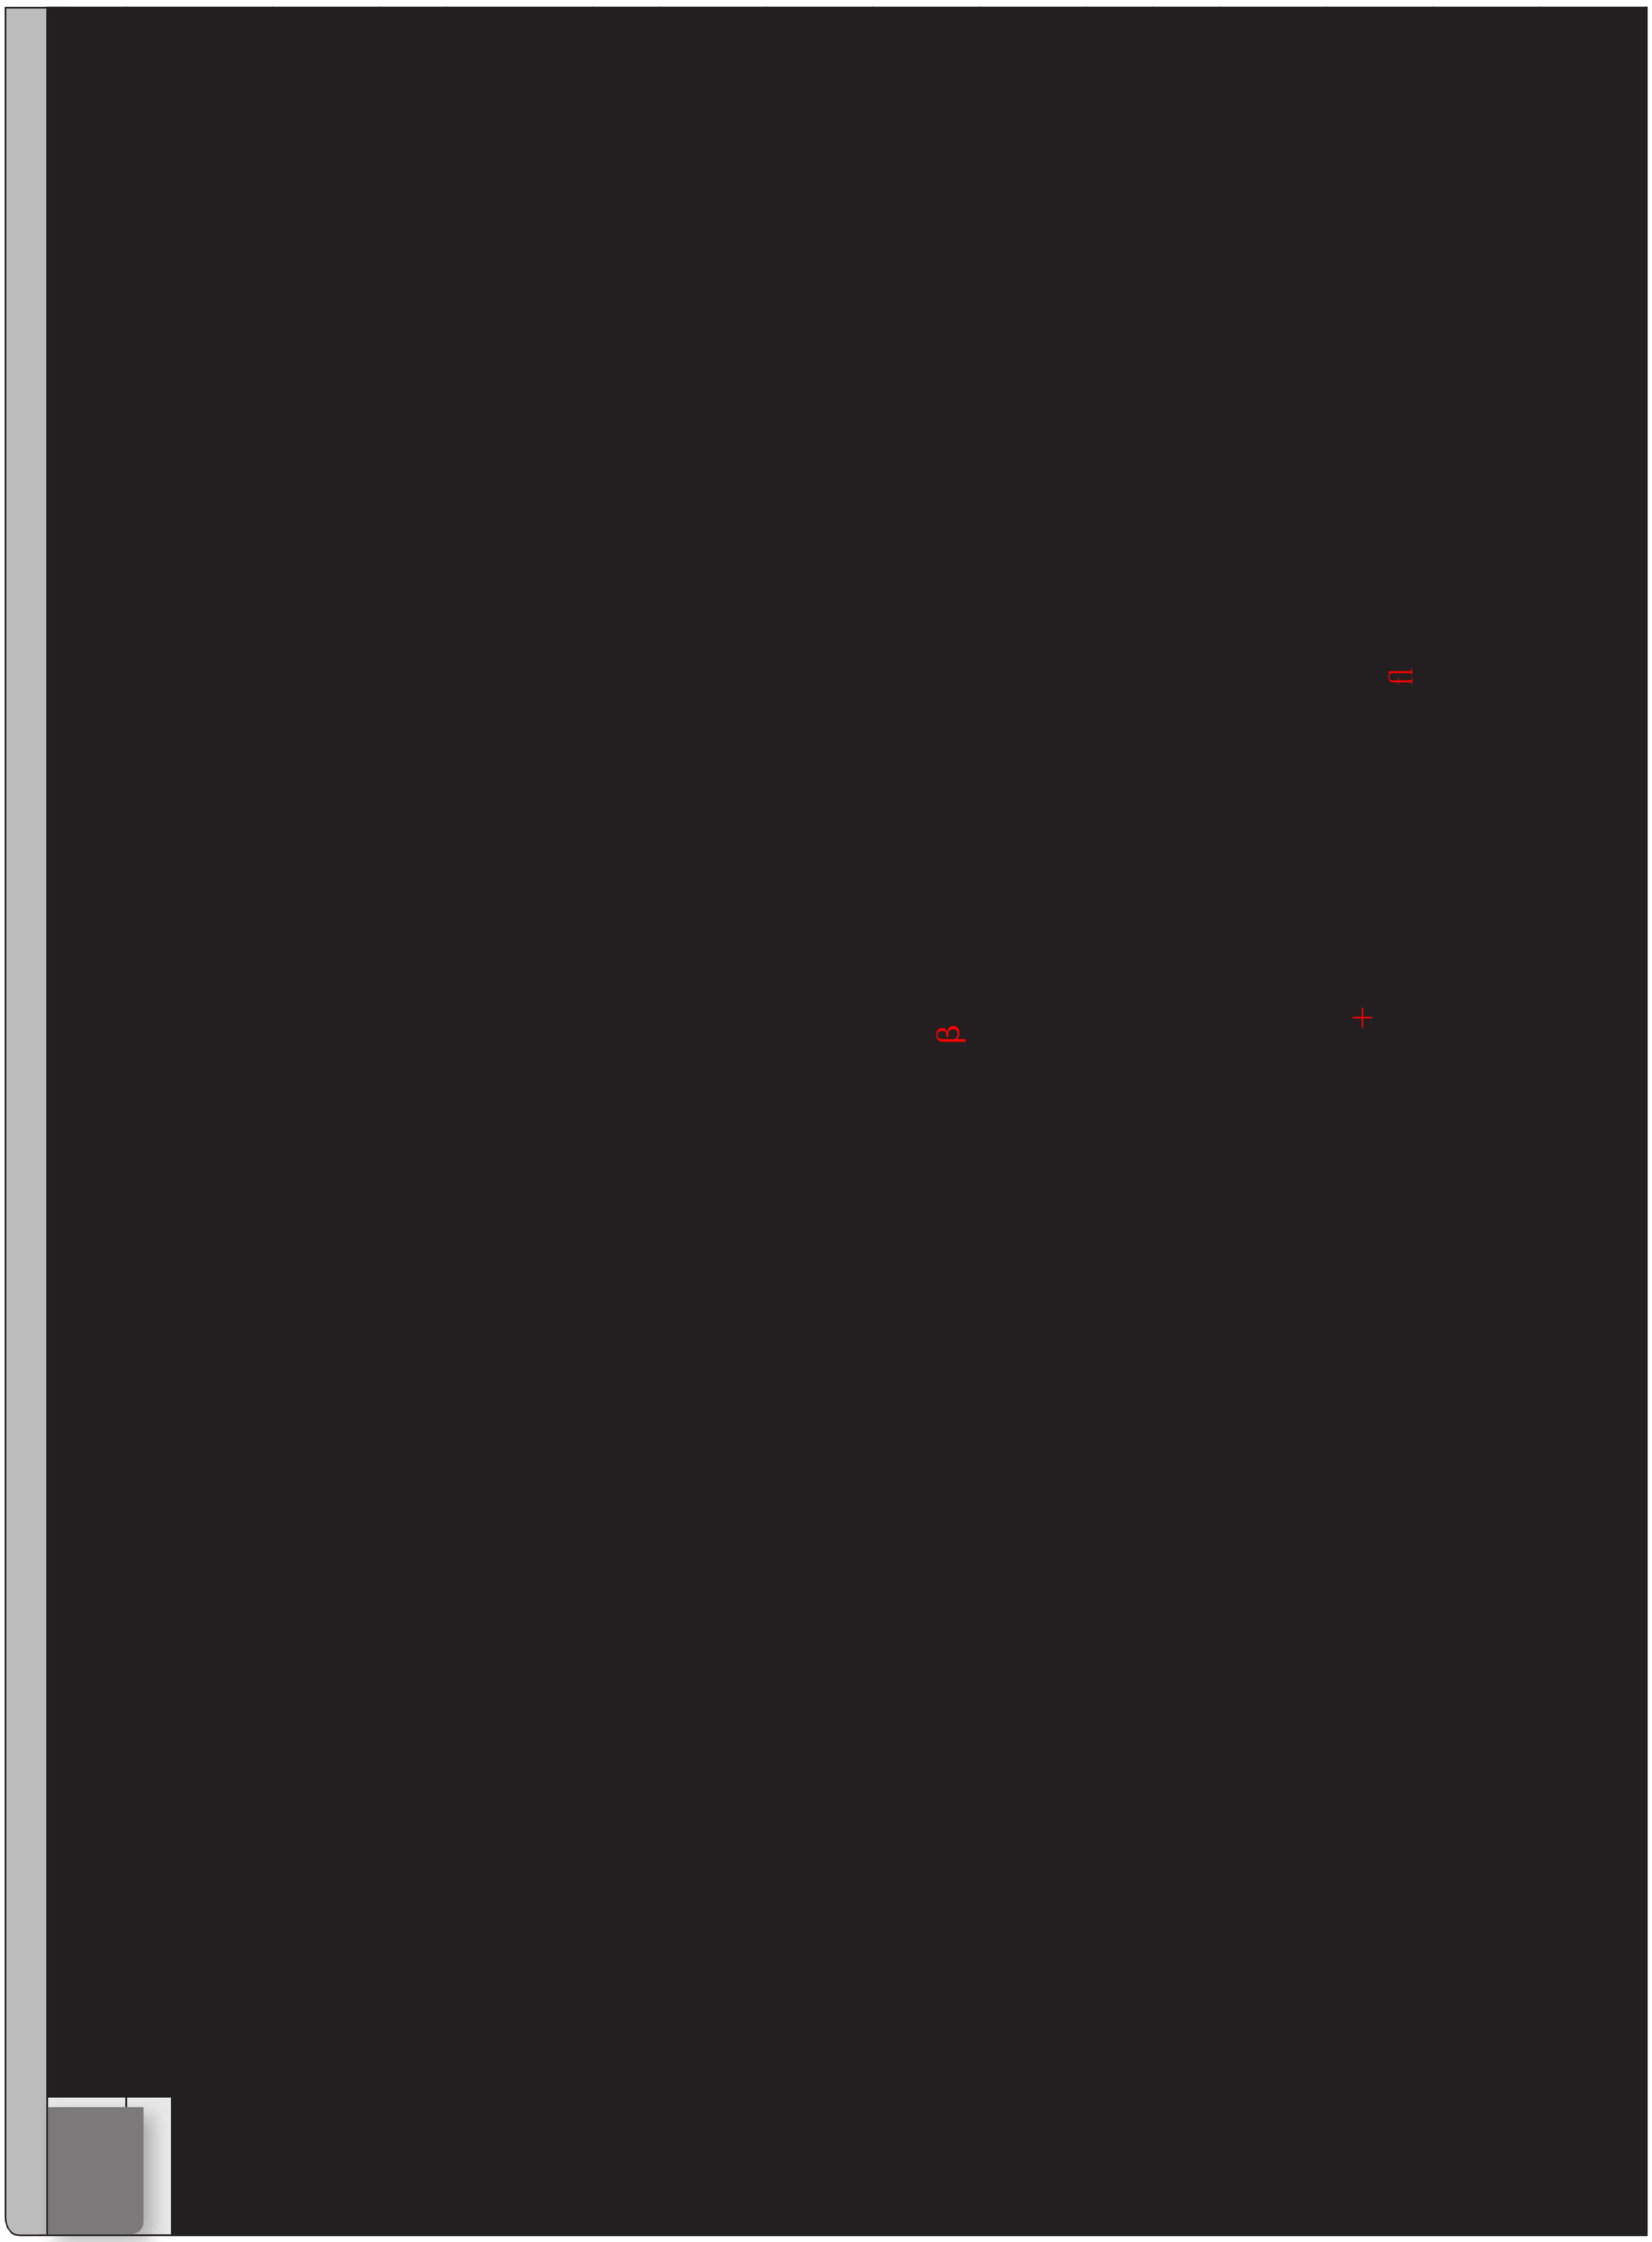
Complement

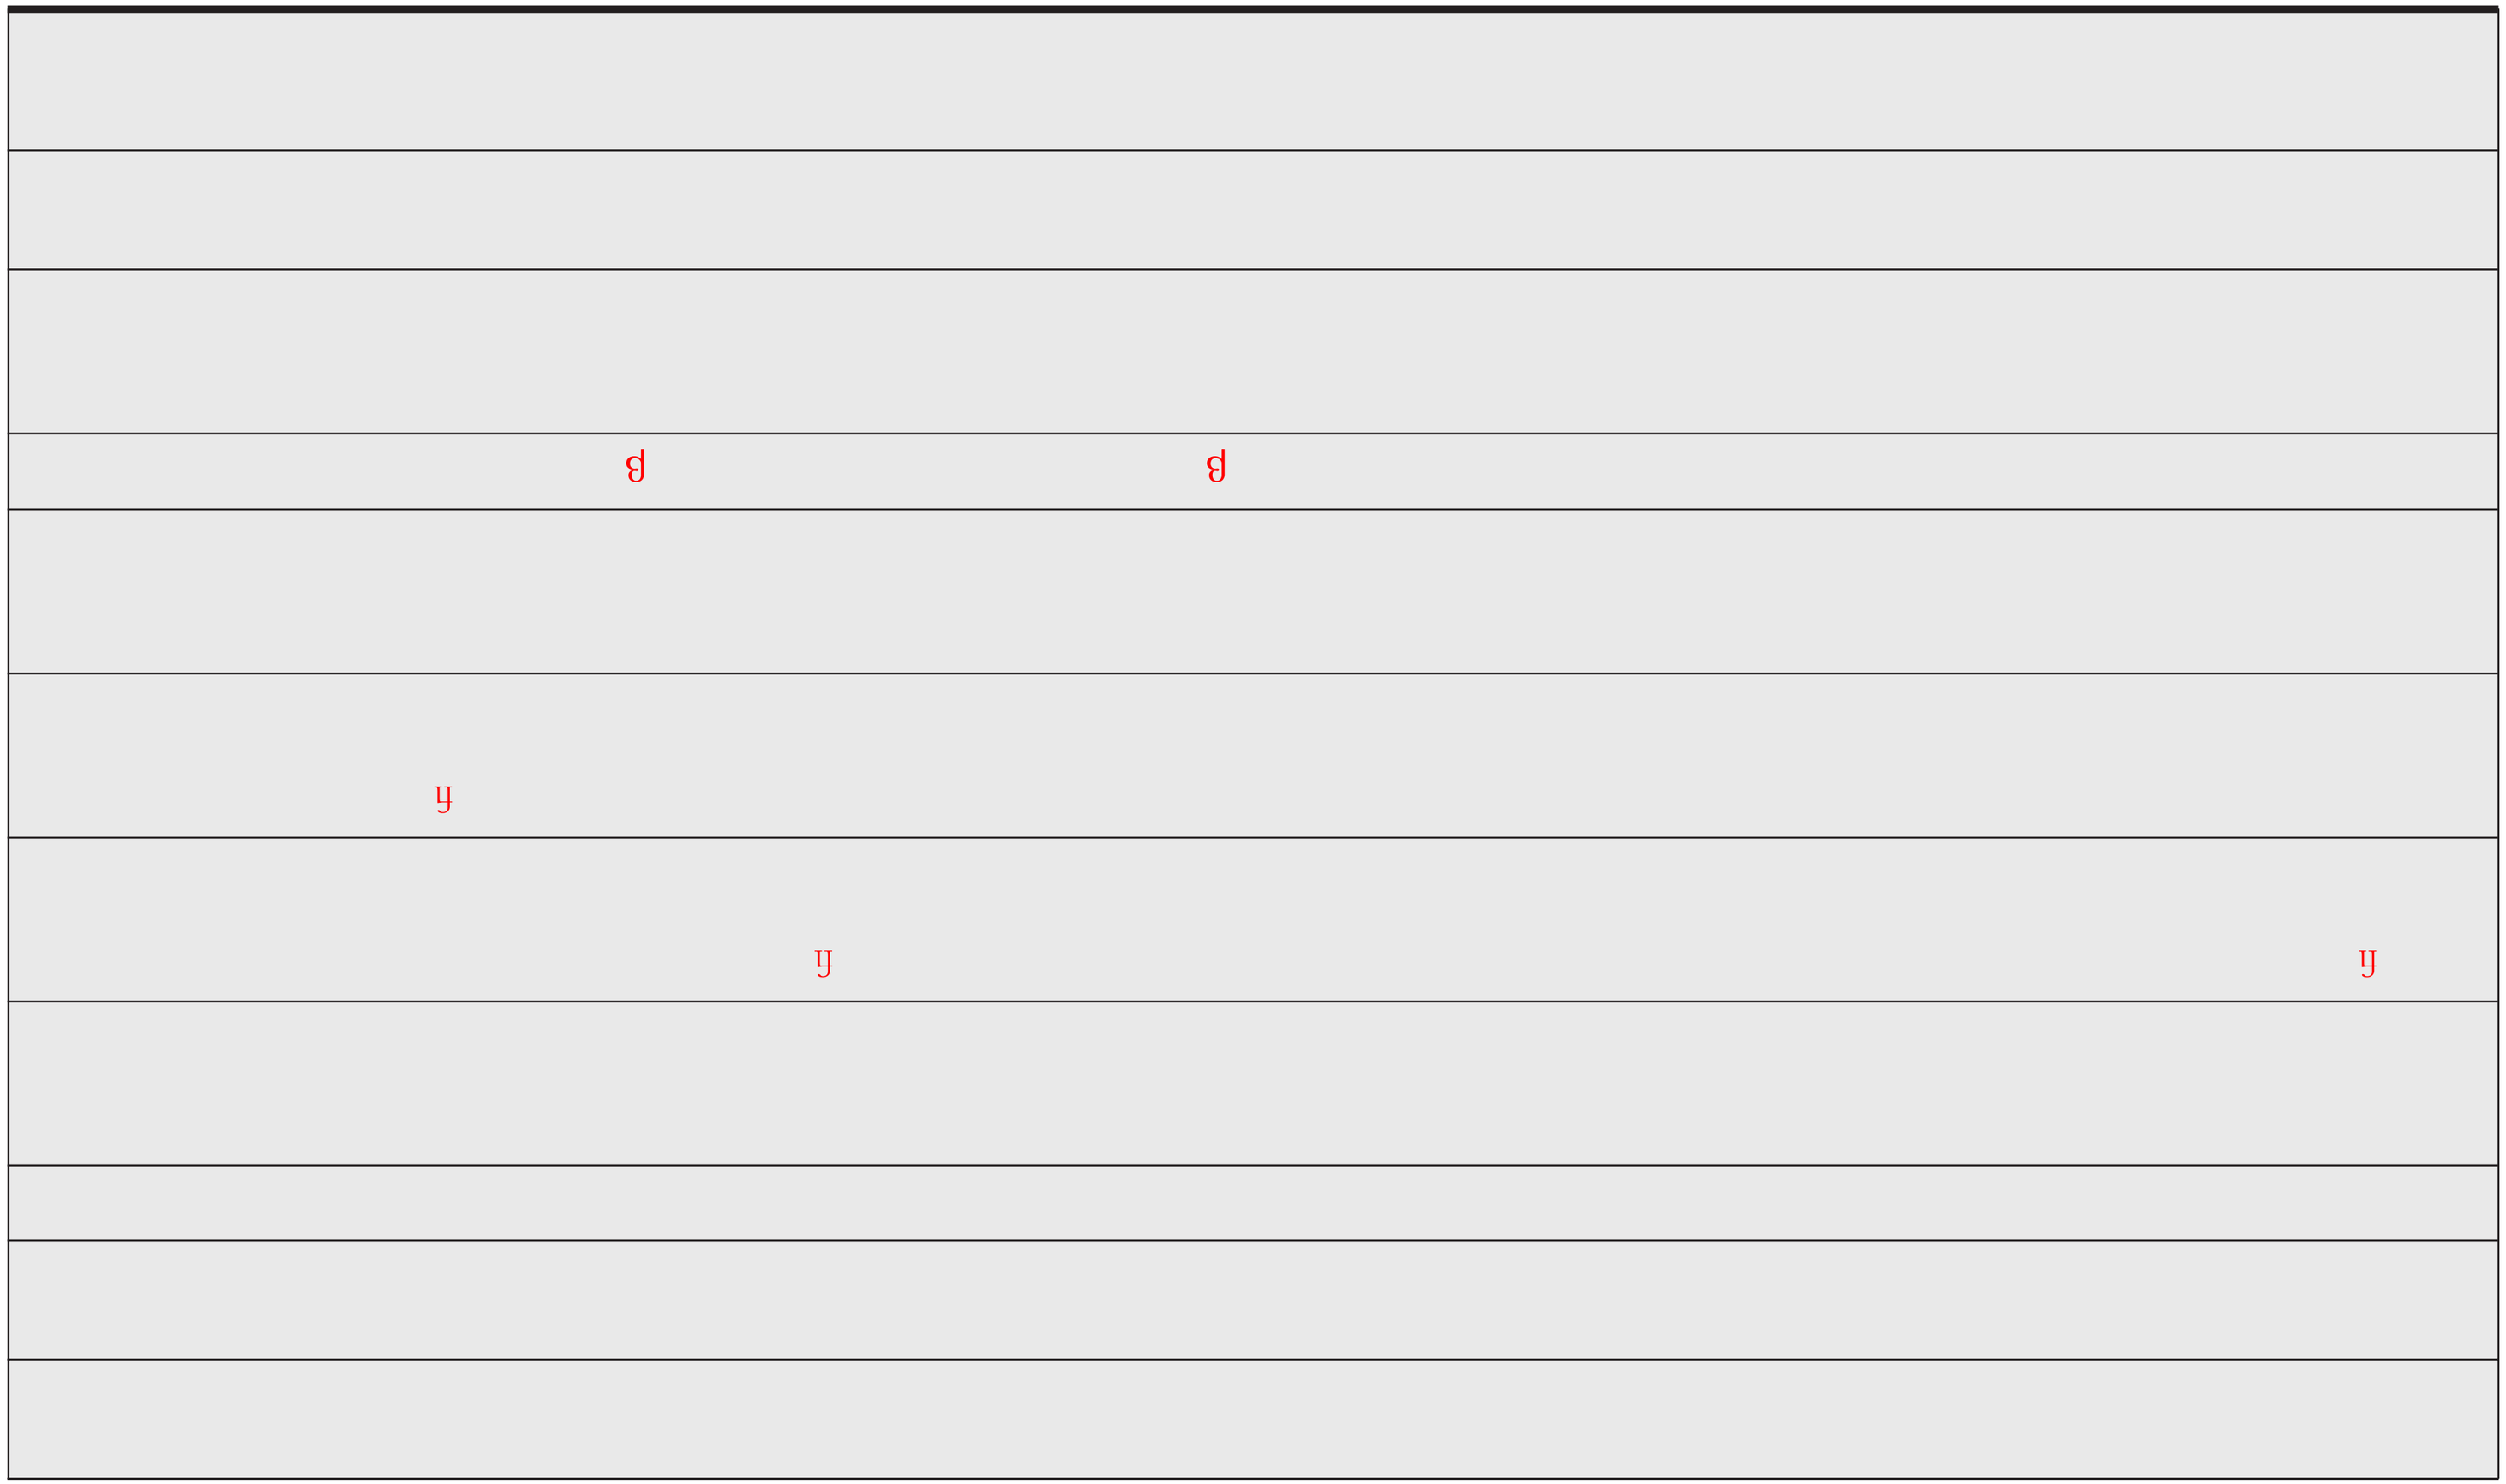
The complement system is a mediator of ischemia–reperfusion injury in the heart, lung, brain, intestines, and muscle.[291] A predominant role for C5b-9 in renal ischemia–reperfusion injury has been demonstrated.[292] In this study, the primary damaging effect of complement was on parenchymal cells rather than vascular endothelial cells. In another study, lack of a functional alternative complement pathway ameliorated ischemic AKI in mice.[293] In this study, mice deficient in factor B, an essential protein in the alternative complement pathway, were functionally and histologically protected against ischemic AKI. Treatment of mice with an inhibitory antibody to mouse factor B prevented the deposition of C3b on the tubular epithelium and systemic generation of C3b and protects against apoptosis and AKI in mice.[294] Loss of polarity of complement receptor 1–related protein y (Crry) in the tubular epithelium precedes activation of the alternative pathway along the basolateral aspect of the tubular cells, and heterozygous gene-targeted mice that expressed lower amounts of Crry are more sensitive to ischemic injury.[295] Also, the inhibition of Crry expression in proximal tubular epithelial cells in vitro resulted in alternative pathway–mediated injury to the cells.[295] Alternative complement pathway activation after renal ischemia reperfusion induces the production of macrophage inflammatory protein-2 (MIP-2) and mouse homolog of IL-8 (KC) by proximal tubule epithelial cells.[296] In addition, the alternative complement pathway, an innate immune system, recognizes hypoxic injury and triggers a systemic inflammatory response through the generation of C3a and a subsequent activation of the NF-κB system.[296]

29.7 Apoptosis in Hypoxic/Anoxic Tubular Injury In Vitro (Cultured Cells)

Cell Type	Type of Injury	Signals	Comment	Reference
MDCK and primary culture rat proximal tubules	Hypoxia		Necrosis also observed	485
Primary culture mouse proximal tubules	Partial ATP depletion (Antimycin A)	Renal growth factors did not ameliorate apoptosis	Severe ATP depletion caused necrosis	36
LLC-PK1 (proximal) and MDCK cells	ATP depletion		Same pattern in LLC-PK1 and MDCK	486
MDCK (distal)	Partial ATP depletion (Antimycin A)	Fas, FADD, caspases, PARP	Severe ATP depletion caused necrosis	487
Opossum kidney (proximal)	ATP depletion (cyanide, 2-deoxy-D-glucose)	Bcl-2/Bax	Prior heat shock attenuated apoptosis	246
Rat proximal tubules	Hypoxia	Caspases Bcl-2	Serine protease inhibitors suppressed caspase-9 activation and apoptosis	488
Rat proximal tubules	Antimycin A	Mitochondrial Ca^{2+} and permeability	L-type calcium channel blocker decreased apoptosis	489
Human tubular cells	Fas transfection	Fas	High but not basal Fas expression caused apoptosis	490
MDCK	Overexpression of ankyrin death domain	Fas	Inhibition of ankyrin Fas interaction decreased apoptosis	491
Rat proximal tubules	Hypoxia Cisplatin Staurosporine	Mitochondrial cytochrome c release	Minocycline upregulates Bcl-2 and decreases apoptosis	492
Rat proximal tubules	ATP depletion	Bid cleavage	Bid cleavage and apoptosis blocked by antiapoptotic Bcl-2 overexpression and caspase-9 inhibition	493
HK-2 cells	Mitochondrial dysfunction	Apoptosis antagonizing transcription factor (AATF)	Silencing of AATF worsened mitochondrial dysfunction	494

MDCK, Madin Darby canine kidney; LLC-PK1, cultured proximal tubule; FADD, fas-associated death domain; PARP, poly ADP ribose polymerase domain; Bax, Bcl-2-associated X protein; HK-2, human kidney-2.





Klotho

Klotho is a transmembrane protein that provides some control over insulin sensitivity and aging. It is increased in the kidney, blood, and urine.[297] Ischemic AKI reduced Klotho in the kidney, blood, and urine. Klotho deficiency resulted in worse AKI, and Klotho overexpression resulted in less AKI. This study suggests that AKI is a state of reversible Klotho deficiency.[297]

The Relative Importance of Proximal Versus Distal Tubular Injury

There is an ongoing debate regarding which nephron segments are most severely injured in ischemic AKI.[84] The target zone for hypoxic injury has also been extensively studied in the isolated perfused rat kidney (IPRK). In this model the target zone predominantly involves the S3 segments of the proximal tubule and also the distal tubules located within the outer stripe of the outer medulla and their cortical equivalent, the medullary rays, those straight sections of the proximal and distal tubules draining the superficial cortical glomeruli. Although the sensitivity of the proximal tubules to injury is well recognized in all models of AKI, the debate over whether the proximal or distal nephron segments are the primary target for hypoxic/ischemic injury has been well reviewed.[84] Of interest in the IPRK model of injury is the presence of a consistent artifact as a result of the absence of an oxygen carrier during erythrocyte-free perfusion. This artifact is the necrosis of mTAL cells first described by Alcorn et al.[298] It had been observed by Leichtweiss et al.[299] that tissue oxygen tension fell sharply in the region of the corticomedullary junction. Studies by Brezis et al.[300] demonstrated that the mTAL lesion resulted from hypoxia and provided support for the hypothesis that countercurrent diffusion of oxygen from descending to ascending limbs of the vasa recta is responsible for the prevailing low oxygen tension of the renal medulla. Subsequently, this group was able to induce a similar lesion in a number of models of renal injury. They have championed the notion that the mTAL segment lies on the brink of hypoxia as a result of the unique architecture of the kidney, which facilitates the countercurrent multiplier required for the formation of concentrated urine.[301] Most recently, it has been demonstrated that the induction of apoptosis targeted only in TAL cells in the absence of neutrophil inflammation in the mouse kidney results in renal failure, oliguria, and an impaired urine concentrating ability.[302]

Other groups have also suggested that the arteriovenous diffusion of oxygen between adjacent parallel arteries and veins is responsible for lowering tissue PO_2 in the corticomedullary region and for maintaining the very low medullary PO_2.[303,304] However, Endre et al.[305] demonstrated in the IPRK in the presence of low concentrations of erythrocytes that mTAL injury was prevented both under control conditions with high perfusate oxygen tension and in the presence of hypoxia.[305] The proximal tubule continued to be injured by hypoxia in the presence of erythrocytes, confirming that mTAL necrosis is an artifact of cell-free perfusion in this model. Nevertheless, coupled with the evidence for preglomerular arteriovenous diffusion of oxygen, which reduces average cortical PO_2 to subvenous levels,[306] the IPRK studies suggest that an even greater amount of the kidney is under threat from hypoxia when renal perfusion is reduced. Such widespread borderline hypoxia may be adaptively useful in priming the oxygen sensor in renal erythropoietin producing cells. However, when there is reduced renal perfusion, critically low levels of oxygen can be reached in tubular regions, particularly where there is high energy demand from transepithelial transport. Clearly, both proximal straight tubules (S3) and mTAL exist in such a region under constant threat of hypoxia. Magnetic resonance (MR) microscopy studies of the IPRK have demonstrated swelling of the cells in these interbundle regions in the outer medulla and their cortical equivalent, the medullary rays, restricting flow through the vascular bundles.[307] These MR observations complement the earlier observations by Thiel et al.,[308] Mason et al.,[309,310] and others that there is erythrocyte aggregation and stasis in the outer stripe of the model after reperfusion following ischemia. This reduction in perfusion may in part mediate the continued injury in this area.

Of greater interest is the observation that frank necrosis of mTAL cells is rarely seen in vivo. However, several studies in the IPRK have observed DNA fragmentation in mTAL cells after brief hypoxia[54] and after 15 or 60 minutes of reperfusion after ischemia.[311] DNA fragmentation has been observed after 24 hours reperfusion following ischemia in vivo in rats,[312,313] although little or no morphologic evidence of apoptosis has been observed in any of these studies. Similar DNA fragmentation was observed in human autopsy specimens after renal hypoperfusion.[314] Recent studies of the Bcl-2 multigene family and growth factors by Gobé et al.[312,314] in a 30 minute bilateral arterial clamp model of ischemia–reperfusion have suggested a way of reconciling the observations of proximal cell necrosis and DNA fragmentation without apoptosis in nearby mTAL. After 24 hours of reperfusion, distal tubules showed a marked increase in the expression of antiapoptotic Bcl-2 and a moderate increase in antiapoptotic Bcl-X_L and proapoptotic Bax. Proximal tubules showed a marked increase in Bax expression and a moderate increase in Bcl-X_L. Twenty-four hours after the expression of the Bcl-2 proteins was increased, IGF-1 and epidermal growth factor (EGF) protein levels were increased in the distal tubule, similar to the Bcl-2 antiapoptotic proteins, and were also detected in the adjacent proximal tubules, suggestive of paracrine action in these tubules. TGF-β expression was moderately increased in regenerating proximal tubules, but no relationship was seen with the pattern of expression of the Bcl-2 genes. An explanation of these results is that the distal tubule is adaptively resistant to ischemic injury via the promotion of survival by antiapoptotic Bcl-2 genes, and its survival allows for the expression of growth factors critical not only to the maintenance and regeneration of its own cell population (autocrine action), but also to the adjacent ischemia-sensitive proximal tubular cells (paracrine action).

Therefore, the hypothesis has been proposed that both the S3 proximal tubule and mTAL cells reside in regions where oxygen availability is borderline. Hypoxia induces both necrosis and apoptosis in proximal tubular cells. Hypoxia triggers apoptosis in mTAL cells but the presence of antiapoptotic Bcl-2 genes prevents the completion of programmed cell death and the DNA fragmentation is repaired. The induction of the growth factors EGF and IGF in these mTAL and distal tubule (DT) cells then provides both autocrine and paracrine mechanisms, respectively, for the recovery of the mTAL and proximal tubules. Because proximal cells are necrotic or have sloughed due to a loss of cell adhesion, proximal tubule recovery is delayed compared to the mTAL. This hypothesis also provides a mechanism for tubular obstruction by casts because viable mTAL cells are the source of Tamm-Horsfall protein.

Tubuloglomerular Feedback

Tubuloglomerular feedback ("tubular communication with the glomerulus") operates within the juxtaglomerular apparatus (JGA) of each nephron where changes are sensed in the salt content of fluid at the luminal macula densa and that information is transmitted to the afferent arteriole to cause compensatory changes in single nephron GFR.[315] nNOS (NOS 1) is expressed in the macula densa and may influence tubuloglomerular feedback. However, micropuncture experiments using NOS antagonists have shown that NO may modulate tubuloglomerular feedback.[315] Local NOS blockade causes the curve that represents tubuloglomerular feedback to shift leftward and become more steep. Changes in macula densa NO production may underlie the resetting of tubuloglomerular feedback, which is required in order to keep the tubuloglomerular feedback curve aligned with ambient tubular flow as tubular flow changes to accommodate physiologic circumstances. Also, macula densa NO production may be substrate limited and dissociated from NOS protein content. The importance of NO to tubuloglomerular feedback resetting and the substrate dependence of NO production have both been found during changes in dietary salt consumption.[316,317] In addition, nNOS inhibition sensitizes the tubuloglomerular feedback mechanism after volume expansion.[318] Macula densa cells detect changes in distal sodium chloride concentration, at least in part, through an apical Na:2Cl:K cotransporter.[319] Macula densa NO directly inhibits Na:2Cl:K cotransport, and NO and angiotensin (AT)II independently alter cotransporter activity.[319] To determine the role of the local renin–angiotensin system on tubuloglomerular feedback, mice with absent renal tissue expression of angiotensin converting enzyme (ACE) were studied.[320] Tubuloglomerular feedback was absent in mice without ACE in the kidney, suggesting that renal tissue ACE is an important contributor to tubuloglomerular feedback.[320] Mice deficient in adenosine A_1 receptors lack tubuloglomerular feedback.[321] Mice deficient in ecto-5′nucleotidase/CD73, the enzyme responsible for adenosine formation from AMP, have an impairment of the tubuloglomerular feedback regulation of GFR.[322]

Taken together, the proximal tubular injury and resultant dysfunction could contribute to the drastic fall in GFR, the hallmark of ischemic AKI. One potential mechanism is increased tubuloglomerular feedback. Specifically, in AKI, decreased proximal tubule reabsorption would increase solute delivery to the macular densa with the resultant constriction of the afferent arteriole and a fall in GFR.[323] In normal nephrons, the maximal fall in GFR with increased solute delivery to the macular densa is approximately 50%. Thus, increased tubuloglomerular feedback could be a major factor in mediating the pathway whereby proximal tubule damage could lower GFR. However, because clinical AKI or ischemic AKI is associated with a 90% fall in GFR, either additional factors or increased sensitivity of tubuloglomerular feedback postischemic injury to the kidney must occur. In that regard, dissected afferent arterioles from ischemic kidneys have been shown to have increased cytosolic calcium concentrations and enhanced vasoconstriction responses to AT-II and endothelin.[324,325] It is thus theoretically tenable that the sensitivity of the tubuloglomerular feedback is indeed enhanced postischemia. However, the role of tubuloglomerular feedback in ischemic AKI remains controversial.[326]

In support of a pathogenic role of tubuloglomerular feedback in ischemic AKI are studies by Brian Meyer and colleagues[55,56] that demonstrated the following: (1) the translocation of NaK-ATPase to the cytoplasm results in depolarization confined to the proximal tubule; (2) the fractional excretion of lithium, a surrogate measure for the fraction of filtered sodium that is delivered to the macula densa, the site of tubuloglomerular feedback, is massively increased; and (3) that these abnormalities persist for the duration of the maintenance phase of postischemic AKI. This study provides evidence for decreased proximal reabsorption of sodium, resultant increased sodium delivery to macula densa, tubuloglomerular feedback, and a resultant filtration failure that accompanies ischemic AKI.

Another pathway whereby tubular injury can contribute to a fall in GFR is by causing intraluminal cast formation and tubule obstruction. This will be the next topic discussed.

TUBULAR CAST FORMATION AND OBSTRUCTION

The classic radiologic findings in early AKI, prior to the realization that contrast is nephrotoxic, was an early dense nephrogram not followed by a pyelogram. Because the nephrogram phase represents contrast entering the tubules by filtration, a persistent nephrogram suggests a tubular obstruction with ongoing glomerular filtration.

Kidneys with ischemic AKI are swollen and, therefore, it was suggested that interstitial edema may lead to tubular collapse secondary to extraluminal-mediated compression.

However, it is clear that recovery from AKI can occur when the kidneys are still enlarged and swollen. An increased excretion of tubular epithelial casts are, however, a hallmark of recovery from AKI.[24] The presence of tubular casts on a renal biopsy, as well as urinary casts, has provided morphologic support for a role in tubular obstruction due to intraluminal cast formation in the pathogenesis of ischemic AKI.[327] As noted previously, although earlier micropuncture studies failed to consistently demonstrate increased tubular pressures postischemia, several subsequent studies provided convincing evidence for the presence of tubular obstruction in experimental ischemic AKI. Arendhorst et al.,[328] using micropuncture techniques during saline loading, demonstrated clear evidence of increased tubular pressures in postischemic, as compared to normal, kidneys. Renal vasodilation to restore renal blood flow also demonstrated increased tubular pressures in ischemic AKI in the rat. Perhaps the most compelling studies, however, were those micropuncture experiments performed by Tanner and Steinhausen.[329] They found that perfusing the proximal tubule with artificial tubular fluid at a rate that did not increase tubule pressure in normal animals increased tubule pressures in animals after a renal ischemic insult. Moreover, venting those obstructed tubules led to improved nephron filtration rates. Burke et al.[330] also demonstrated that the prevention of ischemic AKI in dogs with mannitol led to a decrease in intratubular pressures, suggesting that the induced-solute diuresis led to the relief of the cast-mediated tubular obstruction.

Although it is clear that brush border membranes, necrotic cells, viable cells, and perhaps apoptotic tubular epithelial cells enter tubular fluid after an acute renal ischemic insult, the actual process and predominant location of the cast formation is less clear. It is known that the casts uniformly stain for Tamm-Horsfall protein.[327]

Integrins

Integrins are heterodimeric glycoproteins consisting of different combinations of alpha and beta subunits; they recognize the most common universal tripeptide sequence, arginine-glycine-aspartic acid (RGD), which is present in a variety of matrix proteins.[12] These integrins can mediate cell–cell adhesion via an RGD inhibitable mechanism.[11]

In normal kidneys, proximal tubular cells are stained by the RGD peptide, RhoG-RGD, basolaterally in a punctate pattern and with Bt-RGD only minimally. On the other hand, ischemic kidneys labeling with RhoG-RGD and Bt-RGD occurred at the basolateral and apical aspect of tubular cells as well as on desquamating or desquamated cells within the tubular lumen and also on the vasa rectae.[331] In ischemic kidneys, antibodies to β1 and αV subunits of integrins stained glomeruli and the apical aspect of the proximal and distal tubules. Desquamated cells and cellular conglomerates obstructing the tubular lumina were intensely stained with RGD peptides.[332] Dual labeling experiments with Bt-RGD and antibodies against integrin receptors demonstrated αVβ3 binding sites for RGD peptides in the vasculature and some desquamated cells, whereas the majority of the desquamated cells bind Bt-RGD via β1 integrins.[331]

Experimental results support a role for adhesion molecules in the formation of casts. It has been shown that a translocation of integrins to the apical membrane of tubular epithelial cells may occur with ischemia.[11,226,227] Possible mechanisms for the loss of the polarized distribution of integrins include cytoskeletal disruption, state of phosphorylation, activation of proteases, and the production of NO.[333,334] These integrins are known to recognize RGD tripeptide sequences.[13,332] Thus, viable intraluminal cells could adhere to other luminal or paraluminal cells. The Goligorsky group provided experimental evidence for this cell–cell adhesion process as a contributor to tubule obstruction in ischemic AKI.[335–337] Synthetic cyclical RGD peptides were infused prior to the renal ischemic insult in order to block cell-to-cell adhesion as a component of tubule obstruction.[14,335–338] Using micropuncture techniques, the cyclic RGD tripeptides blocked the rise in tubular pressure postischemic insult.[13] An in vivo study of RGD peptides (cyclic RGDDFLG and RGDDFV) in ischemic AKI in rats demonstrated the attenuation of renal injury and an accelerated recovery of renal function.[14] The systemic administration of fluorescent derivatives of two different cyclic RGD peptides, a cyclic Bt-RGD peptide and a linear RhoG-RGD peptide, infused after the release of a renal artery clamp ameliorated ischemic AKI in rats.[14,337] The staining of these peptides suggests that cyclic RGD peptides inhibited tubular obstruction by predominantly preventing cell-to-cell adhesion, rather than cell-to-matrix adhesion.[332]

In addition to cell–cell adhesion, it is worthy to note that Zuk et al.[339] have demonstrated increased fibronectin in the tubular lumen after an ischemic insult, and fibronectin is known to possess arginine-glycine-aspartic acid (RGD) sequences that are recognized by cellular integrins. Moreover, Tamm-Horsfall protein (THP) is known to possess an RGD sequence, which may or may not be in a position to be recognized by integrins. This possibility, however, led to in vitro cellular adhesion studies in which $LLCPK_1$ cell adhesion to several different matrices (i.e., collagen I and collagen IV) was examined.[333] Interestingly, THP diminished cell adhesion in artificial fluid, mimicking distal tubular fluid but not tubular fluid similar to AKI or collecting duct fluid, which have significantly higher ionic concentrations.[340] In this regard, it has been suggested that THP becomes a polymeric gel in the presence of high ionic strength fluid, but is a non-gel monomeric substance in low ionic strength fluid. Studies have documented that the gel formation by THP is an active process that can be abolished by boiling. A role of the oligosaccharide component of THP in the gel formation was demonstrated because N-glycanase treatment to remove the oligosaccharide abolished the gel formation.[340]

Thus, the intraluminal presence of brush border membranes and viable and nonviable cells in association with the extracellular matrix (eg, fibronectin, THP, adhesion molecules) support their involvement in cast formation in ischemic AKI. The actual tubular obstruction by the casts, however, may only occur in the presence of the impaired vascular responses to renal ischemia. More specifically, if net glomerular filtration pressure was normal, the majority of the tubular casts may be excreted in the urine rather than lodging in the collecting duct and other nephron sites. Tubular factors in the pathogenesis of ischemic AKI are shown in Figure 29.7. The various perturbations in the renal vasculature that occur in association with a renal ischemic insult will now be discussed.

VASCULAR PERTURBATIONS

Ischemic AKI is associated with renal vasoconstriction with a resultant decrease in glomerular hydrostatic pressure and renal plasma flow.[341–343] Not only are circulatory vasoconstrictors, such as catecholamines, AT-II and endothelin, as well as renal sympathetic tone frequently increased in the setting of ischemic AKI,[68] but the renal vascular response to vasoconstrictors has been shown to be enhanced. This increased response to vasoconstrictors is due in part to the earlier mentioned increase in cytosolic calcium concentration in the afferent arterioles of the glomerulus. Endothelial damage is also associated with a diminution of the renal vasodilators, which oppose the action of vasoconstrictors. In experimental sepsis, the NO secondary to iNOS has been suggested to downregulate renal eNOS.[344] Moreover, the renal clamp model of AKI in the rat has been shown to be associated with downregulation of endothelial-derived nitric oxide (eDNO).[324,345] Recent studies have also shown that endothelin receptor antagonists ameliorate the diminution in renal hemodynamics associated with renal ischemia in the isolated perfused rat kidney[346,347] Further support for endothelin as an important mediator of ischemia–reperfusion-induced renal injury is the protective effect of an endothelin-A receptor antagonist in rats after clamping of the renal arteries.[348] Impairment of prostaglandin synthesis by the damaged endothelium can also profoundly enhance renal vascular resistance associated with renal ischemia. In this regard, infusion of prostaglandin E1 may protect against ischemic AKI.[349] Also, inhibition of thromboxane A2 improves renal function in rats exposed to warm ischemia–reperfusion.[350]

Intravital two-photon microscopy is an ideal method to study the microvascular events within the functioning kidney in vivo.[351–354] Intravital two-photon microscopy enables investigators to follow functional and structural alterations with subcellular resolution within the same field of view over a short period of time. Endothelial cell dysfunction within the microvasculature was observed and quantified using the infusion of variously sized, differently colored dextrans or proteins. Movement of these molecules out of the microvasculature and accumulation within the interstitial compartment are readily observed during AKI. The FVB-TIE2/GFP mouse, in which the endothelium is fluorescent, has been used to study morphologic changes in the renal microvascular endothelium during ischemia–reperfusion injury in the kidney.[355] Alterations in the cytoskeleton of renal microvascular endothelial cells correlated with a permeability defect in the renal microvasculature as identified using fluorescent dextrans and two-photon intravital imaging. Also, proximal tubule cell injury was increased in areas adjacent to areas of reduced endothelial injury and dysfunction.

Acute and chronic microvascular alterations are seen in a mouse model of ischemic AKI.[358] Three-dimensional reconstructions of microvascular networks obtained 24 hours following an acute ischemic injury demonstrate an intact endothelial monolayer in areas of increased microvascular permeability. There was no terminal deoxynucleotidyl transferase (TdT) mediated nick-end labeling (TUNEL) staining in microvascular endothelial cells despite the activation of caspase-3. This study demonstrates that detachment and a subsequent loss of endothelial cells following ischemic injury is not a major contributor to altered microvascular permeability.

In a more recent study, it was demonstrated that impaired endothelial proliferation and mesenchymal transition contribute to vascular rarefaction following AKI.[356] In the kidney of Sprague-Dawley rats after ischemic AKI, proliferating endothelial cells were undetectable for up to 2 days following ischemia/reperfusion (I/R). Endothelial mesenchymal transition states were identified.

Toll-like receptor 4 (TLR4) regulates early endothelial activation during ischemic acute kidney injury.[357] Increased TLR4 expression was seen on endothelial cells of the vasa recta of the inner stripe of the outer medulla of the kidney 4 hours after reperfusion.[357] The addition of hydrogen peroxide increased TLR4 expression in MS1 microvascular endothelial cells in vitro. TLR4 was localized to proximal tubules in the cortex and the outer medulla after 24 hours of reperfusion.

Acute alterations of the renal microvasculature, including altered microvascular permeability, are important contributors to the overall pathophysiology of AKI.[358,359] These acute microvascular alterations may have chronic consequences that result in the progression of AKI to chronic kidney disease (CKD).

Oxygen Free Radicals

Studies supported indirect evidence for injury induced by oxygen free radicals (OFRs) during reperfusion.[360,361] Although some studies have demonstrated that activated neutrophils produce OFR injury after ischemia,[362,363] other studies in isolated proximal tubules[364] and the studies in the cell-free isolated perfused rat kidney[365] indicated that OFRs were generated and contributed to the injury process even in the absence of neutrophils. The identification

of the actual species of OFRs involved in reperfusion injury required direct methods of detection rather than a reliance on scavengers.

The direct detection of hydroxyl radicals was initially achieved in isolated proximal tubules by using biochemical traps.[364] Similar studies were subsequently performed in the intact kidney using 0.5 mM salicylate to react with hydroxyl radicals during reperfusion for 15 minutes after an ischemia of 15 minutes.[366] An increase in 2,5 dihydroxybenzoic acid was observed using high performance liquid chromatography (HPLC) with electrochemical detection. Subsequent studies by Kadkhodaee et al.[367] used electron paramagnetic resonance (EPR) and 5,5-dimethyl-l-pyrroline N-oxide (DMPO) as a spin trap and confirmed that hydroxyl radicals were generated during a brief 3 minute reperfusion period following 20 minutes of ischemia. Interestingly, both studies demonstrated a significant generation of hydroxyl radicals in control kidneys, which was abolished by the addition of the scavenger, dimethyl-2-thiourea (DMTU). An increase in an unidentified carbon-centered radical was also identified during reperfusion in the EPR study and could represent an early lipid peroxidation product.[367]

With 60 minutes of reperfusion after 20 minutes of ischemia in the IPRK, tubular damage was prominent in both the cortical and medullary proximal tubule and in the mTAL.[311] Pretreatment with either allopurinol, which acts both to inhibit xanthine oxidase and acts as an OFR scavenger, or DMTU, reduced both the morphologic features of injury and the extent of DNA fragmentation in the mTAL. Taken together, these results suggest that hydroxyl radicals formed during reperfusion after ischemia play a significant role in both necrotic and apoptotic cell injury.

On the background of these postischemic vascular perturbations is the observation that a decrease in renal perfusion pressure is not associated with autoregulation of either GFR or renal blood flow.[324,341,342,368–370] In fact, rather than renal vasodilation, renal vasoconstriction occurs with a fall in renal perfusion pressure in the postischemic kidney. Thus, a degree of hypotension, which is of no clinical significance in the normal kidney, may cause renal damage in the kidney during the recovery phase of AKI. The same increased sensitivity in the postischemic kidney has also been shown to occur with nephrotoxic agents such as aminoglycosides.

Studies to examine the role of Ca^{2+} and calcium channel blockers (CCBs) in the vascular perturbations in experimental ischemic AKI have been performed. These studies demonstrate that intrarenal CCBs can reverse the increased sensitivity to renal nerve stimulation as well as the loss of renal autoregulation, both of which characterize experimental AKI.[371] In addition, other studies in the rat showed that atrial natriuretic peptide (ANP), which attenuates vasoconstrictor-induced increases in $[Ca^{2+}]_i$ in cultured vascular smooth muscle cells,[372] is also protective against ischemic AKI[373] despite the fact that its systemic administration causes a fall in arterial pressure.

Cisplatin-induced or ischemic AKI in vivo and hypoxia/reoxygenation of tubular epithelial cells in vitro induces the production of reactive oxygen metabolites (ROM).[374] The generation of ROM results in tubular epithelial cell death, which is mediated by caspases and/or endonucleases. The inhibition of ROM protects the tubular epithelium from caspase and endonuclease activation and from cell death.

Endotoxemia-Induced Acute Kidney Injury

Recent experimental studies in septic mice have incriminated still another mediator of renal vasoconstriction. The intraperitoneal administration of lipopolysaccharide (LPS) as an endotoxin was associated with a profound decrease in GFR and renal blood flow both in wild-type and iNOS knockout mice. A soluble receptor of TNF, however, was associated with profound improvement in renal hemodynamics in both wild-type and iNOS knockout mice.[375] Because septic patients with renal failure have a high mortality, this observation has potential therapeutic importance.

Sepsis in mice has also been shown to be associated with an impaired response of NO-mediated cyclic GMP in the renal cortex, the agent's secondary messenger for vasodilation. The renal nerves and the activation of the renin–angiotensin system contribute to renal vasoconstriction during sepsis. In this study, renal denervation decreased the high plasma renin levels during endotoxemia and was protective against the decreased GFR and renal blood flow in a normotensive model of endotoxemia-induced sepsis.[376]

Oxygen radicals may contribute to vasoconstriction in endotoxemia-induced AKI.[377] AKI during sepsis is associated with increased NO and oxygen radicals, including superoxide. Renal extracellular superoxide dismutase (EC-SOD) is decreased in endoteoxemia.[378] Antioxidant therapy with chemically dissimilar antioxidants, metalloporphyrin and tempol, preserved GFR and renal blood flow during endotoxemia.[378] This protective effect was reversed by the inhibition of iNOS, suggesting the importance of the bioavailability of NO for the preservation of renal function during endotoxemia.[378]

The demonstration of global renal vasoconstriction in sepsis may depend on the model used. In a nonlethal hyperdynamic model of sepsis in sheep injected with Escherichia coli, renal failure developed despite markedly increased renal blood flow.[379]

In another study in endotoxemia-induced AKI, the role of renal inflammation and apoptosis was determined.[380] In this study, LPS acted on extrarenal TLR4, leading to systemic TNF release and subsequent AKI. Mice with a mutation in TLR4 were resistant to LPS-induced AKI and had less neutrophil infiltration and renal cell apoptosis.[380]

The role of caspase-1 and its associated cytokines was investigated in a nonhypotensive model of endotoxemic AKI.[381] In mice with endotoxemic AKI, the GFR measured by fluorescein isothiocyanate (FITC)-labeled inulin was significantly higher in caspase-1-/- versus wild-type mice at 16 and 36 hours. IL-1 β and IL-18 protein were significantly increased in the kidneys of mice with endotoxemic AKI versus vehicle-treated mice. However, the inhibition of IL-1β with L-1Ra, or the inhibition of IL-18 with IL-18–neutralizing antiserum-treated or combination therapy with IL-1Ra plus IL-18–neutralizing antiserum did not improve the GFR in mice with endotoxemic AKI. These results suggest that neither IL-1β nor IL-18 are the mediators on endotoxemic AKI.[381]

Ghrelin is a stomach-derived growth hormone secretagogue. Ghrelin has been shown to have anti-inflammatory properties. Serum ghrelin levels were increased in endotoxemia AKI accompanied by increased ghrelin receptor (GHSR-1a) protein expression in the kidney.[382] Ghrelin administration significantly decreased serum cytokine levels (TNF-α, IL-1β, and IL-6), serum endothelin-1 levels, serum NO levels, and renal iNOS expression in endotoxemic AKI. When administrated before LPS, ghrelin protected against the fall in glomerular filtration rate. In another study, ghrelin was shown to improve renal function in mice with ischemic AKI.[383]

INFLAMMATION IN ISCHEMIC ACUTE KIDNEY INJURY

Ischemic AKI has been described as an inflammatory disease.[20] This is evidenced by numerous studies demonstrating endothelial injury, leukocyte infiltration in the kidney, and the generation of inflammatory mediators by tubular cells.[20]

Endothelial Cell Injury

Silver nitrate staining of blood vessels was studied in rats at 4 hours after the release of a renal artery clamp.[384] Ischemic AKI resulted in disorganization of endothelial integrity with areas of denudation, partial disappearance of cell–cell borders, and distortion of cell–cell contacts most prominent in the renal microvasculature. Intravital microscopy of blood flow in peritubular capillaries provided direct evidence for the existence of a no-flow phenomenon caused by endothelial injury.[384,385] The administration of endothelial cells or surrogate cells expressing endothelial NOS, either intravenously or intra-arterially, resulted in functional protection against ischemic AKI.[384] These studies suggested that endothelial cell injury is the primary cause of the no-flow phenomenon and that, when ameliorated, there is attenuation of renal function.

It has been demonstrated in mice that injury of renal microvascular endothelium alters the barrier function after ischemia.[355] In this study, circulating von Willebrand factor (vWF), a marker of endothelial injury, was increased in the circulation 24 hours after ischemia. In FVB-TIE2/GFP mice, in which the microvasculature can be visualized, there were alterations in the cytoskeleton and in the integrity of adherens junctions that correlated with a permeability defect identified using fluorescent dextrans and two-photon intravital imaging.[355]

The extension phase of AKI is marked by continued hypoxia and an inflammatory response, which are more marked in the corticomedullary junction.[19] Severely reduced blood flow, stasis, and the accumulation of red blood cells has been documented in the corticomedullary region.[19] Endothelial cell injury is thought to play an important role in the initiation and extension phase of ischemic AKI.[19,386]

Neutrophil Activation

Renal ischemia–reperfusion injury is associated with an increase in infiltrating neutrophils.[387] The adherence of neutrophils to the vascular endothelium is an essential step in the extravasation of these cells into ischemic tissue.[29] Therefore, leukocyte adhesion molecules have been studied in renal injury.[388] After adherence and chemotaxis, infiltrating leukocytes release reactive oxygen species and enzymes that damage the cells.[29] The infusion of normal neutrophils accentuates severe ischemia–reperfusion injury and decreases GFR during ischemia. Activated neutrophils have been shown to further decrease GFR in response to renal ischemia at least in part due to the release of oxygen radicals.[363,389–391] In contrast, the infusion of oxygen radical–deficient neutrophils from patients with chronic granulomatous disease did not worsen the course of ischemic injury.[390] The mechanism by which adherent leukocytes cause ischemic injury is unclear, but likely involves both the release of potent vasoconstrictors including the prostaglandins, leukotrienes, and thromboxanes,[392] as well as direct endothelial injury via the release of endothelin and a decrease in NO.[68,393]

Intracellular adhesion molecule 1 (ICAM-1) has been suggested to play an important role in the pathophysiology of ischemic AKI.[387,394] Increased systemic levels of the cytokines, TNF-α, and IL-1 may upregulate ICAM-1 after ischemia and reperfusion in the kidney.[394] ICAM-1 on endothelial cells promotes the adhesion of neutrophils to these cells and causes tissue damage. The administration of a monoclonal antibody against ICAM-1 protected against ischemic AKI in rats.[387,390] Pretreatment with an ICAM-1 antisense oligodeoxyribonucleotide ameliorated the ischemia-induced infiltration of granulocytes and macrophages and resulted in less cortical renal damage as assessed by a quantitative pathologic grading scale.[395] In parallel, ICAM-1–deficient mice are protected against renal ischemia.[394] Thus, ICAM-1 is a mediator of ischemic AKI, probably by potentiating neutrophil–endothelial interactions.

Red blood cell swelling has been suggested to cause the medullary blood flow congestion, which occurs after renal ischemia and worsens the relative hypoxia in that region of the kidney. The restoration of renal blood flow in experimental renal ischemia in dogs, however, occurs with either an isotonic or hypertonic mannitol induced–diuresis. There is now evidence that upregulation of adhesion molecules may contribute to this impaired medullary blood flow postischemic injury.[388,396,397]

P-selectin, an important molecule involved in the adherence of circulating leukocytes to tissue in inflammatory states, also seems to be involved in the infiltration of the leukocytes during ischemic injury. In fact, renal ischemia has also been shown to be associated with upregulation of endothelial P-selectin with enhanced adhesion of neutrophils.[398] A soluble P-selectin glycoprotein ligand prevented the infiltration of leukocytes and ameliorated ischemia-induced renal dysfunction.[334] In contrast to P-selectin, L-selectin does not appear to mediate tubular damage in the postischemic kidney.[388] After adherence and chemotaxis, neutrophils release reactive oxygen species or oxygen free radicals. IL-17 produced by neutrophils regulates interferon (IFN)-γ–mediated neutrophil migration in the ischemic AKI in mice.[399]

There is evidence that neutrophils mediate tubular injury in AKI.[400] This evidence is derived from studies that show an accumulation of neutrophils in ischemic AKI and studies demonstrating a beneficial role of anti–ICAM-1 therapy in AKI.[394] Also, mice depleted of peripheral neutrophils by antineutrophil serum were protected against ischemic AKI.[394] However, in another study, rats depleted of peripheral neutrophils by antineutrophil serum were not protected against ischemic AKI.[401] In another study, mice were injected with 0.1 mg of the rat IgG2b monoclonal antibody RB6-8C5 (BD Pharmingen Inc., San Diego, CA) intraperitoneally 24 hours before a renal pedicle clamp.[191] This results in the depletion of neutrophils in the peripheral blood and in the kidney during ischemic AKI. In this study, there was slight functional protection and no histologic protection against ischemic AKI in neutrophil-depleted mice.[191]

The kinetics of margination and transmigration of neutrophils in vivo in the kidney and lungs following renal ischemia–reperfusion has been studied.[402] At 24 hours after an ischemic AKI, kidney neutrophil content increased threefold. The neutrophils were found primarily in the interstitium and, to a lesser degree, marginated to the vascular endothelium. Interstitial neutrophils had significantly lower levels of intracellular IFN-γ, IL-4, IL-6, and IL-10, and thus, a tendency for decreased amounts of IL-4 and TNF-α compared to the marginated neutrophils. Transmigration sites of neutrophils were directly associated with areas of increased vascular permeability. The activation of the adenosine 2A receptor significantly decreased both kidney neutrophil transmigration by about half and vascular permeability by about a third. This study suggests that there is a sequential recruitment and transmigration of neutrophils from the vasculature into the interstitium of the kidney at the site of tissue injury in ischemic AKI.

Lymphocytes

The role of lymphocytes in ischemic AKI is an ongoing area of study.[403,404] Lymphocytes have been examined in genetically altered immune-deficient mice. In one study, mice with a combined deficiency of both CD4 and CD8 cells were protected against ischemic AKI at 48, but not at 24 hours postischemic reperfusion.[405] In a follow-up report by the same investigators, nu/nu mice that are athymic and deficient in both CD4 and CD8 T cells were protected against ischemic AKI 24- and 48-hours postischemic reperfusion.[406] To determine the pathogenic T-cell type, mice with targeted genetic deficiencies of either CD4 or CD8 T cells were also studied. CD4-deficient mice, but not CD8-deficient, are protected against ischemic AKI.[406] Therefore, it appears that the pathogenic T-cell subtype in ischemic AKI is the CD4 T cell. However, RAG-1-/- mice, which lack mature T and B lymphocytes, are not protected against ischemic AKI despite lacking both CD4 and CD8 T cells.[407] In a recent study,[408] mice deficient in B lymphocytes alone were protected against ischemic AKI. In summary, CD4 T-cell deficient, nu/nu (lacking mature T cells), and B-cell deficient mice are protected against ischemic AKI, whereas CD8 T-cell and RAG-1-/- (lacking mature B and T cells) mice are not protected.

The effect of a complete depletion of CD4 T cells with a monoclonal antibody in ischemic AKI is not known. In one report,[409] the use of GK1.5 antibody alone to deplete CD4 T cells did not protect against ischemic AKI; however, the complete depletion of CD4 T cells as judged by fluorescence activated cell sorting (FACS) analysis did not occur. Protection did occur when GK1.5 antibody was used with two other antibodies, which resulted in the depletion of both CD4 and CD8 T cells.[409] In another study,[410] the complete depletion of CD4 T cells using the GK1.5 antibody was not protective against ischemic AKI in mice. CXCR3 plays an important role in the recruitment of Th1 cells into the kidney in ischemic AKI.[411] In summary, it is believed that CD4 T cells are important in the pathogenesis of ischemic AKI and that very few T cells in the kidney are enough to contribute to injury.[404,406,409]

Regulatory T cells (Tregs) are known to blunt the immune response. Foxp3+ regulatory T cells play a role in kidney repair after an ischemic AKI.[412] Tregs also contribute to the protective effect of ischemic preconditioning in the kidney.[413] Treatment of mice with a Treg cell–depleting antibody reversed the protective effect of preconditioning on kidney neutrophil infiltration, function, and histology. Sphingosine-1-phosphate receptor (S1PR) agonists reduce ischemic AKI in mice that lack T and B lymphocytes (Rag-1 knockout mice).[414] S1PR agonists also reduce hypoxia-induced

apoptosis in cultured mouse proximal tubule cells. This study shows that the protective effect of S1PR agonists is independent of T cells.

Natural killer (NK) cells are lymphocytes that mediate innate immunity against pathogens and tumors via their ability to secrete cytokines.[415] NK cells are unique in their constitutive expression of receptors for cytokines (eg, IL-18), which are produced by activated macrophages.[416] NK cells are activated by IL-18 independently of IL-12.[417] A model of NK cell activation in injured tissues has been proposed.[418] In this model, it is hypothesized that NK cells are recruited to sites of injury from the bloodstream. Once in the tissue, NK cells become activated and release cytokines like IL-18.[418] In support of this hypothesis, it is known that NK cells play a role in numerous disease processes.[419] NK cell depletion in wild-type C57BL/6 mice is protective against ischemic AKI.[420] An adoptive transfer of NK cells worsened injury in NK-, T-, and B-cell–null Rag2(-/-)γ(c)(-/-) mice with ischemic AKI. NK cell–mediated kidney injury was perforin (PFN) dependent because PFN(-/-) NK cells had a minimal capacity to kill tubular epithelial cells in vitro compared with NK cells from wild-type mice. Alternatively, B cells limit repair after ischemic AKI.[421]

Monocyte/Macrophages

Another inflammatory cell that is a potential mediator of injury in ischemic AKI is the monocyte/macrophage.[404] Macrophages infiltrate the postischemic rat kidney.[422] Macrophage chemoattractants (e.g., monocyte chemoattractant protein 1 [MCP-1]) are increased in the postischemic rat kidney.[404] In a model of macrophage depletion using liposomal clodronate, it was demonstrated that macrophages contribute to tissue damage during acute rejection.[423] It was determined that macrophages are a source of injurious IL-18 in ischemic AKI in mice.[424] Macrophage depletion in the kidney was achieved by using a tail vein injection of liposomal-encapsulated clodronate (LEC). The adoptive transfer of RAW 264.7 cells, a mouse macrophage line that constitutively expresses IL-18 mRNA, reversed the functional protection against AKI in LEC-treated mice. In addition, the adoptive transfer of peritoneal macrophages in which IL-18 function was inhibited also reversed the functional protection in macrophage-depleted mice, demonstrating that IL-18 from the adoptive transfer of macrophages is not sufficient to cause ischemic AKI. Possible sources of injurious IL-18 in AKI include the proximal tubule and lymphocytes. In this regard, freshly isolated proximal tubules from mice release IL-18 into the medium when exposed to hypoxia, and proximal tubules from caspase-1–deficient mice are protected against hypoxic injury.[178] An anti-B7-1 antibody blocks mononuclear cell adherence in the vasa recta of rats and attenuates ischemic AKI both functionally and histologically.[425] Gene therapy in rats expressing an amino-terminal truncated MCP-1 reduced macrophage infiltration and AKI.[426] Two recent studies have demonstrated that macrophage depletion using liposomal clodronate is protective against ischemic AKI in mice.[427,428]

Dendritic cells act as antigen-presenting cells and as messengers between the innate and adaptive immunity. The kidney has a rich network of resident dendritic cells.[429] Dong and colleagues[430] have identified the surveying renal dendritic cell network as the predominant source of TNF-α during the early stages of ischemic AKI.[430]

Proinflammatory cytokines increase the expression of the CX_3C chemokine, fractalkine, on injured endothelial cells. The fractalkine receptor (CX_3CR1) is expressed on NK cells, monocytes, and some CD8+ T cells.[431] Fractalkine has a mucinlike stalk that extends the chemokine domain away from the endothelial cell surface, enabling the presentation of the CX_3C-chemokine domain to leukocytes. Fractalkine serves the dual function of an adhesion molecule and a chemoattractant.[431] Fractalkine is a major chemoattractant for NK cells and monocytes, but not for neutrophils.[432] Fractalkine expression is increased in patients with renal tubulointerstitial inflammation, with the strongest expression localized to vascular sites near to macrophage inflammation.[433] Fractalkine is a strong candidate for directing mononuclear cell infiltration induced by vascular injury.[433] Fractalkine expression is increased in the endothelium of large blood vessels, capillaries, and glomeruli in ischemic AKI.[427] Fractalkine receptor inhibition is protective against ischemic AKI.[427]

Inflammatory Mediators

In renal ischemia–reperfusion, tubular epithelial cells produce TNF-α, IL-1, IL-6, IL-8, IL-18, TGF-β, MCP-1, RANTES, and fractalkines.[20,190,191] Leukocytes produce TNF-α, IL-1, IL-8, MCP-1, reactive oxygen species, and eicosanoids.[20] The anti-inflammatory cytokine, IL-10, inhibits TNF-α, ICAM-1, and iNOS and protects against ischemic and cisplatin-induced renal failure and AKI.[434]

Statins are potent anti-inflammatory drugs.[435] Both in vitro and in vivo studies suggest lipid lowering–independent anti-inflammatory functions of statins.[435] After adhesion to the vascular endothelium, inflammatory cells migrate to the site of inflammation.[435] Statins act independently of lipid lowering to selectively inhibit leukocyte adhesion by direct interactions with the leukocyte-function antigen 1 (LFA-1).[435] Statins reduce macrophage influx and chemokine expression in rat kidneys.[436] Statins are known to decrease the expression of proinflammatory cytokines by inflammatory cells.[435] Simvastatin reduces the expression of IL-6 and MCP-1 in monocytes from hypercholestrolemic patients and in cultured endothelial cells.[435] Pravastatin downregulates TNF-α and MCP-1[437] in human monocytes in vitro. Some of the anti-inflammatory effects of statins are mediated by NO.

Rats were treated with cerivastatin or a vehicle for 3 days before the induction of ischemic AKI.[438] Statin

treatment reduced the increase in serum creatinine by 40% and protected against tubular necrosis. In addition, monocyte and macrophage infiltration was almost completely prevented, ICAM-1 upregulation was decreased, and iNOS expression was reduced.[438] In another study, atorvastatin improved the course of ischemic AKI in aging rats by enhancing NO availability and improving renal hemodynamics.[439]

Proinflammatory cytokines are increased in the serum of animal models of AKI.[66] Data in animal models of AKI suggest that the inflammatory response in AKI is dysregulated. The effect of AKI on the production and elimination of proinflammatory cytokines may be a key mechanism by which patients with AKI have increased distant organ dysfunction and increased mortality. In animals with AKI, TNF-α,[440] IL-1β,[440] IL-6, KC, and granulocyte colony stimulating factor (GCSF) increase in the serum after AKI.[66] Cytokine production also increases in the kidney.[66] Renal cytokine production may contribute to renal injury and cause the increase in serum cytokines. Circulating cytokines may contribute to extrarenal organ injury.

Besides IL-18, there are other cytokines that play a role in ischemic AKI. The TNF-like weak inducer of apoptosis (TWEAK, TNFSF12) is a member of the TNF superfamily. TWEAK activates the Fn14 receptor and regulates apoptosis, proliferation, and inflammation. TWEAK and Fn14 expression was increased in experimental AKI induced by folic acid.[441] The IL-6/IL-6R axis plays a critical role in AKI.[442] High-mobility group box 1 (HMGB1), a nuclear factor released extracellularly as an inflammatory cytokine, is an endogenous ligand for TLR4. A neutralizing anti-HMGB1 antibody protected against ischemic AKI and reduced levels of IL-6, TNF-α, and MCP1.[443] Alternatively, the administration of recombinant HMGB1 after reperfusion exacerbated ischemic AKI. TLR4-deficient mice were protected against AKI and the administration of an anti-HMGB1 antibody or a rHMGB1 did not affect this renoprotection. This study concluded that endogenous HMGB1 promotes kidney damage after IRI, possibly through the TLR4 pathway.

RECOVERY FROM ISCHEMIC ACUTE KIDNEY INJURY

It has been demonstrated in rats that severe ischemic AKI results in a permanent alteration in renal capillary density that contributes to a urinary concentrating defect and renal fibrosis.[444,445] However, in contrast to other organs, the kidney can recover from tubular necrosis, at least in the short term. There are two potential mechanisms of recovery other than cell repair: (1) the dedifferentiation and proliferation of the surviving nonnecrotic tubular cells,[446] and (2) the mobilization and delivery of bone marrow stem cells to the injured kidney.[447]

After an ischemic AKI, there is a proliferation of tubular cells that mimic events in the developing kidney.[448] Epithelial cells are also dedifferentiated during the recovery period.[446] In the postischemic kidney, there is also an expression of genes that encode growth factors.[263,265,449] The dedifferentiation and the proliferation of tubular epithelial cells may result in the spreading of cells over the damaged basement membrane. Cell adhesion molecules like neural cell adhesion molecule (NCAM), cytokines, and KIM-1[59,450] may play a role in these processes. The targeted delivery of hepatocyte growth factor (HGF) to the proximal tubule in transgenic mice resulted in a marked protection against ischemic AKI.[451] Understanding the physiology of repair and the recovery of surviving tubular cells may lead to therapies to hasten the recovery process in humans.

Bone marrow stem cells have the capacity to migrate to other organs.[447] Bone marrow–derived cells can populate and contribute to the turnover of both the normal and injured renal tubular epithelium.[452] Cells from the bone marrow of adult mice are mobilized into the circulation by transient renal ischemia and home specifically to the injured kidney where they differentiate into tubular epithelial cells.[447] It was investigated whether an increase in circulating stem cells, using pharmacologic mobilization from the bone marrow, would improve renal function in mice with ischemic AKI.[453] The pharmacologic increase in stem cells was associated with marked granulocytosis and worsening of renal failure. In the future, therapies aimed at stimulating the proliferation, mobilization, and targeting of stem cells may enhance recovery from ischemic AKI.[447] However, in another study, it was shown that intrarenal cells, not bone marrow–derived cells, are the major sources for regeneration in postischemic AKI. Furthermore, a single injection of bone marrow cells did not make a significant contribution to renal functional or structural recovery.[454]

Mesenchymal stem cells (MSCs) play a role in regeneration and immunomodulation. The administration of MSCs protects against ischemic AKI in rats.[455] In this study, the expression of IL-1β, TNF-α, IFN-γ, and iNOS was significantly reduced by the intravenous administration of MSCs. In addition, the beneficial effects of MSCs were found to be mediated by paracrine actions and not by their differentiation into target cells. Human MSCs improve renal function and survival in mice with cisplatin-induced AKI.[456] The treatment of mice with autologous and allogeneic MSCs after AKI was safe and reduced renal fibrosis in mice that survived an AKI.[457] CD44 and hyaluronic acid interactions recruit exogenous MSCs to injured tissues to improve renal regeneration.[458] Also, MSCs exert beneficial effects on tubular cell repair in an ischemic AKI by the production of the prosurvival and mitogenic growth factor IGF-1.[459] A phase 1 study of MSCs in patients at risk for AKI after cardiac surgery is under way.

Colony stimulating factor (CSF-1) signals directly to renal tubular epithelial cells to mediate repair in mice.[460] Macrophages have been implicated in tissue repair, and CSF-1,

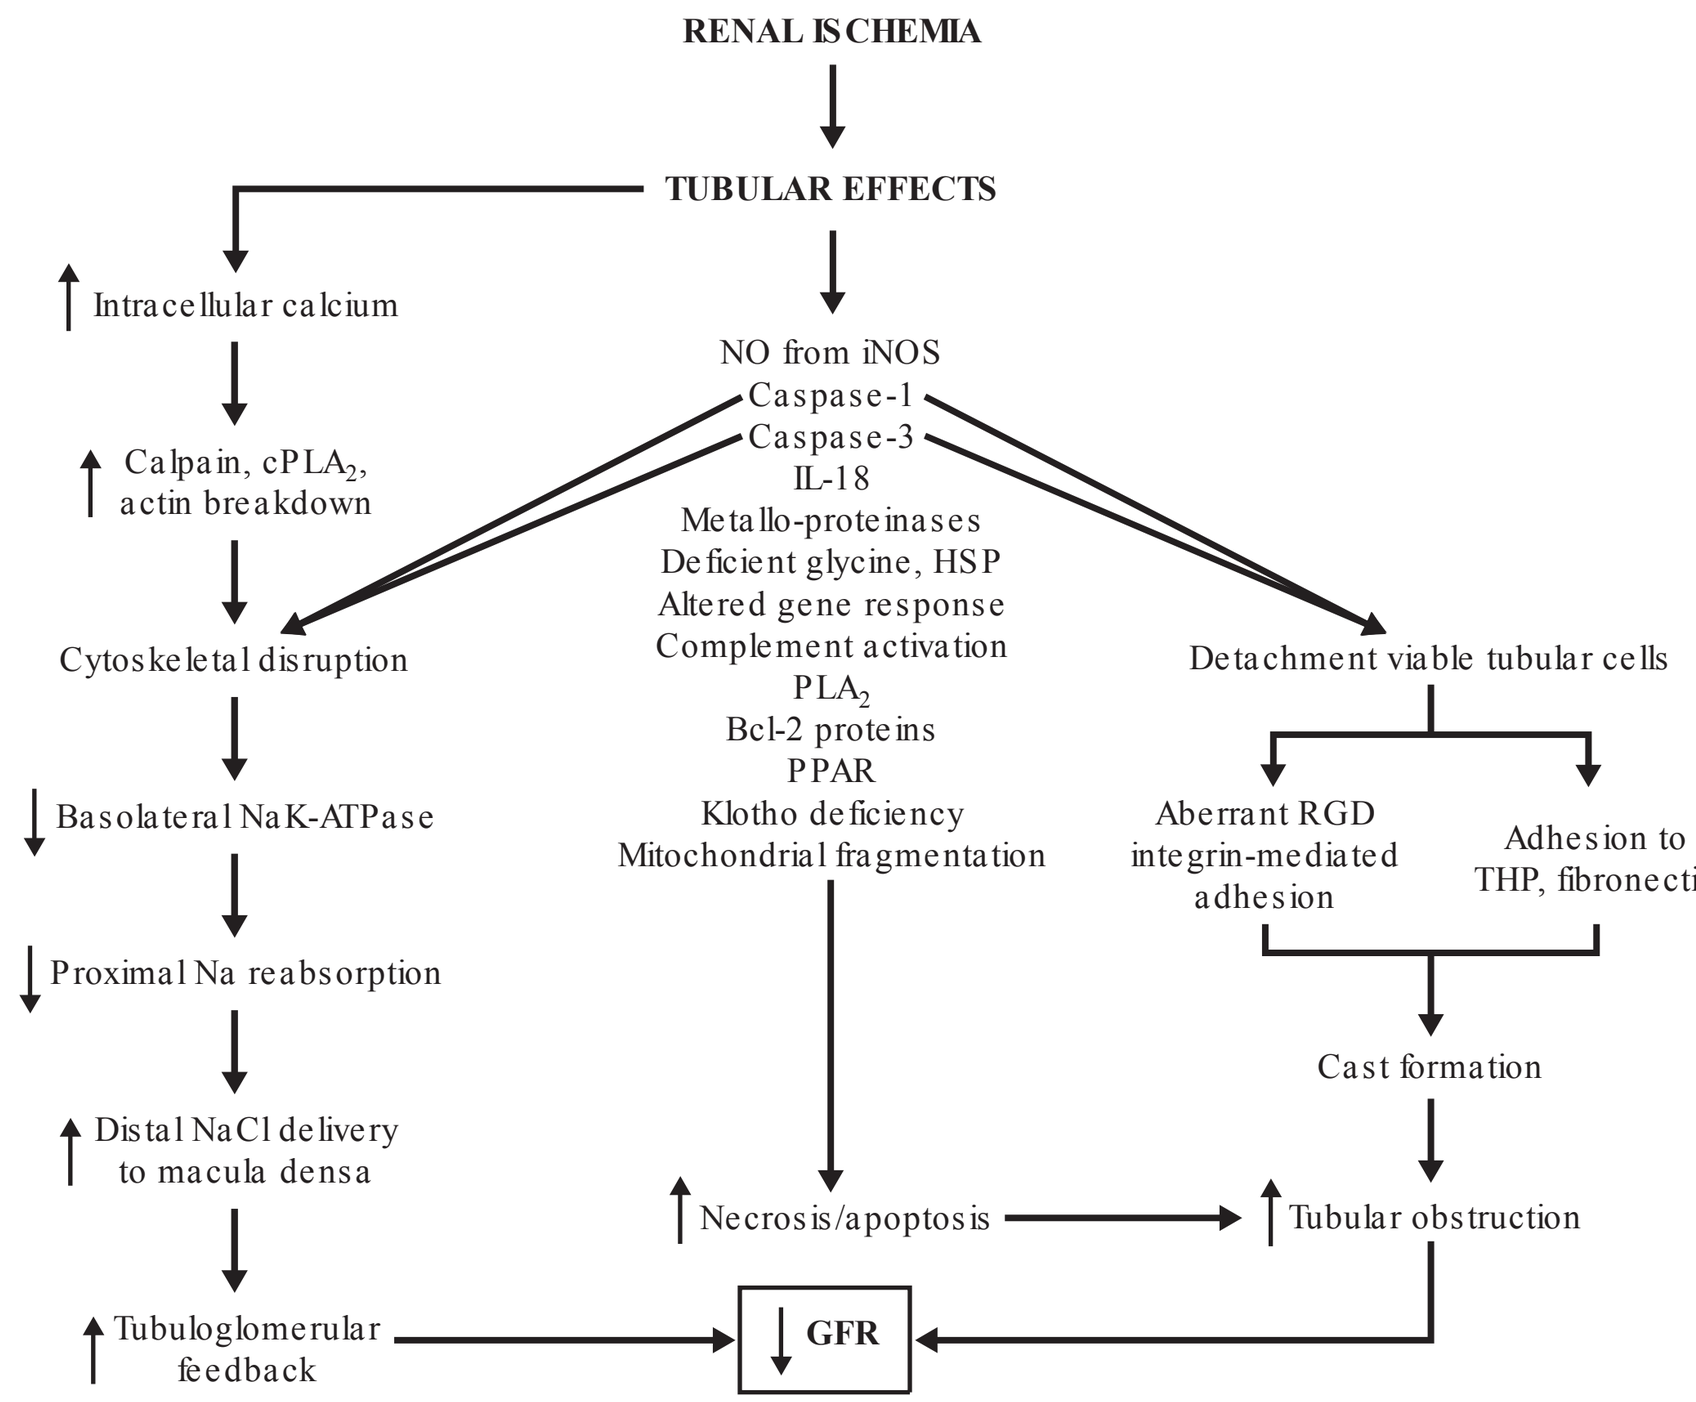


FIGURE 29.8 The tubular factors in the pathogenesis of ischemic acute kidney injury. NO, nitric oxide; iNOS, inducible nitric oxide; IL-18, interleukin 18; HSP, heat shock protein; PLA_2, phospholipase A_2; RGD, arginine-glycine-aspartic acid; THP, Tamm-Horsfall protein; PPAR, peroxisome proliferator–activated receptors; GFR, glomerular filtration rate. the principal macrophage growth factor, is expressed by tubular epithelial cells. Mice injected with CSF-1 had decreased tubular pathology and improved renal function in an ischemic AKI. The study further demonstrated that CSF-1 mediates renal repair by both a macrophage-dependent mechanism and a direct autocrine/paracrine action on tubular epithelial cells (TECs).

SUMMARY

Tubular and vascular perturbations and inflammation combine to cause ischemic AKI. The tubular and vascular events in ischemic AKI are summarized in Figures 29.8 and 29.9. The inflammatory events are summarized in Figure 29.10. Recent laboratory studies using in vivo, cellular, and molecular approaches have provided substantial insight into the pathogenesis of the syndrome. These studies have identified several potential therapeutic interventions, which need to be tested with prospective clinical trials. Interventions that have attenuated experimental ischemic/hypoxic proximal tubule damage include cysteine protease inhibitors, melanocyte stimulating hormone (MSH), specific iNOS inhibition,

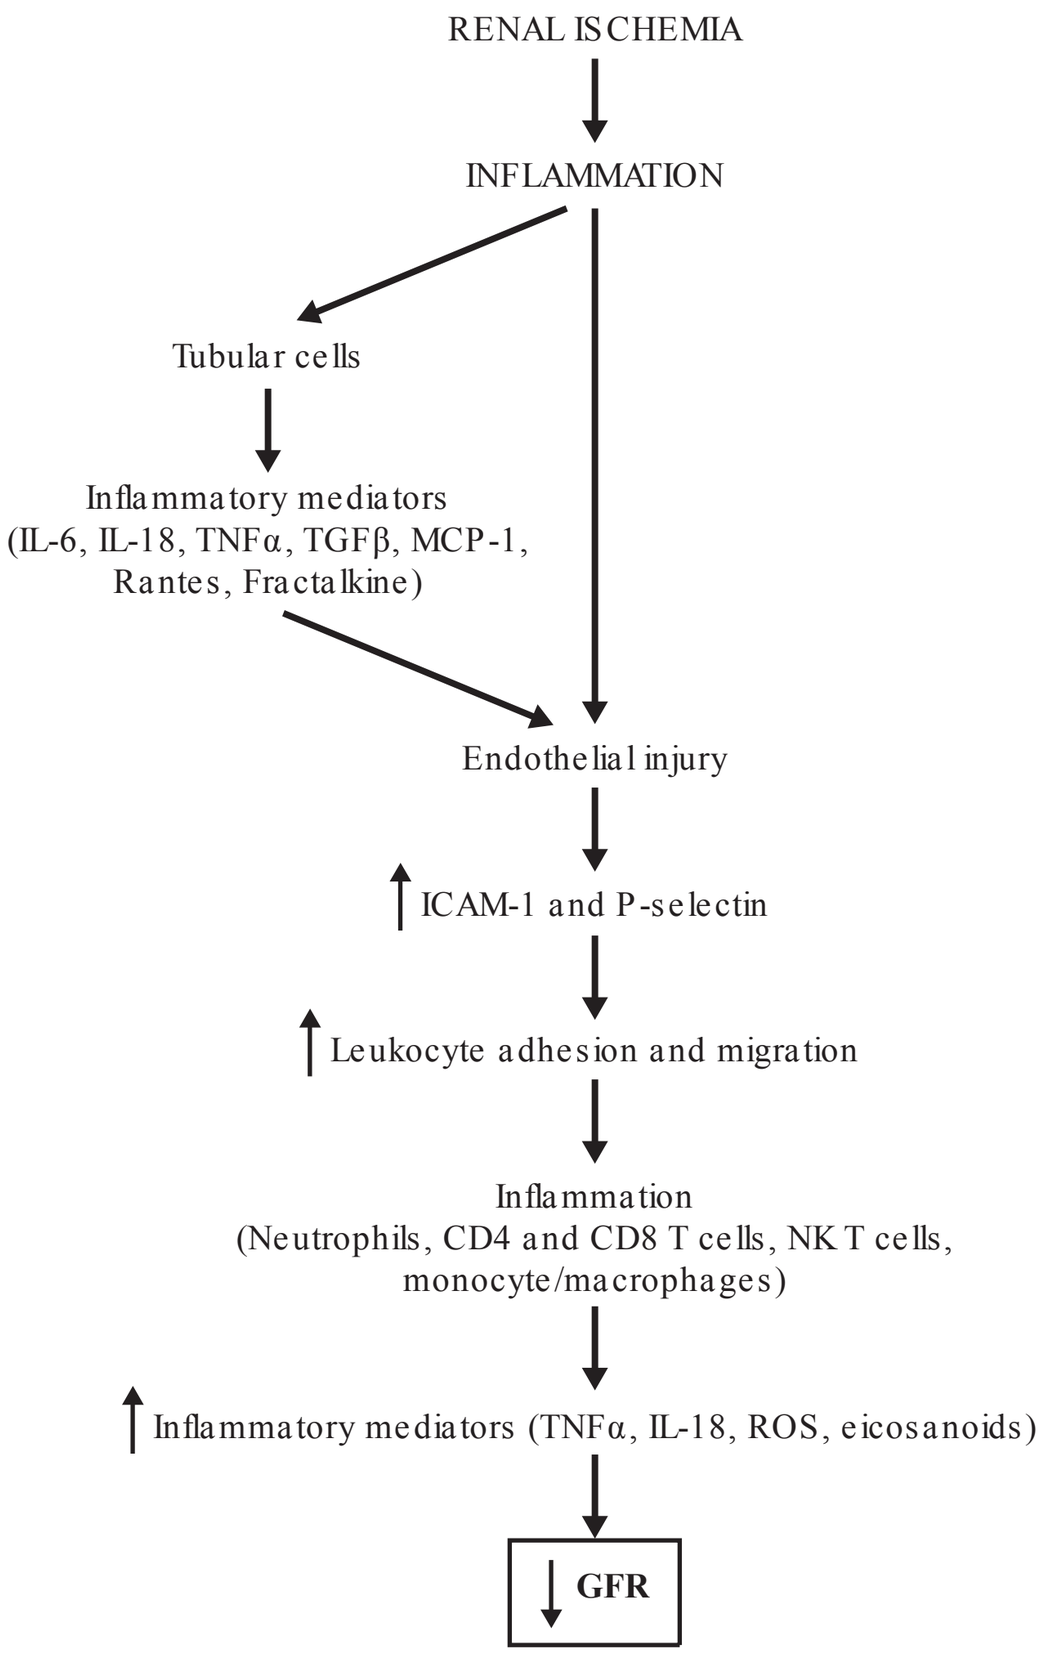

FIGURE 29.10 The inflammatory response in ischemic acute kidney injury. IL, interleukin; TNF-α, tumor necrosis factor alpha; TGF-β, transforming growth factor beta; MCP-1, monocyte chemoattractant protein 1; RANTES, regulated upon activation, normal T cell expressed and secreted; ICAM-1, intracellular adhesion molecule 1; NK, natural killer; ROS, reactive oxygen species; GFR, glomerular filtration rate .

synthetic cyclical arginine-glycine-aspartic acid (RGD) sequences, mannitol, oxygen radical scavengers, TNF soluble receptors, inducers of HSP-70 and anti-ICAM antibodies, endothelin antagonists, IL-18 antiserum, IL-6 inhibition erythropoietin, NGAL, CTLA4 immunoglobulin, fractalkine receptor inhibition, CSF-1, MSCs, IGF-1, macrophage stimulating protein, macrophage inhibition, hemeoxygenase-1, PPAR-α, β/δ activators, CXCR3 inhibition, sphingosine-1-phosphate receptor agonists, siRNA to p53, soluble thrombomodulin, IFN regulatory factor (IRF-1), fibrates, HMGB1 inhibition, ghrelin, Klotho, HIF-1 activation, complement factor B inhibition, and adenosine A1 receptor activation, to mention a few (Table 29.9).

29.9 Some Emerging Therapies for Ischemic Acute Renal Failure

Cysteine protease inhibitors
Caspase inhibitors
IL-18 inhibition
IL-6 inhibition
áMSH
Specific iNOS inhibition
Synthetic cyclical RGD sequences
Oxygen radical scavengers
TNF soluble receptors
Inducers of HSP
Anti-ICAM antibodies
Endothelin antagonists
Endothelial cell infusion
Mannitol with natriuretic peptides or calcium channel blockers
Erythropoeitin
NGAL
CTLA4 immunoglobulin
Fractalkine receptor inhibition
CSF-1
MSCs
IGF-1
Macrophage stimulating protein
Macrophage inhibition
Hemeoxygenase-1
Peroxisome proliferator–activated receptor (PPAR) α, β/δ activators
CXCR3 inhibition
Sphingosine-1-phosphate receptor agonsists
IFN regulatory factor (IRF-1)
Fibrates
High mobility group box (HMGB1) inhibition
Ghrelin
Klotho
HIF-1 activation
Complement factor B inhibiton
Adenosine A1 receptor agonist
Adenosine A2B receptor agonist
siRNA to p53
Soluble thrombomodulin

IL, interleukin; MSH, melanocyte stimulating hormone; iNOS, inducible nitric oxide; RGD, arginine-glycine-aspartic acid; TNF, tumor necrosis factor; HSP, heat shock protein; anti-ICAM, intercellular adhesion molecule-1; NGAL, neutrophil-gelatinase-associated lipocalin; CTLA4, cytotoxic T-lymphocyte antigen 4; CSF-1, colony stimulating factor; MSC, mesenchymal stem cell; IGF-1, insulin-like growth factor 1; CXCR3, chemokine CX-C-motif receptor 3; HIF-1, hypoxia-inducible factor 1; siRNA, small interfering RNA.

CHAPTER

30 Pathophysiology of Nephrotoxic Cell Injury

Brian S. Cummings • Rick G. Schnellmann

Nephrotoxic epithelial renal cell injury is induced by a variety of stimuli, including chemical exposure, which can lead to acute kidney injury (AKI). Chemicals can induce cell injury either directly or indirectly. Examples of chemicals that directly induce renal cell injury include chemotherapeutics, antibiotics, oxidants, metals, and cysteine conjugates. In contrast, indirect chemical insults are initiated at sites removed from renal epithelial cells. Processes that induce indirect renal epithelial cell injury include decreased renal blood flow, renal ischemia, and reperfusion-induced cell injury and death. Inflammatory cells also indirectly and secondarily induce renal epithelial cell injury in a number of models.[1–4]

A secondary effect of nephrotoxicant-induced cell death is the generation of "backleak." After injury, epithelial cells can be released from the basement membrane and adhere to each other via integrins.[5–8] These cellular aggregates form tubular casts that block the flow of filtrate and increase intraluminal pressure, decreasing the single nephron glomerular filtration rate.[5] In addition, the loss of epithelial cells leaves gaps in the basement membrane, allowing tubular filtrate to backleak into the circulation, further decreasing the single nephron glomerular filtration rate. Thus, backleak and the loss of epithelial cells contribute to decreased renal function (Fig. 30.1). Tubular cast formation can be induced by both direct and indirect chemical injury.

After either direct or indirect injury, renal epithelial cells can die or repair and regenerate. The processes involved in renal cell regeneration have been reviewed,[9] and they are categorized into four different mechanisms that include dedifferentiation, proliferation, migration, and redifferentiation—each having defined morphologic characteristics and activation of differential cell signaling pathways. Processes of renal cell regeneration are somewhat similar to epithelial-mesenchymal transition (EMT) in embryonic development and cancer[9] and EMT is hypothesized to mediate fibrosis during chronic kidney injury induced by multiple stimuli.[10,11]

Significant controversy exists concerning the source of postinjury regenerating renal epithelial cells. Although some researchers have suggested that the majority of regenerating epithelial cells are derived from stem cells, present in either the kidney or the bone marrow, most recent studies provide convincing evidence that extratubular cells do not appreciably contribute to epithelial repair and regeneration after AKI.[12] Furthermore, there was no evidence of intratubular "progenitor cells."

The process of renal cell repair begins when cells adjacent to the injured area dedifferentiate, proliferate, and migrate into the denuded areas. Ultimately, the cells differentiate, and tubular structure and function are restored. Of course, such renal cell regeneration is not applicable for all nephrotoxicants. For example, repair of renal proximal tubule cell necrosis induced by the aminoglycoside tobramycin is initiated 4 days after treatment, with cells resuming normal morphology after 14 days.[13] In contrast, a 4-day regimen of the anticancer agent cisplatin also resulted in renal dysfunction with proximal tubular necrosis; however, renal dysfunction persisted.[14]

Several chemicals mediate AKI by inhibiting repair via alteration of differentiation, migration, and proliferation or dedifferentiation. Inhibition of repair with these compounds occurs at concentrations that do not induce overt cell injury. For example, Counts and colleagues studied renal repair and regeneration in vitro in renal proximal tubular cells (RPTCs) using a model that involved mechanical injury[15] and showed that $HgCl_2$; the mycotoxin fumonisin B_1; and the haloalkene cysteine conjugate, S-(1,2)-dichlorovinyl-L-cysteine (DCVC), inhibited the normal proliferative and migratory renal cell responses in the absence of overt cytotoxicity. Thus, mechanisms involved in the pathophysiology of nephrotoxic-induced AKI are not always directly related to cell death.

The goal of this chapter is to review mechanisms by which chemicals produce renal epithelial cell injury and death. Other chapters in this volume, and several excellent reviews, discuss renal cell repair and regeneration, as well as mechanisms of renal cell death and AKI produced by specific chemicals.

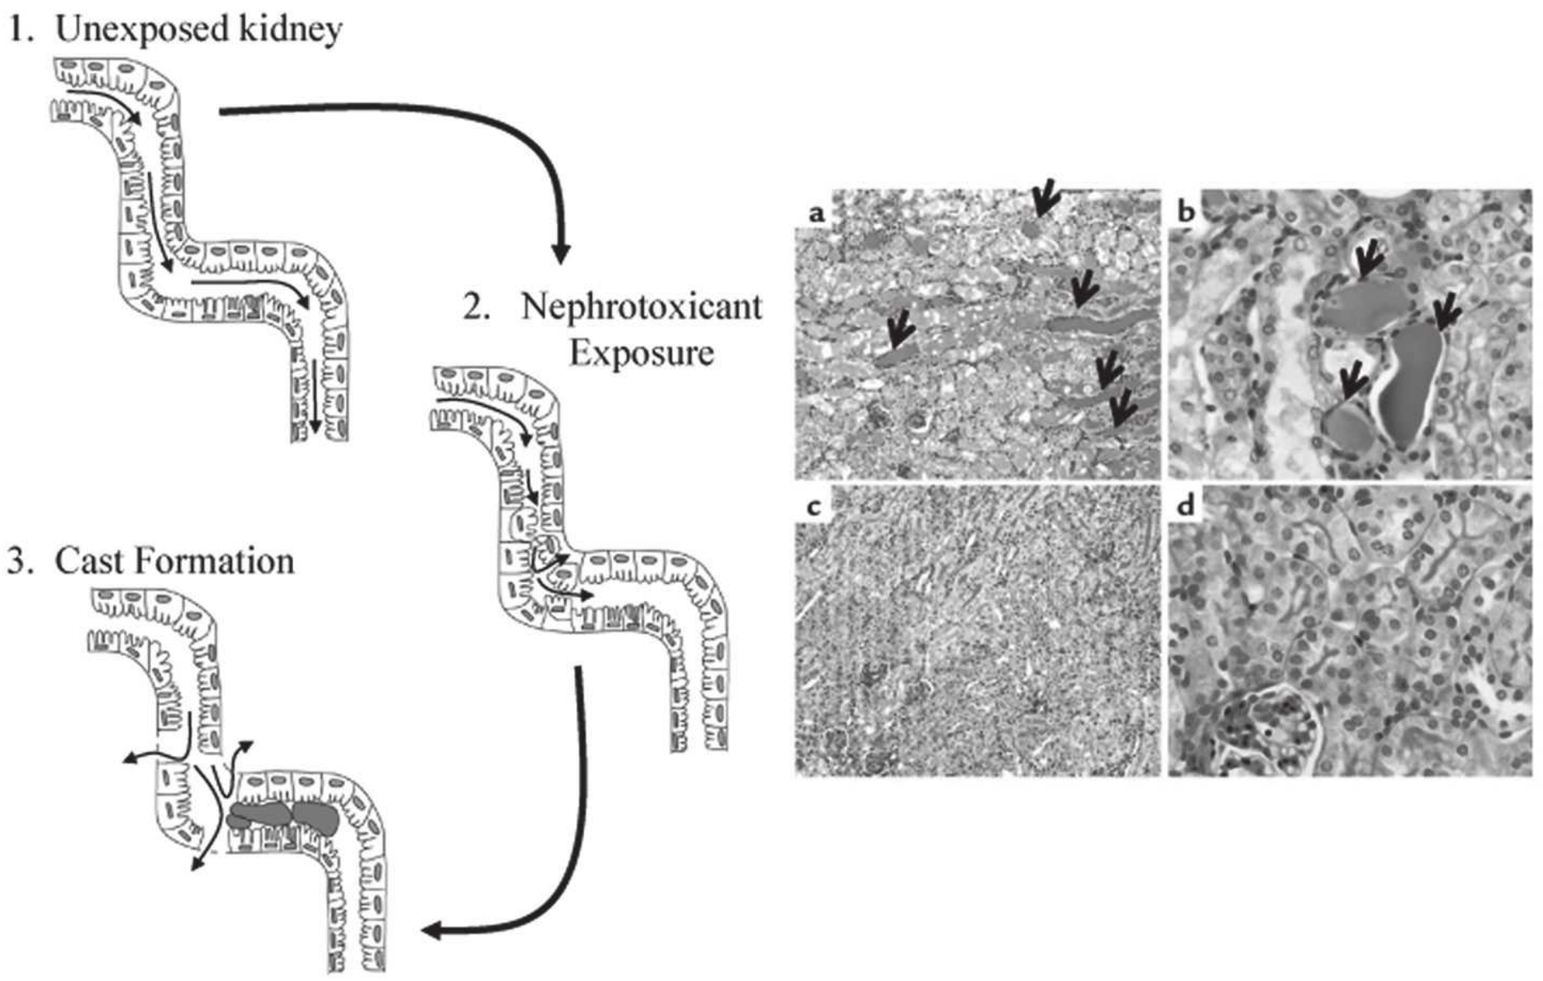

FIGURE 30.1 Cast formation in the nephron. **Left:** *1.* Filtrate flow (as represented by the *small arrows*) through the tubules is constant and unobstructed in unexposed kidneys. *2.* Exposure of the kidney to nephrotoxicants results in cell injury and death, and can induce detachment of the cells from the basement membrane. *3.* Detached cells can adhere to each other and form casts (*pink*), which obstruct filtrate flow and increase intraluminal pressure. This increases permeability in the basement membrane and back leak of filtrate into the interstitium. **Right:** Cisplatin-induced cast formation in wild-type mice (*a* and *b*) and mice mutant for tumor necrosis factor (TNF)-α (*c* and *d*) as determined by PAS staining. The magnification in panels *a* and *c* is ×100, and that in panels *b* and *d* is ×400. Cast formation is visible in panels *a* and *b* as indicated by the *pink/purple* aggregates between the tubules (*arrows*). In contrast, little cast formation can be seen in TNF-α knockout mice (panels *c* and *d*). (Adapted from Ramesh G, Reeves WB. TNF-alpha mediates chemokine and cytokine expression and renal injury in cisplatin nephrotoxicity. *J Clin Invest*. 2002;110(6):835–842, with permission.) (See Color Plate.)

SUSCEPTIBILITY OF THE KIDNEY TO INJURY

The kidney is highly susceptible to numerous agents because of several functional properties of this organ. These include: (1) receiving 20% to 25% of the cardiac output, ensuring high levels of toxicant delivery over a period of time; (2) extensive reabsorptive capacity with specialized transporters promoting cellular uptake of the toxicant; (3) concentrating abilities resulting in high concentrations of toxicants in the medullary lumen and interstitium; (4) biotransformation enzymes for the formation of toxic metabolites and reactive intermediates; (5) high metabolic rate and workload of renal cells causing increased sensitivity to toxicants; and (6) sensitivity of the kidney to vasoactive agents.

Nephrotoxicants can target specific nephron segments. The proximal tubule epithelial cell is typically the primary target; however, other parts of the nephron can also be affected by chemicals with a specificity that is concentration-dependent. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen target the collecting ducts at low concentrations, but also induce damage to the proximal tubules at higher concentrations.[16,17] Furthermore, different segments of the proximal tubule (S_1, S_2, and S_3) are targets for different nephrotoxicants. For example, aminoglycoside antibiotics, chromate, cadmium chloride, and the mycotoxin citrinin primarily target the S_1 and S_2 segments, whereas cyclosporine, $HgCl_2$, uranyl nitrate, cisplatin, bromobenzene, and cysteine conjugates of halogenated hydrocarbons target the S_3 segment.[17,18] Interferon-α, gold, and penicillamine can target cells in the glomeruli, whereas angiotensin-converting enzyme (ACE) inhibitors can target cells in the renal vasculature.[17] Clostridium perfringens B and D and trichloroethylene can target distal tubules, and radiocontrast media, triethanolamine, amphotericin, and nystatin tend to target the loop of Henle. Studies suggesting that trichloroethylene targets the distal tubules are derived from in vitro models only at high doses,[19] whereas agents that target the loop of Henle also can also affect the proximal tubules.[16]

These segmental differences in chemical sensitivity may be attributed to: (1) differences in toxicant delivery to a given segment, (2) differences in transport and uptake among segments, and (3) differences in biotransformation enzymes among segments. Once again, concentration may be a deciding factor.

NEPHROTOXICANT TRANSPORT

Many nephrotoxicants require transport into epithelial cells to induce injury, either by passive diffusion or by active or facilitated transport. Increased accumulation typically correlates to increased injury and decreased cellular function, which leads to AKI.

Several transporters are expressed in the kidney for the purpose of ensuring renal cell homeostatic functions, such as reabsorption and secretion; however, these proteins can also transport nephrotoxicants.[20] Major transporters found in renal cells include, but are not limited to, the organic cation transporters (OCTs),[21,22] organic anion transporters (OATs),[23,24] the organic anion transporting polypeptide (OATP) family,[25,26] and transporters involved in multidrug resistance (MDR) such as P-glycoprotein.[27]

Organic Anion Transporters and Organic Cation Transporters

OATs and OCTs are members of the solute carrier superfamily group 22A (SLC22A: human nomenclature) as assigned by the human genome organization (HUGO) nomenclature committee.[28] Several members in the SLC22A family have homologs with human, mouse, rat, and rabbit kidneys, in addition to having overlapping substrate specificity with each other and with other transporter families. Other than physiologic substrates,[28,29] these proteins also transport drugs, natural products, industrial chemicals, and pollutants.[20,23,30–32]

The OCT family of proteins typically transports small, hydrophobic, positively charged chemicals. Major isoforms include OCT1 (SLC22A1), OCT2 (SLC22A2), OCT3 (SLC22A3), OCT6 (SLC33A16), OCTN1 (SLC22A4), OCTN2 (SLC22A5), and OCTN3 (SLC22A21).[28] Nephrotoxicants transported by OCTs include the chemotherapeutic cisplatin, which is a substrate for OCT2 in humans and rats.[28,33–35] OCT2 may also mediate proximal tubule cell death induced by paraquat, a commonly used herbicide known to induce AKI. OCT1 mediates the toxicity of platinum compounds including cisplatin, oxaliplatin, and carboplatin in Madin-Darby canine kidney (MDCK) cells,[22] and both OCT1 and OCT2 mediate the transport of 1-methyl-4-phenyl-pyridinium, disopyramide, and chlorpheniramine into renal cells.[36] OCT2 was also demonstrated to mediate the nephrotoxicity of ifosfamide both in vitro and in vivo.[37]

OCT1 and OTC2 were recently reported to mediate the transport and toxicity of several antiretroviral drugs used to treat human immunodeficiency virus (HIV) in human embryonic kidney 293 (HEK293) cells.[38] Furthermore, OCT1, OCT2, and OCT3 were reported to mediate the transport of tyrosine kinase inhibitors (TKIs), such as imatinib, in HEK293 cells.[39] More in vivo studies are needed to fully determine the role of OCTs in nephrotoxicity induced by both antiretroviral drugs and TKI.

The OAT families of proteins typically transport small organic anions into cells. Major isoforms include OAT1 (SLC22A6), OAT2 (SLC22A7), OAT3 (SLC22A8), OAT4 (SLC22A11), OAT5 (SLC22A19), OAT6 (SLC22A20), OAT7 (SLC22A9), OAT8 (SLC22A25), OAT10 (SLC22A13), and URAT1 (SLC22A12).[28] Nephrotoxicants reported to be transported by OATs include the mycotoxin ochratoxin A, which is transported into renal tubular cells by OAT1, OAT 3, and OAT 5.[30,31,40] Ochratoxin A transport into renal cells is inhibited by probenecid,[41] an inhibitor of most OAT proteins. Recent studies also suggest that aristolochic acid, an inducer of both acute renal failure (ARF) and cancer, is transported into HEK293 cells via OAT1, OAT3, and OAT4.[42] Other nephrotoxicants whose toxicity is mediated by OCTs include methotrexate (OAT1, OAT2, and OAT3), uremic toxins such as hippuric acid and indoleacetic acid (OAT1 and OAT3), and NSAIDs (OAT1, OAT2, OAT3, and OAT4).[28]

The ability of Hg^{+2} and its cysteine conjugates to induce cell death in vivo and in MDCK cells is altered by inhibitors or substrates of OAT proteins, suggesting that the nephrotoxicity of this environmental contaminant is regulated by these transporters.[23,24] This hypothesis was confirmed by studies demonstrating that overexpression of human OAT1 in MDCK cells altered the nephrotoxicity of these compounds.[43] Other compounds for which toxicity is suggested to be mediated by OATs include the trichloroethylene metabolite DCVC, some chlorinated phenoxyacetate-based herbicides, antiviral drugs, and β-lactam-based antibiotics.[28,44]

Organic Anion Transporting Polypeptides

OATPs are members of the solute carrier O family (SLCO, formerly referred to as the SLC21 family[45]). Endogenous substrates for these proteins include bile acids, hormones, and eicosanoids.[26] Currently, genes for 11 human OATPs, 15 rat OATPs, and 15 mice have been identified.[25,45] Not all of these are expressed in kidney. Furthermore, several OATPs expressed in humans are not expressed in rodents, such as OATP1A2, OATP1B1, and OATP1B3.[45] Additionally, there are several rodent OATPs that do not have a human homolog. Such differences should be taken into account when assessing the role of OATPs in nephrotoxicity.

OATPs demonstrated to be expressed in human kidneys include OATP1A2, OATP2A1, OATP2B1, OATP3A1, OATP4A1, and OATP4C1.[45] Rat and mouse kidneys are reported to express Oatp1a1, Oatp1a6, Oatp2a1, Oatp2b1, Oatp3a1, Oatp4a1, and 4c1[29,46,47] (the lowercase denotes rodent genes). Oatp1a3 is reported to be a rat specific isoform.[29] The expression of several mouse kidney oatp, such as Oatp1a1, Oatp3a1, and Oatp4c1, are reported to differ depending on gender,[47] but it is not known if this trend is replicated in human kidneys.

Several studies demonstrate that OATPs mediate the transport of nephrotoxicants. For example, ochratoxin A (OATP1A2, Oatp1a1), methotrexate (OATP1B1, Oatp1a3), and digoxin (OATP4C1) are known substrates.[29] Studies also suggest that the expressions of OATPs are altered by nephrotoxicants. For example, treatment of mice with nephrotoxic doses of cisplatin for 4 days increases the expression of Oatp2a1 and Oatp2b1 mRNA.[48] Future studies are needed to fully understand the role of OATPs in the pathophysiology of nephrotoxic renal cell injury.

Maillard Reaction Products

Maillard reaction products (MRPs) are members of the ATP-binding cassette super family (ABCC).[29] Substrates for these proteins include hydrophobic molecules, such as

the chemotherapeutics vincristine and doxorubicin. At least six different MRP genes have been identified (designated MRP1-6, and MDR1) and all are expressed in the kidney.[49]

P-glycoprotein is perhaps the most well known MRP. Localized to the apical membrane of proximal tubule cells, MRP is believed to mediate the efflux of organic anions from the kidney. Known substrates for P-glycoproteins include methotrexate and cisplatin.[49,50] The nephrotoxicity of cisplatin is altered by overexpression of P-glcyoprotein.[50] P-glycoprotein may also mediate the nephrotoxicity of diallyl disulfide and S-allyl-cysteine, $HgCl_2$, calcineurin, and cyclosporine.[51–54]

CELL DEATH

The mechanisms by which chemicals induce epithelial cell death are as varied as the chemicals themselves; nevertheless, some commonalities do exist. For example, many chemicals require transport into cells to induce death. Furthermore, regardless, of how nephrotoxicants gain entry into cells, cell death is thought to occur through one of three mechanisms: apoptosis (type I cell death), autophagy (type II cell death), or necrosis (type III cell death).[55,56] Other commonalities that exist in injured and dying cells include activation of proteases, increases in cytosolic Ca^{2+}, changes in mitochondrial function and morphology, and changes in nuclear morphology and chromatin/DNA structure.

Necrosis, apoptosis, and autophagy can be identified by assessing differences in cellular and nuclear morphology. In fact, some suggest that morphology is standard for delineating mechanisms of cell death; however, it is becoming evident that morphology alone is not the best way to identify the mechanisms of cell death.[55] This reflects the fact that the mechanism of death induced by a given chemical is dependent on multiple factors such as the cell type being injured, the time of compound exposure, and the compound dose. Such multiple dependencies are typified by arsenic, which can induce all three types of cell death in a given cell.[55] Additionally, the cell death mechanism may change midway through any series of postinsult events (Fig. 30.2). Thus, a chemical may initiate autophagy, but this pathway may switch to apoptosis as the dose and time of exposure increases, or if p53 is released to the cytosol. Furthermore, apoptosis may switch to necrosis as ATP decreases or if cytosolic Ca^{2+} increases high enough to activate select proteases or induce membrane rupture. Thus, a particular mechanism of cell death cannot always be directly linked to a specific morphology and, possibly, multiple cell death pathways may be activated in a single cell.[55]

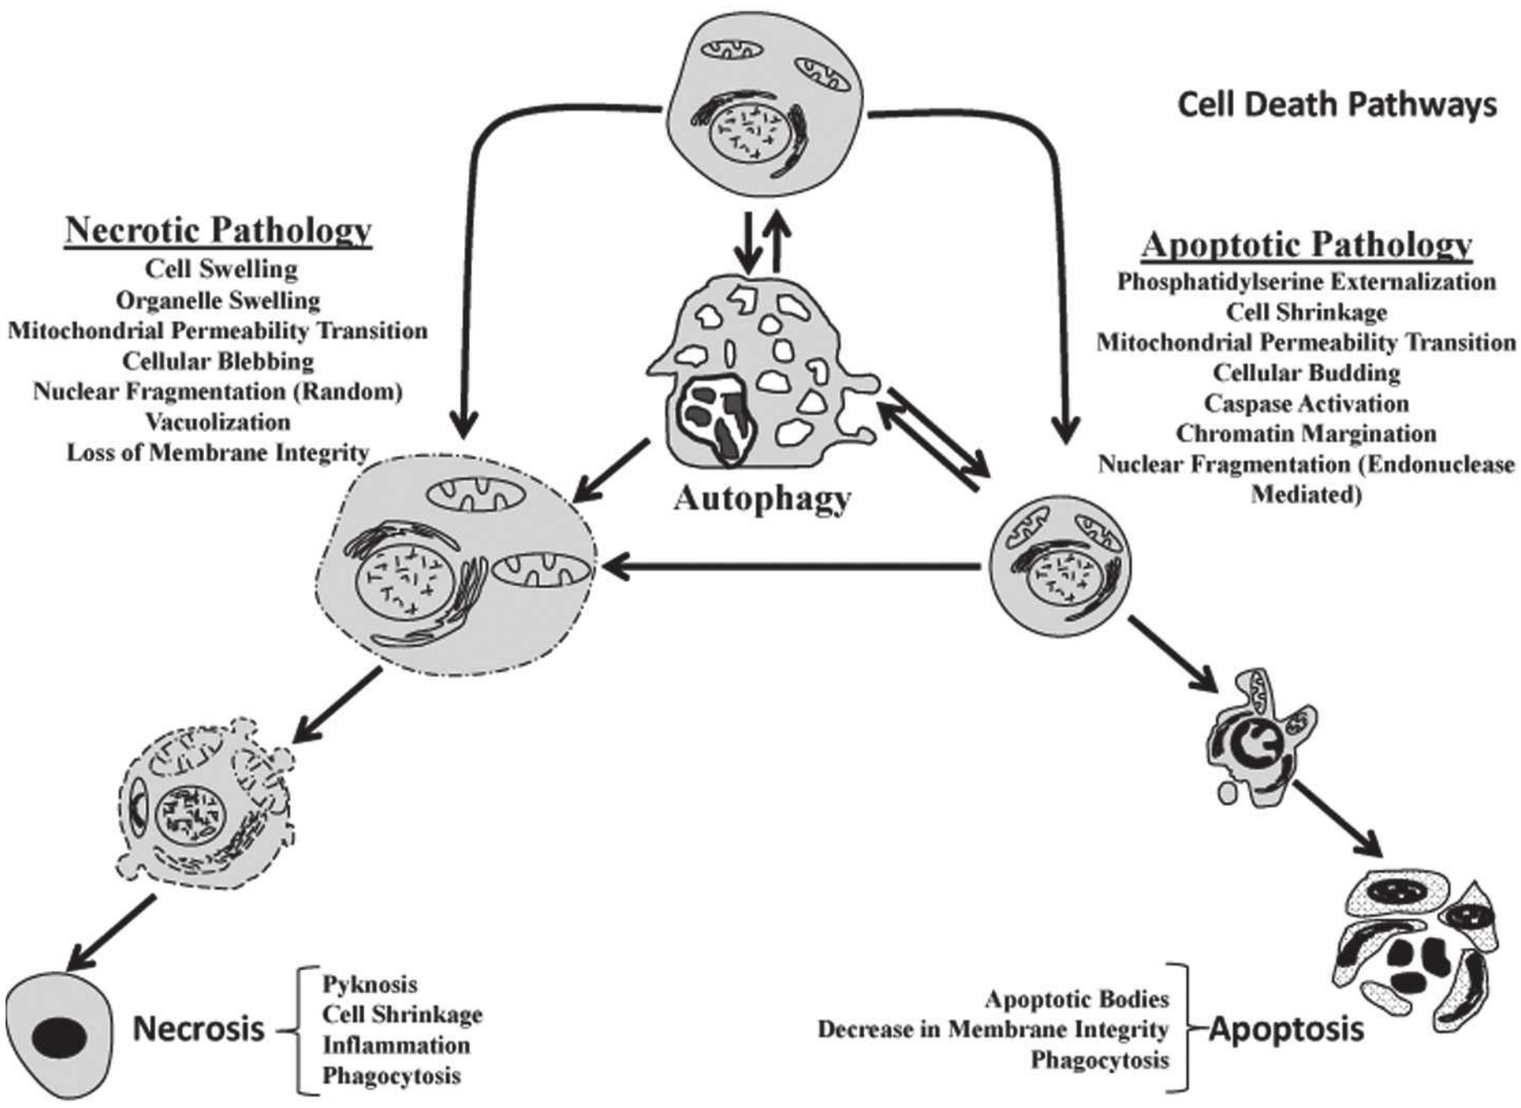

FIGURE 30.2 Schematic comparing the pathologic and morphologic features of necrosis, apoptosis, and autophagy. At the top middle, a normal cell is shown; below the normal cell is an autophagic cell demonstrating mass vacuolization; and autophagosomes (not shown). **Left:** Cell and organelle swelling, followed by vacuolization, blebbing, and increased membrane permeability (lysis) and finally necrotic changes (i.e., coagulation, shrinkage, and karyolysis). **Right:** Cell shrinkage followed by budding and karyorrhexis and finally necrotic changes (i.e., breakup into cluster of apoptotic bodies). The pathologies necrosis and apoptosis are listed. *Double arrows* represent the hypothesis that select pathways can switch. For example, autophagy can lead to cell survival and also progress to apoptosis.

Necrosis

Necrosis affects masses of contiguous cells and is characterized by swelling of organelles and increases in cell volume, after which the cell membrane becomes more permeable and ruptures with the release of cellular contents, followed by inflammation. Historically, necrosis has been used to describe drastic tissue changes occurring after cell death. These include karyorrhexis, karyolysis, pyknosis, condensation of the cytoplasm, and intense eosinophilia.

Morphologic markers for cellular necrosis include a loss of membrane and organelle integrity, cell swelling, and swelling of the endoplasmic reticulum (ER) and mitochondria (Figs. 30.2 and 30.3). Nuclear morphology in necrotic cells is usually typified by pyknosis (nuclear condensation without fragmentation); however, DNA fragmentation can occur in some cases, especially when agents that target the DNA are used. This can give rise to chromatin margination. Cellular blebs also form, but unlike apoptosis, necrotic cell blebs do not typically contain organelles. Necrosis usually induces inflammation, often with the infiltration of neutrophils and inflammatory cells in vivo (Fig. 30.3).

Biochemical markers for necrosis include a drastic and rapid loss of ATP (greater than 70%–80%), rapid and sustained increases in cytosolic Ca^{2+}, leakage of intracellular constituents such as lactate dehydrogenase, DNA fragmentation, and protease activation. A hallmark of necrosis is that it does not require ATP, separating it from both apoptosis and autophagy. DNA fragmentation also occurs in apoptosis, but DNA fragmentation that occurs during necrosis is random and not usually inhibited by caspases. Proteases activated during necrosis include select types of calpains, which are usually activated due to high concentrations of cytosolic Ca^{2+}. Evidence exists that calpains can also be activated during apoptosis (see below); thus, calpain activation alone is not a valid marker for necrosis.

Apoptosis

Apoptosis usually affects scattered individual cells and, morphologically, the cell shrinks whereas organelle integrity is initially retained (Figs. 30.2 and 30.3). Next, chromatin become pyknotic and marginate against the nuclear membrane and, ultimately, the cell shrinks to a dense, round mass

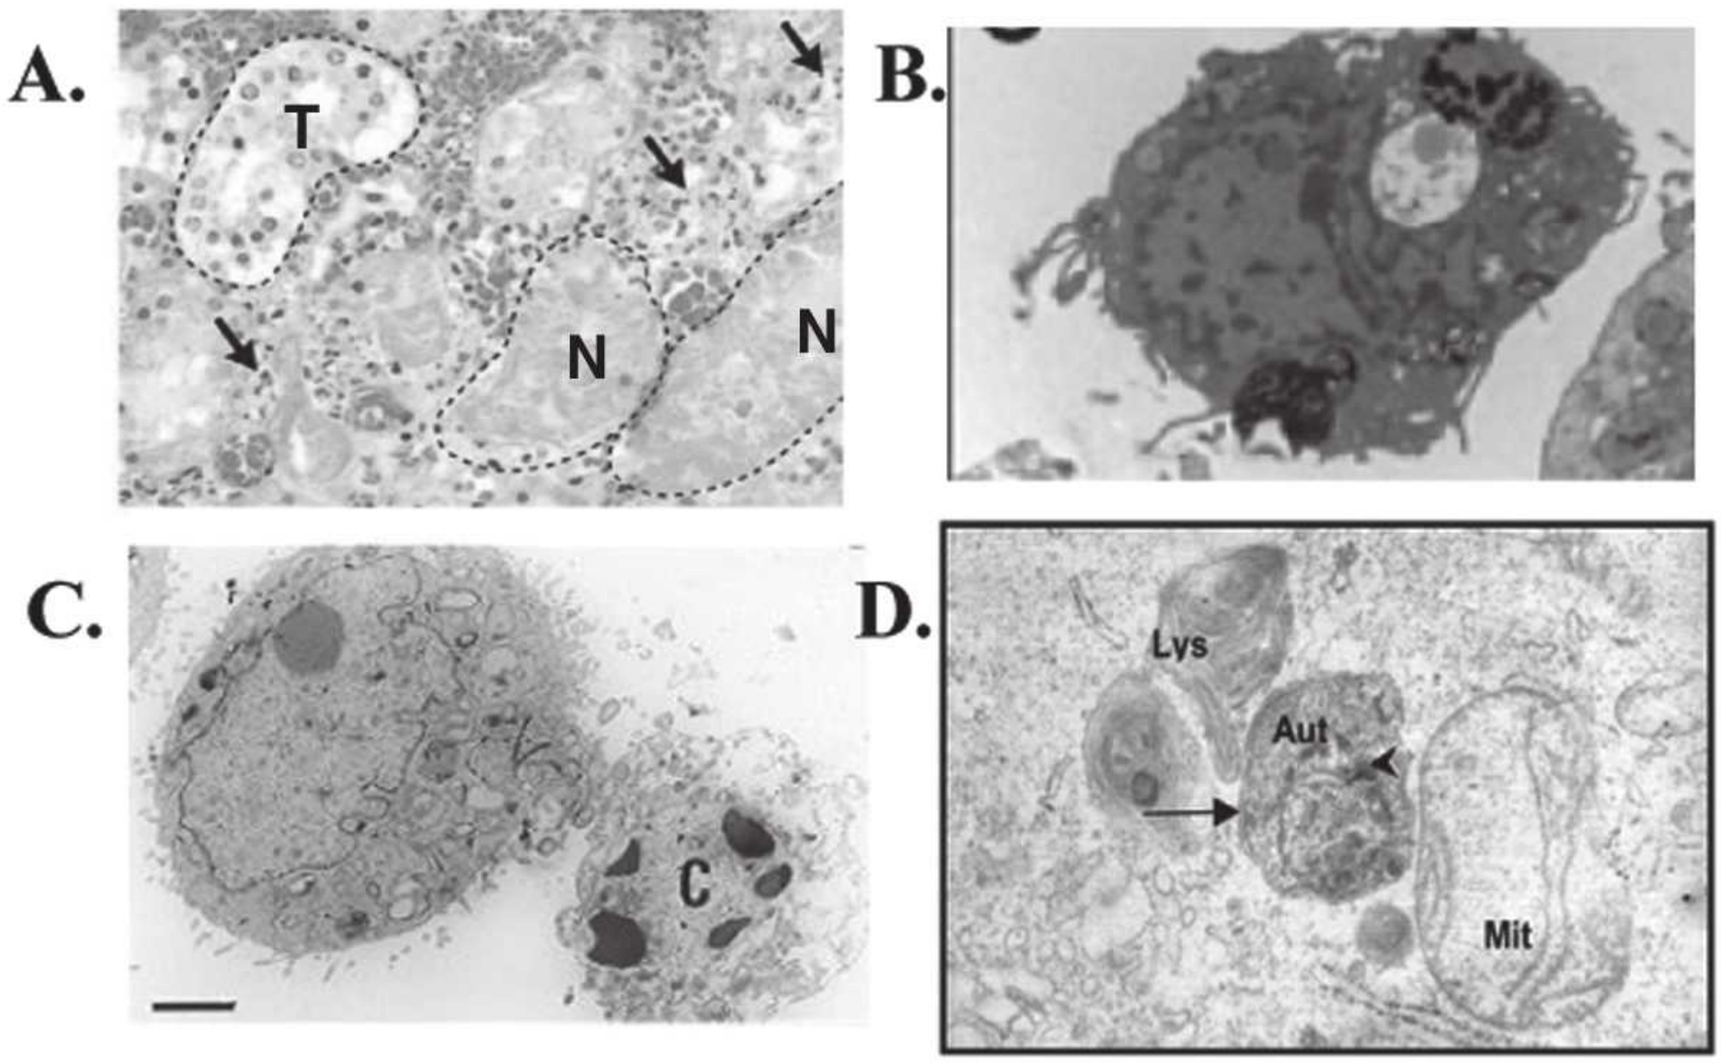

FIGURE 30.3 Comparison of the morphologic features of necrosis, apoptosis, and autophagy in tissues and cells. **A:** Hematoxylin and eosin staining of human kidney tissue after arterial embolization for treatment of renal cancer demonstrating intact tubules (*T*) and necrotic tubules (*N*). Arrows represent neutrophils and mononuclear inflammatory cells. (Modified from Hotchkiss RS, Strasser A, McDunn JE, et al. Cell death. *N Engl J Med.* 2009;361:1570, with permission.) **B:** Transmission electron microscopy (TEM) of necrotic human embryonic stem cells showing loss of membrane integrity without chromatin margination, cytosolic vacuolization, and spilling out of intracellular constituents. Autophagy protects renal tubular cells against cyclosporine toxicity. *Autophagy.* 2008;4(6):72, with permission.)

(apoptotic body) or forms pseudopodia (i.e., buds) containing nuclear fragments and/or organelles that break off into small fragments (apoptotic bodies). In either case, adjacent cells or macrophages phagocytize the apoptotic bodies, and inflammation typically does not occur.

A key difference between necrosis and apoptosis is the activation of caspases in the latter. Caspases are cysteinyl aspartate-specific proteases that belong to an 18-member family.[57–59] Caspases can be divided into three groups based on structural differences and substrate preferences: initiator caspases (caspase -2, -8, -9, -10, and possibly -12), executioner caspases (caspases -3, -6, and -7), and cytokine processors (caspases -1, -4, -5, -13, and -14). Caspases-15 to 18 have been identified in numerous mammals, but not in humans, with the exception of caspase 16.[59]

Initiator caspases are activated by numerous processes including receptor-directed mechanisms and chemical exposure. They mediate chemical-induced apoptosis in numerous cell types, including proximal tubular cells,[60–62] glomerular cells,[63] medullary cells,[64,65] and cells present in the collecting ducts.[66–68] Activation of initiator caspases results in the activation of executioner caspases, which leads to several of the biochemical characteristics of apoptosis. Initiator caspases can also be substrates for executioner caspases.[69]

Caspase-8 is an initiator caspase that plays an integral role in receptor-mediated apoptosis.[69–71] It is activated by membrane receptors such as Fas-ligand and tumor necrosis factor (TNF)-α receptors[71,72] and, in turn, cleaves the Bcl-2 family protein Bid to form tBid.[70] tBid acts on mitochondria to cause the release of pro-apoptotic proteins and results in the activation of caspase-9 and caspase-3. In contrast, caspase-8 can directly activate caspase-9 or caspase-3, independently of the mitochondria (Fig. 30.4).

Caspase-8 can be activated by nephrotoxicants independent of receptor-mediated mechanisms. For example, cisplatin and etoposide activate caspases-8, -9, and -3 in LLC-PK1 cells in the absence of receptor-stimulation.[73] In contrast, cisplatin and cyclosporine activate caspase-3 in the absence of caspase-8 in mouse and rabbit RPTC.[74–76] Thus, the role of caspase-8 in chemical-induced renal cell apoptosis is variable.

Executioner caspases cleave numerous substrates that ultimately result in the morphologic features of apoptosis. Perhaps the most important substrates are proteins that control DNA degradation (DNAase). Caspases are known to mediate the activation of the nuclease DNA fragmentation factor (DFF). DFF is composed of two subunits: a 40-kDa DNAase subunit (CAD/DFF40) and a 45-kDa inhibitor of caspase-activated deoxyribonuclease (ICAD/DFF45).[69] Caspase-3 cleaves ICAD/DFF45 during apoptosis, which results in the release and activation of CAD/DFF40. Active CAD/DFF40 results in double-stranded DNA breaks in chromosomes, giving rise to the characteristic nonrandom DNA-ladderlike pattern seen with apoptosis on agarose gels.[69]

Caspases can also mediate DNA degradation by cleaving poly(ADP-ribose) polymerase (PARP). PARP is involved in DNA repair and maintenance of stability, and regulates DFF40 activity.[69] Caspases-3 and -7 can cleave and inactivate PARP.[77] PARP cleavage is used as a marker for apoptosis in renal cells, including apoptosis induced by antimycin A and DCVC.[78,79] Cleavage of DNA repair enzymes (such as PARP) by caspases is thought to prevent cells from making a futile repair attempt.

Caspases have numerous other substrates other than DNAases. Initiator caspase substrates include other caspases, the pro-apoptotic protein Bid, α-tubulin, and vinculin.[58] Cytokine caspase substrates include inflammatory mediators such as such Il-18, Pro-IL-1B, and Il-17, whereas executioner caspase substrates include protein kinase C (PKC), focal adhesion kinases (FAK), and the cell cycle regulator p21.[58] Cleavage of these proteins is believed to inhibit futile repair attempts, facilitate apoptosis signaling cascades, and allow for cytoskeleton reorganization and packaging of cell constituents into apoptotic bodies.[80]

Caspase-3, perhaps the best studied executioner caspase, can also cleave receptors, such as type 1 inositol(1,4,5) P4 receptor, Ca^{2+}-ATPase, the Na^{+}/Ca^{+} exchanger, and the Na^{+}/K^{+}-ATPase pump.[55] The Na^{+}/K^{+} ATPase may also be cleaved by initiator caspases, such as caspase-8 and -9.[81] Cleavage of these receptors is believed to alter ion homeostasis and facilitate decreases in intracellular K^{+}, which further promotes caspase activation. Cleavage of these receptors also leads to cell size alterations, such as cell shrinkage, early during apoptosis after cleavage of Na^{+}/K^{+} ATPase, or cell rupture due to swelling after Ca^{2+}-ATPase inactivation during late-stage apoptosis/secondary necrosis.

Role of Mitochondria in Apoptosis

The role of mitochondria in cell death cannot be understated, especially for apoptosis. Mitochondria regulate apoptosis by at least two major processes: maintenance of ATP production and release of pro-apoptotic proteins, such as cytochrome c, Bcl-2 family proteins, and DNAases. In addition, mitochondria regulate apoptosis by participating in Ca^{2+} signaling cascades and mediating protease activation.[55]

ATP is considered to be a requirement for both the initiation and execution of apoptosis.[55] It is required for formation of an apoptosome protein complex (see later), which facilitates the activation of caspase-9. It may also be required for transport of pro-apoptotic proteins into the nucleus.[55] ATP may also represent an important switch point between apoptosis or necrosis; depleting ATP below 30% transforms apoptotic liver cell death to necrotic death patterns.[82] In addition, ATP is needed to maintain Na^{+}/K^{+} ATPase pumps on the plasma membrane, and pump inactivation will eventually lead to cellular swelling, pathologic increases in intracellular Ca^{2+}, and cellular lysis, which is typical of necrosis.

Cytochrome c is a heme protein bound to the inner mitochondrial membrane, transferring electrons between complexes III and IV of the electron transport chain. Release of cytochrome c from mitochondria activates the intrinsic pathway of apoptosis. Cytosolic cytochrome c will bind

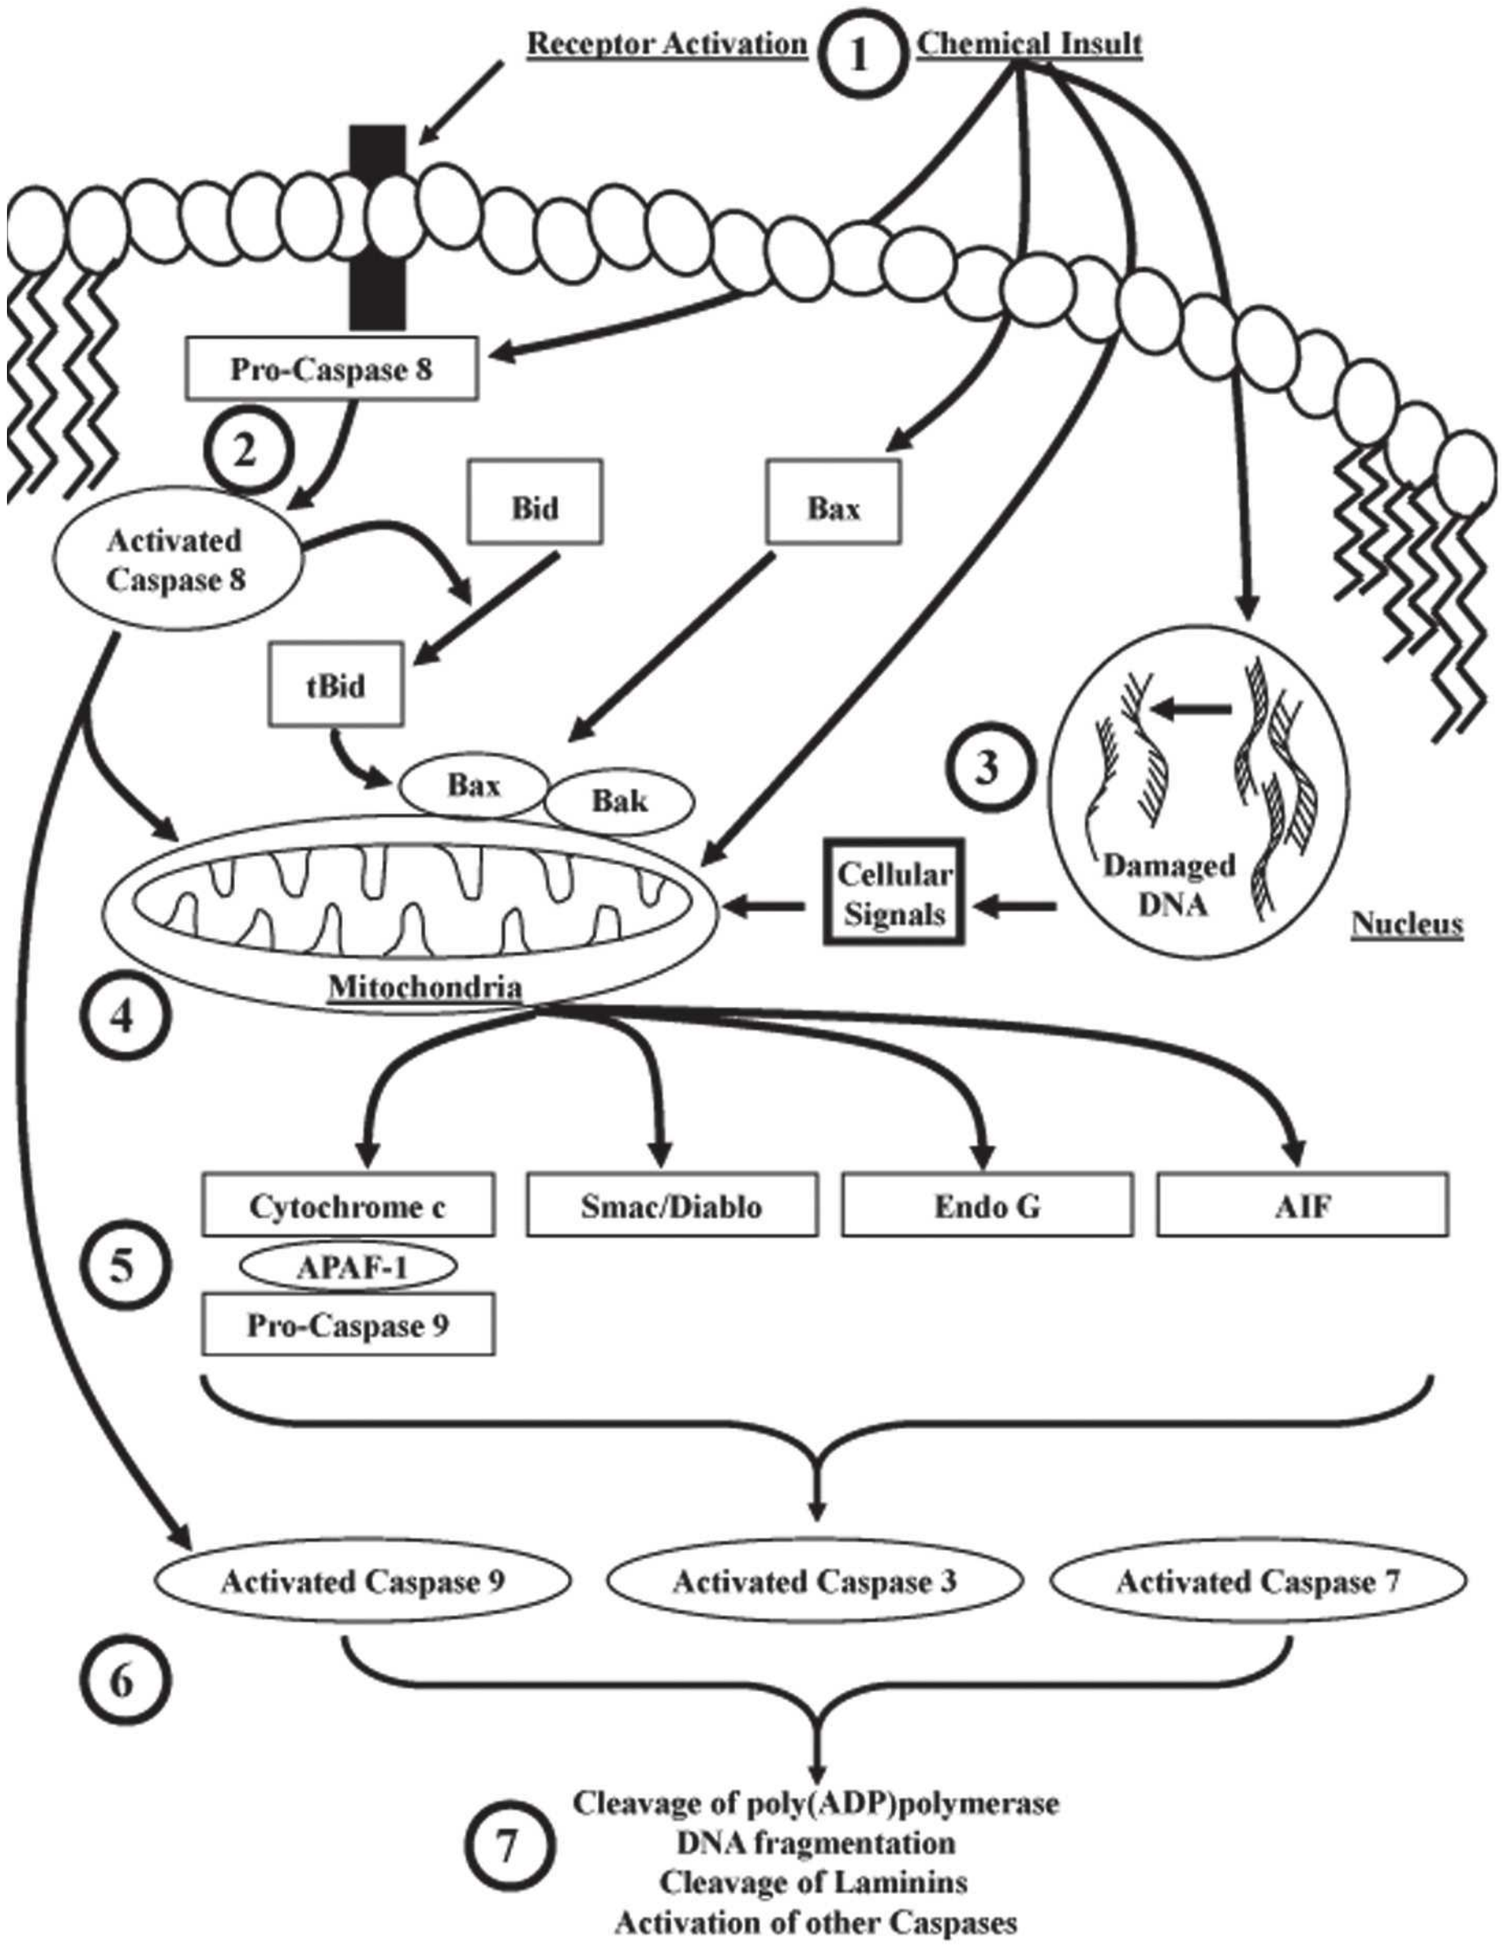

FIGURE 30.4 Cell signaling cascades involved in the activation of caspases and apoptosis. **1:** Receptor-mediated death signals or chemicals can initiate apoptosis through multiple mechanisms. **2:** Pro-caspase 8 is activated by receptor-mediated signals at the cellular membrane or directly by chemicals. Once activated, caspase-8 cleaves Bid to t-Bid, which interacts with Bax/Bak to induce mitochondrial-mediated apoptosis or directly activates caspase-9 and other caspases. **3:** Some chemicals cause DNA damage that signals the release of pro-apoptotic proteins from the mitochondria. **4:** Receptor-mediated signals, direct chemical injury, or signals resulting from DNA damage can all cause cytochrome c, Smac/Diablo, Endo G, and AIF release from the mitochondria. **5:** Released cytochrome c forms a complex with APAF-1 and pro-caspase 9, resulting in caspase-9 activation. **6:** Activated caspase-9 cleaves and activates pro-caspase-3 and -7, which can also be activated by caspase-8 independently of cytochrome c. **7:** Activated caspases (e.g., 3 and 7), AIF, and Endo G cause the classical markers of apoptosis such as cleavage and activation of poly(ADP)polymerase, inactivation of inhibitors of DNases leading to DNA fragmentation, cleaved laminins, and the activation of other caspases.

to apoptotic protease activating factor 1 (APAF-1), which promotes the binding and proteolytic cleavage of pro-caspase-9 to caspase-9 (the apoptosome),[83] and then activated caspase-9 cleaves and activates executioner caspases (i.e., caspases-3, -6, and -7) (Fig. 30.4). Nephrotoxicants known to induce cytochrome c release in correlation with apoptosis include cisplatin and DCVC.[71,84] Cytochrome c release from the mitochondria is associated with a decrease in the mitochondrial inner membrane potential and the accumulation of several pro-apoptotic proteins such as Bad, Bax, and Bax at the mitochondria (Fig. 30.4). Other pro-apoptotic proteins released from the mitochondria include apoptosis-inducing factor (AIF), Smac/Diablo, Omi, and Endo G (Fig. 30.4).[70,71,85–92]

Bad, Bak, Bax, and Bid belong to the Bcl-2 family of pro-apoptotic proteins, which are characterized by specific regions of homology, termed Bcl-2 homology domains.[93] Under nonstressed conditions, these proteins exist bound to proteins in the mitochondria and cytosol.[70] After toxicant exposure, Bax, Bid, or Bak can dissociate and translocate to the mitochondria which initiates the formation of a pore complex that causes membrane rupture[55] and subsequent loss of mitochondrial membrane potential, facilitating the release of cytochrome c, Endo G, Smac/Diablo, Omi, and AIF (Fig. 30.4).[68,70,74] Bid mediates apoptosis induced by hypoxia and ATP depletion in cultures of rat RPTC[94]; Bax mediates proximal tubular apoptosis in mice treated with cisplatin in vivo[65]; and Bak is elevated during apoptosis in primary bovine glomerular endothelial cells induced by TNF-α or lipopolysaccharide (LPS[95]) or during ischemia-reperfusion-induced renal cell apoptosis in mice.[96]

In contrast to Bax, Bid, and Bak, Bcl-2 is an anti-apoptotic protein.[60] Increased Bcl-2 prior to toxicant exposure protected numerous cells, including renal cells,[96] from toxicant-induced apoptosis.[96] The protective effect of Bcl-2 may be the result of its ability to bind Bax, Bid, and Bak, preventing them from inducing mitochondrial pore formation, altering mitochondrial membrane permeability, initiating the release of mitochondrial pro-apoptotic proteins, and activating caspases.[97] Overexpression of Bcl-2 protected against ATP-depletion-induced apoptosis in cultures of rat RPTC,[94] and upregulation of Bcl-2 protected kidney epithelial cells both in vitro and in vivo against apoptosis induced by hypoxia, azide, cisplatin, and staurosporine.[98]

AIF is released from mitochondria in response to decreases in the mitochondrial membrane potential induced by ATP depletion[86,99]; ischemia-reperfusion; anti-fas antibodies[100]; or exposure to high concentrations of Ca^{2+},[101] t-butyl hydroperoxide,[101] or atractyloside.[101] Cellular pathologies associated with AIF release are similar to those seen with caspases (chromatin condensation and oligonucleosomal DNA fragmentation).[100] Recent studies suggest that increases in cytosolic Ca^{2+} and calpain activation also facilitate the release of AIF from mitochondria[102]; and studies in LLC-PK1 cells support this hypothesis.[103]

AIF is a protease with properties similar to caspases, including being inhibited by N-benzyloxycarbonyl-Val-Ala-Asp-fluoromethylketone (Z-VAD-fmk), a commonly used broad spectrum caspase inhibitor.[86] Thus, the decrease in renal cell death observed in the presence of Z-VAD-fmk may be a result of AIF or caspase inhibition. AIF can induce DNA fragmentation independently of caspases.[69] AIF is released in opossum kidney (OK) cells after ATP depletion-induced by sodium cyanide and 2-deoxy-D-glucose.[87,99] AIF is also activated in HEK293 cells after exposure to cadmium,[104] in LLC-PK1 cells after exposure to cisplatin,[105] and in OK cells after exposure to the peroxisome proliferator-activated receptor agonist ciglitazone.[106]

Smac/Diablo is a pro-apoptotic protein released from the mitochondria to the cytosol during apoptosis. It blocks anti-apoptotic activity of inhibitors of apoptosis proteins (IAP), which increase apoptosis.[89] The ability of Smac/Diablo to promote apoptosis is not exclusively a result of its ability to bind IAP.[107] Smac/Diablo functions at the same level of executioner caspases, but downstream of the Bcl-2 family of proteins.[90]

Smac/Diablo is expressed in the mouse kidney and in several renal cell models.[108] It mediates apoptosis in vivo in mice after treatment with high concentrations of folic acid or after exposure of cultures of renal epithelial cells to TNF-α.[89] Increased expression of Smac/Diablo potentiates TNF-α- and etoposide-induced apoptosis in HEK293 cells[107]; however, similar to several other pro-apoptotic proteins, expression of Smac/Diablo is not essential for apoptosis in kidney cells. For example, acetaminophen-induced renal cell apoptosis proceeds in a caspase-dependent manner in the absence of Smac/Diablo activity.[109]

Omi is a mammalian serine protease homologous to bacterial HtrA endoprotease.[110] Omi localizes to the mitochondria and is expressed ubiquitously in a number of cell types including RPTC.[91] Omi is released from the mitochondria after exposure to apoptotic stimuli and binds to, and cleaves, IAP.[91] Omi-directed degradation of IAP facilitates caspase activation and the subsequent biochemical and morphologic features of apoptosis. In addition, Omi can translocate to the nucleus and activate the transcription factor p73, which induces pro-apoptotic proteins such as bax.[69] Omi participates in both caspase-independent and caspase-dependent cell death,[69,111] an event that has been proven using either siRNA against Omi, or a synthetic inhibitor, called ucf-101, in in vitro and in vivo models, including primary cultures of mouse RPTC.[91,111] More work is needed to determine if Omi can mediate cell death induced by other nephrotoxicants.

Autophagy

Autophagy is essentially "a cell eating itself."[112,113] This process was originally thought to be a cell survival pathway activated to produce energy during times of metabolic stress, such as starvation.[113] Some cells undergoing autophagy can recover; however, ample evidence exists that autophagy itself leads to cell death, specifically referred to as type II cell death.[55,112,113]

Significant evidence shows that autophagy mediates renal cell death.[56,114,115] The role of autophagy in renal cell death differs depending on the experimental conditions.[56] Further, it is difficult to determine if autophagic cells are a result of a cell death mechanism, or a failure in repair or survival mechanism.[56] Complicating this issue is that induction of autophagy is cell- and toxicant-dependent. Nevertheless, clear correlations exist between nephrotoxicity and autophagy. Autophagic cells are present in vivo in rat renal cells after ischemia-reperfusion and after treatment of mice with tunicamycin, a stimulant of ER Ca^{2+} release.[56] In vitro, autophagy was identified in HK-2 cells after exposure to H_2O_2, in RPTC cultures after exposure to cisplatin, and in primary cultures of human renal cells treated with cyclosporine A.[56,116]

Morphologic markers for autophagy include the presence of autophagic vacuolization of the cytoplasm and the autophagosome, which forms near the lysosome and can contain cytosolic organelles (Figs. 30.2 and 30.3).[55] This occurs in the absence of chromatin condensation. Double-membrane vesicles, autophagosomes, are formed and fuse with lysosomes to facilitate protein degradation[112] and other morphologic changes that are best identified using transmission electron microscopy.

Biochemical markers of autophagy include expression of microtubule-associated protein-1 light chain 3 (LC3), and degradation of the cell signaling adaptor p62.[112] LC3 is only considered an autophagic cell marker when it is cleaved to a lower molecular weight protein called LC3II. Cleavage allows LC3 to bind to phosphatidylethanolamine, which facilitates the formation of autophagosomes. Autophagosome formation is also facilitated by two kinases: autophagy-specific phosphatidylinositol 3-kinase (PI3K) Vps34 (also called human class III PI3K) and target of rapamycin (TOR) kinase.[56,112]

Beclin-1 is another protein whose expression is critical for autophagy. Beclin-1 facilitates formation of autophagosomes by regulating Vps34 (human class III PI3K[56]). It contains a BH-3 only domain, and is inhibited by other BH-3 only domain containing proteins called Bcl-2 and Bcl-X_L.[55] Proteins containing BH3-only domains are typically pro-apoptotic; however, beclin-1 does not induce apoptosis. In fact, beclin-1 is cleaved by caspases. Cleavage of beclin-1 by caspases is believed to be an important switch point used by cells to inhibit autophagy and stimulate apoptosis.[55]

p53, another regulator of autophagy, is a tumor suppressor protein found in the cytosol of living cells in an inactivated state and bound to the co-repressor Mdm2 (see later). The release of p53 from Mdm2 is stimulated by ionization radiation, DNA damage, oxidative stress, and several other death-inducing stimuli. Released p53 can translocate to the nucleus and induce apoptosis, cell cycle alterations, and the transcription of several proteins, including those that mediate autophagy.[55] Interestingly, cytosolic p53 (unbound to Mdm2) appears to inhibit autophagy in nonrenal cells.[117] It is not known if p53 can regulate autophagy in renal cells using similar mechanisms.

INITIATORS OF CELLULAR INJURY

Nephrotoxicants initiate renal cell injury by a variety of mechanisms. Some initiate toxicity directly because of their reactivity with selected cellular macromolecules, such as observed with the antifungal drug amphotericin B, which increases the permeability of the plasma membrane to cations,[118] the mycotoxin fumonisin B_1 that inhibits sphinganine (sphingosine) N-acyltransferase,[119] and aminoglycosides that bind initially to cellular anionic phospholipids.[120] Other nephrotoxicants initiate toxicity following biotransformation to a reactive intermediate or a stable metabolite, and nephrotoxicants can initiate toxicity indirectly through the production of reactive oxygen species.

Role of Biotransformation

Renal xenobiotic metabolism contributes significantly to whole-body metabolism and/or renal toxicity of numerous chemicals because of the role of the kidney as a primary route of xenobiotic excretion. Some chemicals require metabolism or biotransformation to a toxic reactive intermediate for cellular injury to occur (Fig. 30.5). Then the reactive intermediate binds covalently to critical cellular macromolecules, which are thought to interfere with the normal functioning of the macromolecules and thereby initiate cellular injury. Often, these reactive intermediates or "alkylating" agents are electrophiles that bind to cellular nucleophiles. The renal xenobiotic-metabolizing enzymes found in experimental animals and humans have been reviewed by Lock[121] and are summarized in Table 30.1. These include cytochrome P-450, flavin containing monooxygenase (FMO), and glutathione S-transferase (GST).

Cytochrome P-450

The kidney contains many of the xenobiotic-metabolizing enzymes found in the liver; however, in general, their concentration within the kidney is lower. For example, renal cytochrome P-450 ranges between 0.1 and 0.2 nmol per mg microsomal protein across a variety of species, which represents approximately 10% of hepatic cytochrome P-450.[121] The distribution of cytochrome P-450 also varies along the nephron, with the highest levels typically found in the S_2 segment, followed by the S_3 and S_1 segments, with the other tubular segments having less than 10% of that of the S_1 segment.[121]

The renal cytochrome P-450 system is active against a variety of endogenous and exogenous compounds, and numerous cytochrome P-450 isoforms have been identified in renal tissue. For example, cytochromes P-450 1A1, 1A2,1B1, 2A, 2B1, 2B2, 2B6, 2B9, 2B10, 2C2, 2C11, 2E1, 2J2, 2J3, 2J5, 2J9, 3A1, 3A4, 4A1, 4A2, 4A3, 4A5, 4A6, 4A8, 4A11, 4F1, 4F4, 4F5, 4F6, 4F11, and 4F12 have been identified in renal cells of the human, mouse, rat, and rabbit kidney.[121–125]

Cytochrome P-450 expression depends on the species and sex being studied, as well as the site along the nephron. For example, cytochrome P-450 2A, 2C, and 2E are present in male mouse kidneys but are barely detectable in female mouse kidneys.[121] Several studies suggest differences in the expression of cytochrome P-450 isoforms between human and rodent kidneys. An important example is the expression of cytochrome P-450 2E1, which has been detected in renal proximal and distal tubular cells of mice and rats, but not human kidneys.[121,122,126] In contrast, both human and rodent kidneys express high amounts of cytochrome P-450 4A isoforms. However, rat kidneys express 4A1, 4A2, and 4A3, whereas the human kidney appears to express 4A11.[122,127] Such differences in xenobiotic expression must be considered when assessing the role of biotransformation in chemical-induced nephrotoxicity.

In contrast to the liver, fewer compounds are documented to produce nephrotoxicity through renal cytochrome P-450

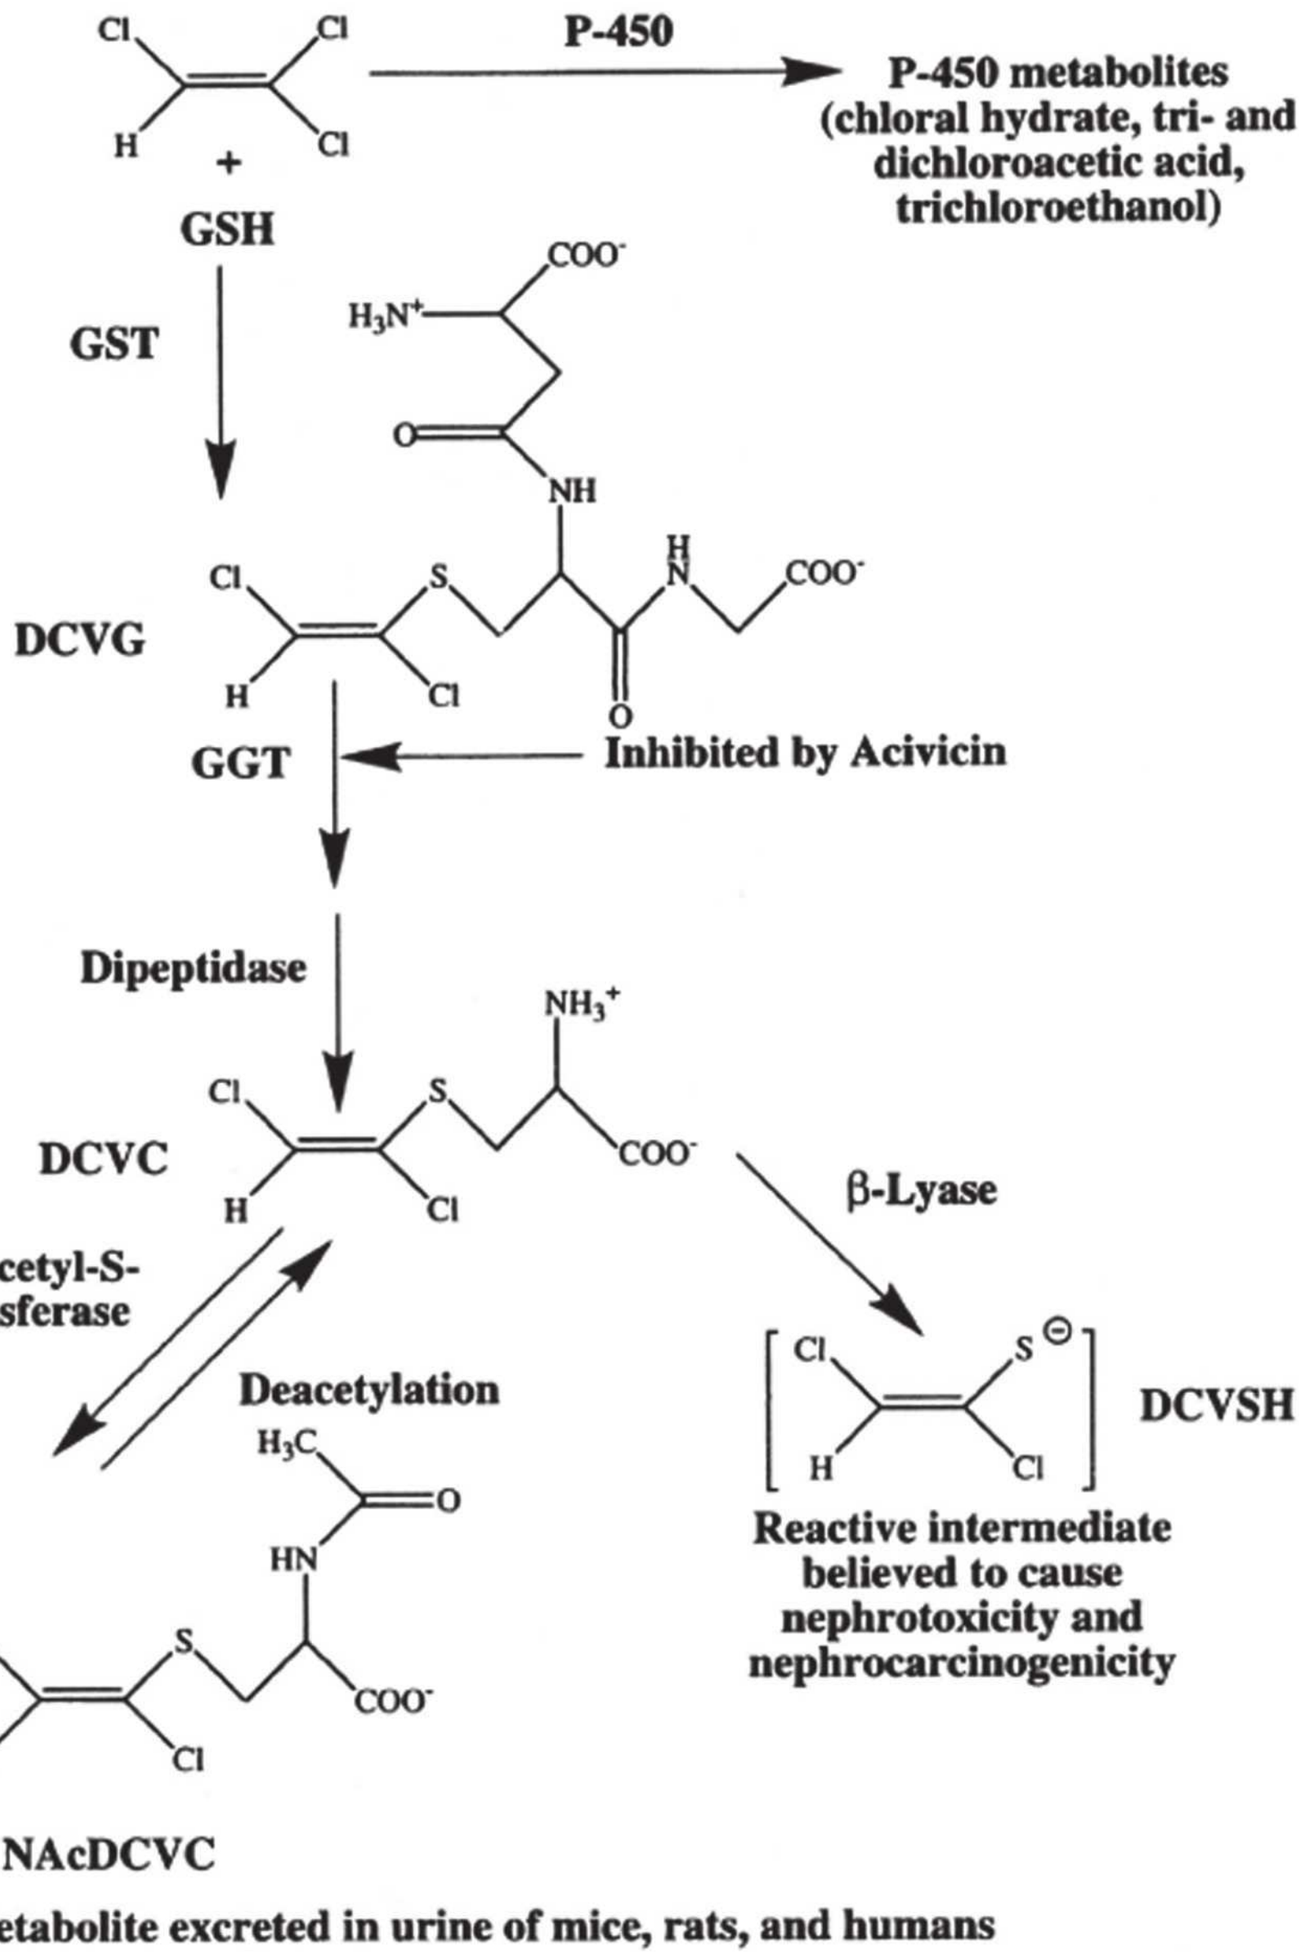

FIGURE 30.5 The bioactivation of trichloroethylene by the glutathione-(GSH-) conjugation pathway. Trichloroethylene (*top left*) can be metabolized by either cytochrome P-450 to the compound listed (*top right*) or be conjugated to GSH by the glutathione S-transferase (GST) to form S-(1,2)-dichlorovinyl-glutathione (DCVG). These reactions can occur either in the liver or in the kidney. DCVG formed in the liver is delivered to the kidney via the bile or the blood where the high concentrations of γ-glutamyltransferase (GGT) and dipeptidase in the kidney results in the cleavage of the GSH moiety and the formation of S-(1,2)-dichlorovinyl-L cysteine (DCVC). Metabolism of DCVC by *N*-acetyl-S-transferase produces *N*-acetyl-S-(1,2)-dichlorovinyl-L-cysteine (NAcDCVC), which is excreted in the urine of mice, rats, and humans exposed to trichloroethylene. NAcDCVC also can be deacetylated back to DCVC. Metabolism of DCVC by cysteine-conjugate β-lyase results in the formation of a reactive thiol that can rearrange to form a protein acylating species. (From Cummings BS, Parker JC, Lash LH. Role of cytochrome P450 and glutathione S-transferase alpha in the metabolism and cytotoxicity of trichloroethylene in rat kidney. *Biochem Pharmacol.* 2000;59:531, with permission.)

bioactivation, although renal cytochrome P-450 contributes to the nephrotoxicity of chloroform[128,129] by metabolizing it to the unstable trichloroethanol, which releases HCl to form phosgene. Phosgene reacts with: (1) two molecules of glutathione to produce diglutathionyl dithiocarbonate, (2) water to produce two molecules of HCl and CO_2, (3) cysteine to produce oxothizolidine-4-carboxylic acid, or (4) cellular macromolecules to initiate toxicity.[128,130,131]

Chloroform bioactivation by renal cytochrome P-450 is sex- and species-dependent. The marked sex difference in the nephrotoxicity of chloroform is reversed by castration of males or treatment of females with testosterone, suggesting that the renal cytochrome P-450 responsible for chloroform bioactivation is under androgenic control.[130,132] Because cytochrome P-450 isozymes 2B1 and 2E1 are present in male mice and are expressed in female mice treated with testosterone, these isozymes may be responsible for renal chloroform bioactivation.[131]

Acetaminophen is metabolized in the mouse kidney by cytochrome P-450 2E1 to the reactive intermediate N-acetyl-p-benzoquinoneimine (NAPQ), which binds to cellular proteins.[132,133] In the liver, NAPQ binds to a selenium binding protein (58 kDa),[134,135] microsomal glutamine synthetase (44 kDa),[136] cytosolic N-10-formyl tetrahydrofolate dehydrogenase (100 kDa),[135,137] and mitochondrial glutamate dehydrogenase (50 kDa).[137] It is possible that similar protein binding may occur in renal cells.

Studies also suggest that acetaminophen mediates renal cell death in mouse RPTC by inducing ER stress.[109] In this model, acetaminophen treatment increased the expression of GADD153, an ER stress protein, and induced caspase-12 cleavage and apoptosis—independently of caspase-3, -9,

Flavin-containing Monooxygenase

Flavin-containing monooxygenase (FMO) oxidizes the nucleophilic nitrogen, sulfur, and phosphorus moieties of a number of chemicals, including DCVC, tamoxifen, and cimetidine.[121,138,139] The role of FMO in nephrotoxicity has received less attention than cytochrome P-450, but several FMO are expressed in the kidney. Like cytochrome-P450, renal FMO expression and activity is species- and sex-dependent. For example, rabbit kidneys express FMO1, 2, 4, and 5, but not 3, and FMO1 is expressed in the female, but not the male kidney.[121] FMO3 activity is detected in the kidneys of rats, dogs, mice, rabbits, and humans.[140] Rat kidneys appears to have two- to sixfold greater activity levels (as determined by methionine S-oxidase activity) than other species, including humans.[141] Studies in human kidney microsomes demonstrate that FMO1, FMO3, and FMO5 are all expressed, but at different levels.[141] Furthermore, samples from African American patients had significantly more FMO1 activity compared to their Caucasian counterparts, suggesting that the expression of renal FMO isoforms may differ depending on race.[141] Studies in mice

suggest that sex- and age-dependent differences exist for the expression of FMO mRNA in the kidney[142]; however, no differences in the expression of FMO1, FMO3, or FMO5, and overall FMO activity were detected between human male and female kidney microsomes.[141] Thus, more work is needed to determine if FMO expression is sex-dependent in human kidneys.

In vitro, FMO1, FMO3, FMO4, and FM05 metabolize cysteine S-conjugated S-allyl cysteines, whereas FMO3 metabolizes DCVC.[141] However, little DCVC was metabolized in human kidney microsomes, even though FMO3 was expressed in these tissues, suggesting that FMO may not contribute to the nephrotoxicity of this compound in human renal cells. In contrast, treatment of human proximal tubular cells with the FMO inhibitor methimazole decreased DCVC-induced apoptosis.[143] Studies also suggest that FMO catalyzed sulfoxidation of the sevoflurane (a commonly used anesthetic) degradation product fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether mediates its renal toxicity.[144] Other nephrotoxicants suggested to be metabolized by FMO include 4-amino-2,6-dichlorophenol.[145] 4-amino-2,6-dichlorophenol is a metabolite of 3,4-dichloroanaline, a common industrial manufacturing intermediate. Finally, FMO may also mediate the nephrotoxicity of some pesticides such as organophosphate thioether compounds.[146]

Glutathione S-Transferase

The conjugation enzymes glucuronosyltransferases, sulfotransferases, and glutathione S-transferases (GST) are located in the kidney where they conjugate both endogenous and exogenous compounds. These enzymes increase the water solubility, excretion, and elimination of several nephrotoxicants.[121] Although this typically decreases renal cell injury, some nephrotoxicants are bioactivated by these enzymes.

GST mediates the conjugation of the tripeptide glutathione (GSH, γ-glutamylcysteinlyglycine) to compounds with electrophilic centers.[121] They are considered phase II biotransformation enzymes and are divided into cytosolic, membrane associated, and mitochondrial members. There are seven different cytosolic subfamilies (A, alpha; M, mu; P, pi; T, theta; O, omega; S, sigma; and Z, zeta). Microsomal GST is referred to as membrane-associated proteins in eicosanoid and glutathione metabolism (MAPEG), whereas mitochondrial GST is called K (kappa) GST.[121,147] All of these GSTs, with exception of GST S, are expressed in rat and human kidneys,[19,121,126,147] and GST expression in normal human RPTC appears to be similar to those observed in rat RPTC.[126]

GST expression can differ among nephron segments. For example, in the rat kidney, GST A is expressed primarily in proximal and distal tubules, whereas GST M and P are primarily expressed in the distal tubules.[19,121,126] These expression patterns differ from a previous study, especially with regard to GST A in distal tubules.[121,148] Thus, more research is needed to resolve this discrepancy.

As mentioned previously, conjugation of toxicants to GSH is normally a detoxification pathway in which electrophiles are neutralized and made more amenable for excretion. Unfortunately, numerous extrarenally formed glutathione conjugates are nephrotoxic. For example, the extrarenal conjugation of GSH is important for the nephrotoxicity of $HgCl_2$,[149] halogenated alkenes, and aromatics, and possibly acetaminophen.[131,150,151] The nephrotoxicity of the halogenated alkene trichloroethylene in rats and humans is believed to be a direct result of its conjugation with GSH to form S-(1,2)-dichlorovinyl-glutathione, and the subsequent processing of the glutathione-conjugate to DCVC in RPTC (Fig. 30.5).[19]

In vivo, trichloroethylene is conjugated with GSH in the liver and delivered via the bile or blood to the kidney. The expression of enzymes, such as γ-glutamyl transferase and dipeptidase in the RPTC and biliary and intestinal tract, results in the cleavage of the γ-glutamyl and glycyl moieties, respectively, and the formation of DCVC. Metabolism of DCVC by N-acetyl-S-transferase produces N-acetyl-S-(1,2)-dichlorovinyl-L-cysteine, which is excreted in the urine of mice, rats, and humans exposed to trichloroethylene.[152] N-acetyl-S-(1,2)-dichlorovinyl-L-cysteine also can be deacetylated back to DCVC. Metabolism of DCVC by cysteine-conjugate β-lyase results in the formation of a reactive thiol that can rearrange to form a protein acylating species. A strong correlation exists between increases in markers of renal injury (proteinuria, creatinine clearance, glucosuria) and GSH metabolites of trichloroethylene in the blood and urine of humans exposed to high amounts of trichloroethylene.[153] Key determinants in the nephrotoxicity of trichloroethylene and similar chemicals, such as sevoflurane, isoflurane, and desflurane, which utilize this common pathway of biotransformation,[144,154] appear to be dependent on γ-glutamyl transferase, dipeptidase, and cysteine-conjugate β-lyase activity found in the kidney.

Role of Reactive Oxygen Species

Reactive oxygen species (ROS) mediate cellular injury during inflammatory responses, ischemia-reperfusion, and after nephrotoxicant exposure. Cellular ROS are generated during the normal function of the mitochondrial and microsomal electron transport chains as a result of the incomplete reduction of O_2 to water (Fig. 30.6).[155] Superoxide anion free radical is produced by a one-electron reduction of O_2, and H_2O_2 is produced by a two-electron reduction of O_2. Superoxide anion can dismutate to form H_2O_2, or H_2O_2 can be formed directly. The hydroxyl radical is formed from H_2O_2, and the superoxide anion free radical is formed via the metal-catalyzed Haber-Weiss reaction or the superoxide-driven Fenton reaction. Ferrous iron (Fe^{2+}) appears to be the major intracellular initiator of the reaction, but cuprous ions may participate as well. The precise source and form (e.g., ferritin) of the ferrous iron is still unclear.

One source of Fe^{2+} may be the heme-moiety that resides in the active site of cytochrome P-450 isoforms.[156]

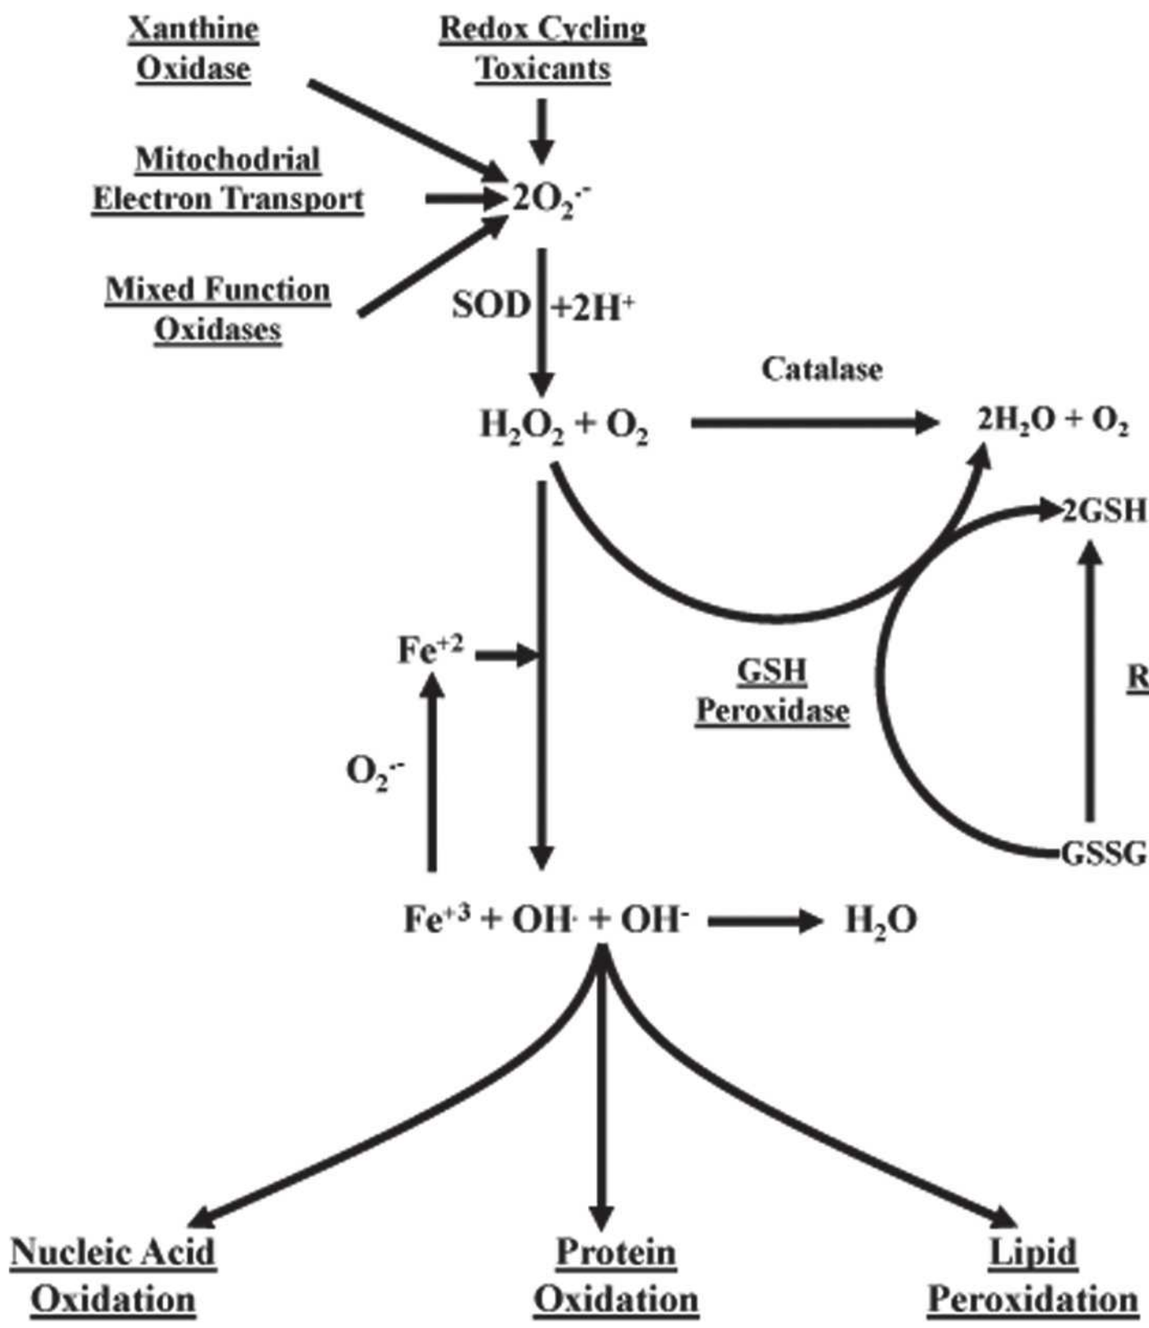

FIGURE 30.6 A schematic representation of the major pathways and possible intracellular targets and oxidants. Detoxification pathways and protective agents are also shown. See text for details. *GSH,* glutathione; *GSSG,* glutathione disulfide; *SOD,* superoxide dismutase.

This hypothesis is supported by the observation that rats treated intraperitoneally with cisplatin for 4 days had significantly lower renal cytochrome P-450 compared to control rats, and the decrease in P-450 correlated with increases in bleomycin-detectable iron content in the kidney. Piperonyl butoxide (a cytochrome P-450 inhibitor) decreased cisplatin-induced release of iron in the kidney and the functional and morphologic markers of kidney toxicity.[157] These same effects were observed in LLC-PK_1 cells; thus, P-450 may serve as one source of Fe^{2+} to initiate the formation of ROS.

Superoxide anion acts as a reductant for Fe^{3+}, and the Fe^{2+} generated reduces H_2O_2 to the hydroxyl radical, which reacts rapidly with adjacent molecules. Superoxide anion and H_2O_2 are less reactive, and H_2O_2 may diffuse away from the initial site of formation to produce injury at a distant site within the cell. Although H_2O_2 readily crosses cell membranes, superoxide anion and hydroxyl radicals do not. Because ROS production is a natural byproduct of metabolically active cells, such as the kidney, significant defenses exist against the normal production of ROS or those produced under pathologic conditions (Fig. 30.6).

The term "oxidative stress" is commonly used to describe conditions that lead to increased ROS formation. Chemicals may initiate oxidative stress indirectly by augmenting ROS production. For example, Walker and Shah[158] showed that gentamicin enhances H_2O_2 generation in isolated rat renal cortical mitochondria, and Lund and associates[159] showed that mitochondria isolated from rats treated with $HgCl_2$ have elevated H_2O_2 production.

Another mechanism by which chemicals produce oxidative stress is through "redox cycling." Certain compounds, especially quinones, can undergo a one-electron reduction to a semiquinone radical and a second one-electron reduction to the hydroquinone. The hydroquinone is oxidized to the quinone, and the cycle begins again, hence the term "redox cycling." During the reduction process, superoxide anion is formed from O_2, and oxidative stress ensues. For example, Brown and colleagues[160] demonstrated that menadione (2-methyl-1,4-naphthoquinone) produces toxicity in isolated rat renal epithelial cells through its ability to undergo redox cycling and cause oxidative stress. It should be recognized that the ability of quinones to undergo redox cycling varies with the quinone, and some quinones produce toxicity through their ability to arylate cellular macromolecules, particularly protein sulfhydryls.[160,161]

ROS can induce lipid peroxidation, inactivate enzymes by directly oxidizing protein sulfhydryl or amino groups, depolymerize polysaccharides, and induce DNA strand breaks. Lipid peroxidation results from the interaction of free radicals with polyunsaturated fatty acid side chains of membrane phospholipids to form free radicals and relatively stable lipid hydroperoxides.[162] Transition metals can catalyze the decomposition of lipid hydroperoxides, which results in the formation of alkoxyl and peroxyl free radicals that propagate the reaction. Lipid breakdown products such as hydroxylated fatty acids, 2-alkenyls, and 4-hydroxyalkenyls, are toxic, and may contribute to organelle and cellular dysfunction. Thus, ROS-induced degradation of membrane lipids

decrease cellular membrane integrity, alter enzymatic activity and transport properties, and induce isotropy.[163] The oxidation of protein sulfhydryl and amino groups by ROS can alter enzyme activity and membrane structure and function to the point that cell death will ensue. Finally, ROS can produce DNA strand breaks. Although H_2O_2 does not directly damage DNA, its stability and ability to diffuse throughout the cell allows it to come into contact with metal-based enzymes, like cytochrome P-450, which catalyze the formation of hydroxyl radicals, which can damage DNA.

A variety of structurally diverse nephrotoxicants produce renal cell injury by mechanisms involving oxidative stress, including $HgCl_2$,[159,162] haloalkene cysteine conjugates,[164,165] cyclosporine A,[165] and cisplatin.[76,166,167] The diversity of these nephrotoxicants highlights the critical and common roles that ROS play in the mechanism of renal cell death.

MEDIATORS OF CELL INJURY

Numerous common cellular pathways that mediate cell death have been identified. It is generally thought that upon initial exposure, nephrotoxicants will activate at least one, if not more, of these pathways. For necrosis, apoptosis, and possibly autophagy, a point exists along the sequence, yet to be identified, referred to as the point of no return. Here, the cell will die irrespective of any intervention. Also, along this sequence are switch points at which the cell death pathways may change from one mechanism to another. Investigators have tried to identify the sequence of deleterious events, the point of no return, and switch points for years and these efforts have led to the identification of numerous intracellular mediators critical in the generation of renal cell injury and death.

p53 and p21

The tumor suppressor protein p53 and the cell cycle inhibitor protein p21 can mediate renal cell death and acute renal failure.[76,168,169] Activation of p53 typically induces cell death and cell cycle arrest.[76,169] Activation of p21 is protective against numerous types of nephrotoxic events, including ischemia and cisplatin exposure.[168–171] p53 can induce p21 during renal cell injury, but p21 can also be activated independently of p53.[172] The mechanisms of p53-meidated activation of p21 are under study, but may involve increases in transcription. Transcription and signaling kinases are believed to mediate mechanisms by which p21 expression is increased independently of p53.[168,173]

p53 is activated in renal cells by agents that that induce DNA damage, like cisplatin,[172,174] and it is activated in renal cells after ischemia and oxidative stress subsequent to exposure to bromate, Fas, antimycin A, histone deacytelylase (HDAC) inhibitors, and aristolochic acid.[175,176] The mechanism of p53 activation involves its phosphorylation at numerous serine residues, followed by its release from the regulator protein Mdm2. Other regulators of p53 include ataxia telangiectasia mutated kinase (ATM), ataxia telangiectasia and Rad-3 related kinase (ATR), checkpoint kinase (ChK), and NF-kB.[169]

After activation, p53 can translocate to the nucleus or the mitochondria, or remain in the cytosol. In the nucleus, p53 induces the transcription of a number of genes, including p21,[172] and can activate several apoptotic pathways such as those involving caspases.[75] Translocation of p53 to the mitochondria results in its interaction with the outer mitochondrial membrane and binding with the anti-apoptotic proteins Bcl-2 and Bcl-xL.[169] This interaction releases the pro-apoptotic proteins Bax and Bak, which induce mitochondrial pore formation in mitochondria and facilitate the release of the pro-apoptotic proteins cytochrome c, Omi, Smac/Diablo, and Endo G.[55] Both nuclear and cytosolic p53 may regulate autophagy, and studies suggest that p53 localization represents a key switch point between autophagy and apoptosis.[55]

Pharmacologic and molecular studies demonstrate that inhibition of p53 decreases cisplatin-induced apoptosis in rabbit RPTC through a mechanism that includes caspase inhibition of.[75,76,169] In support of this hypothesis, others have demonstrated that inhibition of p53 nuclear translocation inhibits AKI and renal cell death in vivo after renal ischemia in rats.[177] Of note, p53 inhibition in these studies did not totally inhibit cell death; thus, quite possibly, p53-independent mechanisms contribute to nephrotoxicity induced by cisplatin, oxidative stress, ischemia, and other DNA damaging agents.

Induction of p21 occurs in response to DNA damage and p53-induced cell cycle arrest.[170] p21 is also activated independently of p53 by transcriptional-mediated mechanisms and by mechanisms involving mitogen activated protein kinases (MAPK).[168,173] p21 is a cyclin-dependent kinase (cdk) inhibitor that interacts with numerous cdk, such as cdk2, to control cell cycle.[168,170,178] Activation of p21 decreases renal cell death induced by cisplatin and ischemia reperfusion.[168] The mechanism of protection is linked to its ability to alter the cell cycle and allow for cell repair. In support of this hypothesis, knockout mice lacking p21 exhibited increased renal cell cycle activity and apoptosis, and were more susceptible to cisplatin and ischemia-induced ARF compared to wild type controls.[170] The majority of studies with p21 and renal cell death have focused on cisplatin and ischemia reperfusion. More work is needed to determine if p21 can mediate other forms of chemical-induced nephrotoxicity.

Signaling Kinases

Signaling kinases alter the activity, expression, or localization of another protein by altering its phosphorylation, including other signaling kinases. Signaling kinases differ in terms of the amino acids targeted for phosphorylation (serine/threonine/tyrosine), the location within a cell (membrane-bound or cytosolic), and the protein targeted for phosphorylation.

Table 30.2 lists several signaling kinases identified in the kidney, the site within the kidney or cell involved, the nephrotoxicant involved, and several references to studies that suggest critical roles for signaling kinases both in the development of renal cell death and in the recovery of renal cells after toxicant-induced injury.

Protein Kinase C

Protein kinase C (PKC) is a family of serine/threonine kinases, and at least 12 different mammalian isoforms have been identified. These are divided into conventional PKC (cPKC: α, $\beta_{1/2}$, and γ), novel PKC (nPKC: ϵ, ϵ', δ, η, θ, and μ), and atypical PKC (aPKC: τ, λ, and ζ).[179] The isoforms differ in terms of preferred substrates and mechanisms of action. Activation of cPKC is Ca^{2+}- and diacylglycerol-dependent, whereas activation of nPKC is Ca^{2+}-independent.[180] In contrast, activation of aPKC is independent of both Ca^{2+} and diacylglycerol. RPTC have been reported to express α, β_1, β_2, ζ, δ, λ, and ϵ,[181,182] and several other isoforms are expressed in the kidney of rats, mice, and humans.[183]

PKC is reported to mediate the toxicity of cisplatin, ischemia, oxidants, and TNF-α in multiple renal cell models.[184–189] The exact role of PKC in renal cell death depends on the toxicant and the specific isoform(s) involved.[190,191] For example, activation of PKC-α in rabbit RPTC during cisplatin treatment results in mitochondrial dysfunction and cell death,[189] and similar findings have been reported for PKC-ϵ in RPTC after oxidative stress.[192] Interestingly, PKC-ϵ targeted several mitochondrial proteins including complexes I and IV, and F(0)F(1)-ATPase in RPTC.[192] In contrast, activation of PKC-ζ after exposure to t-butylhdyroperoxide mediates cellular repair.[190,191]

MAPK (ERK1/2, p38 and JNK)

MAPK are serine-threonine kinases activated by a cascade of protein-protein interactions. They mediate cell growth, adhesion, differentiation, gene expression, and apoptosis. They can also mediate activation of p53.[193,194] ERK1/2 (p42/44MAPK), p38 MAPK, and c-jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK) are three of the

30.2 Selected Signaling Kinases Involved in Renal Cell Injury, Survival, or Repair

Kinase	Location	Nephrotoxicant	Reference
Protein Kinase C (PKC)			
Conventional PKC

[c]2,3,5-tris-(glutathion-s-yl)hydroquinone.

most studied MAPK. These kinases are activated by additional kinases: MAPK/extracellular signal-regulated kinase or MEK.[195]

ERK1/2, also referred to as extracellular regulated kinases,[196] are activated through epidermal growth factor receptor (EGFR), which is mediated by a small G-protein Ras.[197,198] Studies show that ERK1/2 is activated in renal cells after exposure to cisplatin, oxidants, bromate, and aminoglycosides.[115,189,198,199] ERK1/2 activation in these studies is reported to be protective, which correlates with the role of this kinase in survival and proliferation.[197,200,201] The ability of ERK1/2 to act as prosurvival signals is partially due to their ability to translocate to the nucleus and activate transcription factors such as AP-1, Elk-1, and c-Myc.[202] In addition, ERK1/2 can phosphorylate and inhibit caspase-9, which can inhibit apoptosis.[69]

The role or ERK1/2 in renal cell injury is toxicant- and cell-dependent, and some studies suggest that ERK1/2 can mediate apoptosis.[203,204] For example, Arany et al.[205] demonstrated that ERK activation mediated cisplatin-induced renal cell death in vivo and in vitro in mouse models. However, the same investigators observed that ERK activation protected against oxidant-induced (H_2O_2) cell death.[205] Interestingly, cisplatin-induced ERK activation and renal cell death was dependent on EGFR and c-Src activation. Studies by Zhuang and colleagues[206,207] also showed that exposure of RPTC to H_2O_2 activates Src, EGFR, and ERK1/2, as well as protein kinase B (Akt) and phosphoinositide-3-kinase (PI3K). ERK1/2 activation in this model was proposed to mediate apoptosis by activating caspase-3.[207] EGFR-induced activation of ERK1/2 is also believed to mediate 2,3,5-tris-(glutathione-S-yl)hydroquinone (TGHQ)-induced death in LLC-PK1 cells.[198,208] Thus, activation of ERK1/2 in renal cells after toxicant exposure may not always result in survival.

p38 MAPK and JNK/SAPK are activated in response to cellular stress, inflammation irradiation, heat shock, ROS, LPS, TNF-α, and IL-1.[209–211] These proteins are activated by Rac, a small G protein that activates distinct MEK rather than those involved in ERK1/2 activation.[210] p38 and JNK are generally thought to mediate cell death and cytostasis; however, like ERK1/2, the role of p38 and JNK in renal cell injury is toxicant- and cell-dependent. For example, activation of p38 by nephrotoxicants such as cisplatin and bromate in renal cell lines activates p53 and induces cell death.[169,199] In contrast, activation of p38 in primary cultures of RPTC after oxidant induced injury mediates dedifferentiation.[206] The detailed mechanisms of Src, EGF-R, PI3K, ERK1/2, and p38/SAPK activation, the targets of these kinases, and their role in cell death produced by diverse toxicants remain to be determined.

Altered Calcium Homeostasis

The role of Ca^{2+} in the pathophysiology of nephrotoxic cell injury cannot be understated. Intracellular Ca^{2+} homeostasis is necessary for cell viability because Ca^{2+} is a second messenger that plays a critical role in a variety of cellular functions.[55,212] With regard to cell death Ca^{2+} can mediate necrosis, apoptosis, and autophagy.[55,112] Initially, it was thought that only high, supraphysiologic increases in Ca^{2+} would induce cell death; however, it is now accepted that even small changes in Ca^{2+} signaling can significantly affect cell death, especially with regard to apoptosis.[55,213]

Ca^{2+} interacts with many key organelles known to participate in cell death, including the ER and the mitochondria. Ca^{2+} also mediates the activation of several proteins involved in cell death, such as calpains, endonuclease, phospholipase A_2, and protein kinases. Recent studies suggest that interaction of Ca^{2+} with calpains mediates activation of the pro-apoptotic protein AIF.[102] There is also a well-documented requirement of Ca^{2+} for autophagy[112] that directly links the release of ER Ca^{2+} stores and activation of AMP activated proteins kinases and calcium/calmodulin kinase β.[112] The ability of Ca^{2+} to stimulate autophagy in response to nephrotoxicant-induced renal cell exposure has not been heavily studied.

Cytosolic free Ca^{2+} is ~100 nM and is tightly regulated in the face of a large extracellular-intracellular gradient (10,000:1) by a series of pumps and channels located on the plasma membrane and ER. Mitochondria were not originally thought to participate in Ca^{2+}-mediated cell signaling processes under normal conditions. The advent of more advanced techniques for measuring low Ca^{2+} has changed this view, and strong evidence supports the idea that mitochondria are integral to Ca^{2+} signaling under both normal and pathologic conditions.[55]

Increases in intracellular/cytosolic free Ca^{2+} can induce cell injury and death after nephrotoxicant exposures. The source of this Ca^{2+} is typically the ER or the extracellular space (i.e., from the plasma membrane). Release of Ca^{2+} from the ER increases cytosolic free Ca^{2+} from ~100 nM to 300 nM within seconds.[214] Such increases are typically transient and buffered by transport of Ca^{2+} back into the ER, to the extracellular space or into the mitochondria. As mentioned above, release of ER Ca^{2+} can induce autophagy, and buffering of ER Ca^{2+} release by the mitochondria can induce apoptosis. Entry of Ca^{2+} from the extracellular space can increase the cytosolic free Ca^{2+} to μM levels—and even mM levels—if membrane integrity is lost. Such increases typically induce necrosis.

Decreasing the extracellular Ca^{2+} concentration or blocking extracellular Ca^{2+} influx will decrease cell death.[215–217] For example, increases in cytosolic free Ca^{2+} were observed in a hypoxia model using rat RPTC and in a mitochondrial inhibitor model using rabbit RPTC, and chelating intracellular Ca^{2+}, or decreasing the influx of extracellular Ca^{2+}, decreased cell death.[216–219] Nephrotoxicants that increase cytosolic free Ca^{2+} include $HgCl_2$,[220,221] pentachlorobutadienyl-glutathione,[167] pentachlorobutadienyl-L-cysteine,[222] tetrafluoroethyl-L-cysteine,[223] DCVC,[224–226] oxidants,[227,228] sevoflurane, miconazole,[229,230] cyclosporine A,[231] and gentamicin.[158]

Ca^{2+} is proposed to mediate apoptosis by both direct and indirect methods.[213] The direct pathway involves Ca^{2+}-mediated activation of calpains, which can induce caspases and.[55,232] Apoptosis may ensue, provided that ATP is maintained above 20% to 30%.[82] Furthermore, as mentioned above, the mitochondria can buffer ER Ca^{2+} release. Transport of Ca^{2+} into the mitochondria can activate Ca^{2+}-mediated matrix dehydrogenases, which can stimulate ATP and ROS production. Furthermore, Ca^{2+} uptake into the mitochondria can result in permeabilization of the outer mitochondrial membrane, which leads to opening of the permeability transition pore and release of pro-apoptotic proteins such as cytochrome c and AIF.[55,233,234]

The indirect pathway of Ca^{2+}-mediated apoptosis involves the activation of the phosphatase calcineurin,[213] which results in activation of the nuclear factor protein of activated T-cells (NFAT), which then increases the expression of pro-apoptotic Fas and TRAIL. Calcineurin activation may be mediated by calpain, which cleaves an endogenous inhibitor of calcineurin called cain/cabin 1.[235] The contribution of calcineurin to nephrotoxicant-induced epithelial renal cell injury has not received much attention; however, calcineurin inhibitors used during transplants surgeries induce significant renal proximal tubule injury,[236] suggesting that calcineurin acts to protect renal cells from damage.

Proteinases

Nonphysiologic activation of proteinases in the cytosol, organelles, or membranes can disrupt the normal function of these structures, leading to cell death and ARF. Proteases known to mediate nephrotoxic-induced renal cell injury include those found in the lysosomes (serine and cysteine proteases), along with calpains and caspases.

Lysosomal Proteases

Proteases found in lysosomes include serine and cysteine proteases that are acidic hydrolases. These require a lower pH to facilitate degradation (~pH 5) and thus will not typically function if released into the cytosol. They can mediate cell death during extreme cases of hypoxia and ischemia reperfusion, which induce lysosomal rupture in correlation with acidosis.[237] In contrast, less evidence exists that these proteases mediate nephrotoxicant-induced cell death.[238] In support of this hypothesis, studies with cysteine and serine proteinase inhibitors revealed these compounds to be ineffective in protecting rabbit RPTC segments from antimycin A, tetrafluoroethyl-L-cysteine, bromohydroquinone, and t-butylhydroperoxide.[239] Several inhibitors of lysosomal proteases, such as the cysteine proteinase inhibitor t-trans-epoxysuccinyl-leucylamido(4-guandino)butane (E64), have been shown to protect against RPTC injury induced by cyclosporine A[240]; however, E64 was only slightly protective, as was an aspartic acid proteinase inhibitor. These results suggest that lysosomal cysteine and aspartic acid proteinases do not play a significant role in RPTC death produced by these nephrotoxicants.

Calpains

Calpains, a group of least 15 isoforms of Ca^{2+}-activated neutral cysteine proteinases, comprise two groups. Group 1 calpains, typical calpains, contain a Ca^{2+}-binding domain, and include calpains 1, 2, 3, 8, 9, 11, 12, and 14.[241,242] Group 2, atypical calpains, lack a Ca^{2+}-binding domain, and include calpains 5, 6, 7, 10, 13, and 15.[241,242] Calpains 1, 2, 5 7, 10, 13, and 15 are reported to be expressed ubiquitously in the cytosol, whereas calpains 3, 6, 8, 9, 11, and 12 have more select tissue expression.[243]

With regard to renal cell death, the most heavily studied calpains are 1, 2, and 10, which have been implicated in cell death induced by numerous toxicants including bromohydroquinone, antimycin A, tetrafluoroethyl-L-cysteine, and t-butylhydroperoxide.[216,218,244,245] Evidence for roles of calpain in cell death in many of these studies was derived from the use of calpain inhibitors such as calpeptin. Calpeptin also inhibited increases in calpain activity induced by hypoxia in RPTC, and protected against renal dysfunction in rats subjected to ischemia reperfusion.[246,247] These studies suggest that calpains mediate cell death by enhancing extracellular Ca^{2+} influx and/or by cleaving cytoskeletal proteins.[218,241,244] Thus, calpains may play a critical role in cell death produced by a wide range of nephrotoxicants and renal dysfunction; however, calpains are also suggested to play a role in the pathology of several other diseases, including Alzheimer, Duchenne muscular dystrophy, and diabetes.[243]

Historically, calpains were thought to be primarily cytosolic, but several membrane-associated calpains are known to exist, including calpain 10. Calpain 10 is expressed in the mitochondrial fraction of the kidney of multiple species, and it appears to mediate mitochondrial dysfunction induced by oxidants, Ca^{2+} overload, and thapsigargin.[248,249] Calpain 10 appears to induce mitochondrial dysfunction by cleaving complex I of the electron transport chain.[250] Recently, calpain 10 has been suggested to mediate renal cell viability and aging in the kidney in vivo,[251] and mitochondrial biogenesis in the kidney through regulation of the peroxisomal proliferator activator receptor γ coactivator 1-α (PGC-1α,[252] see later).

Calpains are key mediators of apoptosis and necrosis, inhibiting apoptosis and inducing necrosis by cleaving and deactivating caspases, including caspases-3, -7, -8, and 9.[253,254] Originally it was thought that calpains only inhibited apoptosis; however, it is now accepted that calpains can actually participate in apoptosis signaling cascades.[55,234] The role of calpains in necrosis or apoptosis appears to be cell type–dependent, and it is unclear whether calpains can also mediate apoptosis, or autophagy for that matter, in renal cells exposed to nephrotoxicants.

Caspases

Caspases are cysteine proteases. The role of caspase activation in renal cell apoptosis has been discussed previously, but it is important to note that caspase activity is not always

needed for apoptosis. For example, caspase-2-directed permeabilization of the mitochondrial membrane results in the release of the pro-apoptotic proteins cytochrome c and Omi, which occurs in the absence of any caspase-2 catalytic activity. Similar results are seen with caspase-2 mediated release of AIF.[234,255–257] Our work demonstrated that apoptosis induced by four diverse toxicants (cisplatin, vincristine, staurosporine, and A23187) proceeded in rabbit RPTC in the presence of caspase inhibitors and the absence of caspase-3, -8, and -9 activity.[258] The mechanisms involved in caspase-independent apoptosis in renal cells appear to involve the activation of DNAases such as Endo G and AIF.[69] This is supported by studies in renal cells showing that cisplatin-induced apoptosis is mediated by Endo G as opposed to caspases.[259,260]

Phospholipase A_2

Phospholipase A_2 (PLA_2) cleaves glycerophospholipids at the sn-2 ester bond, releasing fatty acids and lysophospholipids.[261] They are classified into five different families: secretory PLA_2 ($sPLA_2$), cytosolic PLA_2 ($cPLA_2$), platelet-activation factor (PAF) acetylhydrolases, lysosomal PLA_2, and calcium-independent PLA_2 ($iPLA_2$).[261,262] These proteins have different substrate preferences, Ca^{2+}-dependencies, and biochemical characteristics. Isoforms representing $cPLA_2$, $sPLA_2$, and $iPLA_2$ are all expressed in human, rat, rabbit, and mouse kidneys.[263–269]

PAF acetylhydrolase is expressed in microsomes and cytosol in rat and human kidneys,[270,271] but information about its expression in renal epithelial cells is lacking. Lysosomal PLA_2 is Ca^{2+}-independent and is an acidic hydrolases identical to peroxiredoxin 6.[272,273] Few studies exists assessing lysosomal PLA_2 expression in the kidney, but studies of peroxiredoxin 6 indicate that it is expressed in the proximal and distal tubules of rat kidneys.[274] The roles of PAF acetylhydrolase and lysosomal PLA_2 in nephrotoxicant-induced cellular injury are not well understood and deserve further study.

PLA_2 contribute to the mechanisms of cell injury and death by metabolizing glycerophospholipids and releasing fatty acids. The high concentrations of polyunsaturated fatty acids in plasma and organelle membranes make them prime targets for oxidants. Increase in lipid peroxidation facilitates PLA_2 activation and the production of fatty acids and lysophospholipids. This further enhances PLA_2 activity, which enhances phospholipid degradation to the point that membrane integrity is lost and intracellular Ca^{2+} increases which facilitates cell swelling and the activation of $sPLA_2$.

Recently, roles for $cPLA_2$ and $iPLA_2$ in nephrotoxicity have received much attention. Data from these studies demonstrate that PLA_2 mediates nephrotoxicant-induced cell injury in a cell- and toxicant-dependent manner. $cPLA_2$ or $iPLA_2$ is reported to mediate nephrotoxicity induced by oxalate, cisplatin, and isoflurane, as well as oxidants such as H_2O_2, t-butylhydroperoxide, and menadione.[174,267,275,276] $cPLA_2$ and $iPLA_2$ also mediate cell death induced by Fas and TNF-α, hypoxia, anoxia, and ischemia/reperfusion.[72,67,277–280]

PLA_2 are both initiators and executioners of nephrotoxicant-induced cellular death. They can act as executioners when they are activated after initial increases in cytosolic Ca^{2+}. This is especially true for $sPLA_2$, which is activated by mM concentrations of Ca^{2+}, which typically occur after loss of membrane integrity.[281,282] $cPLA_2$ is not directly activated by Ca^{2+}, but μM increases in Ca^{2+} facilitate translocation of $cPLA_2$ to membranes, which increases its activity.[281,283] Increase in Ca^{2+} also induce signaling kinases, such as ERK, that activate $cPLA_2$ and $iPLA_2$.[284–286] The metabolites of PLA_2 (fatty acids and lysophospholipids) can induce cell death by causing inflammation, mitochondrial dysfunction, and lipid peroxidation.[174,267,277]

PLA_2 can also initiate nephrotoxicant cell injury independently of Ca^{2+}. This is more the case for $iPLA_2$ than $cPLA_2$ or $sPLA_2$. $iPLA_2$ mediates cisplatin- and oxidant-induced nephrotoxicity in primary cultures of RPTC and several other renal cell lines.[174,267,287] The mechanisms involved also include cleavage of phospholipids and release of lipid mediators, except Ca^{2+} is not involved in the initial phases of injury.[277,287]

Most of our knowledge about the role of $iPLA_2$ in nephrotoxicant-induced cell injury is derived from studies using pharmacologic inhibitors, such as bromoenol lactone.[262] Studies using small interfering RNA also demonstrate that inhibition of $iPLA_2$ isoforms (groups VIA and B, commonly called $iPLA_2\beta$ and γ) induce cytostasis, apoptosis, and mitochondrial dysfunction in renal cell lines and primary cultures of RPTC.[277,288,289] These pathologies have been directly linked to changes in phospholipid metabolism and release of fatty acids.[277,290] Genetically modified mice lacking specific forms of $iPLA_2$ do exist,[291,292] but few studies have used these models to address roles of $iPLA_2$ in nephrotoxicant-induced cell injury.

Similar to $iPLA_2$, much of the knowledge about the role of $cPLA_2$ in nephrotoxicant-induced cell injury is derived from studies using inhibitors such as arachidonyl trifluoromethyl ketone or methyl arachidonyl fluorophosphonate.[262] Alteration of $cPLA_2$ activity using arachidonyl trifluoromethyl ketone alters oxidant-induced renal cell necrosis in multiple renal cell models.[275,293] Genetically altered mice lacking specific forms of $cPLA_2$ (group IV PLA_2 or $cPLA_2\alpha$) do exist, and suggest that these mice experience some alteration in kidney function.[294,295] Few studies exist using knockout mouse models to study the role of $cPLA_2$ in nephrotoxicant-induced cell death.

Compared to $iPLA_2$ and $cPLA_2$, less is known about the role of $sPLA_2$ in nephrotoxicity. Activation of $sPLA_2$ increased cell death in renal carcinoma cells in correlation with membrane hydrolysis,[296] and mediated cell death induced by IL-1-stimulated release of fatty acids, such as arachidonic acid, in HEK293 cells.[297] Thus, $sPLA_2$ may mediate renal cell injury after inflammation.[298,299] One role for $sPLA_2$ in nephrotoxicity is regulation of other PLA_2. This hypothesis is supported by studies in LLC-PK1 cells exposed to the oxidants H_2O_2 and menadione.[293] These studies suggest that

PLA_2 cross-talk can mediate certain types of nephrotoxicant-induced renal cell injury.

MITOCHONDRIA, ENDOPLASMIC RETICULUM, LYSOSOMES, AND THE CELL MEMBRANE

Mitochondria, ER, lysosomes, and the cell membrane all play roles in nephrotoxic cell injury as well as play roles in necrosis, apoptosis, and autophagy. As mentioned previously, these types of cell death do not proceed through mutually exclusive pathways consisting of single-event sequences. The interplay among necrosis, apoptosis, and autophagy is often mediated by cellular organelles, and key biochemical mediators of switches among necrosis, apoptosis, and autophagy include Ca^{2+} and ATP. These mediators are often controlled by the function of specific organelles, such as the ER (Ca^{2+}), the cell membrane (Ca^{2+}), and the mitochondria (ATP). In addition, lysosomes are critical mediators of autophagy.

Because of the presence of multiple cell death pathways and multiple targets, inhibition of one pathway may not block nephrotoxicant-induced cell death, but rather switch it from one type to another. This is often accompanied by an alteration in organelle function. For example, if a treatment blocks oxidative stress associated with DCVC, pentachlorobutadienyl-L-cysteine, or tetrafluoroethyl-L-cysteine exposure to RPTC, the rate of cell death is diminished, but the cells eventually die due to mitochondrial dysfunction (Fig. 30.7).[300] Thus, a given chemical can cause cell death by interacting with numerous organelles, and blocking interaction at one organelle may not decrease cell death. Rather it

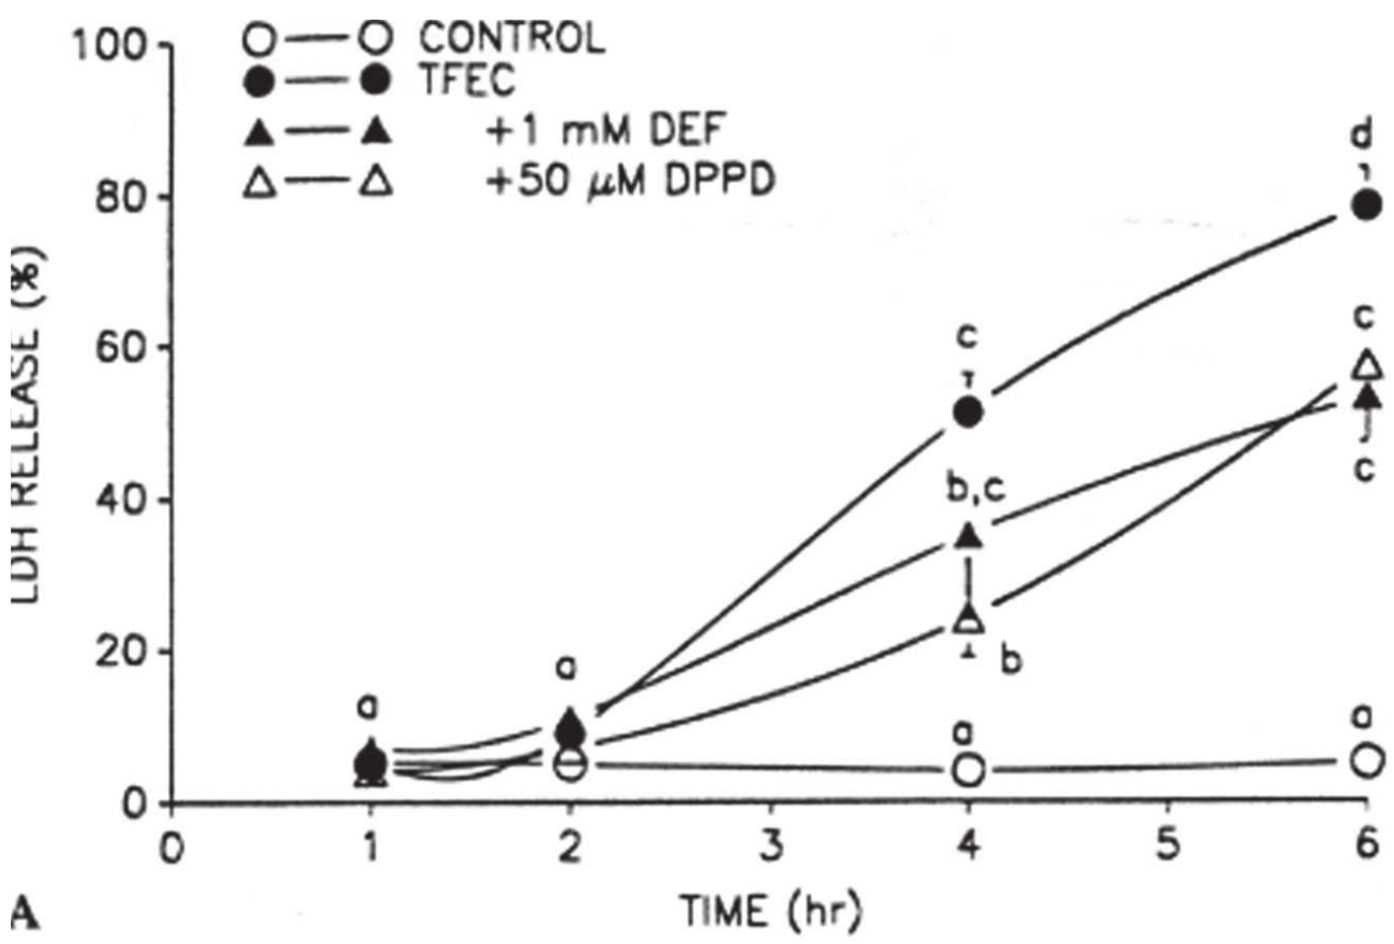

FIGURE 30.7 A: The time-dependent effects of deferoxamine (DEF) and N,N′-diphenyl-1,4-phenylenediamine (DPPD) on S-(1,1,2,2-tetrafluoroethyl)-L-cysteine (TFEC)-induced cell death (lactate dehydrogenase [LDH] release) from rabbit renal proximal tubules. DEF and DPPD were added at the same time as TFEC (25 μM). Values are means ± SEM. Values at a given time point or within a given treatment with different superscripts are significantly different from one another ($P \leq 0.05$). **B:** The time-dependent effects of DEF and DPPD on TFEC-induced lipid peroxidation (malondialdehyde [MDA] formation) in rabbit renal proximal tubule suspensions. Values are means ± SEM. Only the TFEC alone is significantly different from controls ($P \leq 0.05$). (Adapted from Groves CE, Lock EA, Schnellmann RG. Role of lipid peroxidation in renal proximal tubule cell death induced by haloalkene cysteine conjugates. *Toxicol Appl Pharmacol.* 1991;107:54, with permission.)

may alter the organelle targeted, which can switch the mechanism of cell death.

Mitochondria

The renal tubular reabsorption of solutes and water requires a large expenditure of energy. Although ATP is generated by both oxidative phosphorylation and glycolysis, ~95% of renal ATP is formed by oxidative phosphorylation.[301] The amount of oxidative phosphorylation that occurs within a given cell varies along the nephron. Thus, toxicants that interfere with mitochondrial function and anoxia will produce cell injury and death, particularly in tubular cells that have limited glycolytic capabilities, such as the S_1 and S_2 segments of the proximal tubules.

Many nephrotoxicants cause mitochondrial dysfunction prior to cell death. For example, $HgCl_2$ altered mitochondrial function and mitochondria morphology in vivo in renal cortical mitochondria prior to proximal tubule necrosis.[302,303] When added to isolated rat renal cortical mitochondria, $HgCl_2$ produced similar changes in various respiratory parameters.[302,303] $HgCl_2$ also decreased mitochondrial function in rabbit RPTC prior to the onset of cell death.[304]

The mechanism of mitochondrial dysfunction induced by nephrotoxicants is toxicant-specific. Pentachlorobutadienyl-L-cysteine initially uncouples oxidative phosphorylation in RPTC cells by dissipating the proton gradient.[305–307] In contrast, tetrafluoroethyl-L-cysteine does not uncouple oxidative phosphorylation, but inhibits state-3 respiration by inhibiting sites I and II of the electron transport chain.[307] Other nephrotoxicants that have been shown to affect mitochondrial function include cisplatin,[308,309] citrinin,[310–313] ochratoxin A,[314,315] cephaloridine,[316,317] N-(3,5)-dichlorophenyl-succinimide,[318] DCVC,[319,320] and 2-bromohydroquinone.[321]

Mitochondria can act as primary or secondary mediators of necrosis, apoptosis, or autophagy.[55,322,323] When mitochondria are the primary target of nephrotoxicants, release of cytochrome c and other apoptotic inducing proteins (see previous) can occur early in the apoptotic process. If mitochondria are not a direct target of the nephrotoxicant, these proteins may still be released, but later in the apoptotic process. Central to the role of the mitochondrion in apoptosis is its ability to release pro-apoptotic proteins that activate caspases.[83] Mitochondria can also release caspase-independent DNAases such as Endo G and Omi (Fig. 30.4).

As previously described, a key difference in mitochondrial function during apoptosis and necrosis is the maintenance of ATP during apoptosis. Cellular ATP acts with the mitochondrial membrane potential as a switch that dictates whether a cell dies by apoptosis or necrosis.[82] If the mitochondrial membrane potential is lost quickly and cellular ATP is drastically decreased (below 20% to 10% of normal), then necrosis occurs. Events that result in the rapid loss of mitochondrial membrane potential include a rapid influx of Ca^{2+} into the mitochondria and the rupture of the inner and/or outer mitochondrial membranes.[82] In contrast, if the loss of membrane potential is slower and ATP is maintained through oxidative phosphorylation or glycolysis, then the cell is more likely to die through apoptosis. It should be noted that the majority of cells in culture derive their energy from glycolysis and can maintain ATP levels in the presence of mitochondrial dysfunction. Consequently, cultured cells are generally more susceptible to apoptosis than cells in vivo.

Mitochondria can mediate autophagy by mediating the activation of p53 and caspases.[55] As mentioned previously, cytosolic p53 can inhibit autophagy,[117] whereas caspases can cleave the pro-autophagic protein beclin-1.[55] Cleavage of beclin-1 by caspases is believed to be a primary signal by which cells switch from autophagy to apoptosis. However, more studies are needed to prove that such mechanism occurs during nephrotoxicant-induced renal cell death.

Studies are focusing on the exact protein targets within the mitochondria. For example, experiments seeking to determine the effect of hypoxia on mitochondrial electron transport chain constituents in rabbit RPTC reveal that complex I may be particularly sensitive.[324,325] Other studies have revealed that cisplatin-induced changes in oxidative phosphorylation, membrane potential, and ATP levels in rabbit RPTC are all preceded by inhibition of F(0)F(1)-ATPase (complex IV).[189]

Recent studies in renal cortical mitochondria suggest that an increase in Ca^{2+} influx activates mitochondrial calpain 10, which induces mitochondrial dysfunction by cleaving proteins in complex I of the electron transport chain (see previous text).[248,249,326] Such studies are critical to the understanding of the pathology of mitochondrial-mediated renal cell death and to identifying novel therapeutic targets for inhibition of renal cell death and possibly AKI.

The mechanisms by which toxicants induce release of mitochondrial cytochrome c have also received recent attention. Cytochrome c is normally bound to the inner mitochondrial membrane in association with cardiolipin, a mitochondrial-specific phospholipid. Oxidation of cardiolipin results in cytochrome c release,[55] and oxidant-induced release of cytochrome c is reported to be preceded by cardiolipin peroxidation.[327] These data may explain the protective effect of mitochondrial antioxidants[55] and may explain why inhibition of mitochondrial PLA_2 ($iPLA_2\gamma$)-induced apoptosis in renal cells, such as this enzyme, is suggested to aid in repair of phospholipid oxidation.[55,277] Once released from cardiolipin, cytochrome c may gain entry to the cytosol through a pore formed in the outer mitochondrial membrane by the pro-apoptotic proteins Bax, Bid, or Bak (see previous).

Endoplasmic Reticulum

The ER is the site of protein synthesis and processing as well as bioactivation and detoxification pathways, including those involving cytochrome P-450 and FMO. The ER is also a key regulator of cellular Ca^{2+} homeostasis. Under physiologic conditions, ER Ca^{2+} is typically released after receptor activation through the binding of inositol triphosphate (IP_3) to IP_3 receptors on the ER. Cytosolic free Ca^{2+} increases as a consequence of the ER Ca^{2+} release and is subsequently

decreased by ER uptake via the smooth ER Ca^{2+}-ATPases (SERCA) or extrusion via the plasma membrane Ca^{2+}-ATPase. Similar to the mitochondria, the ER can mediate necrosis, apoptosis, and autophagy.

Schnellmann and colleagues demonstrated that ER Ca^{2+} release is an important signaling pathway in RPTC necrosis.[214,216] Specifically, depletion of ER Ca^{2+} stores with the SERCA inhibitors thapsigargin or cyclopiazonic acid prior to antimycin A or hypoxia exposure inhibited necrosis.[214,216] Also, Ca^{2+} release from the ER activated calpains (calpain 1 and 2), which led to further disruption of ion homeostasis, cleavage of cytoskeleton proteins, and cell swelling, which ultimately resulted in necrosis.[214,218,219,244]

The cytoprotective effects of some stress proteins may be mediated through their ability to regulate ER Ca^{2+}. For example, iodoacetamide and DCVC can activate heat shock proteins (HSPs), calreticulin, and glucose related protein 78 (GRP78) in LLC-PK1 cells.[328] HSPs are typically ER localized proteins that are critical mediators of protein folding. Glucose-related protein 78 and calreticulin are Ca^{2+} binding proteins that aid in the sequestering of Ca^{2+} during toxic stress. Sequestering of Ca^{2+} by these proteins may protect renal cells by preventing cellular oxidative stress induced by Ca^{2+}-mediated mitochondrial injury.[329,330] The increased expression of Ca^{2+}-sequestering HSPs after injury is meant to condition the cell to withstand further necrotic injury.

The ER also mediates apoptosis induced by numerous nephrotoxicants, including acetaminophen, tunicamycin, Fas, and TNF-α.[109] A role for Ca^{2+} in calpain activation and subsequent activation of caspase has been described, as has a role for Ca^{2+} in induction of mitochondrial pore formation. It is suggested that the source of this Ca^{2+} is the ER.[55] ER Ca^{2+} release is also known to mediate the activation of the murine caspase-12 in mouse RPTC.[331] Mice in which caspase-12 had been genetically deleted were resistant to renal cell apoptosis induced by the ER stress agents tunicaymycin, brefeldin A, and thapsigargin, compared to wild-type animals. In contrast, kidneys from mice null for caspase-12 underwent similar degrees of apoptosis caused by the Fas antibody, TNF-α plus cycloheximide, or staurosporine—both agents that cause apoptosis by mechanisms other than ER stress. The key to the activation of caspases-12 in contrast to other caspases may be perturbations in the ER membrane and/or Ca^{2+} levels.

ER Ca^{2+} release is also hypothesized to mediate apoptosis by receptor-mediated mechanisms. Studies in nonrenal cells suggest that an ER Ca^{2+} receptor, type 3 inositol-1,4,5-trisphosphate (Ins[1,4,5]P_3), was upregulated in lymphocytes undergoing dexamethasone-induced apoptosis,[55,332] and that inhibition of Ins(1,4,5)P_3 receptors made T-lymphocytes resistant to apoptosis.[333] Interestingly, sensitivity to apoptosis in T-lymphocytes was restored after artificially increasing cytosolic Ca^{2+}. It is possible that Ca^{2+} released by the Ins(1,4,5) P3 receptor may induce apoptosis by mechanisms described previously (caspase activation, mitochondrial-mediated mechanisms, etc.). It is unknown whether Ins(1,4,5)P3 mediates nephrotoxicant-induced renal cell apoptosis.

Several studies have shown that autophagy is induced by ER stress and ER Ca^{2+} release,[56,115,116,334] and some of these studies have been performed in kidney tissue and renal cells.[56,116] For example, cyclosporine and thapsigargin, agents known to induce ER stress, increase autophagy in primary cultures of human renal cells and in rat kidneys after cyclosporine exposure in vivo.[116] Additionally, tunicamycin or brefeldin A induced autophagy in immortalized rat proximal tubular cells.[115] Mechanisms involved in autophagy induced by ER Ca^{2+} release have been discussed.[112]

Plasma and Organelle Membranes

Some nephrotoxicants can interact with the plasma membrane directly, increase ion permeability, and disrupt ion homeostasis. For example, amphotericin B is an antifungal polyene that binds to cholesterol in the plasma membrane and forms a pore that increases potassium and proton permeabilities.[118,335] Several heavy metals such as silver, gold, mercury, and copper can also react with the plasma membrane and increase potassium permeability.[336,337] It remains to be determined how changes in potassium and proton permeability ultimately lead to cell death.

Toxicants can disrupt cell volume and ion homeostasis by directly or indirectly inhibiting energy production. The loss of ATP inhibits the activity of membrane transporters that maintain differential ion gradients across the plasma membrane. The Na^+-K^+-ATPase is responsible for maintaining the normal Na^+ and K^+ gradients and the secondary ion transport processes. As ATP levels decrease, Na^+-K^+-ATPase activity decreases, resulting in K^+ efflux and Na^+ influx and a decrease in the normally negative membrane potential.[338] The decrease in the negative membrane potential allows Cl^-, as well as additional Na^+, to enter down a concentration gradient resulting in water influx and cellular swelling. Similar mechanisms can occur in kidney cells. For example, treatment of rabbit RPTC suspensions with the mitochondrial inhibitor antimycin A inhibits respiration within 1 minute, followed by ATP depletion, and the loss of the sodium and potassium gradients and transport over the next 5 to 10 minutes (Fig. 30.8).[219,339] Subsequent studies demonstrated that increases in Cl^- influx occurred between 15 and 30 minutes, during the late stages of cellular injury, followed by cellular rupture.[340] Decreasing extracellular NaCl concentrations by 50% with iso-osmotic substitution of mannitol decreased Cl^- influx, cellular swelling, and cellular rupture.[341] Furthermore, hyperosmotic incubation buffer decreased the cellular swelling and cellular lysis but not the increased Cl^- influx.[341] Thus, the delayed increase in Cl^- influx may be the trigger for the water influx and additional Na^+ influx that provides the osmotic force for cellular swelling and rupture.

Increased Cl^- influx occurs during the late stages of cell injury in RPTC and LLC-PK1 cells exposed to a variety of injury stimuli and toxicants, including $HgCl_2$, t-butylhydroperoxide, bromohydroquinone, tetrafluoroethyl-L-cysteine, and hypoxia.[341,342] The mechanism by

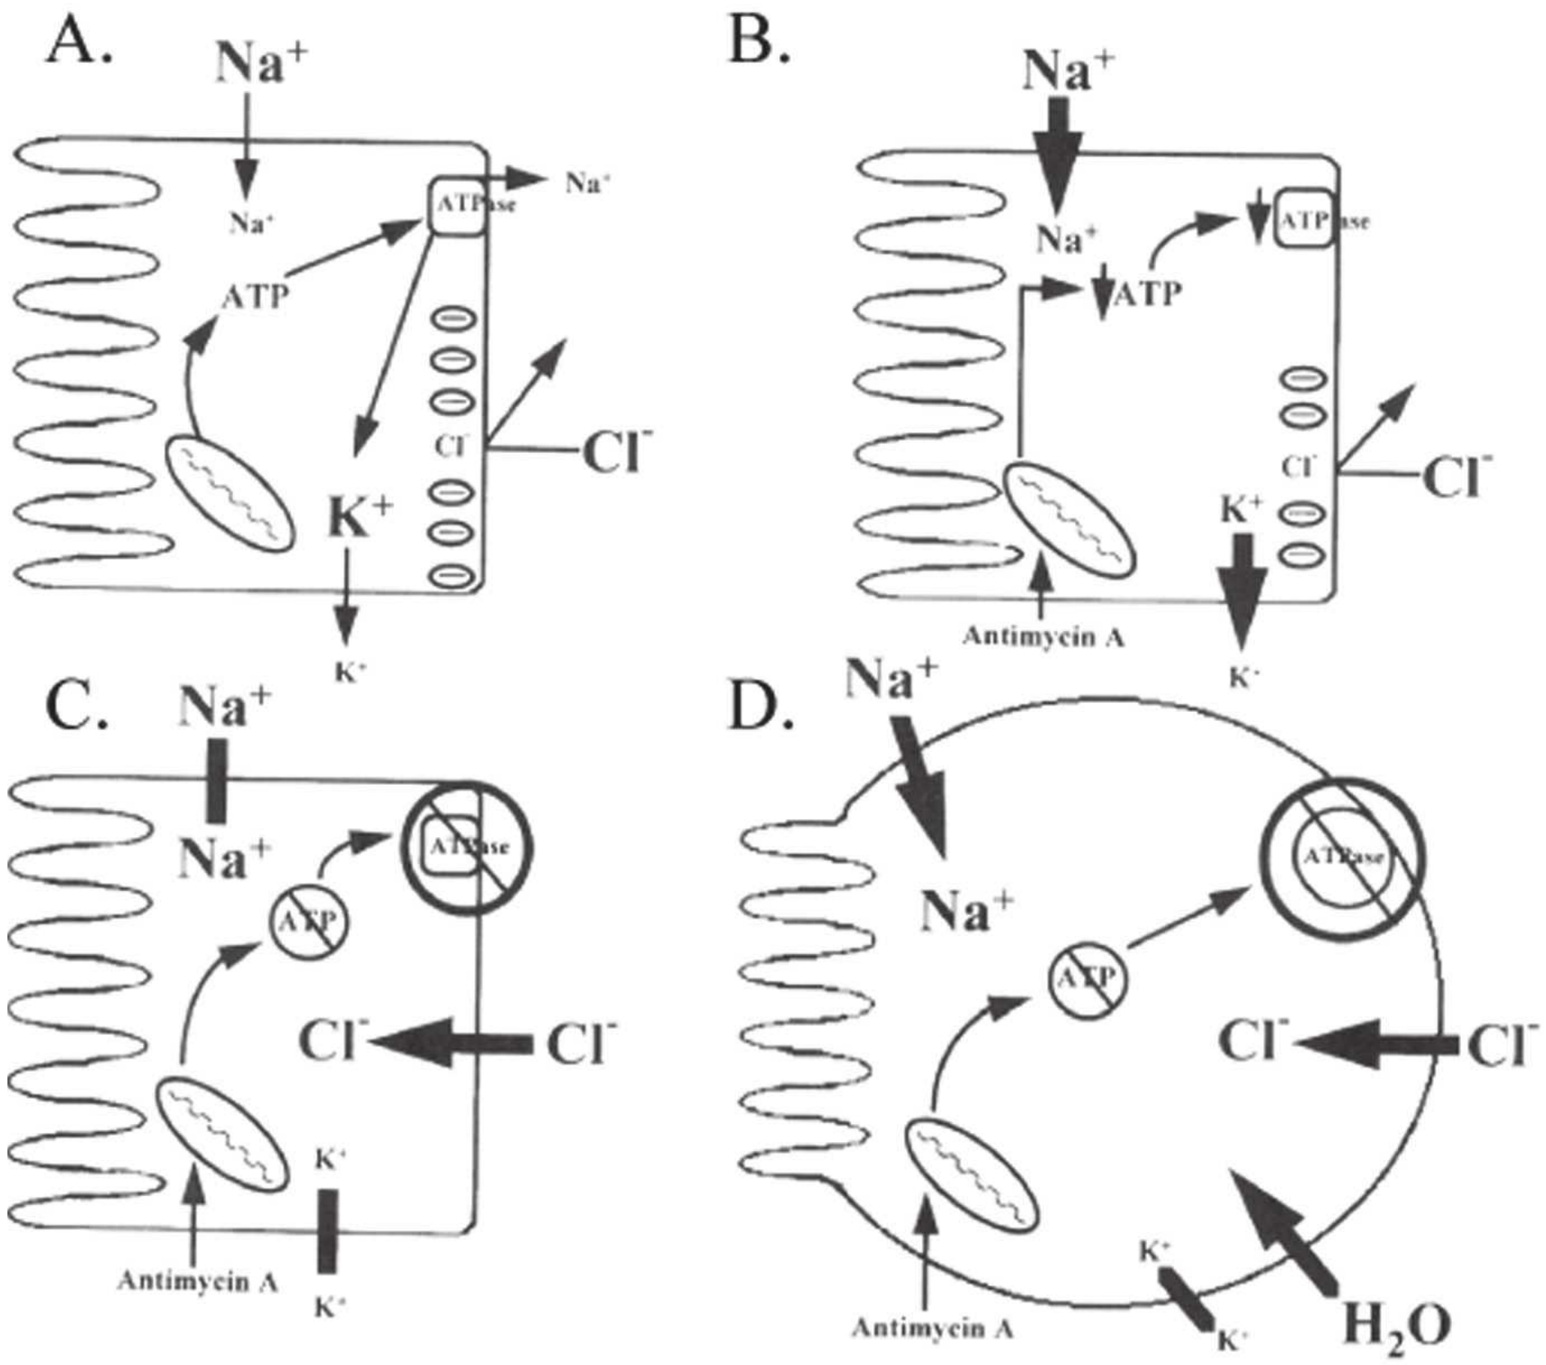

FIGURE 30.8 **A:** A schematic representation of a normally functioning renal cell. Note that the inside of the cell is negative with respect to the outside, which decreases the ability of Cl^- to enter the cell. **B:** The addition of a mitochondrial inhibitor such as antimycin A blocks cellular respiration, decreases ATP levels and Na^+-K^+-ATPase activity, increases Na^+ influx and K^+ efflux, and decreases the membrane potential. **C:** Subsequently, there is an increase in Cl^- influx (down the concentration gradient) by an unidentified pathway. **D:** The increase in Cl^- influx results in water influx, increased Na^+ influx, and cellular swelling. These processes provide the osmotic force that ultimately leads to cellular lysis.

which Cl^- influx occurs under these conditions is still under study, but was inhibited by blockers of Ca^{2+}-activated Cl^- channels (e.g., niflumic acid, indanyloxyacetic acid [IAA-94], 5-nitro-2-[3]-phenylpropylamino-benzoate [NPPB], and diphenylamine-2-carboxylate [DPC]).[150–153] The Cl^- influx was insensitive to the Cl^- channel blockers 4-acetamide-4′-isothiocyanostilbene-2,2′-disulfonic acid (SITS) and diisothiocyanostilbene-2,2′-disulfonic acid (DIDS) or to the Cl^- transport inhibitors bumetanide and hydrochlorothiazide.[341] Therefore, the Cl^- influx that occurs during the late phase of cell death may be through a Ca^{2+}-activated Cl^- channel.

The plasma membrane can also mediate apoptosis due to the presence of death receptors. These include receptors for TNF-α, Fas, and LPS, all of which mediate renal cell apoptosis.[343,344] The exact receptors involved depend on the toxicant and cell type, but typically activate the extrinsic caspase-mediated pathway (see previous text). Additionally, and as mentioned previously, plasma membrane Ca^{2+} receptors can directly mediate apoptosis[213]; however, this pathway has not received as much attention with regard to nephrotoxicant-induced renal cell injury.

Lysosomes

Lysosomes are membrane-bound vesicles that pinch off from the Golgi-apparatus and contain a variety of hydrolytic enzymes.[345] Lysosomes contain hydrolytic enzymes that function as intracellular digestive enzymes under normal conditions. Lysosomes play an important role in the nephrotoxicity of several compounds such as aminoglycoside antibiotics. Lysosomes can also mediate a specific pathology called α_{2u} nephropathy. α_{2u}-Nephropathy occurs in male rats when compounds such as unleaded gasoline, d-limonene, 1,4-dichlorobenzene, tetrachloroethylene, decalin, 2,2,4-trimethylpentane, and lindane bind to α_{2u}-globulin, which prevents its normal degradation in renal proximal tubular cells.[346,347] α_{2u}-Globulin is synthesized in the liver of male rats under androgen control. Serum α_{2u}-globulin (18.7 kDa) is freely filtered by the glomerulus with approximately half being reabsorbed via endocytosis in the S_2 segment of the proximal tubule. The binding of these agents to α_{2u}-globulin inhibits its normal degradation and results in the accumulation of α_{2u}-globulin in the proximal tubule. Over time, the size and number of lysosomes increase, and characteristic protein-droplet morphology is observed. Ultimately, this leads to single-cell necrosis, the formation of granular casts at the junction of the proximal tubule and the thin loop of Henle, and cellular regeneration.

Recent data show that a 73 kDa heat shock cognate protein mediates the binding of α_{2u}-globulin to a 96 kDa membrane glycoprotein in male rat kidney lysosomes.[348] This HSP also is involved in the degradation of other cellular proteins. Treatment of rats with 2,2,4-trimethylpentane increases the rate of transport of not only α_{2u}-globulin into the lysosome, but also increases the rate of lysosomal

transport of many proteins. Increased transport is a result of α_{2u}-globulin-mediated increases in the level of the receptor proteins in the lysosomal membrane. Thus, α_{2u}-globulin may induce lysosomal overload by increasing the rate of transport of cellular proteins to the lysosome. In this manner, chronic exposure to the preceding compounds may lead to a chronic nephropathy, and may increase the incidence of renal adenomas/carcinomas by nongenotoxic mechanisms.

α_{2u}-Globulin nephropathy is sex- and species-specific, occurring in particular strains of male rats but not in female rats, male or female mice, rabbits, or guinea pigs. This raises the question if humans are at risk for α_{2u}-globulin-induced nephropathy and renal tumors. The current evidence suggest no because: (1) humans do not synthesize α_{2u}-globulin; (2) humans secrete fewer proteins in general and, in particular, fewer low-molecular-weight proteins in the urine than the rat; (3) the low-molecular-weight proteins in human urine are either not related structurally to α_{2u}-globulin, do not bind to compounds that bind to α_{2u}-globulin, or are similar to proteins in female rats, male Black Reiter rats, rabbits, or guinea pigs that do not exhibit α_{2u}-globulin nephropathy; and (4) mice excrete a low-molecular-weight urinary protein that is 90% homologous to α_{2u}-globulin but do not exhibit α_{2u}-globulin nephropathy and renal tumors after exposure to α_{2u}-globulin nephropathy-inducing agents.[349]

Aminoglycoside antibiotics also induce lysosomal dysfunction and cause acute renal failure (ARF) (see Chapter 31).[120,350,351] In this case, the aminoglycosides are filtered, bound to anionic phospholipids in the brush border, reabsorbed by endocytosis in the S_1 and S_2 segments of the proximal tubule, and accumulated in the lysosomes. Over time, the size and number of lysosomes increase and electron-dense lamellar structures called myeloid bodies appear. The myeloid bodies contain undegraded phospholipids and are thought to occur through aminoglycoside-induced inhibition of lysosomal hydrolases such as sphingomyelinase and phospholipases. However, the steps between lysosomal phospholipid overload and tubule cell death are less clear.

Lysosomes play a central role in autophagy.[56,112,113,237] Basically, autophagosomes formed during autophagy fuse with the lysosomes, which leads to the degradation of cellular proteins.[112] Studies in renal cells and tissues demonstrate that autophagy occurs after nephrotoxicant exposure including that induced by cyclosporine, cisplatin, thapsigargin, and after ischemia reperfusion.[56,115,116,237,352] Because it is not clear if nephrotoxicant-induced renal cell autophagy mediates cell death or survival, it is not known if the role of the lysosome in this type of pathology is protective or damaging. Further studies are needed to address this gap in knowledge.

CELLULAR DEFENSES

Renal epithelial cells have numerous defenses against both reactive intermediates and ROS (Fig. 30.6). GSH is the primary cellular protectant and the most abundant cellular nonprotein thiol in cells. It is found in high concentrations in at least three subcellular compartments (cytosol, mitochondria, nucleus).[353] Normally, GSH detoxifies electrophiles by forming a glutathione conjugate either directly or with the aid of GST. This includes compounds containing a quinone nucleus such as bromohydroquinone, which results in formation of mono- and di-substituted glutathione conjugates in renal cells.[321]

GSH also acts in conjunction with glutathione peroxidase and glutathione reductase to neutralize ROS. This produces organic peroxide that is reduced to water and alcohol by glutathione peroxidase, forming glutathione disulfide (Fig. 30.6). Glutathione disulfides are reduced to glutathione by glutathione reductase in an NADPH-dependent reaction. Catalase and superoxide dismutase are two other enzymes that detoxify ROS. Superoxide dismutase converts the superoxide anion to hydrogen peroxide, and catalase converts the hydrogen peroxide to water.

Several studies show that the activity of glutathione-dependent enzymes differs among the nephron. Differences in the activity of these enzymes may account for differences in the susceptibility of different kidney regions to oxidative stress. Cummings and associates[354] reported that the levels of glutathione peroxidase and γ-glutamylcysteinyl synthetase are higher in rat proximal tubular cells than distal tubule cells. The activity of glutathione reductase and GST appeared to be equal between the two cell populations; however, the proximal tubular cells had a much higher concentration of glutathione than distal tubular cells (27 nmol per mg for proximal tubular cells versus 13 nmol per mg for distal tubular cells).[355]

In order to protect against nephrotoxicant-induced cellular injury, GSH must be able to cross plasma and organelle membranes. The dicarboxylate carrier is one protein responsible for transport of GSH into mitochondria, and overexpression of this protein protected normal rat kidney-52E cell lines from both oxidant (t-butylhydroperoxide) and DCVC-induced apoptosis.[356] Protection against injury correlated to increases in mitochondrial GSH concentration, as well as decreased mitochondrial dysfunction, the release of cytochrome c, and caspase activation.

Vitamin C (ascorbic acid) is a very effective reducing agent and free radical scavenger and functions in the recycling of the vitamin E radical back to vitamin E.[357] Like GSH, vitamin C can detoxify compounds containing a quinone nucleus such as bromohydroquinone, but in this case vitamin C reduces the bromoquinone and the bromoquinone radical back to bromohydroquinone.[321]

Vitamin C can also promote repair and regeneration after nephrotoxicant-induced injury. For example, pharmacologic levels of vitamin C improved recovery of rabbit RPTC after exposure to t-butylhydroperoxide and DCVC.[358–360] Increased recovery correlated to increased cell number and mitochondrial function.[358] Vitamin C may also improve recovery by promoting collagen deposition in the extracellular matrix.[358] The effect of vitamin C was not the result of its antioxidant function, because both t-butylhydroperoxide and

DCVC caused the same amount of damage in treated and untreated cultures, and vitamin C was added after injury and removal of the nephrotoxicants.

Vitamin E (α-tocopherol) is a lipid-soluble antioxidant found in cell membranes.[361] Vitamin E is a chain-breaking antioxidant because it contributes an electron to a peroxyl radical formed during lipid peroxidation and thereby prevents further lipid peroxidation. The vitamin E radical produced is unreactive and is recycled back to vitamin E. Vitamin E suppresses cyclosporin A-mediated toxicity in vivo in rat renal kidneys by inhibiting lipid peroxidation.[362] Vitamin E also protects against cephaloridine-induced toxicity in freshly isolated rat proximal tubule cells.[363] The protective effect of vitamin E on proximal tubule cell death correlated to decreases in lipid peroxidation.

Glycine

Glycine is cytoprotective in a number of models of renal injury.[364] In addition, several other small amino acids with similar structure to glycine, including D- and L-alanine, β-alanine, and 1-aminocylopropane-1-carboxylic acid, also protect against nephrotoxicity. This suggests that there is a structural requirement for cytoprotection with these compounds.

Glycine is cytoprotective against a diverse group of chemical insults such as anoxia, metabolic inhibitors, bromohydroquinone, halogenated alkene, and alkane cysteine conjugates and, to a lesser extent, t-butylhydroperoxide and $HgCl_2$.[215,365] The mechanism of glycine cytoprotection has remained elusive, but studies suggest that glycine acts during the terminal phase of cell injury.[365] Further, the mechanism of protection may be receptor-based as the neuronal glycine receptor antagonist strychnine protected against renal cell injury under a variety of conditions.[341,366] Strychnine binds to a low-affinity binding site on the basolateral membrane of the rabbit RPT cell in a saturable and reversible manner at the same concentrations that are cytoprotective.[245] Proteins corresponding to two of the three subunits of the neuronal strychnine-sensitive glycine receptor are expressed at the basolateral membrane as well, which may represent the glycine receptor β subunit.[366,367] The signal transduction pathway for the neuronal glycine receptor involves Cl^-. Collectively, these studies suggest that glycine and strychnine are cytoprotective by directly or indirectly altering Cl^- influx. These compounds may inhibit the ability of Cl^- to increase the osmotic force, which drives increases in cell swelling during injury.

Alternatively, Nichols and associates[368] proposed that glycine is cytoprotective in hepatocytes through its ability to inhibit calpains. However, Edelstein and coworkers[246] reported that glycine did not inhibit calpain activity in rat RPT exposed to hypoxia. Studies in rabbit RPT demonstrated that glycine and strychnine did not inhibit basal calpain activity, but did inhibit calpain activity observed during the late phase of cellular injury.[369] Later studies confirmed that glycine does not directly affect calpain activity, but rather inhibited toxicant-mediated extracellular Ca^{2+} influx, calpain translocation, and Cl^- influx.[369]

Acidosis

Acidosis is not a normal cellular defense mechanism per se; however, decreasing extracellular pH is cytoprotective in a variety of in vitro models of renal cell injury.[370,371] For example, reducing the extracellular pH to 6.8 to 7.0 protected against anoxia-induced cell death in isolated renal tubules.[371–373] In addition, Rodeheaver and Schnellmann[370] demonstrated that extracellular acidosis (pH 6.4) ameliorated renal proximal tubular cell death produced by a series of mitochondrial inhibitors (antimycin A, rotenone, carbonyl cyanide-p-trifluoromethoxyphenylhydrazone, oligomycin) and ion exchangers (nigericin, monensin, valinomycin), but potentiated cell death produced by the oxidants t-butylhydroperoxide, hydrogen peroxide, and ochratoxin A. Thus, the effect of extracellular acidosis on renal cell injury is toxicant-specific. Increased cell death in the presence of oxidants correlated to increases in oxidized GSH (GSSG), lipid peroxidation, and mitochondrial dysfunction. This suggests that extracellular acidosis during oxidant exposure decreases free radical detoxification.

It is unlikely that extracellular acidosis protects against nephrotoxic-induced renal cell injury by preserving mitochondrial function or ATP levels.[370–372] This hypothesis is supported by studies demonstrating that extracellular acidosis initiated at various times after toxicant exposure was still cytoprotective.[238,371] For example, extracellular acidosis initiated 15 minutes after antimycin A or carbonyl cyanide-p-trifluoromethoxy phenylhydrazone addition—a time point after the cessation of respiration, depletion of ATP, and increases in intracellular sodium and decreases in intracellular potassium—was completely cytoprotective at 45 and 105 minutes, respectively; however, cytoprotection did not prevent increases in Cl^- influx that occurs in the late stages of cell injury. Extracellular acidosis initiated 2 hours after tetrafluoroethyl-L-cysteine or t-butylhydroperoxide addition also was cytoprotective 2 hours later. These results demonstrate that the cytoprotective effect of extracellular acidosis occurs very late in the cell injury process distal to Cl^- influx.

Peroxisomes and Peroxisomal Proliferating Activated Receptors

Peroxisomes are membrane-bound vesicles that contain degradative enzymes for fatty acids and amino acids.[345] Peroxisomes also contain catalase, which converts H_2O_2 to oxygen and water. Thus, peroxisomes are a major site of antioxidant defense. In addition, peroxisomal proliferation has been linked to the preservation of mitochondrial function[374] and the reduction in renal cell death following injury induced by gallic acid,[375] cisplatin,[259,376] and ischemia/reperfusion-induced injury.

Peroxisomes also may protect against renal cell death via mechanisms linked to the activation of peroxisomal proliferator-linked receptors (PPAR). PPAR are members of a nuclear hormone-activated receptor and transactivation protein family.[377] At this time three different PPAR have been identified and cloned (PPAR-α, PAR-β/δ, and PPAR-γ,).[377] PPAR-β/δ are

detected in almost all tissues including the kidney cortex.[377–379] PPAR-γ is present in distal medullary collecting ducts, glomeruli, and the renal microvasculature.[379,380] PPAR-α is expressed in the proximal tubule, medullary thick ascending limbs, and the glomerular mesangial cells. It is hypothesized that differences in the distribution of PPAR isoforms may result in different mechanisms of protection between different cells.

Toxicants that activate PPAR are structurally diverse and include plasticizers (di(2-ethyhexl)phthalate),[381] herbicides,[382] hypolipidemic drugs (fenofibrate, clofibrate, and clofibric acid),[377] and antidiabetic drugs[377,383] (e.g., troglitazone and rosiglitazone).[383–385] Activators of PPAR increase the number of peroxisomes within the cell and increase the expression of enzymes for fatty acid β-oxidation including fatty acyl-CoA oxidase, enoyl-CoA hydratase/3-hydroxyacyl-CoA dehydrogenase bifunctional enzyme, and 3-ketoacyl-CoA thiolase.[381,382,386] Activators of PPAR isoforms also increase mitochondrial enzymes including carnitine palmitoyltransferase, medium chain acyl-CoA dehydrogenase, and pyruvate dehydrogenase complex.[376,379] The increase in these proteins is believed to be key in the protection against nephrotoxicants.[377,379,387]

Activation of PPAR, at least activation of PPAR-α, appears to protect against renal cell death. This hypothesis is supported by studies showing that the PPAR-α agonists clofibrate and WY14643 protect against ischemia/reperfusion-induced renal cell dysfunction in rat kidneys.[379,388] In addition, knocking out PPAR-α increased cisplatin-induced renal cell apoptosis in mouse kidneys, in correlation with the release of Endo G from the mitochondria.[259]

The mechanism of protection afforded by a PPAR-α agonist against nephrotoxicant-induced renal cell injury correlates to increases in mitochondrial function. This is demonstrated by in vivo studies demonstrating that PPAR-α induction correlated to increased mitochondrial medium-chain acyl-CoA dehydrogenase and pyruvate dehydrogenase complex activity, which correlated to decreases in cisplatin-induced proximal tubular necrosis.[376]

Schnellmann and colleagues demonstrated that overexpression of peroxisomal proliferator-activated receptor γ coactivator-1α (PGC-1α), the master regulator of mitochondrial biogenesis, induced mitochondrial biogenesis in renal proximal tubular cells.[252,389] Further, PGC-1α expression was increased following sublethal injury induced by t-butylhydroperoxide, and only returned to base values after mitochondrial function was restored. Interestingly, overexpression of PGC-1α following oxidant injury stimulated the recovery of mitochondrial and cellular function. These data suggest that PGC-1α is a therapeutic target for stimulating renal cell recovery and regeneration after nephrotoxicity.

SPECIFIC TOXICANTS

It is critical to identify the ultimate toxic species and the cell type targeted in order to understand the mechanism by which a chemical produces nephrotoxicity. For example, is the glomerulus, proximal convoluted tubule, proximal straight tubule, the thick ascending limb of Henle, or the distal convoluted tubule the target of the parent compound, a primary, or secondary metabolite? Thus, biotransformation, toxicokinetic, and morphologic studies are paramount in determining the sites of biotransformation, which metabolites reach the kidney, the quantity of metabolites in the kidney, the target cell type in the kidney, and ultimately the mechanism of nephrotoxicity. Other chapters in this book focus on specific toxicants such as analgesics (Chapter 32), antibiotics (Chapter 31), antineoplastics (Chapter 31), heavy metals (Chapter 34), immunosuppressives (Chapter 31), and radiocontrast media (Chapter 33).

Acknowledgments

The authors would to thank Dr. Jennifer G. Schnellmann for critically reviewing this manuscript. Preparation of this chapter was supported by National Institutes of Health grants ES-04410 (RGS), ES-12239 (RGS), DK-62028 (RGS), VA Merit Award (RGS), and EB008153 (BSC).

CHAPTER

31 Antibiotic- and Immunosuppression-Related Renal Failure

Marc E. De Broe

AMINOGLYCOSIDE ANTIBIOTICS

Nephrotoxic injury is a common complication of aminoglycoside antibiotic therapy. Studies that have used well-defined measures of nephrotoxicity indicate an incidence rate of 7% to 36%.[1–9] This variability reflects differences with respect to the nephrotoxicity potentials of aminoglycoside antibiotics in clinical use as well as differences among patients receiving these drugs. A survey of clinical studies published between 1975 and 1982 revealed that the average incidence of nephrotoxicity caused by specific aminoglycoside antibiotics was gentamicin, 14%; tobramycin, 12.9%; amikacin, 9.4%; and netilmicin, 8.9%.[10] In critically ill patients, the incidence of aminoglycoside nephrotoxicity may rise twofold.[11]

Clinical Aspects

The clinical expression of aminoglycoside nephrotoxicity has been well described.[12–16] Lopez-Novoa and colleagues wrote a comprehensive review on the mechanisms of aminoglycoside nephrotoxicity.[17] The earliest and most common expression of aminoglycoside renal tubular cell alterations is increased urinary excretion of low molecular weight proteins[18,19] and of lysosomal and brush-border membrane enzymes.[18–21] These changes may be detected within 24 hours of initiating drug therapy, and the frequency and magnitude of these changes increase as a function of dose and duration of therapy. Unfortunately, these changes do not predict which patients will progress to acute renal failure (ARF). This probably reflects the fact that several mechanisms underlie the expression of the enzymuria and proteinuria.[13] With repeated dosing, the amount of enzymes and low molecular weight proteins excreted in the urine may increase quite sharply, which may signify the onset of proximal tubular cell necrosis.[13]

Nonoliguric renal failure is a common expression of aminoglycoside nephrotoxicity[22] and may reflect a direct inhibitory effect on solute transport along the thick ascending limb of Henle's loop[23] or possibly tubulointerstitial cell injury,[24] which results in impaired ability to maintain a hypertonic medullary interstitium. Inhibition of adenylate cyclase may also contribute to the polyuria.[25] Neither mechanism, however, adequately explains the maintenance of normal to high urine output, even in the face of severe depression of whole kidney glomerular filtration rate (GFR). The slow evolution of ARF, which has been attributed to a variable susceptibility of renal proximal tubular cells to aminoglycoside toxicity,[12,26] may allow for the development of maximal compensatory adaptation by residual intact nephrons. In addition, micropuncture experiments[27] implicate a marked depression of solute and water transport along the proximal tubule such that the large increase in the fraction of filtrate escaping reabsorption along the proximal tubule may overwhelm the reabsorptive capacity of the distal nephron and contribute to the pattern of nonoliguric renal failure. When oliguria occurs, it usually signifies the influence of one or more complicating factors (e.g., ischemia or another nephrotoxin), especially if the oliguria appears early in the course of aminoglycoside administration. Studies in animals have shown that aminoglycoside therapy sensitizes the kidney to a subsequent ischemic or nephrotoxic insult,[28–37] such that the severity of the ARF is substantially greater than that predicted by the sum of the individual insults. Deterioration of other proximal tubular transport processes may occur during aminoglycoside toxicity and, in rare cases, may mimic a Fanconi-like syndrome.[38] Hypokalemia and hypomagnesemia secondary to renal potassium and magnesium wasting may also appear.[39,40]

Depression of GFR is a relatively late manifestation of aminoglycoside nephrotoxicity. In humans, depression of GFR typically does not occur before 5 to 7 days of therapy have been completed[15] unless there has been a major complicating factor such as renal ischemia. Studies in animal models of aminoglycoside nephrotoxicity have implicated activation of the renin–angiotensin system,[41] reduction in the size and density of glomerular endothelial fenestrae,[42–44] tubular obstruction,[45] tubular back leak,[27] and release of platelet activating factor from mesangial cells[46] as pathogenic factors causing depression of GFR.

The majority of patients with aminoglycoside nephrotoxicity recover renal function clinically, although in some cases the time to recovery may be prolonged.[16] Chronic renal failure is a distinctly uncommon complication of pure aminoglycoside

nephrotoxicity in humans, so that when it occurs, it usually signifies the contribution of some additional factor. Animal studies indicate, however, that incomplete regeneration with interstitial fibrosis does occur,[47] and the same may be true for humans.[48]

Morphologic Alterations

Aminoglycosides cause tubular cell necrosis that in animal models is largely confined to the proximal convoluted tubule and pars recta.[49–51] In humans, the renal tubular site of injury is less well established,[24,52] due in part to the fact that little human biopsy material has been available for study. Moreover, in human subjects, the development of ARF in conjunction with aminoglycoside administration typically occurs in association with other insults such as sepsis and renal ischemia,[24,53,54] and each of these insults has been shown to interact synergistically with aminoglycoside antibiotics to magnify the severity and sites of tubular cell injury.[31–37]

The earliest lesion seen by electron microscopy is an increase in the number and size of secondary lysosomes, also called cytosegrosomes or phagosomes.[49–51] Examples of this

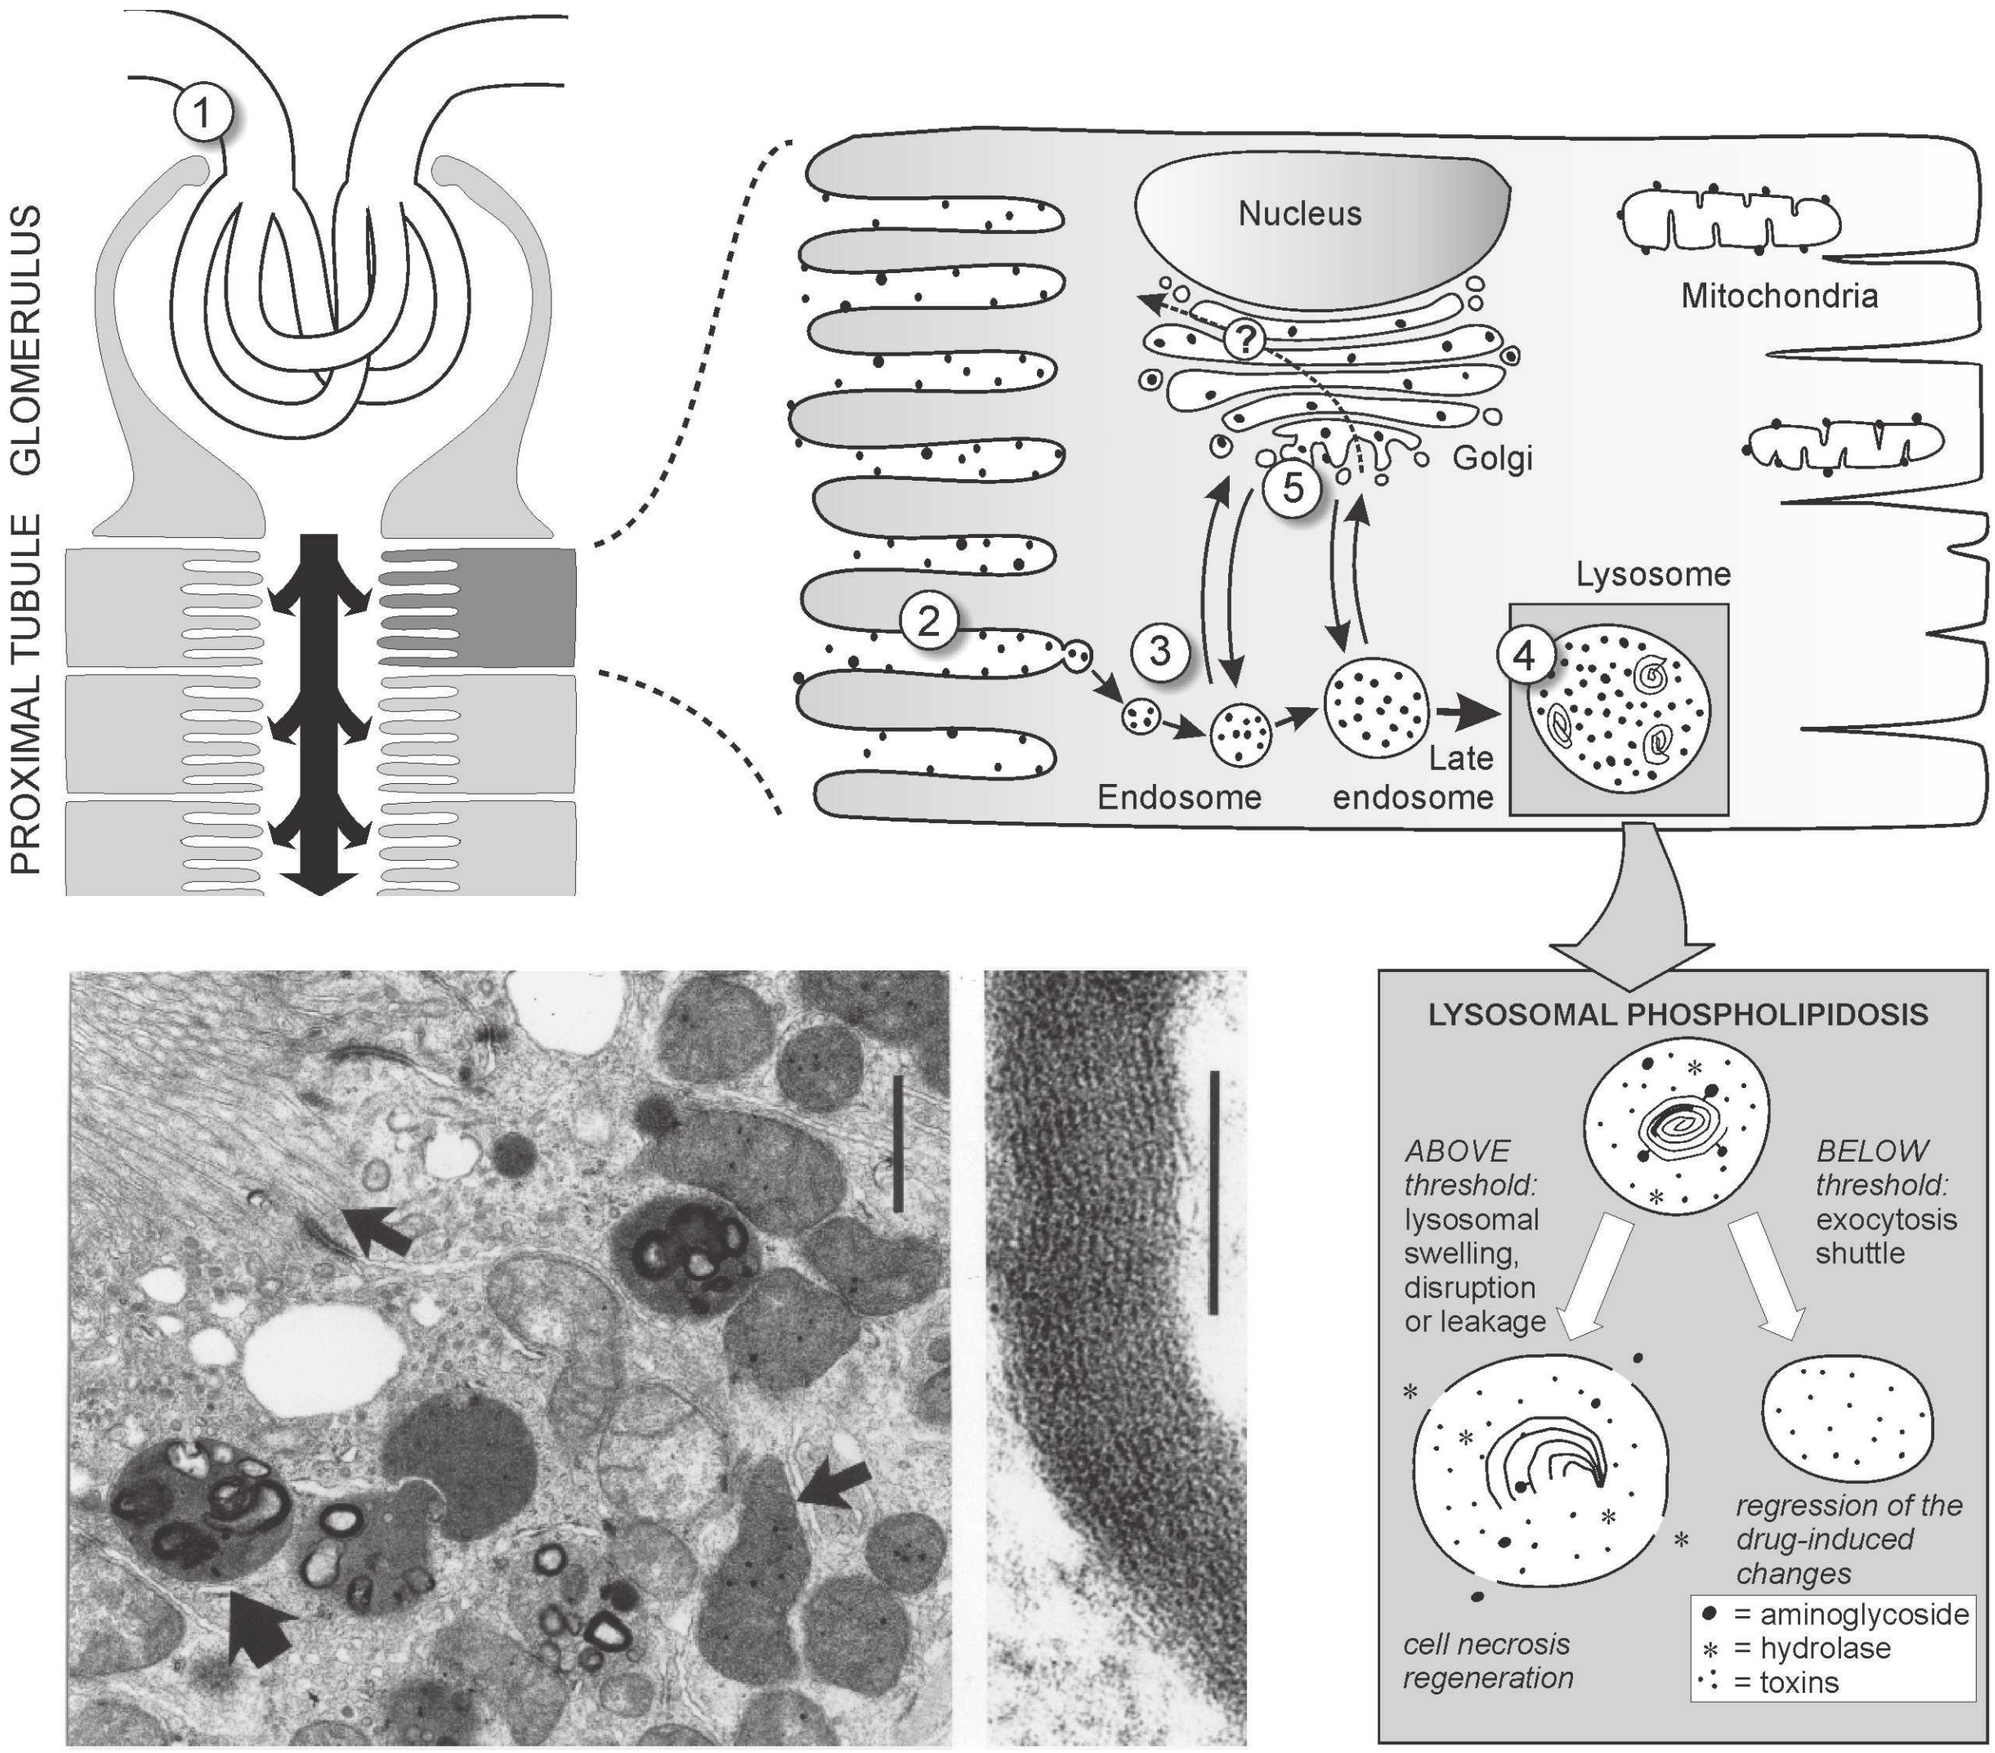

FIGURE 31.1 **Above**: Binding uptake and intracellular trafficking of gentamicin in renal proximal tubular cells. **A:** After glomerular filtration (*1*), gentamicin (•) is shown binding to the surface membrane (*2*) and being internalized by a receptor (megalin) mediated endocytic process (*3*). Gentamicin also enters the cell through fluid phase endocytosis. It moves through the endocytic system into late endosomes and from there into lysosomal structures (*4*). A small but quantifiable fraction (5%–10%) of gentamicin directly traffics from the surface membrane into the trans-Golgi network (*5*) and from there throughout the Golgi Apparatus. **Below left**: Ultrastructural appearance of proximal tubular cells after 4 days of gentamicin treatment, showing lysosomes containing dense lamellar and concentric structures (*large arrow*), while brush-border, mitochondria (*small arrow*), and peroxisomes are unaltered. Upon higher magnification the structures in lysosomes show a periodic pattern. Bar left = 1 μm, middle = 0.1 μm. **Below right**: Internalization and lysosomal sequestration of gentamicin. (Adapted from Verpooten GA, Tulkens PM, Molitoris BA. Aminoglycosides and vancomycin. In: De Broe ME, Porter GA, Bennett VM, Verpooten GA, eds. *Clinical Nephrotoxins – Renal Injury from Drugs and Chemicals,* 2nd ed. Dordrecht, The Netherlands: Kluwer Academic Publishers; 2003:151–170.)

lesion are shown in Figure 31.1. Secondary lysosomes are primary lysosomes that have coalesced with endocytic or autophagic vacuoles. Many of these lysosomes contain myeloid bodies, electron-dense lamellar structures of concentrically arranged and densely packed membranes. These lysosomal alterations probably represent autophagic vacuoles arising from sequestration of fragments of membranes and organelles damaged in the early phase of toxicity and are undergoing lysosomal processing. In experimental animals receiving single parenteral drug doses or continuous drug infusion, these changes have been observed as early as 6 to 12 hours posttreatment.[56] Both the number and size of lysosomal myeloid bodies increase as a function of dose and duration of drug therapy and are accompanied by progressive expansion of the volume of the cell occupied by engorged lysosomes.[50,56,57] These morphologic alterations also have been convincingly demonstrated in human kidney material.[58,59] Studies in experimental animals and in cultured cells have demonstrated that the myeloid bodies are composed of membranes rich in phospholipids[60,61] and form as a consequence of the lysosomal accumulation in high concentration of aminoglycosides. This lysosomal accumulation of aminoglycosides inhibits lysosomal phospholipases[62,63] and possibly other lysosomal enzymes and impairs the degradation of cell membrane.[61,64] Similar alterations have been induced by a variety of compounds that accumulate within the lysosomal compartment and interfere with the activity of lysosomal enzymes.[65–67]

Following lysosomal alterations, the following occurs: a decrease in the density and height of brush-border microvilli, dilation of the cisternae of rough endoplasmic reticulum, and the appearance of cytoplasmic vacuolization in tubular epithelial cells.[51,56] As injury progresses, brush-border membrane fragments and extruded myeloid bodies, membrane vesicles, and cytoplasmic debris begin to be seen within tubular lumina.[51,68] Later in the course of nephrotoxicity, mitochondrial swelling becomes evident, and patchy but extensive tubular epithelial cell necrosis and desquamation occur. Many tubules, both proximal and distal, are filled with eosinophilic, granular material that, by electron microscopy, is composed of cytoplasmic debris, membrane fragments, and myeloid bodies. Transmission electron microscopy of the urine reveals the presence of myeloid bodies and fragments of brush-border membranes.[68–70]

Proximal tubular cells manifest an apparent variable susceptibility to aminoglycoside toxicity evident by the appearance of cell regeneration simultaneously with ongoing cell necrosis.[26,47,50,57,71] In several animal studies virtually complete recovery of renal structure and function has been observed during continued aminoglycoside administration.[72,73] One explanation for these observations is that the renal tubular epithelium had acquired resistance to the nephrotoxic effects of the aminoglycoside antibiotic. Sundin and colleagues[74] report that the "acquired resistance" reflects selective inhibition of aminoglycoside uptake by renal proximal tubular cells, the mechanism of which does not involve a reduction in the membrane content of phosphatidylinositol or megalin. In animal models, cell regeneration can be detected by [^{3}H]thymidine incorporation into DNA after only 4 days of low-dose aminoglycoside administration and before cell necrosis is evident by light microscopy.[57,74] The magnitude of DNA labeling correlates with the dose and duration of drug administration.[75] Of particular interest is the observation that quantitatively similar labeling is observed in renal cortical interstitial cells as in tubular epithelial cells.[57,75,76] This finding raises the question of the role of these interstitial cells in the pathogenesis of aminoglycoside toxicity. Eventually most areas of the affected kidney regain normal architecture and function, but residual scarring containing collections of collapsed, atrophic tubules may occur focally in the cortex.[47,48,51] In animal models of aminoglycoside nephrotoxicity, the degree of tubular cell necrosis correlates reasonably well with the decline in renal excretory function. A similar correlation is lacking in human material.[24,52,58]

Pathogenesis

The pathogenesis of aminoglycoside nephrotoxicity is intimately linked to the renal pharmacology of these drugs.[77–80] Aminoglycoside antibiotics are organic polycations with a net cationic charge that, at pH 7.4, ranges from +4.47 in the case of neomycin to +2.39 for amikacin. Because these compounds are highly hydrophilic, they are poorly absorbed across the intestinal tract and therefore must be given parenterally. They are distributed in a volume slightly greater than extracellular volume and are eliminated from the body without metabolic transformation. The route of elimination is almost exclusively by the kidneys, and the principal mechanism of excretion is glomerular filtration. Of toxicologic significance is the fact that small amounts of aminoglycoside antibiotics are selectively transported into proximal tubular cells by adsorptive endocytosis,[81–83] which has been shown to occur across the basolateral as well as the apical membrane.[83] Several lines of evidence have implicated anionic phosphatidylinositol as a membrane binding site for aminoglycosides.[84,85] More recent studies also suggest a role for megalin, an endocytic receptor for cationic ligands, in the uptake of aminoglycoside antibiotics across the brush-border membrane of renal proximal tubular cells.[86] Indeed, by using the specific antagonist receptor-associated protein, blocking the activity of megalin in perfused rat proximal tubules, a reduction of 20% in gentamicin clearance ensued. Nagai demonstrated similar results in rats treated with maleate, impairing the receptor-mediated uptake of megalin ligands.[87] Megalin knockout mice are protected against aminoglycoside nephrotoxicity.[88]

Following endocytosis, the aminoglycosides are translocated into the lysosomal compartment, where they accumulate in millimolar concentrations and reside with a half-life measured in days.[78] As noted, the lysosomal compartment is the site of myeloid body formation consequent to aminoglycoside-induced inhibition of lysosomal enzymes such as phospholipase, sphyngomyelase, etc. When the concentration of drug and/or the amount of lysosomal phospholipid reaches a critical threshold, an injury cascade is triggered that eventuates in irreversible cell injury with

progression to necrosis.[56] However, neither the sequence nor the specific mechanisms involved in the progression to cell death have been clearly established. Sandoval and colleagues report that within 15 minutes of endocytosis gentamicin traffics to the Golgi complex as well as to the lysosomal compartment of LLC-PK1 cells[89,90] and rat renal proximal tubular cells.[91] These observations raise the possibility that the Golgi complex may provide a pathway for the redistribution of aminoglycoside antibiotics to other intracellular compartments and thereby broaden the potential for these drugs to disrupt a variety of organellar functions. For example, the depression of protein synthesis observed early in the course of gentamicin administration may signify retrograde transport of gentamicin to the endoplasmic reticulum.[91] The reason gentamicin and presumably other aminoglycoside antibiotics are transported from the endosomal compartment to the Golgi complex is not known; but, it may reflect an effect of these agents to perturb endosomal fusion[92] possibly as a consequence of binding to megalin[92] or to membrane-acidic phospholipids.[93,94]

A growing body of evidence supports the view that the pathogenesis of aminoglycoside toxicity is causally related to the capacity of these cationic drugs to bind to and perturb the function and structure of biologic membranes. Aminoglycosides have been shown to bind to anionic[62,84,95–102] but not to neutral phospholipids.[62,84,96,98] Among the anionic phospholipids, aminoglycosides bind most avidly to phosphatidylinositol 4,5-bisphosphate (PIP_2).[84,97,103–105] Several approaches have been used to gain insight into the molecular interaction between aminoglycosides and anionic phospholipids.[84,95,98,101,102,106–108] All models indicate an electrostatic interaction between a protonated amino group and the anionic phosphate group. Ramsammy and Kaloyanides[107] propose a model that, in addition to an electrostatic interaction between a protonated amino group and the phosphate group, also involves formation of hydrogen bonds between an amino group of gentamicin and the carbonyl groups of glycerol. This model explains aminoglycoside-induced changes in the biophysical properties of artificial membranes (i.e., an increase in the transition temperature and a decrease in glycerol permeability of phosphatidylinositol [PI]-containing liposomes).[100] Both changes signify that gentamicin induces a decrease in membrane fluidity, and this finding has been confirmed in brush-border membranes as assessed by changes in the fluorescence polarization of membrane probes[96] and by electron spin resonance spectroscopy.[109] Aminoglycosides also have been shown to promote membrane aggregation,[106,110] a process that requires neutralization of surface charge. In a comparative study of aminoglycoside-induced aggregation of PI-containing liposomes,[106] it was observed that the rank order with respect to efficacy in neutralizing membrane surface charge was neomycin > gentamicin = tobramycin = netilmicin = spermine. The rank order for inducing aggregation of liposomes was neomycin > gentamicin > tobramycin > netilmicin = spermine and was identical to the rank order of these agents with respect to depressing glycerol permeability.[106] This rank order also coincides precisely with the established clinical nephrotoxicity potentials of these drugs. Because depression of glycerol permeability was shown to be dependent on hydrogen bonding between one or more amino groups of the drug and carbonyl groups of the glycerol backbone,[107] these data suggest that the membrane toxicity of aminoglycosides is closely linked to their potentials to engage in hydrogen bonding. Importantly, the rank order in terms of nephrotoxicity potentials does not coincide with the net cationic charge of these agents.[106] This observation emphasizes that spatial orientation of charge rather than net charge is a critical determinant of toxicity.

Schacht and colleagues[97,99,104,111] utilize a variety of methods to assess aminoglycoside-induced perturbations of PIP_2-containing membranes as a measure of the ototoxicity potentials of these antibiotics. Increased fluorescence of 1-anilino-8-naphthalenesulfonate,[99] increased permeability to carboxy fluorescein,[104] and increased surface tension of monomolecular film of phosphatidylcholine (PC)/PIP_2[111] were shown to correlate precisely with the ototoxicity potentials of aminoglycoside antibiotics. These studies have led to the hypothesis that the ototoxicity of aminoglycosides is causally related to their binding to PIP_2 and disruption of this signaling mechanism.[112]

The studies cited here provide the foundation for the hypothesis that the toxicity of aminoglycoside antibiotics is causally related to their capacity to interact electrostatically and by hydrogen bonding to membrane anionic phospholipids and, thereby, to perturb the biophysical properties and function of cell membranes. It is well established that these drugs interact with and perturb the function of plasma membranes,[13,113–116] lysosomes,[13,56,57–64,117–122] mitochondria,[51,123–126] and microsomes.[127–129] It remains unclear, however, whether toxicity results from disruption of a single critical membrane function or multiple membrane functions. It is possible that the injury cascade is triggered by the rupture of lysosomes engorged with aminoglycoside antibiotic and with myeloid bodies. The resultant release of potent acid hydrolases and high concentrations of drug into the cytoplasm might cause disruption of a number of critical intracellular processes including mitochondrial respiration,[51,123–126] microsomal protein synthesis,[127–129] intracellular signaling via the PI cascade[130–133] as well as generation of hydroxyl radicals[134–136]—all of which have been observed in experimental models of aminoglycoside toxicity. However, the observation that gentamicin is transported to the Golgi complex shortly after endocytic uptake[89,90] provides an alternate mechanism by which these drugs gain access to other organelles. Recently, proteomic analysis following gentamicin administration indicates energy production impairment and a mitochondrial dysfunction occurring in parallel to the onset of nephrotoxicity.[137]

Further insight into the pathogenesis of aminoglycoside nephrotoxicity has been gleaned from studies of interventions that modify the severity of this disorder in

experimental animals. Williams and colleagues[138–140] first reported that polyasparagine and polyaspartic acid (PAA) inhibited binding of gentamicin to rat renal brush-border membrane in vitro and when injected in vivo conferred protection against the development of aminoglycoside nephrotoxicity without inhibiting the renal cortical accumulation of drug. These findings have been confirmed and extended by three groups of investigators.[141–149] The mechanism by which PAA protects against aminoglycoside nephrotoxicity was shown to be related to the ability of PAA, a polyanion, to form electrostatic complexes with the polycationic aminoglycoside antibiotics[146,150,151] presumably within the endocytic compartment,[148] thereby preventing aminoglycosides from binding to anionic phospholipids, from inhibiting lysosomal phospholipase degradation of phospholipid, from forming lysosomal myeloid bodies, and from disrupting the PI cascade.[150] Additional support for this theory is provided by the observation that PAA prevented gentamicin from depressing glycerol permeability or aggregating PI-containing liposomes,[150] effects previously shown to be dependent on gentamicin binding electrostatically and by hydrogen bonding to PI.[100,107] Subsequently, other compounds capable of forming electrostatic complexes with aminoglycosides have been reported to protect against nephrotoxicity.[152–155]

An analog of pentoxifylline, HWA-448, was shown to protect against gentamicin toxicity in a cell culture model.[156] Similar to PAA, HWA-448 did not depress the membrane binding or cellular uptake of gentamicin. It remains unknown whether HWA-448 forms a complex with gentamicin within the endosomal compartment.

Recently, it was demonstrated that glibenclamide (a sulfonylurea) has protective effects against gentamicin-induced nephrotoxicity in rats.[157] Morales et al. suggest that the pleiotropic effects of metformin can decrease gentamicin nephrotoxicity by improving mitochondrial homeostasis.[158]

31.1 Risk Factors for Aminoglycoside Nephrotoxicity

Patient factors
- Older patients[a]
- Preexisting renal disease
- Magnesium potassium, calcium deficiency[a]
- Intravascular volume depletion,[a] hypotension[a]
- Hepatic syndrome
- Sepsis syndrome[a]
Aminoglycoside factors
- Recent aminoglycoside therapy
- Larger doses[a]
- Treatment of three or more days[a]
- Drug choice: gentamicin,[a] amikacin[a]
- Frequent dosing interval[a]
Concomitant drugs
- Amphotericin B
- Cephalosporines
- Cisplatin
- Clindamycin
- Cyclosporine
- Foscarnet
- Furosemide
- Intravenous radiocontrast agents
- Piperacillin
- Vancomycin

[a]Concurrent with experimental nephrotoxicity data.

Treatment and Prevention of Aminoglycoside Nephrotoxicity

The efficacy of PAA and other anionic compounds in preventing nephrotoxicity in humans has yet to be established. Therefore, the primary focus of treatment is prevention, and this can be accomplished by understanding and modifying, when possible, the risk factors (Table 31.1) for this complication.[159–161] Risk factors may be categorized into those that are determined by the individual patient and not easily influenced, if at all, and those that are determined by the clinician and potentially controllable (Table 31.1).

Prominent among the risk factors peculiar to the patient and not modifiable is advanced age.[159] The mechanism is probably multifactorial and includes age-related decline of renal function that, if not appreciated and corrected for, results in excessive dosing.[162] Animal studies suggest that aging is associated with altered renal pharmacokinetics accompanied by increased renal cortical accumulation of drug.[163] Increased susceptibility of the aging kidney to aminoglycoside toxicity has also been suggested,[164] possibly on the basis of an age-related impaired capacity for cellular repair and regeneration. Male gender has been shown to carry increased risk for aminoglycoside nephrotoxicity in the rat,[165] whereas female gender has been identified as a risk factor in humans.[159] The reason for this difference has not been established.

Obesity carries increased risk for aminoglycoside nephrotoxicity that is unexplained by differences in the volume of distribution or renal clearance of drug.[166] The increased risk associated with chronic liver disease[159] may be related to the alterations in extracellular volume, hemodynamics, and electrolyte balance commonly observed in this disorder, all of which are known to promote renal cortical accumulation of drug.[78] Preexisting chronic renal insufficiency is associated with increased risk primarily due to failure to adjust appropriately the dose of aminoglycoside for the level of impaired kidney function.[167] Renal hypoperfusion from any

cause carries an increased risk of aminoglycoside nephrotoxicity whether the renal ischemic insult occurs before,[85] during,[34] or after drug administration.[32] The latter observation is particularly worthy of note because it implies that the increased risk of nephrotoxicity persists even after the drug has been discontinued. The prolonged half-life of aminoglycosides in renal cortex[78] may contribute to this risk. Three components of the septic state—renal hypoperfusion, endotoxemia, and hyperthermia—have been identified as factors contributing to the heightened risk of nephrotoxicity during aminoglycoside therapy.[35–37] Renal hypoperfusion[35,85] and endotoxemia[33,168] are associated with increased accumulation of drug in renal cortex; however, this factor alone does not explain the increased risk.

Of those risk factors that are potentially modifiable by the clinician, the most important are daily drug dose, interval of dosing, and the duration of therapy. A direct relationship between total dose (daily dose plus duration of therapy) and nephrotoxicity has been consistently found in experimental animals[26,47,51,56,71] and in humans.[9,15,159,160,167] Animal studies have shown that the same dose of a drug administered in two or three divided doses leads to greater renal accumulation of the drug and greater nephrotoxicity than if it was given as a single dose.[169,170] Two trials in humans found that the dosage schedule had a critical effect on the renal uptake of gentamicin, netilmicin,[171] amikacin, and tobramycin.[172] The study was carried out in patients with normal renal function (serum creatinine between 0.9 and 1.2 mg per dL, proteinuria lower than 300 mg per day) who had renal cancer and submitted to nephrectomy. Before surgery patients received gentamicin (4.5 mg/kg/day), netilmicin (5 mg/kg/day), amikacin (15 mg/kg/day), or tobramycin (4.5 mg/kg/day), as a single injection or as a continuous intravenous infusion over 24 hours. The single-injection schedule resulted in a 30% to 50% lower cortical drug concentration of netilmicin, gentamicin, and amikacin compared with administration by continuous infusion (Figs. 31.2 and 31.3). For tobramycin, in humans as well as in rats, no difference in renal accumulation could be found, indicating the linear cortical uptake of this particular aminoglycoside. Administration of drug by continuous intravenous (IV) infusion carries the highest risk of nephrotoxicity with respect to gentamicin, tobramycin, and netilmicin but not amikacin.[80,170,173] These observations have stimulated studies in humans to assess the antimicrobial efficacy of once per day dosing with an aminoglycoside administered alone or in combination with a β-lactam antibiotic.[174–177]

Several meta-analyses pooled the data of individual randomized controlled trials (RCTs) (Table 31.2),[178–187] including a meta-analysis specifically of the studies in immunocompromised patients.[187] It is apparent that only the meta-analyses that combine the results of the individual RCT by means of a fixed-effects model yielded significant results in favor of less nephrotoxicity in the single daily dose regimens. However, given the inhomogeneity of the study designs and the different aminoglycoside used, it seems

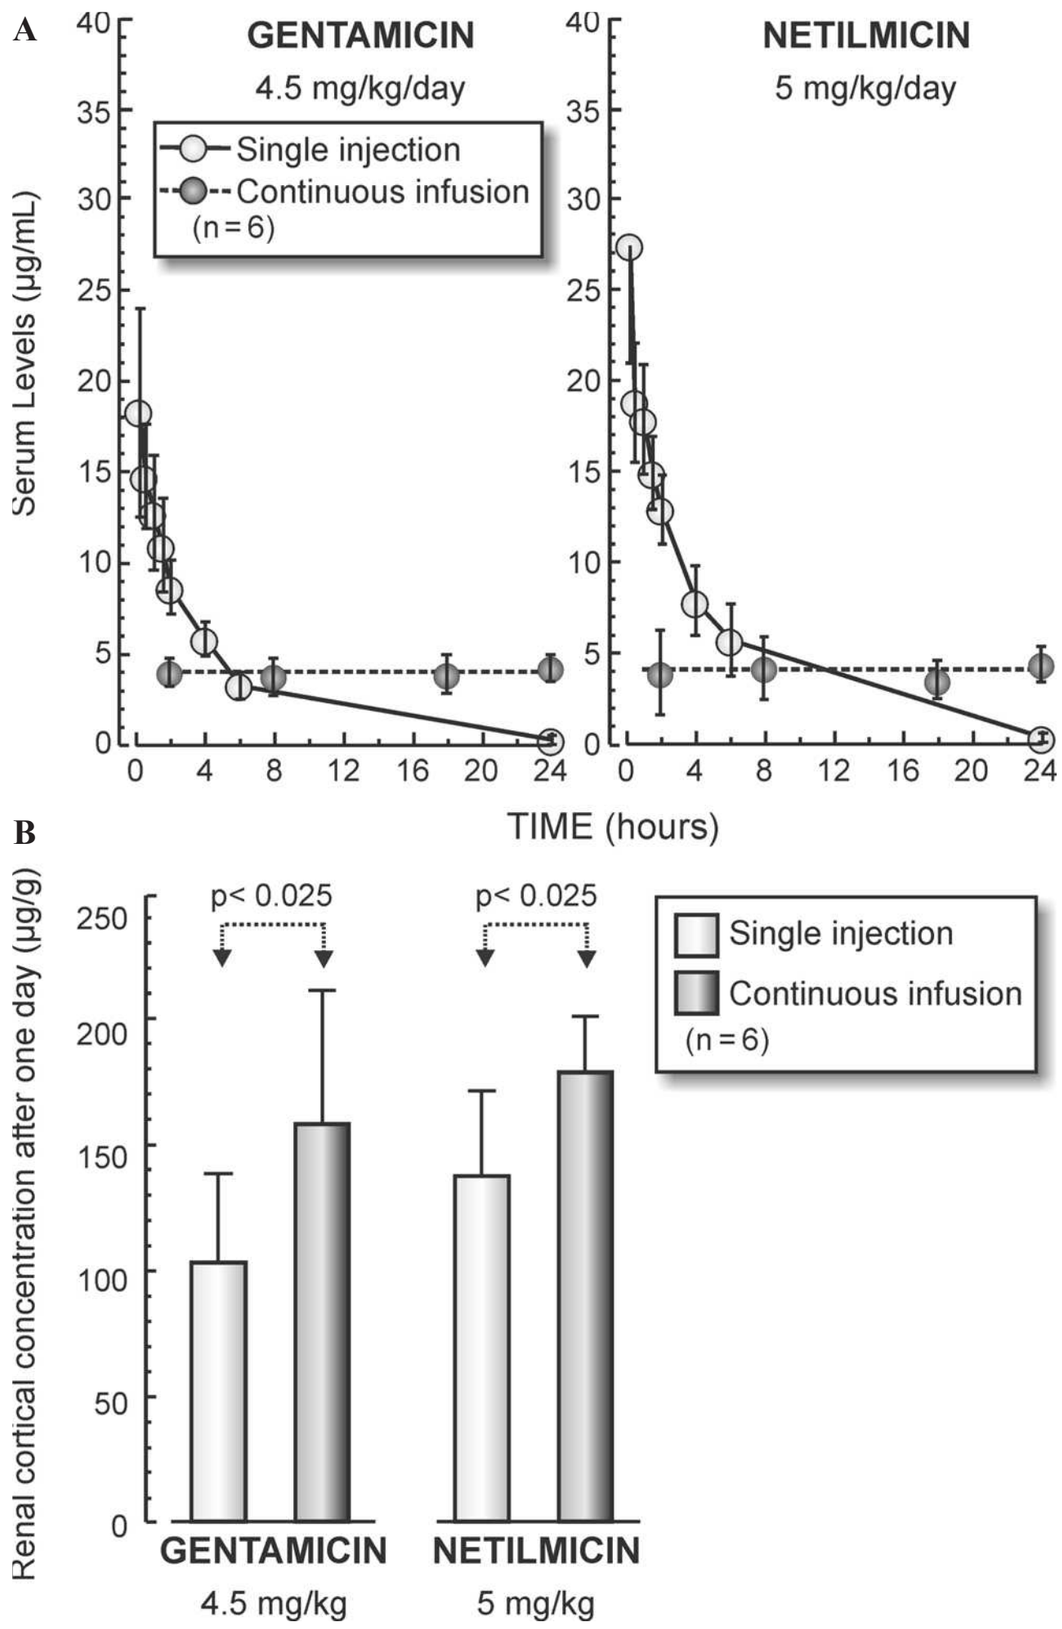

FIGURE 31.2 **A:** Course of serum concentrations of gentamicin and netilmicin after administration of the dose by a 30-minute intravenous injection or by continuous infusion of 24 hours. **B:** Cortical concentration of gentamicin and netilmicin after administration by the previously mentioned administration schedules. (From Verpooten GA, et al. Once-daily dosing decreases renal accumulation of gentamicin and netilmicin. *Clin Pharmacol Ther.* 1989;45:22, with permission.)

prudent to use the random effects model to combine the individual studies. The meta-analyses that used this technique did not show a significant difference in the two dosing regimens. Nevertheless, in all analyses the single daily dose regimen was associated with a decrease in nephrotoxicity. Even the most recent prospective study[188] evaluating the efficacy and nephrotoxicity of once daily administration of gentamicin versus multiple daily administration in 52 children could not show a difference in incidence of nephrotoxicity in both groups. Although a decrease in nephrotoxicity rates in once daily dose regimens has not been established, extended interval dosing strategies have never been associated with an increased risk of nephrotoxicity. The main reason why the majority of acute care hospitals[189] have adopted this strategy

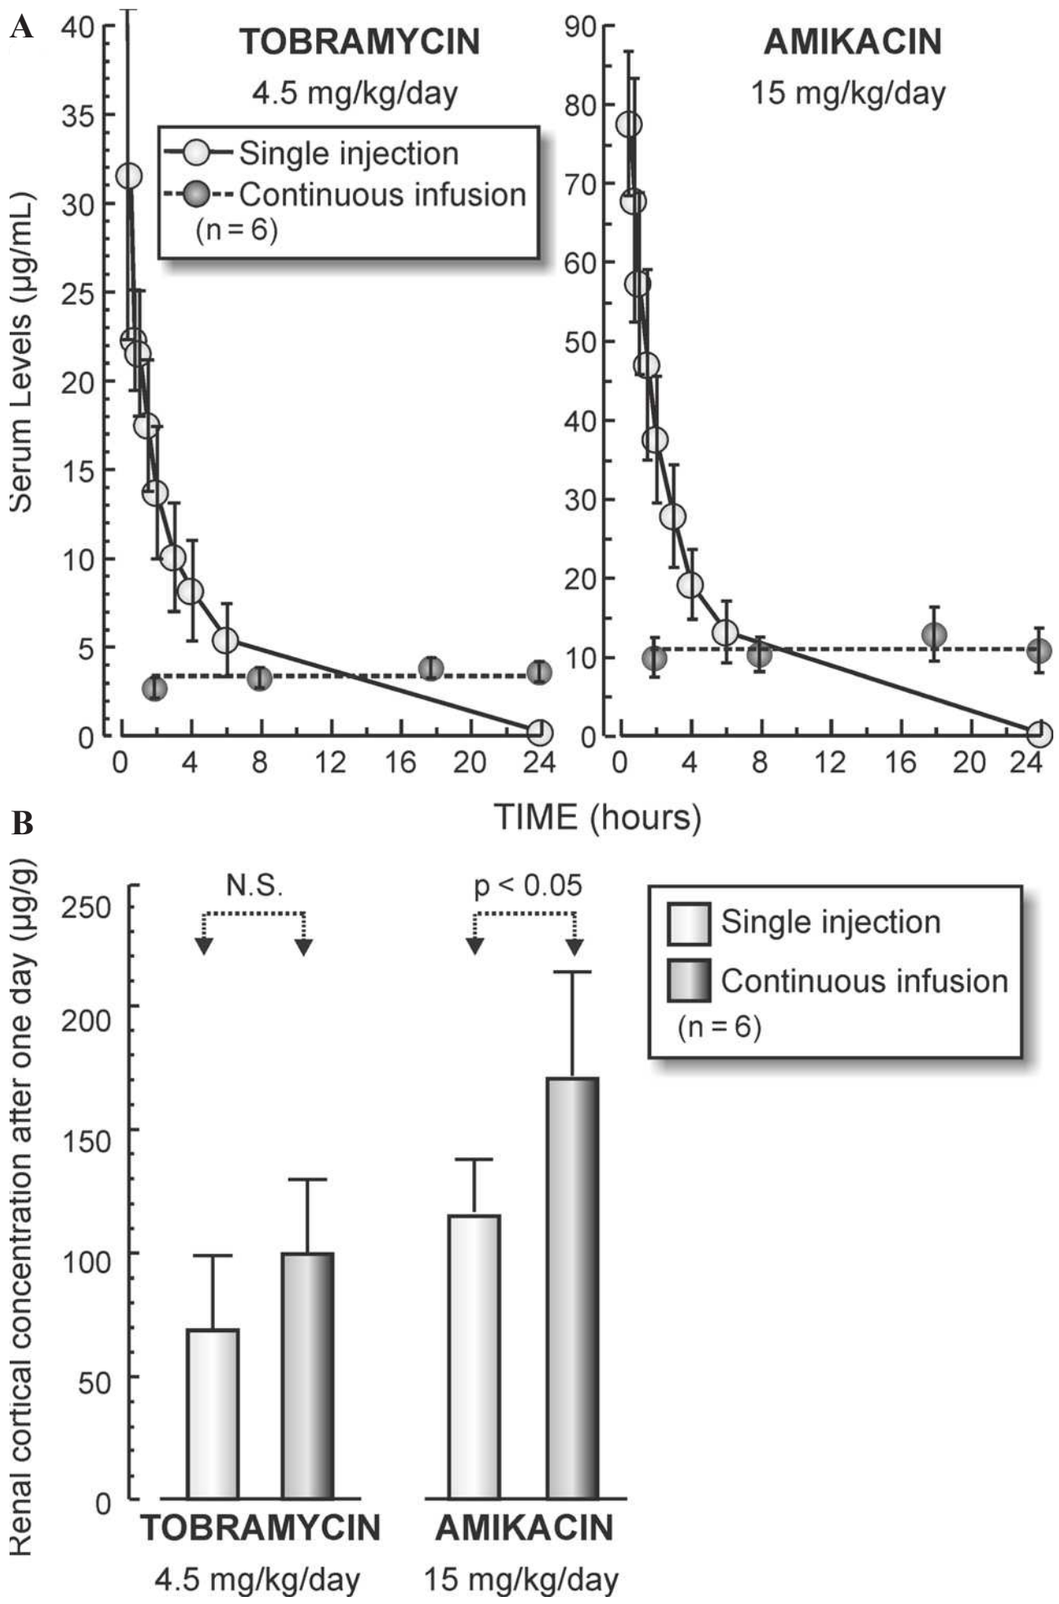

FIGURE 31.3 **A:** Course of serum concentrations of tobramycin and amikacin after administration of the dose by a 30-minute intravenous injection or by continuous infusion of 24 hours. **B:** Cortical concentration of tobramycin and amikacin after administration by the previously mentioned administration schedules. (From De Broe ME, Giuliano RA, Verpooten GA. Influence of dosage schedule on renal cortical accumulation of amikacin and tobramycin in man. *J Antimicrob Chemother.* 1991;27[Suppl C]:41, with permission.)

is that once daily dosing provides a cost-effective method for administration of aminoglycosides by reducing work load among service personnel and by reducing or even eliminating the need for therapeutic drug monitoring.[190–192]

Volume depletion,[193] hypokalemia,[194] hypomagnesemia,[195] and metabolic acidosis[196] all carry increased risk for nephrotoxicity. In the case of volume depletion and hypokalemia, the increased risk appears to be related to increased accumulation of drug in renal cortex.[78] The mechanism underlying the increased risk associated with hypomagnesemia has not been definitely established but may relate to the competition between divalent cations and the cationic aminoglycoside antibiotics for critical membrane binding sites.[197] In the case of metabolic acidosis, the reduced pH promotes increased protonation of aminoglycoside antibiotics and augments the reactivity of these organic polycations with membrane anionic phospholipids.[64,101,119]

In rats it was shown that uric acid worsens gentamicin-induced nephrotoxicity. The mechanism is likely to implicate downregulation of MMP9.[198]

Finally, the risk of nephrotoxicity has been shown to be augmented when aminoglycoside antibiotics are administered in conjunction with certain drugs and pharmaceutical agents, some of which have intrinsic nephrotoxicity potential. These include amphotericin B,[177] cephalothin but not third generation cephalosporins,[199] vancomycin,[200,201] cisplatin,[202] furosemide,[203] calcium channel blockers,[204] radiocontrast agents,[205] and nonsteroidal anti-inflammatory drugs.[206] Many of these synergistic interactions have been identified in animal studies so that the relevance of these observations to humans remains to be established. Nevertheless, prudence dictates that potentially nephrotoxic drugs should be avoided if possible in patients who are receiving or have recently completed therapy with aminoglycoside antibiotics.

The prevention of aminoglycoside nephrotoxicity requires that these drugs be used only for well-defined indications and that they be prescribed in the appropriate dose and for the appropriate duration to achieve the therapeutic goal. Optimization of therapy for aminoglycosides requires understanding the relationship between exposure and response as well as that between exposure and toxicity. Furthermore, daily administration is much preferred, and stopping therapy as quickly as possible (a week or less may be optimal) will contribute to the ability to optimize therapy.[207] Dosing based on individualized drug pharmacokinetics derived from measurements of serum drug concentration would appear to be a rational approach. Unfortunately, prospective studies have failed to demonstrate that dosing based on drug pharmacokinetics reduces the incidence of nephrotoxicity.[208] Indeed, eight prospective, RCTs specifically designed to investigate the effect of pharmacokinetic dosing[209] on aminoglycoside expression of nephrotoxicity could be identified from the literature.[210–217] These individual studies have been unable to detect any change in the incidence of this adverse event. Nevertheless, close monitoring of serum drug concentration is still warranted, especially in high risk patients to ensure that therapeutic concentrations are achieved. Even when those factors known to influence risk are absent or have been minimized or eliminated, aminoglycoside nephrotoxicity will still occur in a certain percentage of appropriately dosed patients. These patients exhibit excessive renal accumulation of drug or increased sensitivity to a given level of drug accumulation.[218] The clinician must be constantly alert to the possibility of aminoglycoside nephrotoxicity and monitor all patients on aminoglycoside therapy for this potential complication. The intensity of monitoring is dictated in part by the relative risk factors present. At a minimum, frequent measurements of serum creatinine concentration,

31.2 Meta-analysis of the Incidence of Nephrotoxicity in Single Daily Dosing versus Multiple Dosing of Aminoglycosides

Author	No. of RCT	Method	Results (95% CI)
Blaser and König, 1995[172]	24	Summation	RR 0.82

generally every 2 to 3 days, should be performed. In high risk patients, daily creatinine clearances and urinalysis may be required to detect early signs of toxicity before a rise in serum creatinine concentration or serum trough level of drug becomes evident. Hoffmann et al. showed in rats that a number of recently developed urinary markers (among them Kim-1) had an increased sensitivity of aminoglycoside nephrotoxicity in rats.[219,220] How far this can be extrapolated to the human situation has not been studied thouroughly. If renal injury occurs, then the drug should be stopped if possible or the dosage should be reduced to prevent the accumulation of drug in serum and further toxic injury related thereto. Careful attention must be paid to maintaining fluid and electrolyte balance and avoiding potential insults to the kidney related to renal hypoperfusion or exposure to other potential nephrotoxins. Even when nephrotoxicity is recognized early and the drug is discontinued, renal failure may progress over the next 5 to 10 days, with the serum creatinine and blood urea nitrogen (BUN) rising to disturbingly high levels, where they may remain for a number of days before renal function slowly begins to improve. No specific therapy for hastening recovery has been identified to be effective in humans. In an animal model, epidermal growth factor was shown to accelerate recovery.[221] The prognosis for recovery of renal function is generally good except in those cases where the underlying disease exposes the kidney to persisting or recurrent insults related to sepsis, hypotension, and hypoperfusion.

Nagai and Takano reviewed the possibility of coadministration of agents which may inhibit the binding of nephrotoxicity drugs (particularly aminoglyclosides) to receptor(s) responsible for the endocytic processes in renal proximal tubular cells which might reduce the incidence of nephrotoxicity.[222]

Trimetazidine is an anti-ischemic metabolic agent improving cardiac glucose utilization through inhibition of fatty acid. Gentamicin nephrotoxicity is attenuated by the cytoprotective effect of trimetazidine. It may be inferred that trimetazidine inhibits also the reabsorption and consequently the accumulation of gentamicin in the proximal tubular cell.[223]

β-LACTAM ANTIBIOTICS

The β-lactam antibiotics comprise the penicillins, cephalosporins, and carbapenems. ARF has been observed with this class of antibiotics as a result of acute proximal tubular cell necrosis or allergic interstitial nephritis. Studies in animals have established the relative nephrotoxicity potentials of β-lactam antibiotics as cephaloglycin > cephaloridine >> cefaclor > cefazolin > cephalothin >>> cephalexin, ceftazidime, and penicillins, which do not exhibit clinical

nephrotoxicity.[224] The selective toxic potential of β-lactam antibiotics toward renal proximal tubular cells appears to be causally linked to their concentrative uptake by the organic anion transport system and their intrinsic reactivity toward sensitive intracellular target proteins.[224,225] The importance of the organic anion transport system to the nephrotoxic potential of these agents is supported by the observations that (1) toxicity is restricted to β-lactams that are secreted by this transport system, (2) toxicity can be prevented by inhibition of organic anion transport, and (3) maneuvers that increase the intracellular uptake of drug augment toxicity.[224,225] The product of intracellular drug concentration and time, defined as the area under the curve (AUC), is an important determinant of toxicity. Among the cephalosporins, the greatest AUC is observed with cephaloridine.[224,225] This agent is readily transported into proximal tubular cells across the basolateral membrane; however, its egress across the apical membrane is retarded due to the fact that cephaloridine is a zwitterion and the cationic moiety impedes its permeation across the luminal membrane.[226] Therefore, at equivalent doses, the AUC for cephaloridine is significantly higher than that of other cephalosporins. Cephaloglycin, the most nephrotoxic of the cephalosporins released for clinical use, has a renal cortical AUC only one fifth that of cephaloridine.[227] The greater nephrotoxicity of cephaloglycin reflects the fact that it is far more reactive than cephaloridine toward sensitive intracellular target proteins.[224,228] Three molecular mechanisms have been implicated in the pathogenesis of cephaloridine nephrotoxicity: (1) lipid peroxidation,[229] (2) competitive inhibition of mitochondrial carnitine transport and fatty acid oxidation,[230,231] and (3) inhibition of mitochondrial respiration consequent to inactivation by acylation of mitochondrial anionic substrate transporters.[232,233]

In the case of the other nephrotoxic β-lactam antibiotics, the pathogenesis of toxicity appears to be linked primarily to depression of mitochondrial respiration. This conclusion is supported by the following observations from in vivo animal studies.[224,225,227,232,233]

1. The nephrotoxic potential of β-lactams correlates with the magnitude of inhibition of mitochondrial respiration.
2. Irreversible inhibition of mitochondrial respiration occurs within 1 hour after administration of a nephrotoxic dose.
3. Inhibition of respiration precedes the appearance of ultrastructural mitochondrial damage that resembles ischemic and cyanide injury.

Although only a limited number of β-lactam antibiotics cause toxic injury after in vivo exposure, many of these agents exhibit the capacity to inhibit in vitro mitochondrial respiration, especially that component supported by succinate.[234] Inhibition of mitochondrial respiration is observed within 5 minutes of in vitro drug exposure. Increasing the concentration of succinate reverses the inhibition, presumably as a consequence of competitive displacement of drug from the mitochondrial membrane anionic carrier. However, as the exposure of mitochondria to drug is augmented by raising the product of drug concentration and time, inhibition of mitochondrial respiration becomes progressively irreversible, which has been attributed to drug-induced acylation and inactivation of the transporter.[224,225] The rank order of cephalosporins with respect to their potential to acylate target proteins in vitro is ceftazidime > cefaclor > cephaloglycin > cephalothin > cephaloridine > cefazolin >> cephalexin, and several penicillins.[224,225] This order is at variance with their in vivo nephrotoxicity potential, which is cephaloglycin > cephaloridine >> cefaclor > cefazolin > cephalothin >>> cephalexin, ceftazidime, and the penicillins. The explanation for the differences between the in vitro and in vivo toxicity potentials of these drugs resides in the important role of concentrative uptake of these drugs into intact proximal tubular cells by the organic anion transport system. Although ceftazidime and cefaclor exhibit high acylation activity in vitro, the AUC of these agents is low (only 7% that of cephaloridine and only 37% that of cephaloglycin), and this severely restricts their interaction with the mitochondrial anion transporter.[224,225] Mitochondrial injury also has been implicated as the major mechanism of nephrotoxicity caused by imipenem.[235,236] This drug is marketed in combination with cilastin, which inhibits the enzymatic breakdown of imipenem by cytoplasmic and brush-border dihydropeptidase and also inhibits its nephrotoxicity.

The therapeutic–nephrotoxic ratio of these agents is much more favorable than that of aminoglycoside antibiotics. The incidence of serum creatinine elevations is difficult to say with certainty, but severe nephrotoxic ARF is uncommon.[237,238] Similar to other antibiotics, high doses and prolonged therapy elevate the risk of nephrotoxicity. In animal studies, the incidence and severity of toxicity associated with β-lactam antibiotics were augmented by combined therapy with aminoglycoside antibiotics,[239] by renal ischemia,[240] and by endotoxemia.[241] In three prospective studies in human subjects, the combination of an aminoglycoside antibiotic with cephalothin was associated with a significantly higher incidence of nephrotoxicity.[242–244] Early reports suggested a possible interaction between several second generation cephalosporins and aminoglycoside antibiotics.[245] In contrast, a recent prospective study provides no evidence that combination therapy with third generation cephalosporins and an aminoglycoside antibiotic potentiates the risk of nephrotoxicity.[177]

The diagnosis of nephrotoxic ARF secondary to β-lactam antibiotics is suggested by the appropriate clinical setting in combination with a urine sediment and urinary indices typical of acute tubular cell necrosis. Establishing the precise diagnosis may be difficult in the presence of septicemia, hypotension, or other nephrotoxic drugs. It should be kept in mind that β-lactam antibiotics also cause ARF secondary to allergic interstitial nephritis.[246] The pattern of the rise in the BUN and serum creatinine may be indistinguishable from that seen with acute tubular cell necrosis.

The presence of large numbers of red and white blood cells in the urinary sediment, especially if associated with eosinophiluria and systemic signs of hypersensitivity (rash, fever, and eosinophilia), strongly suggests the diagnosis of allergic interstitial nephritis. However, in many patients, these clues are equivocal so that it may be necessary to perform a kidney biopsy to establish the correct diagnosis.

VANCOMYCIN

Vancomycin use in clinical medicine has increased significantly in recent years as a consequence of the rise in the incidence of methicillin-resistant staphylococcal infections. Because this antibiotic is poorly absorbed from the gastrointestinal tract, it is usually administered intravenously for the treatment of systemic infections. Vancomycin is not appreciably metabolized, and it is excreted essentially (80%–90%) entirely by the kidneys, primarily by glomerular filtration, as there is no evidence that the drug undergoes tubular absorption or secretion.[247] Therefore, drug dosing must be modified in subjects with renal failure.[248] Animal studies demonstrated that vancomycin had nephrotoxic and ototoxic potential.[249] The present data[250] suggest that oxidative stress and oxidative phosphorylation play an important role in vancomycin-induced nephrotoxicity. Erythropoietin seems to act as an antioxidant, diminishing the toxic oxidative effects of vancomycin on renal tissue. Early clinical experience in human subjects revealed a significant incidence of nephrotoxicity, which in retrospect may have been due to impurities generated during the initial manufacturing process.[251] More recent reports indicate that the incidence of nephrotoxicity associated with vancomycin ranges between 0% and 7% when given as sole therapy.[252] Animal studies initially suggested that vancomycin and aminoglycoside antibiotics interacted synergistically to cause ARF.[253] Recent reports indicate that a similar interaction occurs in humans.[201,202] Indeed, in a meta-analysis the incidence of nephrotoxicity associated with combination therapy was 13.3% greater than therapy with vancomycin alone. In a prospective study, comparing continuous versus intermittent infusion of vancomycin in severely ill patients, Wysocki et al.[254] found a significant rise in serum creatinine during treatment only in those patients who received vancomycin with other antibiotics including aminoglycosides. Monitoring vancomycin serum concentrations is not cost-effective in preventing vancomycin-induced nephrotoxicity in patients with normal renal function because the correlation between serum levels and antibacterial efficacy or toxicity remains controversial.[255] It should be noted that vancomycin has been reported to cause allergic interstitial nephritis[256]; however, this appears to be an uncommon complication. Teicoplanin, a glycopeptide antibiotic similar to vancomycin, is devoid of nephrotoxicity.

Recent data suggest higher rates of nephrotoxicity with recently recommended doses aiming to achieve the currently recommended trough level of 15 to 20 μg per mL.[257–260] These studies show an incremental risk of nephrotoxicity associated with higher vancomycin doses, ranging from 12% to 42.7% of patients. The risk increases with higher vancomycin maximum trough levels, longer duration of vancomycin use, concomitant use of other nephrotoxic agents, and in paitents who are crtically ill or have a previously compromised renal function.

Vancomycin has been a cornerstone antibiotic for the treatment of severe gram-positive infections in dialysis patients for decades. Whereas subtherapeutic vancomycin levels convey a risk of treatment failure and the further emergence of resistance in staphylococci, supratherapeutic vancomycin levels are associated with a dose-related incremental risk for nephrotoxicity and ototoxicity. Consequently, a narrow therapeutic range with a trough-level target between 15 and 20 μg per mL is recommended. Vancomycin dosing in hemodialysis patients is mainly influenced by the timing of administration (during or after dialysis), the type of filter used, and the duration of dialysis. Actual body weight, the interdialytic interval, and residual renal function are also considerations. As in patients with normal kidney function, a weight-based loading dose of 20 to 25 mg per kg should be used in dialysis patients. Although most fixed-dose maintenance regimens fail to reach target levels in the majority of hemodialysis patients, straightforward evidence on optimal maintenance dosing is lacking.[261]

Studies on the optimal dosing strategy for vancomycin in chronic kidney disease (CKD) patients and those on dialysis are needed.

SULFONAMIDE ANTIBIOTICS

The sulfonamide antibiotics and their metabolites are excreted primarily by the kidneys by a process involving glomerular filtration, tubular absorption, and tubular secretion.[262] The high incidence of nephrotoxic ARF observed with the first generation sulfonamides was due to their low solubility and the resultant precipitation of drug in the form of crystals that caused intratubular obstruction.[263] Sulfadiazine, a poorly soluble sulfonamide, continues to be used today in combination with pyrimethamine for the treatment of Toxoplasma encephalitis; nephrotoxicity manifested as hematuria, crystalluria, renal colic, and ARF may complicate therapy in 5% of cases.[264,265] These abnormalities usually subside with hydration and alkalinization of the urine.

Trimethoprim-sulfamethoxazole is administered intravenously in high concentration as therapy for Pneumocystis jiroveci pneumonia. Although the solubility of sulfamethoxazole is high, ARF secondary to crystal deposition of the parent drug or a metabolite has been reported.[266,267] More commonly, the elevation of serum creatinine observed in patients treated with this combination drug reflects inhibition of tubular secretion of creatinine by trimethoprim.[268,269] This effect is more pronounced in subjects with baseline elevation

of the serum creatinine secondary to underlying chronic renal insufficiency. Failure of the BUN to rise in proportion to the rise in serum creatinine should call attention to the correct diagnosis.

Sulfonamides including sulfamethoxazole also have been implicated in causing acute hypersensitivity reactions and ARF secondary to allergic interstitial nephritis.[246]

ANTIFUNGAL AGENTS

Amphotericin B is widely used as the drug of choice for the therapy of systemic fungal infections, especially in immunocompromised patients.[270,271] Unfortunately, the clinical application of this drug is accompanied by a number of dose-dependent toxic side effects, the most serious of which is ARF.[272,273] Amphotericin B is a polyene that consists of a large lactone ring with seven conjugated double bonds, seven hydroxyl groups, and a sugar moiety. It exhibits the propensity to bind to membrane sterols and form membrane pores, which in mammalian cells are estimated to be composed of eight molecules of cholesterol alternating with eight molecules of drug.[274] The resultant increase in membrane permeability to small electrolytes is thought to be a dominant factor in the toxicity of the drug. Amphotericin B binds preferentially to ergosterol, the major sterol of fungi, and this presumably explains the selective toxicity of this and similar drugs for fungi.[275]

The reason amphotericin B causes nephrotoxicity in humans and experimental animals is not apparent from its pharmacokinetics.[276,277] Because amphotericin B is poorly transported across the gastrointestinal tract, it must be administered intravenously. Its volume of distribution is about 4 L per kg. Up to 95% of drug in serum is bound, primarily to β-lipoproteins. The major depot site for amphotericin B is the liver, where up to 41% of administered drug can be recovered compared to 6% in the lung and 2% in the kidney. The elimination of amphotericin B from serum can be described by a triexponential curve, the half-lives of which are 24 hours, 48 hours, and 15 days, respectively. Less than 10% of administered drug is recovered in the urine, and there are no known metabolites.

Although the kidney is not a major route of amphotericin B elimination, it is the major site of toxicity, the incidence of which is influenced by daily drug dose, duration of therapy, and the presence of potentiating factors.[278,279] The clinical expression of amphotericin B nephrotoxicity is dominated by the appearance of azotemia and creatininemia, which may occur early in the course of drug therapy[279–281] and reflects depression of renal blood flow and GFR secondary initially to a reversible rise in renal vascular resistance. With prolonged therapy, depression of renal function may persist as a consequence of injury to tubular epithelium[282] and possibly the renal vasculature.[283] A variety of abnormalities of tubular function may be seen as well. These include incomplete distal renal tubular acidosis,[284] hypokalemia and hypomagnesemia secondary to renal tubular wasting of these cations,[285,286] and loss of urine concentrating capacity.[287] The urinary sediment frequently contains evidence of microscopic hematuria, pyuria, and cylinduria. Although most of these abnormalities are reversible after the drug is discontinued, full recovery may be delayed for a number of months. Chronic renal insufficiency may occur with prolonged or multiple courses of therapy.

Insight into the pathogenesis of amphotericin B nephrotoxicity has been gleaned from studies in experimental animals.[288] It has been shown that intravenous administration of amphotericin B elicits an acute depression of renal blood flow and GFR in association with an increase in renal vascular resistance that is not mediated by the renal nerves, by angiotensin II, by endothelium-dependent factors, or by tubular glomerular feedback.[289–292] These hemodynamic alterations have been shown to be modifiable by a variety of interventions including administration of calcium channel blockers,[293] a selective dopamine-1 receptor agonist,[294] saline loading,[295,296] atrial natriuretic peptide,[292,297] and theophylline suggesting its direct vasoconstrictive effect.[292] Depolarization of vascular smooth muscle consequent to the formation of membrane pores was postulated as the basic mechanism by which amphotericin B augmented renal vascular resistance.[288,292] Amphotericin B also induces tubular dysfunction in the rat that mimics alterations observed in humans.[297] The dominant site of tubular injury in the rat is the inner stripe of the outer medulla,[298] a zone that functions on the verge of hypoxia even under physiologic conditions. Investigators have postulated that hypoxic injury to this zone results from the demand for increased oxygen to support increased sodium transport stimulated by the heightened influx of sodium across the apical membrane made permeable by amphotericin B at a time when the supply of oxygen is reduced as a consequence of amphotericin B-induced reduction in renal blood flow.[298,299]

A contributory factor to the toxicity of amphotericin B is deoxycholate, the vehicle in which the drug is suspended. Deoxycholate was shown to be cytotoxic to renal tubular cells in vitro.[300] Various alternate vehicles and formulations for suspending amphotericin have been investigated in an attempt to reduce toxicity. Administration of amphotericin B in liposomes[276,301] or with other lipid preparations[302] has been reported to reduce the nephrotoxicity of this agent without compromising its therapeutic efficacy.

Lipid preparations of amphotericin B, commonly used to treat fungal infections, have been demonstrated to have reduced nephrotoxicity compared to conventional amphotericin B. However, a comprehensive comparison of nephrotoxicity induced by different lipid preparations of amphotericin B has not been performed. A meta-analysis was conducted to evaluate nephrotoxicity associated with amphotericin B lipid complex (ABLC) and liposomal amphotericin B (L-AmB).[303] Eleven studies reported between 1995 and 2008 were identified comparing nephrotoxicity resulting from the use of these agents. Eight of the 11 studies

were included in the meta-analysis. The Cochran-Mantel-Haenszel test was used to determine odds ratio (OR) and relative risk (RR), and the Breslow-Day test was used to analyze homogeneity of ORs across different studies. Analysis of all 8 studies (n = 1160) included in the meta-analysis showed an increased probability of nephrotoxicity in patients treated with ABLC versus L-AmB (OR, 1.75; RR, 1.55), but there was a significant lack of homogeneity across these studies ($P < 0.001$). After excluding the study by Wingard et al.,[304] the probability of experiencing nephrotoxicity was more similar between the two AmB lipid preparations (OR, 1.31; RR, 1.24; n = 916), particularly when the analysis included only the salvage patient population reported by Hachem et al.[305] (OR, 1.12; RR, 1.09; n = 839); the seven remaining studies were more homogeneous by Breslow-Day test ($P = 0.054$). Their results suggest that nephrotoxicity is generally similar for ABLC and L-AmB in patients receiving antifungal therapy and prophylaxis.

In a recent retrospective study conducted in 100 consecutive patients receiving L-AmB atdoses of 1, 3, and 5 mg per kg, hepatotoxicity was defined as an increase of bilirubin greater than 1.5 mg per dL or AST and ALT greater than three times the normal range. Nephrotoxicity was defined as an increase in serum creatinine of 0.5 mg per dL or an increase of 50% from baseline. Overall nephrotoxicity with L-AmB was common and often multifactorial. Lipid amphotericin B products are associated with lower rates of nephrotoxicity than conventional amphotericin; however, in this analysis, L-AmB was associated with a high incidence of nephrotoxicity.[306]

A recent study aimed at comparing the available evidence on the efficacy and safety of deoxycholate and lipid amphotericin B formulations (AMBF) in the treatment of invasive fungal disease in neonates.[307] The reviewed reports show that both amphotericin B deoxycholate (DAMB) and lipid formulations appear to have equal efficacy in treating invasive fungal disease (IFD) in neonates. The adverse effects of DAMB in neonates are considerably less than those in older children and adults. There is a trend of more nephrotoxicity reported with DAMB than with lipid formulations; however, the range reported is very wide (0%–70%). Neonates with normal baseline renal function appeared to tolerate DAMB relatively well. DAMB is inexpensive and effective in treating neonatal IFD. It appears to be safe for use as first-line therapy if the underlying risk for nephrotoxicity is low. Renal function and potassium have to be monitored closely. A sodium intake of 4 mEq/kg/day may significantly reduce DAMB nephrotoxicity.

A number of factors have been identified as potentiating the risk of amphotericin B nephrotoxicity (Table 31.3), and the physician should strive to eliminate or minimize these risk factors whenever possible. Fisher and coworkers[278] observed a 1.8-fold increase in risk of nephrotoxicity for each 0.1 mg per kg increment in the daily dose of amphotericin B. The risk of nephrotoxicity was increased 15.4-fold in patients who had an elevated serum creatinine prior to the start of amphotericin B therapy and 12.5-fold in patients who received diuretics during the course of amphotericin B therapy. The latter observation may reflect the powerful influence of sodium depletion on this complication. Sodium loading has been shown to minimize amphotericin B nephrotoxicity[279] so that special attention should be paid to ensure that the patient is optimally volume-repleted prior to the initiation of therapy with this agent (Fig. 31.4).

31.3 Risk Factors for Amphotericin B Nephrotoxicity

Daily drug dose
Duration of therapy
Chronic renal insufficiency
Sodium depletion
Renal hypoperfusion
Concomitant drug therapy/exposure
Diuretics
Aminoglycosides
Cisplatin
Radiocontrast agents
Cyclosporine

ANTIVIRAL AGENTS

Acyclovir is a potent antiviral agent effective in the treatment of infections caused by herpes simplex viruses.[309] Its major route of excretion is the kidney, which accounts for approximately 80% of total body clearance.[310] Given the fact that the renal clearance of acyclovir exceeds the creatinine clearance by severalfold, it follows that a substantial fraction of drug must be eliminated by tubular secretion, which promotes the attainment of tubular fluid concentrations in excess of the drug's estimated solubility of 1.3 mg per L.[310] The objective of the study by Gunness P et al.[311] was to determine whether acyclovir is a substrate for human BCRP. Transfected human embryonic kidney (HEK293) cells (containing the wild-type ABCG2 gene) were exposed to [8-(14) C]acyclovir (1 μmol per L) in the presence or absence of the BCRP inhibitor fumitremorgin C (FTC). Intracellular acyclovir accumulation was assessed using a liquid scintillation counter. Coexposure to FTC resulted in a significant (five-fold) increase in the intracellular accumulation of acyclovir.

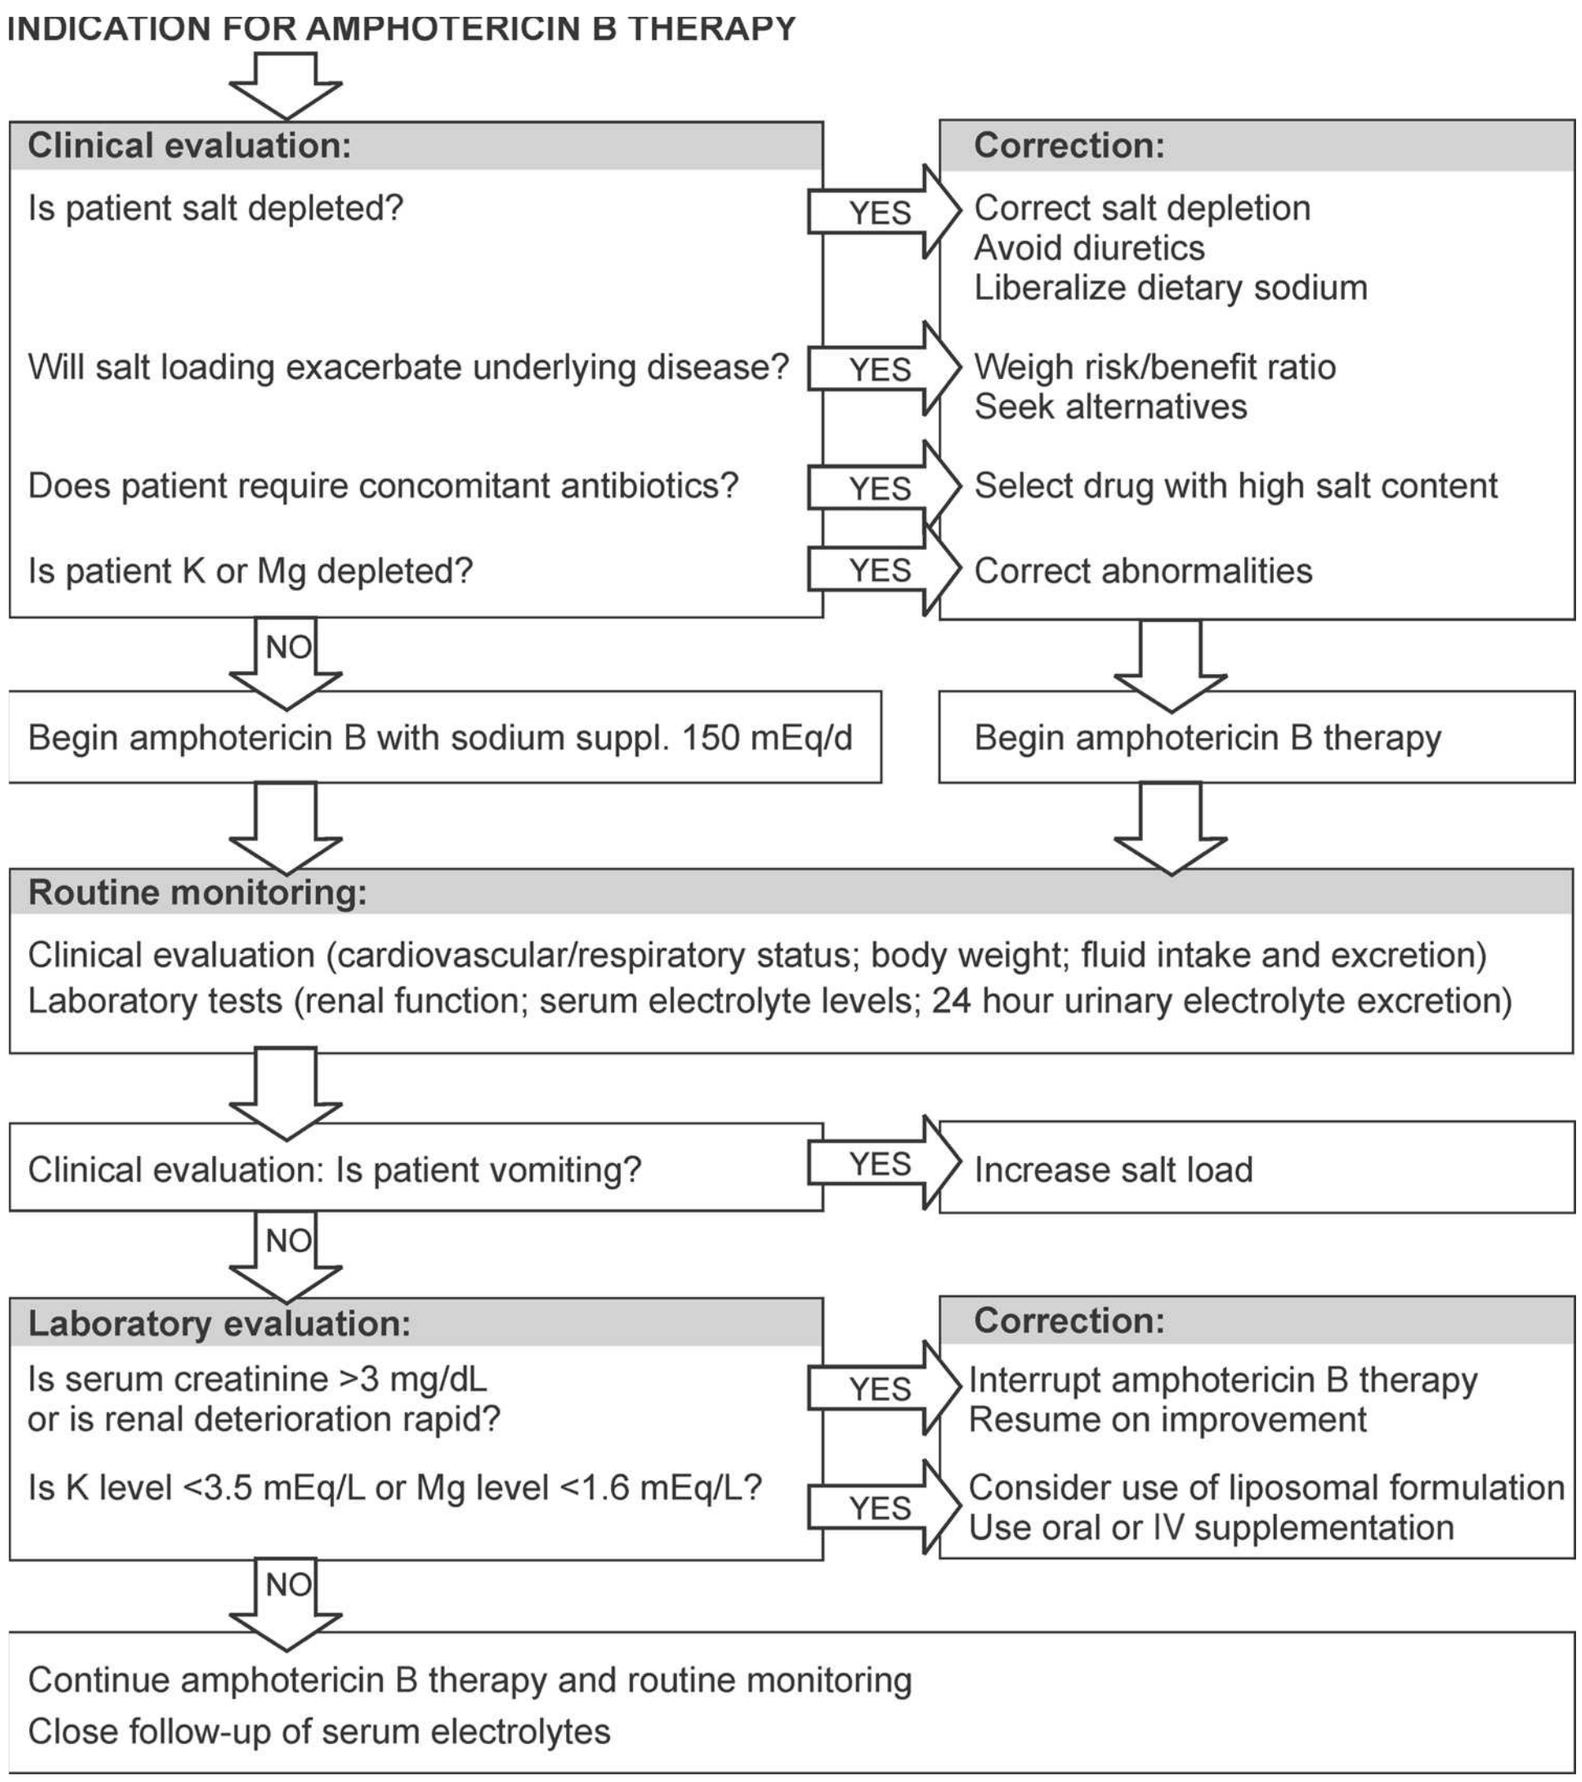

FIGURE 31.4 Proposed approach for management of amphotericin B therapy. (From Bernardo JF, Sabra R, Vyas SJ, Branch RA. Amphotericin B. In: De Broe ME, Porter GA, Bennett VM, Verpooten GA, eds. *Clinical Nephrotoxins – Renal Injury from Drugs and Chemicals,* 2nd ed. Dordrecht, The Netherlands: Kluwer Academic Publishers; 2003:199–222.)

They found that acyclovir is a substrate for human BCRP/ABCG2. The study provides direct evidence for the role of human BCRP in acyclovir transport and its potential significance with respect to renal tubular transport of acyclovir and the direct renal tubular insult (nephrotoxicity) induced by the drug. Approximately 85% of the drug recovered in the urine is unchanged; the remainder is recovered as the principal metabolite, 9-carboxymethoxymethylguanine.[310] In several large series, acyclovir has been reported to cause elevation of the BUN and serum creatinine in 10% to 15% of cases.[312,313] In one series of 23 patients, an incidence of acute renal insufficiency of 48% was reported.[314] The clinical expression of nephrotoxicity may range from asymptomatic azotemia to renal colic with nausea and vomiting. Examination of the urinary sediment may reveal microscopic hematuria, pyuria, and birefringent crystals. The pathogenesis of acyclovir-induced ARF has been attributed to intratubular obstruction caused by precipitation of drug[313] as well as direct tubular cell toxicity.[315,316] High drug dose, rapid drug infusion, and low urine volume predispose to the development of ARF. In about half the cases, the onset of azotemia occurs during the first few days of therapy; it is usually transient and frequently resolves in response to increased fluid intake even when drug therapy is continued. Severe renal failure has been reported, however, even in patients who were prehydrated.[317] Fortunately, even in these cases, renal function usually recovers. In the rat infusion of acyclovir caused a decrease in whole kidney and single nephron GFR and renal plasma flow in association with an increase in renal vascular resistance.[318]

A retrospective review was conducted by Schreiber et al.[319] on all children (mean age 81 months; n = 126 [74 boys])

who were treated with aciclovir in a tertiary center between July 2005 and January 2006 and who met our inclusion criteria. GFR was calculated on the first day of treatment and at the peak measured creatinine level while on therapy, using Schwartz's method. Aciclovir therapy was associated with a significant increase in serum creatinine levels and a parallel decrease in GFR (n = 93; both P ≤.0001). Children with immunosuppression who received a variety of other nephrotoxic drugs exhibited more severe nephrotoxicity than those not receiving nephrotoxic drugs. In multiple regression analysis, the use of nephrotoxic drugs (P = .02) and impaired GFR at baseline (P = .04) were predictive for nephrotoxicity. Within the recommended age-dependent dosage schedule of aciclovir there was no effect of dose per kilogram, age, or sex on nephrotoxicity. The predictors of aciclovir nephrotoxicity were the concomitant use of nephrotoxic drugs and impaired GFR at baseline.

Foscarnet is an antiviral agent that is being used with increasing frequency for the treatment of cytomegalovirus infections and acyclovir-resistant herpes virus infections, particularly in immunocompromised individuals.[320,321] This agent is excreted unchanged in the urine by glomerular filtration and tubular secretion.[322] Major complications of therapy include ARF, often severe and of uncertain pathogenesis,[323,324] and electrolyte abnormalities that include hypercalcemia, hypocalcemia, hypophosphatemia, hypomagnesemia, and hypokalemia.[265,325] ARF secondary to crystal deposition has been described as well.[326] Volume expansion by infusing saline has been reported to greatly reduce the incidence and severity of ARF.[324,327]

Cidofovir is an antiviral nucleotide analog indicated for the treatment of cytomegalovirus retinitis in patients with AIDS.[328] The drug is eliminated primarily by the kidneys by glomerular filtration and tubular secretion via the organic acid transport system.[329] The major complication of therapy with this agent is nephrotoxic injury to proximal tubular cells but this complication can be significantly reduced by the coadministration of probenecid which presumably blocks the renal tubular uptake of cidofovir and decreases the renal elimination of the agent.[330]

Atazanavir belongs to the protease inhibitor class and is used in combination with other antiretroviral drugs. Recently stone formation and less common crystal nephropathy was decribed with this drug.[331,332] Atazanavir is metabolized in the liver and only 6% is excreted unchanged by the kidneys and insoluble at acid pH. Consequently risk factors to develop renal complications are volume depletion, alkaline urine, and liver dysfunction resulting in a decrease of metabolism of the drug.[333]

Tenofovir, another antiretroviral drug, has gained widespread use on the basis of its efficacy, tolerability, and patient-friendly dosing schedule.[334] Herlitz and colleagues[335] demonstrated that tenofovir is a proximal tubular mitochondrial toxin in humans. Renal histology in 10 HIV patients with tenofovir associated clinical nephrotoxicity demonstrated that proximal tubular injury with tenofovir was associated with nephrotoxicity and varying degrees of chronic tubulointerstitial scarring. Prominent eosinophilic inclusions within proximal tubular cell cytoplasm, which represented giant, abnormal mitochondria, were noted on light microscopy. These inclusions are easily identifiable, as they stain brightly with hemaotxylin and eosin stain or fuchsinophilic with trichrome stain. On electron microscopy, mitochondria varied widely in shape and size; some were small and rounded, whereas others were swollen with irregular contours. Loss and disorientation of cristae were observed in enlarged mitochondria, whereas the overall number of mitochondria was significantly decreased in some tubular cells.

These drugs act primarily by decreasing mitochondrial DNA (mtDNA) replication by inhibiting mitochondrial DNA polymerase-γ, which is the only enzme capable of replicating mtDNA. As a result, mtDNA and a number of the mtDNA-encoded enzymes involved in electron transport chain function and oxidative phosphrylation are depleted resulting in disturbed mitochondrial function. This ultimately causes, among other effects, a deficit in adenosine triphosphate production, impaired cell function, and cell injury and/or death.[336,337]

Renal handling of tenofovir consists in a combination of glomerular filtration and proximal tubular secretion, which in part explains the proximal tubular toxicity of tenofovir.[338] Tenofovir is transported via organic anion transporter-1 (OAT-1) from the basolateral into proximal tubular cells, where it is translocated into the urine through apical efflux transporters such as multidrug resistance protein-2 (MRP-2) and MRP-4. Using kidney tissue from OAT-1, MRP-4 knockout mice and wild type mice, Kohler et al. demonstrated that both OAT1 and MRP4 have a direct role in transport and efflux of tenofovir, regulating levels of tenofovir in proximal tubules. Disruption of OAT1 activity prevents tenofovir toxicity but loss of MRP4 can lead to increased renal proximal tubular toxicity. These data help to explain mechanisms of human TDF renal toxicity.[339] Impaired MRP-driven efflux activity can reduce tenofovir secretion and increase intracellular concedntrations. A single-nucleotide polymorphism in the MRP-2 efflux transporter gene (ABCC2) has been documented in HIV-positive patients who developed tenofovir-induced nephrotoxicity, supporting this hypothesis.[340] Endogenous anions and other drugs may compete with tenofovir for these efflux transport pathways. The excretory pathway defects can lead to increased tenofovir trafficking through and/or increased concentrations within proximal tubular cells, enhancing risk for mtDNA depletion and mitochondrial dysfunction. Genetic factor testing (for the single-nucleotide polymorphism in ABCC2) to identify high-risk patients and targeted interventions reduces OAT-1 transport of tenofovir into tubular cells and may allow HIV-positive patients to be protected from nephrotoxicity of the drug. Out of these series of observations, one may conclude that tenofovir may cause toxic tubular damage (mitochondrial toxin) in exposed HIV patients. The clinical expression

of this form of nephrotoxicity can develop at any time point during treatment with this drug. Patients may not recover from the injury and develop CKD. The renal handling of tenofovir can explain the small subset of HIV patients developing this form of nephrotoxicity.

PENTAMIDINE

Pentamidine has been used for the treatment of P. jiroveci pneumonia since the 1950s. In the pre-AIDS era, pentamidine therapy was complicated by ARF in about 25% of cases.[341] The incidence of ARF in patients with AIDS treated with pentamidine appears to be substantially higher than this figure, and it is unexplained by greater drug dose, longer duration of therapy, or concomitant therapy with other potentially nephrotoxic agents.[342] The mechanism of pentamidine-induced ARF has not been established. Although pentamidine is concentrated in the kidney,[343–345] pharmacokinetic studies utilizing a high-performance liquid chromatography assay indicate that <5% of the drug is excreted in the urine each day.[344,346] The mechanism of renal elimination is not known.

Pentamidine nephrotoxicity presents as nonoliguric ARF beginning 7 to 10 days after the start of therapy. Urinalysis reveals mild proteinuria, microscopic hematuria, pyuria, and cylinduria. Most patients experience mild to moderate ARF, but occasionally severe renal failure necessitating dialysis therapy occurs. In one series, azotemia was accompanied by hyperkalemia in association with a picture of hyperchloremic metabolic acidosis.[342] Renal magnesium wasting has been observed in several cases.[347] Recovery of renal function usually begins within a week after stopping drug therapy and in most cases returns to baseline within several weeks.

Chronic renal insufficiency, volume depletion, cumulative dose, and concurrent use of other nephrotoxic drugs heighten the risk of pentamidine nephrotoxicity in humans.[269,348] In the rat, pentamidine nephrotoxicity was potentiated by amphotericin B, tobramycin, and cyclosporine, whereas it was ameliorated by fosfomycin, D-glucaro-1,5-lactam, verapamil, and enalapril.[349]

NEPHROTOXICITY OF CYCLOSPORINE

Since its clinical use as an immunosuppressant drug in the early 1980s, cyclosporin A (CsA) has tremendously improved the outcome of solid organ (kidney, heart, liver, lung, and pancreas) and bone marrow transplants.[350,351] In more recent years, the immunosuppressive properties of CsA have also been used in the treatment of autoimmune diseases (psoriasis, uveitis, and severe rheumatoid arthritis) as well as steroid-resistant nephrotic syndrome.

The major side effect of CsA is its renal toxicity. Although, in preclinical animal studies, renal side effects were not observed,[352–354] early reports from clinical practice revealed the nephrotoxicity of CsA.[355–357] Since that time, numerous observations have added to the overwhelming evidence of three different forms of cyclosporine nephrotoxicity.[358–366] This toxicity is not restricted to only the field of kidney transplantation but has also unequivocally been documented in heart,[367,368] bone marrow,[368] liver,[369,370] and pancreas transplantation,[371] as well as in a variety of autoimmune diseases,[372–375] in which a priori rejection of the kidney graft is absent.

Based on experimental data and clinical experience, this chapter intends to summarize the present knowledge about the three different forms of cyclosporine nephrotoxicity: ARF (with sometimes protracted course evolving to chronicity); the hemolytic–uremic-like syndrome; and chronic irreversible nephrotoxicity.

Clinical Pharmacology of Cyclosporin A

The selective immunosuppressive effects of CsA were described for the first time in 1976.[376] CsA is a lipophilic fungal peptide with a molecular weight of 1.203 daltons, consisting of 11 amino acids (Fig. 31.5). As a consequence of its high hydrophobicity, CsA interacts easily with phospholipid bilayer membranes, whereas some CsA amino acids form a hydrophilic active immunosuppressive site.[377]

CsA is available for clinical use in three formulations: one stabilized in castor oil (Cremophor) for IV injection, the second as a microemulsion formulation (Neoral), and a third formulation as soft gelatin capsules. The pharmacokinetic profile of the conventional CsA formulation (Sandimmune) exhibits a high degree of interpatient and intrapatient variability.[378–380] Pharmacokinetic studies in healthy subjects and renal transplant recipients have shown that the more recent microemulsion formulation of CsA possesses superior pharmacokinetic characteristics, with more complete and predictable absorption of the drug from the gastrointestinal tract, resulting in less pharmacokinetic variability.[381,382] In clinical trials, the microemulsion formulation of CsA increased drug exposure and reduced the incidence of acute rejections, without incremental toxicity.[383–385]

In the circulation, CsA is mainly bound to high, low, or very low density lipoproteins and to chylomicrons.[386] Only a small fraction of CsA circulates unbound. The volume of distribution ranges from 4 to 8 L per kg of body weight.[387] Due to its hydrophobicity, CsA dissolves extensively in cell membranes and tissue lipids.[388] CsA accumulates in lymphocytes, liver, kidney, heart, lung, and neural and muscle cells.[389]

CsA has a median half-life of 6.4 to 8.7 hours and is predominantly eliminated by hepatic metabolism through specific isoenzymes of the cytochrome P-450 superfamily.[390] More than 90% of the parent compound and the metabolites are excreted in the bile, whereas only 6% is eliminated by the kidneys.[388] Significant individual differences in CsA clearance rates,[390,391] with a median value of 12 mL/min/kg, can be explained by wide genetic differences among individuals in the content of cytochrome P-450 isoenzymes, as well as a variety of other factors such as patient age,[392] the functional status of the liver,[393] and interactions with other

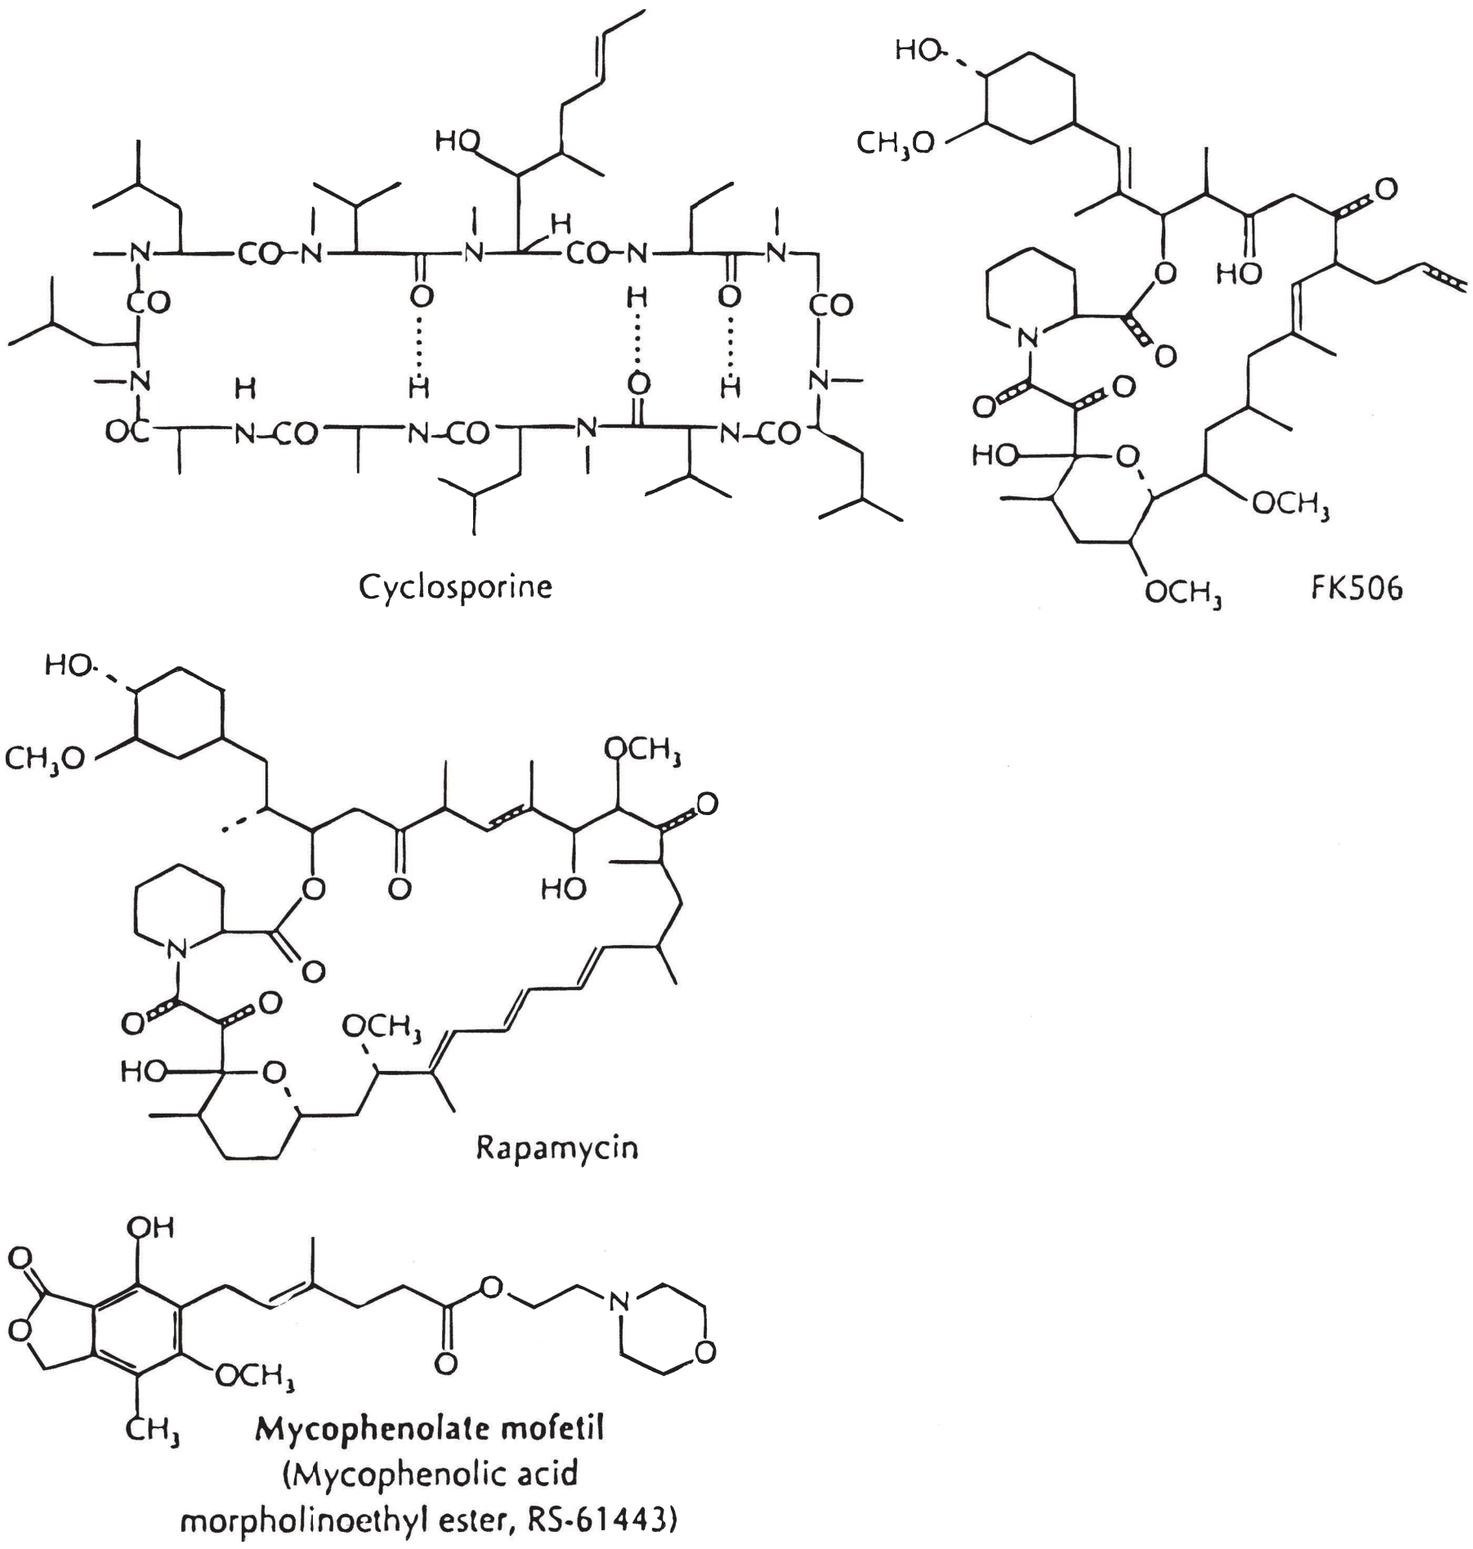

FIGURE 31.5 Structure of new immunosuppressive drugs.

drugs.[394] Independent of the intrinsic nephrotoxicity of CsA, its complex clinical pharmacokinetic profile entails the potential hazard of incorrect dosing, ultimately resulting in irreversible renal damage or acute rejection of the graft.

To optimize CsA therapy, monitoring of CsA trough levels in serum, plasma, or whole blood by means of radioimmunoassays or high-performance liquid chromatography is common clinical practice.[395] Monitoring CsA trough levels has limited value, however, for the assessment of adequate immunosuppression or predicting protection from nephrotoxicity.[396,397] The AUC is more informative and a better indicator of drug exposure[398] but is expensive and time consuming. Large-scale clinical trials using Neoral C_2 monitoring in renal and liver transplant recipients have demonstrated low acute rejection rates and good tolerability with a low adverse event profile to at least one year posttransplant.[399–403] Neoral C_2 monitoring provided a more accurate assessment of delayed and/or low absorbers of CsA in these studies. Neoral C_2 monitoring in maintenance renal transplant recipients showed that 26% to 49% of the patients, managed by monitoring of cyclosporine trough levels, were treated with excessive doses of CsA, adversely affecting graft function.[404–406] Dose reduction to optimal C_2 levels, between 600 and 800 ng per mL, in these patients, resulted in improvement of graft function, without increased risk for rejection.[404] These data provide evidence that monitoring of C_2 levels may result in more adequate dosing of cyclosporine.

Immunosuppressive Mechanism of Cyclosporin A

CsA blocks the activation of T cells, mainly through inhibition of transcription of lymphokines, most notably interleukin-2 (IL-2), the main growth factor for T cells.[407] By inhibiting IL-2 expression in T cells, CsA prevents helper T cells from orchestrating a response to foreign antigens.

The immunosuppressive effect of FK506 (tacrolimus) is similar to that of CsA,[408] as a logical consequence of a similar molecular mechanism of action of both drugs (Fig. 31.6).[409] CsA and FK506 bind with high affinity to intracellular target proteins, called immunophilins, which possess cis–trans isomerase activity. These immunophilins have been identified respectively as cyclophilins in the case of CsA[410] and FK-binding proteins in the case of FK506 and rapamycin.[411] The binding of CsA or FK506 is a prerequisite of their immunosuppressive potential because it has been demonstrated that the CsA- or FK506-immunophilin complex competitively binds directly to the serine–threonine phosphatase

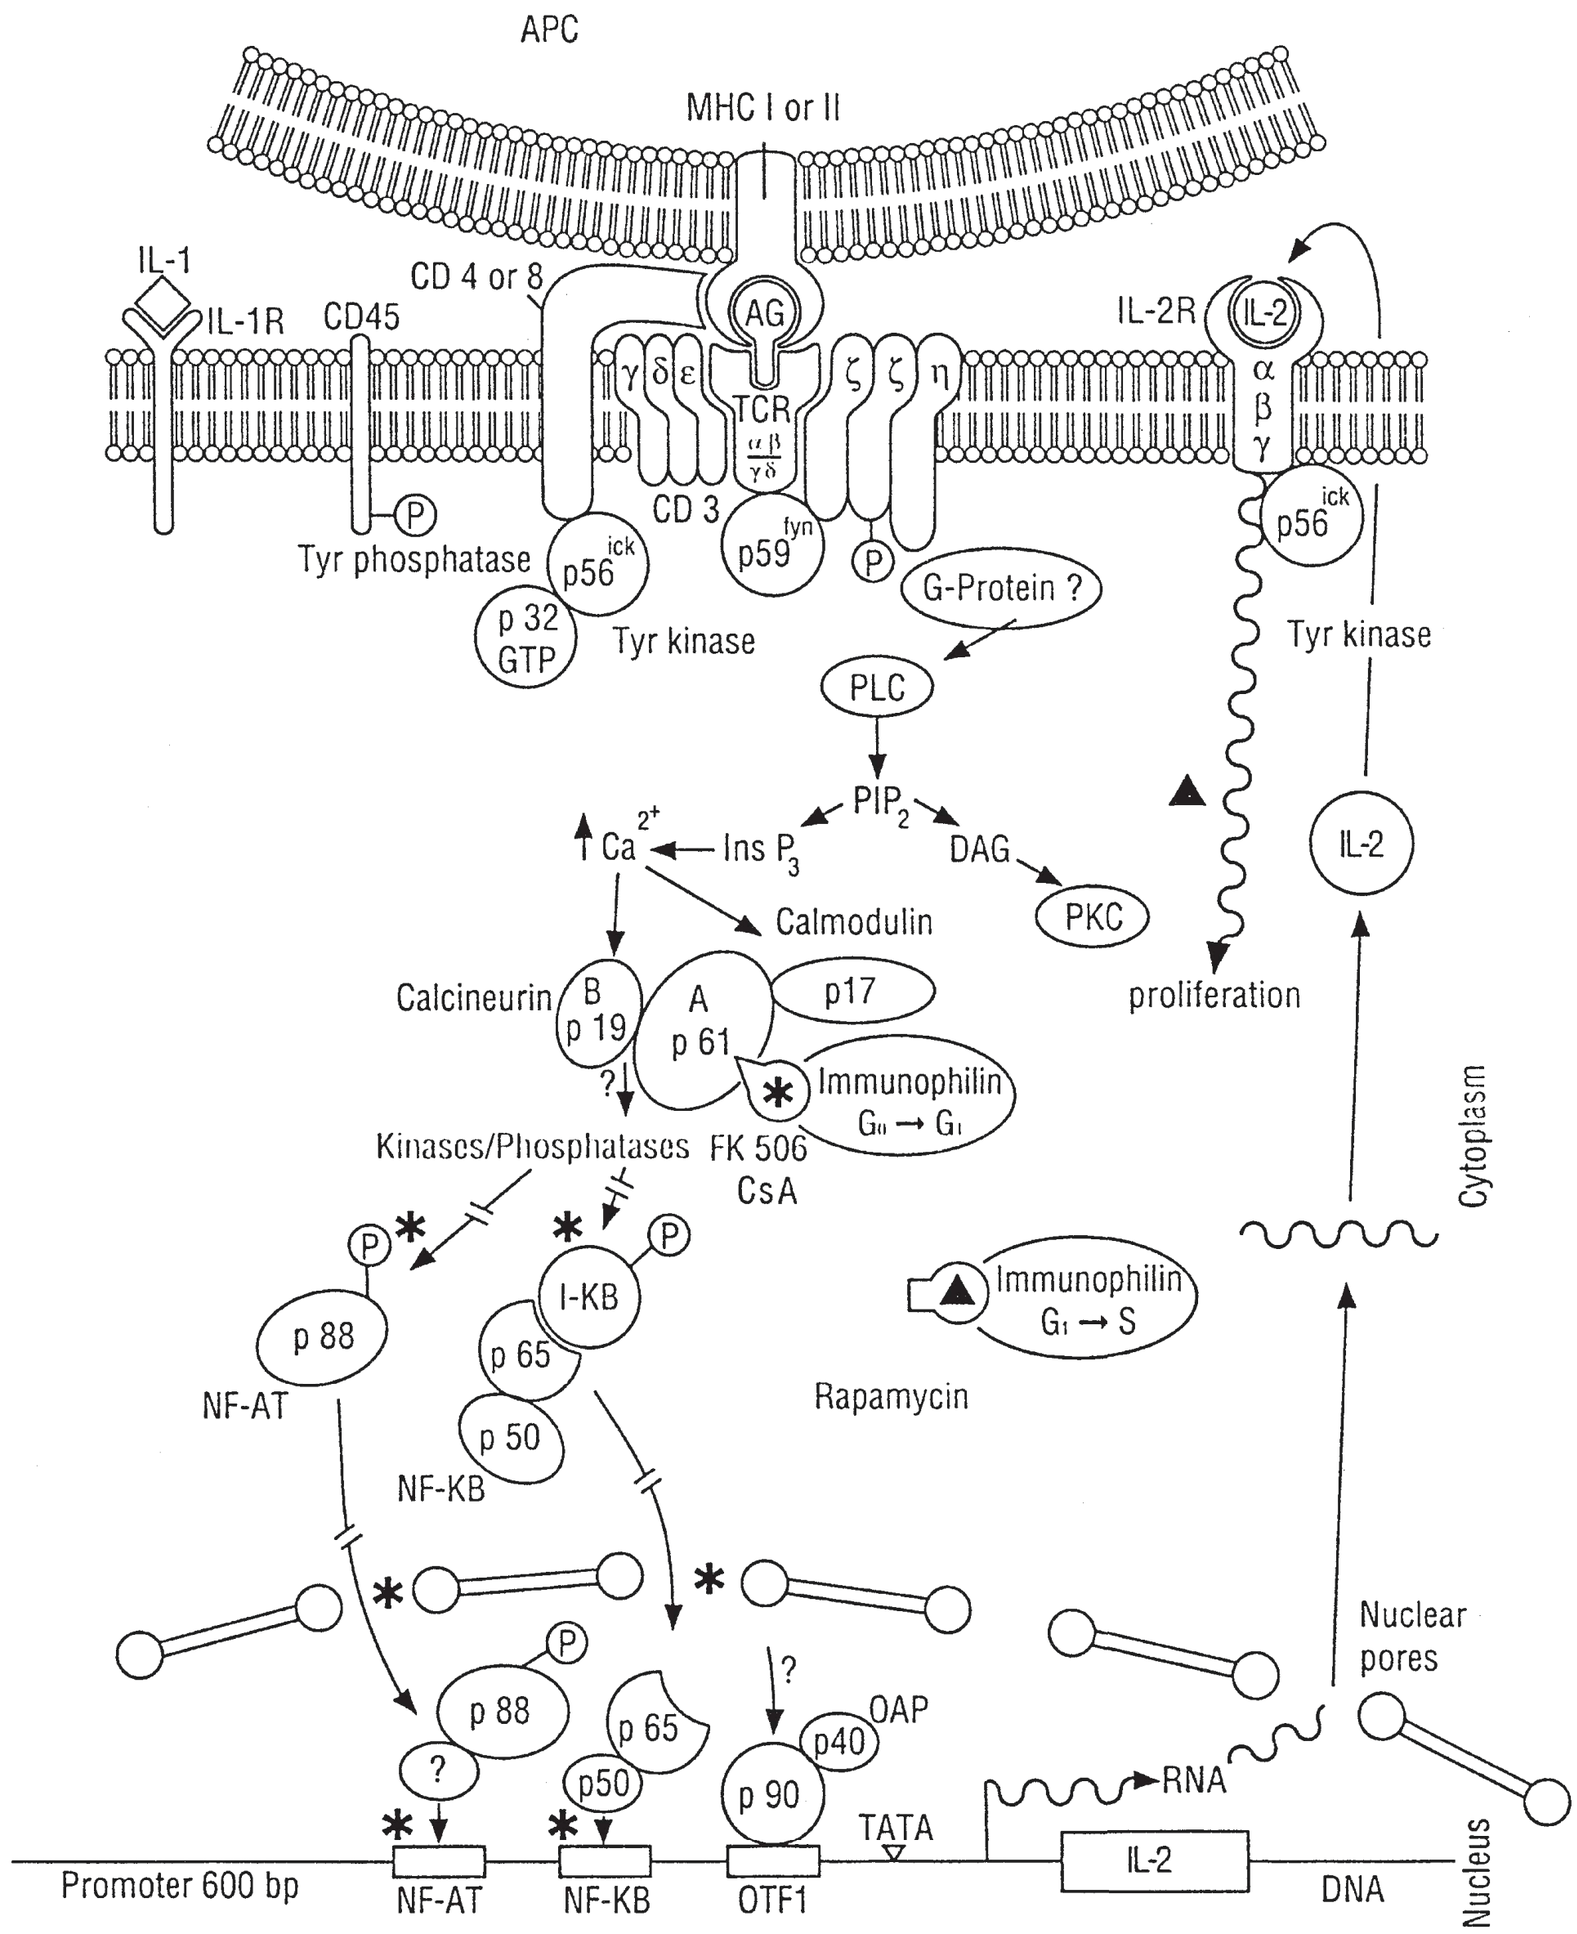

FIGURE 31.6 Cyclosporine (CsA) and FK506 both interfere, by binding to their respective immunophilins, with the function of intracellular molecules that transmit calcium-associated signals between the cell receptor (TCR) and the activation of lymphokine genes (interleukin-2) in the nucleus. Transcriptional regulation of interleukin-2 (IL-2) gene expression is modulated by the combination of transcription factors (e.g., NF-AT, NF-κ B, OTF-1) interacting with their corresponding recognition sites at the IL-2 promoter. These DNA/protein complexes, together with RNA polymerase II (RNA pol II), result in the antigen-inducible transcription of IL-2. Potential intervention sites for the pentameric complex (Calcineurin A [p61], B [p19], calmodulin [p17], immunophilin, drug), involving (e.g., modification and translocation) antigen-inducible transcription factors (NF-AT [p88], NF-κ B [p50, p65]), are indicated by *asterisks*. CyA and FK506 interfere with the G_0 to G_1 transition of the cell cycle, whereas rapamycin interferes with the G_1 to S transition (indicated by a *triangle*). *AG,* antigen; *APC,* antigen presenting cell; *DAG,* diacylglycerol; *Ins P_3,* inositoltriphosphate; *MHC,* major histocompatibility class; *PiP_2,* phosphatidylinositolbiphosphate; *PKC,* protein kinase C; *PLC,* phospholipase C. (From Baumann G. Molecular mechanism of immunosuppressive agents. *Transplant Proc.* 1992;24[Suppl 2]:4, with permission.)

calcineurin[412,413] in the presence of Ca^{2+}. The inhibition of calcineurin by the drug–immunophilin complex results in an altered modification pattern of the cytoplasmic components of transcription factors, thereby disturbing their nuclear translocation.[409]

Potential substrates for calcineurin are the nuclear factor of activated T cells (NF-AT) and the nuclear factor of immunoglobulin (light chain in B cells) (NF-κB), which were both reported as being affected in their IL-2 promoter binding activity by CsA and FK506, but not by rapamycin. This could explain the similarity of the immunosuppressive effect of CsA and FK506, in contrast to rapamycin, although rapamycin shares the same affinity as FK506 for the FK-binding protein.[414,415]

Experimental Nephrotoxicity of Cyclosporin A

Much of our knowledge of cyclosporine nephrotoxicity derives from experimental studies in animal models. The understanding of the pathogenesis of chronic cyclosporine nephrotoxicity has long been hampered, however, by the lack of an experimental model until a number of investigators developed a suitable animal model of chronic cyclosporine nephrotoxicity.[416–420]

Functional Alterations Induced by Cyclosporin A

It has been unequivocally established that CsA profoundly alters renal and glomerular hemodynamics. Acute and/or chronic CsA administration induces a decline in GFR, with a concomitant reduction in renal blood flow and an increase in renal vascular resistance as a consequence of vasoconstriction,[421–424] preferentially at the level of afferent arterioles.[425] These hemodynamic effects are mainly responsible for the acute cyclosporine nephrotoxicity and probably contribute also to the pathogenesis of chronic nephrotoxicity by inducing chronic renal ischemia. The possible underlying mechanisms of this vasoconstrictor effect of CsA are discussed in "Pathophysiologic Studies of Cyclosporine Nephrotoxicity."

Although early pathologic studies suggested that CsA is a primary tubular toxin,[425] the results of clearance experiments conflict with that premise.[426] CsA reduces the end proximal tubular flow rate[427] and increases proximal fractional reabsorption.[428] The latter is due to an inadequate adaptive reduction in the absolute rate of proximal reabsorption.[429] CsA causes a resetting of the tubuloglomerular feedback with onset at lower tubular flow rates and greater maximum response.[430]

CsA-treated rats show a reduction of sodium chloride reabsorption in the distal nephron, including Henle's loop,[427,428] most likely as a secondary response to the decreased proximal tubular fluid delivery. This reduced sodium delivery to and reabsorption from the distal nephron results in reduced distal acidification and potassium secretory capacity through a decreased generation of a negative transmembrane potential. This explains the observed hyperkalemic metabolic acidosis in CsA-treated rats[431] as well as in CsA-treated kidney transplant recipients.[432]

In summary, CsA reduces renal blood flow and GFR predominantly through vasoconstriction of the afferent arterioles. Effects of CsA on tubular function consist of increased proximal tubular reabsorption and decreased distal sodium delivery, which induce hyperkalemic metabolic acidosis.

Morphologic Alterations Induced by Cyclosporin A

The renal pathology induced by CsA is largely dose-related and time-related. For clarity, we focus on two distinct pathologic patterns: the acute (potentially reversible) toxic injury and the chronic (essentially irreversible) nephrotoxicity induced by CsA.

At supratherapeutic levels (100 mg/kg/day by mouth [PO]), CsA induces mainly tubular pathology consisting of isometric vacuolization of tubular cells, accumulation of eosinophilic bodies often representing giant mitochondria, and microcalcifications in proximal tubules by 21 days.[425,433–435] The effects on the proximal tubule tend to be most prominent in the S3 segment[436] and become more widespread at very high doses. These pathologic alterations are reversible after dose reduction or withdrawal of CsA. In contrast to the acute toxic injury, chronic administration of CsA (12.5 mg/kg/day) for 3 to 10 weeks induces striking morphologic alterations in the medullary rays of the cortex of the rat.[416] These changes progress in time and result in areas of focal or striped interstitial fibrosis with foci of atrophic proximal tubules, which are most prominent in the subcapsular cortex.[437,438] The severity of the lesion progresses with treatment and is exacerbated by salt depletion.[420] Withdrawal of CsA does not reverse the observed structural changes.[437]

Besides the striped interstitial fibrosis, mild glomerular endothelial damage, glomerular hypercellularity, and mesangial matrix expansion[417] are observed after long-term CsA administration. Morphometric analysis with three-dimensional reconstruction of individual glomeruli[439] shows subsets of glomeruli with small volume with significant reduction in GFR,[440] alternating with hypertrophic glomeruli.

At the vascular level, scanning electron microscopy shows focal narrowing of the afferent arteriolar diameter that progresses with time of CsA treatment and parallels the decrease in inulin clearance.[362] CsA nephropathy is associated with degenerative hyaline changes in the walls of afferent arteriolar-sized blood vessels,[441] which can disappear after discontinuation of CsA.[442,443]

Pathophysiologic Studies of Cyclosporine Nephrotoxicity

Numerous studies have focused on different pathophysiologic mechanisms of cyclosporine nephrotoxicity. We sequentially discuss mechanisms of renal vasoconstriction, cellular and molecular mechanisms, mechanisms of matrix protein accumulation, and studies on lipid peroxidation.

Mechanisms of Cyclosporin A-Mediated Renal Vasoconstriction. As mentioned previously, administration of CsA induces a marked afferent arteriolar vasoconstriction resulting in decreased renal blood flow and GFR. The renal sympathetic nervous system has been implicated in the renal functional effects of CsA because the α-adrenergic antagonists phenoxybenzamine[421] and prazosin[444] prevent a CsA-induced fall in renal blood flow and GFR. Moreover, a significant increase in renal afferent and efferent nerve activity has been demonstrated in CsA-treated rats.[445] The relevance of the activated sympathetic nervous system to the pathophysiology of cyclosporine nephrotoxicity in kidney transplantation is questionable, however, because the renal allograft is denervated. Nevertheless, increased sensitivity of the denervated organ to circulating catecholamines[445] or significant reinnervation of renal allograft after transplantation[446] is a possible explanation.

Rodent models of cyclosporine nephrotoxicity consistently show activation of the renin–angiotensin–aldosterone axis, in contrast to results in humans. Besides increased plasma renin activity in CsA-treated rats,[434,447] hyperplasia of the juxtaglomerular apparatus,[419,448,449] as well as elevated renin synthesis and release in juxtaglomerular cells,[450,451] has been documented in experimental animals during CsA therapy. However, angiotensin-converting enzyme (ACE) inhibitors show conflicting effects on renal blood flow in CsA-treated rodents, with improvement in some studies[421,452] but not in others.[422,453] More recent experimental studies suggest that CsA-related chronic interstitial injury is mediated by angiotensin II, because renin–angiotensin blockade prevents CsA-induced tubulointerstitial fibrosis.[454,455] However, in human cardiac and renal allograft recipients treated with CsA, plasma renin is suppressed,[367,456] suggesting that the renin–angiotensin system is not of primary importance in human cyclosporine nephrotoxicity.

Hypovolemia could contribute to renal vasoconstriction with CsA therapy because CsA-treated rats have reduced plasma volume and saline expansion reverses the deficits in renal blood flow and GFR.[457] Studies with furosemide,[458] mannitol,[459] and chronic sodium depletion[416] have demonstrated that hypovolemia potentiates cyclosporine nephrotoxicity. Sodium depletion enhanced fibrosis and the expression of TGF-β1 and matrix proteins in experimental CsA nephropathy.[460] However, there is evidence implicating hypovolemia and sodium-depletion as an exacerbating rather than as a causative factor of human cyclosporine nephrotoxicity.

Much attention has been paid to the potential role of an altered eicosanoid metabolism in cyclosporine nephrotoxicity. In animal models, CsA consistently increases the generation of thromboxane A_2 (TxA_2), a potent renal vasoconstrictor,[461–463] whereas its effects on vasodilatory prostaglandins are controversial.[457,464,465] Pharmacologic manipulation of thromboxane metabolism with a specific TxA_2 receptor antagonist[466,467] or a TxA_2 synthase inhibitor[468] partially prevented the CsA-induced acute decline in GFR and renal blood flow in normal rats. The TxA_2 receptor antagonist also attenuated chronic cyclosporine nephrotoxicity in rats with renal isograft.[469] The relevance of these data to human cyclosporine nephrotoxicity, however, is controversial.[470,471]

Another potential mediator of CsA-induced vasoconstriction is the platelet activating factor (PAF) because it has been demonstrated that rat mesangial cells release increased quantities of PAF when incubated with CsA, and CsA-stimulated cell contraction is abolished by the PAF antagonists BN52021 and alprazolam.[472] Chronic cyclosporine nephrotoxicity is also attenuated in rats treated with the PAF antagonist BN52063.[473]

More recently, the role of endothelin, the most potent vasoconstrictor yet identified, has been advocated in CsA-induced vasoconstriction. CsA treatment has been shown to stimulate endothelin production[474,475] and promote glomerular endothelin binding in vivo.[476] Endothelin appears to mediate CsA-induced renal vasoconstriction in the rat.[477] The resulting reduced single-nephron GFR and glomerular plasma flow rate, as well as the decreased glomerular capillary pressure, were attenuated by an antiendothelin antibody.[478] Similarly, the endothelin receptor antagonist BQ123 has the potential to prevent hypoperfusion and hypofiltration induced by CsA.[479] Recent work additionally demonstrated that CsA selectively modulates renal mRNA expression for endothelin peptide and one of its receptor subtypes in a site-specific way.[478] In humans, the endothelin receptor antagonist bosentan markedly blunted the renal hypoperfusion effect of CsA.[480]

Experimental data indicate that an enhanced 5-HT2 (serotonin)-mediated vasoconstriction plays an important role in the suppression of renal blood flow (RBF) autoregulation induced by CsA, because the administration of ritanserin, a pure 5-HT2 antagonist, restored the RBF autoregulation.[481] In vivo studies in humans demonstrated reduced basal and stimulated NO production from the endothelium of forearm resistance vessels in cyclosporine-treated renal transplant recipients.[482] This suggests endothelial dysfunction and may provide a potential mechanism to explain cyclosporine-induced hypertension.

Elevated cytosolic calcium is yet another attractive candidate to explain the CsA-induced vasoconstriction. This has been demonstrated in cultured rat mesangial cells[483] as well as in vascular smooth muscle cells.[484] The augmented transmembrane Ca^{2+} influx and intracellular Ca^{2+} mobilization could account for the protective effects of calcium channel antagonists in acute[485–487] as well as chronic[488,489] cyclosporine nephrotoxicity.

In summary, the acute or subacute effects of CsA on renal hemodynamics are likely mediated by a number of vasoactive substances such as endothelin, serotonin, impaired NO production, TxA_2, and PAF. At the cellular level, CsA induces increased intracellular Ca^{2+}, resulting in contraction of vascular smooth muscle cells as well as mesangial cells. Calcium channel blockers are able to protect against these effects.

Cellular and Molecular Mechanisms of Cyclosporine Nephrotoxicity. CsA modulates mitochondrial calcium fluxes, resulting in reduced mitochondrial swelling, respiration, and calcium discharge.[490,491] Additionally, CsA modulates cytosolic calcium regulation in mesangial cells.[483,492]

In T lymphocytes, CsA only affects calcium-dependent pathways on T-lymphocyte activation. As stated previously in "Immunosuppressive Mechanism of Cyclosporin A," the immunophilin-ligand complex inhibits the Ca^{2+}-dependent phosphatase calcineurin, which is an important step in signal transmission pathways. The analogy of immunosuppressive effect of FK506, as well as its nephrotoxicity, has led to an attractive hypothesis stating that cyclosporine nephrotoxicity could be inherent to its immunosuppressive effect[493]; a similar hypothesis was formulated with regard to FK506.[494]

The mechanisms underlying the linkage of nephrotoxic effects to immunosuppressive effects of CsA or FK506 are still unknown. However, the blocking of T cell activation by CsA or FK506 is an attractive explanation because it has been shown that a mononuclear cell infiltrate is part of cyclosporine nephrotoxicity.[495] Alteration of the repair function of these cells could therefore be a possible mechanism inducing interstitial fibrosis.

Administration of CsA in vivo to rats causes a marked impairment of microsomal protein synthesis.[496] Additional studies have shown a dose-dependent and time-dependent translational alteration of intracellular protein synthesis produced by cyclosporine.[497]

The role of this decreased renal microsomal protein synthesis induced by CsA is speculative but could, if persistent with long-term cyclosporine treatment, alter renal cell matrix and interstitial cell interactions favoring fibrosis.[497]

Recent in vitro studies showed that CsA induces apoptosis in tubular epithelial cells in a dose-dependent and time-dependent manner.[498–501] This effect was mediated by the induction of iNOS,[498] caspases,[499] or Fas.[500]

Mechanisms of Matrix Protein Accumulation. Interstitial fibrosis, the end point of chronic cyclosporine nephrotoxicity, results from an excessive extracellular matrix accumulation, which represents an imbalance between rates of extracellular matrix production and degradation. Cyclosporine has been shown to enhance the production of specific extracellular matrix components in mouse and rat kidney,[502,503] as well as in renal cells in culture.[504] In the presence of CsA, angiotensin II is known to induce interstitial collagen formation.[505] Blockade of the renin–angiotensin system with angiotensin II receptor antagonists or ACE inhibitors markedly abrogated the tubulointerstitial fibrosis without improving renal hemodynamics.[454,455,506] The location of the angiotensin receptor type 1 mRNA in the outer medulla and medullary rays might explain the peculiar striped pattern of fibrosis noted in an experimental model of chronic cyclosporine nephrotoxicity.[507] All together, these data strongly suggest that CsA-induced interstitial fibrosis could be mediated by angiotensin II, independent of its hemodynamic effects.

Several recent studies also implicated transforming growth factor-β1, a potent immunosuppressive and fibrogenic cytokine, as a potential mediator of CsA-induced interstitial fibrosis.[508–514] Enhanced intragraft expression of TGF-β was associated with interstitial fibrosis in patients treated with CsA.[508] In animals, CsA induced an increased expression of TGF-β1, both at the mRNA and the protein level, again associated with tubulointerstitial fibrosis.[509–511,514] Similarly, CsA stimulated expression of TGF-β1 in renal cells.[512,513] The fibrogenic effects, induced by CsA, were abrogated by a neutralizing anti-TGF-β1 antibody.[513,514]

In contrast to the already mentioned enhanced collagen formation induced by CsA, recent work demonstrates an increased expression at both the transcriptional (mRNA) level and protein level of tissue inhibitor of metalloproteinases (TIMP-1) in a rat model of chronic cyclosporine nephrotoxicity.[515,516] Moreover, Duymelinck and associates show that cholesterol feeding accentuates the cyclosporine-induced elevation of renal plasminogen activator inhibitor type 1 (PAI-1).[517] This increased expression and production of TIMP-1 and PAI-1, induced by CsA, could result in a decreased degradation of extracellular matrix, which would in turn lead to progressive extracellular matrix accumulation and interstitial fibrosis.

In summary, CsA-induced interstitial fibrosis results from a combination of increased synthesis of matrix components, as well as decreased degradation of extracellular matrix. Angiotensin II and transforming growth factor-β1 may play a role in the process of increased collagen formation induced by CsA, whereas the TIMP-1 and the PAI-1 likely mediate the decreased degradation of extracellular matrix induced by CsA.

Studies on Lipid Peroxidation. It has been shown that in vitro incubation of rat renal microsomes or human liver microsomes with CsA induces dose-related lipid peroxidation.[518,519] Lipid peroxidation seems to be the main mechanism of free-radical toxicity.[520–522] Reactive oxygen species through a peroxidative process may increase the availability of arachidonate metabolites and enhance prostanoid production.[523–525] Recent in vivo studies in the rat indicated that cyclosporine nephrotoxicity is accompanied by dose-related systemic and renal lipid peroxidation,[526] preceding the fall in GFR.[527] Concurrent treatment with antioxidants (i.e., vitamin E,[526] melatonin,[528] or N-acetylcysteine[529]), suppressed CsA-induced lipid peroxidation and reduced functional and structural damage. The mechanism by which CsA-induced lipid peroxidation could contribute to cyclosporine nephrotoxicity is putative, including direct cellular toxicity,[530] thromboxane-mediated ischemia,[531] or peroxidation-linked excess extracellular matrix production.[532] Several reports suggest that calcineurin inhibitors, CsA and tacrolimus, have pro-oxidant activity and they increase the susceptibility of low density lipoprotein to oxidation in humans.[533–535]

Clinical Nephrotoxicity of Cyclosporin A

CsA can cause a wide spectrum of renal functional and morphologic impairments, including a marked and rapidly reversible decrease in GFR and renal plasma flow[359] and a chronic form of renal damage in patients treated for more than 6 months with a potential evolution to end-stage renal disease.[364,367] Thrombotic microangiopathy is another relatively uncommon but serious adverse effect of cyclosporine.[362,536]

Acute Renal Failure Induced by Cyclosporin A

Acute cyclosporine renal dysfunction is not infrequent in clinical practice and occurs not only in patients with kidney transplantation[355] but also in heart,[537] liver,[358] and bone marrow[356] transplant recipients. This acute form of nephrotoxicity may occur within weeks following initiation of CsA therapy and can also be observed after years of drug therapy.[538] The incidence of this acute renal injury can be enhanced by extended graft preservation,[361] preexistent renal histologic lesions,[539] donor hypotension, and perioperative complications.[540]

Acute cyclosporine nephrotoxicity has clinical features similar to those of acute renal allograft rejection, including an abrupt fall in GFR, impaired urinary concentrating capacity, and sodium retention.[541] Hypertension is observed in up to 50% of patients, whereas metabolic acidosis, hyperkalemia, and hyperuricemia are less frequent.[542] Characteristic of this syndrome of acute reversible renal dysfunction induced by CsA is the rapid recovery of renal function on reduction of the CsA dose.[359,543]

Delayed kidney graft function is a less frequent severe form of protracted ARF with oliguria induced by CsA.[541] Its incidence varies largely between centers,[544,545] presumably reflecting different strategies of immunosuppressive treatment or variations in time of ischemia of the kidney before transplantation.[546,547]

Although nephrotoxicity due to cyclosporine alone is rarely observed with CsA trough blood levels below 200 ng per mL,[380,548] blood level monitoring has proved unreliable in the differential diagnosis between acute cyclosporine nephrotoxicity and acute rejection of kidney allografts.[380]

The difficulty in differentiating acute rejection from cyclosporine nephrotoxicity in the setting of kidney transplantation often compels performance of a kidney biopsy.[549,550] On a histologic basis, cyclosporine nephrotoxicity is often a diagnosis of exclusion with the absence of definite signs of acute rejection, such as intimal arteritis[551,552] or intratubular lymphocytes.[553] Histologic features of cyclosporine nephrotoxicity are nonspecific and include arteriolar hyalinosis,[554,555] as well as isometric vacuolization of proximal tubular cells.[556]

Analogous to experimental data obtained in animal models, CsA causes a dose-related and time-related fall in GFR and renal plasma flow in humans induced by renal vasoconstriction.[557,558] In two studies, the intrarenal blood flow was significantly reduced after oral cyclosporine intake, but hypoperfusion could not be elicited by tacrolimus.[559,560] The beneficial effects of different calcium channel blockers on this CsA-induced renal hypoperfusion[561–566] suggest this vasoconstriction is mainly affected at the afferent arteriolar level because it has been demonstrated that calcium antagonists preferentially reduce glomerular afferent arteriolar tone.[567]

In contrast, coadministration of indomethacin unmasks CsA-induced renal vasoconstriction and potentiates cyclosporine nephrotoxicity by reducing the intrarenal prostaglandins.[568] This suggests a role for the eicosanoids in the CsA-induced vasoconstriction. Further arguments in favor of this possibility are the partial beneficial effects observed with a specific TxA_2 synthase inhibitor[471] and with dietary regimens with omega-3 polyunsaturated fatty acids.[569]

Although a role for increased vascular renin activity in cyclosporine-induced renal and peripheral vasoconstriction has been suggested,[570,571] investigators have never detected any significant preventive effect of ACE inhibition on the decline in renal blood flow and the increase in renal vascular resistance induced by CsA.

Unlike in animal models, prazosin did not significantly affect GFR, renal plasma flow, or renal vascular resistance in patients who had undergone transplant and were treated with CsA,[572] thus questioning the role of the sympathetic nervous system in cyclosporine nephrotoxicity.

Endothelin has been implicated as a causative agent in CsA-induced vasoconstriction (see "Experimental Nephrotoxicity of Cyclosporin A"). Although intrarenal injections of antiendothelin antibodies protected against the effects of cyclosporine,[474] administration of specific endothelin receptor antagonists has shown conflicting results.[479,573]

Chronic Cyclosporine Nephrotoxicity

The main clinical issue associated with CsA treatment is, however, the chronic nephrotoxicity[367] that is clinically defined by progressive renal dysfunction with hypertension. Histologic lesions can already appear after 6 months of CsA therapy,[364,574] with progression over time, even after CsA dose reduction.[371] As mentioned previously, chronic cyclosporine nephrotoxicity has been documented in other clinical settings besides kidney transplantation.[367–375] Chronic cyclosporine nephrotoxicity is related to the cumulative CsA dose[371,575] and may be irreversible even after CsA discontinuation.[576]

The clinical features of chronic cyclosporine nephrotoxicity are nonspecific, including a slowly progressive decline of renal function over months or years, severe arterial hypertension, mild proteinuria, and tubular dysfunction.[541] In renal allografts, differential diagnosis with chronic rejection is often impossible on clinical grounds alone, thus necessitating the performance of a kidney biopsy.[577]

The histopathologic lesions of chronic cyclosporine nephrotoxicity have been extensively studied and are now well known.[365,366,578,579] Histopathologic findings in 2-year protocol biopsies from a randomized study showed

comparable lesions in renal allografts under cyclosporine and tacrolimus treatment.[580] They include renal arteriolar damage (the so-called CsA-associated arteriolopathy), tubular atrophy, and (striped) interstitial fibrosis, as well as glomerular sclerosis. These lesions are nonspecific, however, except for the CsA-associated arteriolopathy.

The vascular lesions are located almost exclusively in the arterioles and arteries, with up to two layers of smooth muscle cells, and usually consist of circular nodular protein deposits or mucoid thickening of the intima, which contributes to narrowing or occlusion of the lumen.[365] CsA-associated arteriolopathy affects a limited number of arterioles in a dose-related manner.[579]

Tubulointerstitial changes may be nearly diffuse, but usually there are narrow stripes of atrophy and fibrosis, apparently corresponding to areas of cortex with afferent arteriolar lesions.[365] This interstitial fibrosis progresses over time.[371] Tubular atrophy is nearly always found in areas with interstitial fibrosis[581] and likewise progresses with time.[371] CsA-induced glomerulopathy consists of global or focal and segmental sclerosis.[366,582] Again, the number of affected glomeruli increase with time.[371]

Although the histologic features of chronic cyclosporine nephrotoxicity have been well characterized, the differential diagnosis with chronic rejection of the renal allograft in kidney transplantation still often remains difficult.[583]

A great matter of debate is whether prolonged therapy with CsA can result in progressive, irreversible renal damage, ultimately leading to end-stage renal disease. This was advocated by some authors[584,585] but denied by others.[572,586] Multicenter studies in renal transplant patients showed reduced but stable renal function after up to 3 to 5 years of CsA treatment.[587,588] Conversion from CsA to azathioprine in kidney transplant recipients after 3 months significantly improved the creatinine clearance at 5 years' posttransplantation.[589] In patients who have undergone pancreas transplant, a sequential functional and morphologic study has unequivocally shown the progressive character of the histologic lesions due to cyclosporine nephrotoxicity.[371] This was strongly correlated with CsA blood levels, CsA dose, and magnitude of the decline in creatinine clearance during the first posttransplant year.[371] Analysis of sequential protocol biopsies of renal allografts over a period of 10 years, in a prospective study of 120 kidney-pancreas transplant recipients, confirmed this progressive character of renal histologic lesions, induced by calcineurin inhibitors.[590] In this study, severe histologic damage was present in 58.4% of the renal allografts by 10 years.

Altogether, these data point out that chronic cyclosporine nephrotoxicity has a progressive and irreversible character once the histologic lesions have arisen. Assessment of the renal function, be it by means of serum creatinine or creatinine clearance, underestimates the magnitude of the problem due to the relatively low sensitivity of those methods and to the slow progression of the renal damage induced by cyclosporine.

The pathophysiology of chronic cyclosporine nephrotoxicity in humans is a matter of extensive investigation, mainly through experimental models (see "Pathophysiologic Studies of Cyclosporine Nephrotoxicity").

Hemolytic–Uremic-like Syndrome Induced by Cyclosporin A

Thrombotic microangiopathy is a relatively uncommon but serious adverse effect of cyclosporine in renal[362] and nonrenal[536] transplant recipients, with an overall 43% graft survival rate.[591,592] The most striking morphologic changes are an extensive thrombotic process in the renal microcirculation, with several glomerular capillaries occluded by thrombi extending from the afferent arterioles and containing platelet aggregates.[365] Laboratory anomalies include thrombocytopenia, hemolytic anemia, and deterioration of the renal function.[362] In the setting of kidney transplantation, the differential diagnosis of hemolytic–uremic syndrome and vascular rejection is not obvious.[591] According to a retrospective study of 29 patients with calcineurin-inhibitor induced thrombotic microangiopathy, repeated plasma-exchange induced a recovery of the renal allograft function in 80% of the patients.[593]

This hemolytic–uremic-like syndrome induced by CsA reinforces the concept that the vascular endothelium is the main target in this form of CsA toxicity. That CsA can damage vascular endothelium is confirmed by the high plasma concentration of factor VIII-related antigen, found in recipients of renal allograft given CsA and having clinical signs of nephrotoxicity.[594] Recent work shows significantly higher plasminogen-activator inhibitor levels in patients treated with CsA who underwent renal transplant, compared to patients who were not treated with CsA, suggesting a decreased fibrinolytic activity in the former patients.[595] This could account for the increased risk of hemolytic–uremic syndrome induced by CsA.

Pharmacogenetics of Calcineurin Inhibitors

With nephrotoxicity continuing to be a major factor in late kidney damage, it is important to understand better the mechanisms of drug-induced nephrotoxicity to develop therapeutic strategies and identify early biomarkers.[596] However, from a clinical point of view, none of these biologic pathways identified in experimental studies brought a clinical benefit for the patients, either in terms of early markers or in terms of therapeutic alternatives, including endothelin inhibitors or angiotensin receptor blockers.

Variability in calcineurin inhibitor (CNI) intestinal absorption and metabolism is attributed, at least in part, to the variability in expression and function of CYP3A enzymes (mainly 3A4 and 3A5) and the ATP dependent multidrug efflux transmembrane transporter P-glycoprotein (Pgp), a product of ABCB1 gene (previously MDR-1).

Pgp, a product of ABCB1 gene (previously MDR1), is a membrane protein that functions as an ATP-dependent

exporter of intracellular xenobiotics. In the kidney, Pgp is constitutively expressed on the brush border of proximal tubular cells and on the distal tubule. It has been suggested that Pgp is instrumental in CsA nephrotoxicity.[597] CsA is a substrate of Pgp, and variations in expression and/or function of Pgp could lead to accumulation of CsA, along with other cytotoxic agents, within the tubular cell.[598]

Already in 1998, Napoli et al. demonstrated a pharmacokinetic interaction between sirolimus CsA increasing the concentration of both immunosuppressive drugs in the renal tissue.[599] In clinical studies, it was noticed that sirolimus had no nephrotoxic effect; however, when used in combination with CsA, the nephrotoxic effect of CsA was potentiated.[600]

Anglicheau et al.[601] studied in vitro the role of P-glycoprotein (Pgp) in CsA cytotoxicity and the CsA-sirolimus interaction. Cyclosporine and sirolimus are Pgp substrates. The authors hypothesized that the Pgp activity level may affect cyclosporine cytotoxicity by interfering with the ability of Pgp to remove cyclosporine from within tubular cells, and that an interaction between cyclosporine and sirolimus on Pgp function may explain the enhancement of cyclosporine nephrotoxicity by sirolimus. Cyclosporine cytotoxicity was evaluated in primary cultures of normal human renal epithelial cells (HRECs) by cell viability and cytotoxicity assays. Verapamil, quinine, PSC833, and PGP-4008 were used as Pgp inhibitors. Rhodamine-123 (R-123), a fluorescent substrate of Pgp, was used to assess Pgp-mediated transport. Cyclosporine exerted a concentration-dependent cytotoxic effect on HRECs that was significantly increased by inhibition of Pgp activity. Sirolimus exerted an inhibitory effect on R-123 efflux in HRECs and increased cellular cyclosporine concentrations in a dose-dependent manner. These data demonstrate that Pgp plays a critical role in protecting renal epithelial cells from cyclosporine toxicity. The inhibitory effect of sirolimus on Pgp-mediated efflux and the cellular concentration of cyclosporine could explain the exacerbation of cyclosporine nephrotoxicity observed clinically.

Transcriptomic analyses of in vitro models of CNI nephrotoxicity have been used to identify two new molecular mechanisms that may play a role in early CNI-induced nephrotoxicity: EMT and endoplasmic reticulum (ER) stress. In vitro evidence that CsA induces EMT in proximal tubular epithelial cells has been provided. Potential mediators and downstream effectors of CsA-induced changes were identified by large-scale expression analysis using Affymetrix microarrays. PKC-β has been identified as a potentially important mediator, which may be responsible for CsA-induced TGF-β1 upregulation. In addition, the E2A transcription factors E12/E47 may play a key role in the altered expression profile of CsA-treated cells and, thus, cell phenotype.[602] These in vitro findings regarding EMT have been translated in vivo. De novo vimentin expression has been used as a marker of tubular mesenchymal transition in rats treated with CsA. Whereas tubular vimentin, a nonspecific marker of regeneration, is virtually absent from vehicle-treated rat kidneys, de novo expression is markedly increased in CsA-treated rat kidneys, together with a CsA-induced increase in collagen 3 and fibronectin mRNA expression, suggesting that CsA induces tubular expression of mesenchymal markers in vivo.[603] Whether CsA EMT is important to the increasingly recognized role of EMT in renal fibrosis needs further investigation using more specific tools indicating EMT.

Endoplasmic reticulum stress results from the accumulation of misfolded proteins within the ER. The relevance of the induction of ER stress by CsA was boosted by the finding that CsA exposure in vivo results in the upregulation of the ER stress marker BiP mRNA in renal allograft biopsies. In a rat model of CsA nephrotoxicity, Han et al. reported that a short-term treatment of CsA for 7 days activated the unfolded protein response, exemplified by the induction of BiP, and a proapoptotic response characterized by the upregulation of capsase 12 and CHOP.[604]

Recent progress in molecular biology and functional genetics like transcriptomics and whole genome studies will lead to the discovery of genes associated with kidney injury and the characterization of stress response pathways.

Summary

CsA is a potent immunosuppressive drug with nephrotoxic side effects. Independent of the intrinsic nephrotoxic properties of CsA, its complex clinical pharmacokinetic profile could cause incorrect dosing, ultimately resulting in irreversible renal damage.

The clinical nephrotoxicity of CsA consists of three entities with different expressions of renal damage induced by CsA (i.e., ARF, hemolytic–uremic-like syndrome, and chronic cyclosporine nephrotoxicity). The ARF is essentially reversible and mainly hemodynamically mediated through afferent arteriolar vasoconstriction. Dosage reduction of CsA reverses the nephrotoxic effects. The hemolytic–uremic-like syndrome consists of an extensive thrombotic process at the level of the glomerular capillaries, causing loss of kidney function in more than half of the cases. Chronic cyclosporine nephrotoxicity is an irreversible renal damage characterized by a specific arteriolopathy and striped interstitial fibrosis, resulting in slow progressive decline of renal function.

TACROLIMUS (FK506)

Tacrolimus (FK506) is a fungal product, a new macrolide immunosuppressant agent, which has shown important potential in transplantation and in the treatment of autoimmune diseases.[605–607] Although it is many times more potent than cyclosporine, allowing the use of lower doses, both drugs have similar nephrotoxic properties.[608,609]

Molecular Action

Cyclosporine and FK506 have dissimilar chemical structures (Fig. 31.5)—nevertheless, both agents bind to a similar class of ubiquitous intracellular receptors: immunophilins,

molecules that are cis–trans prolyl isomerases. These intracellular binding proteins are well conserved through evolution and change the confirmation of cyclosporine and FK506. The cytosolic receptor for FK506 (FKBP) has been well characterized.[610] This drug-immunophilin complex must bind to calcineurin, a calcium-dependent protein phosphatase, to allow the immunosuppressant actions of the drugs in lymphocytes (Fig. 31.6).[611,612] Similar calcineurin-mediated dephosphorylation of cyclosporine and FK506 may lead to inhibition of signal transduction in other cell types and organs, which mediates both the desirable immunosuppressant effects and the possibly toxic effects.

Cyclosporine and FK506 are powerful immunosuppressive drugs that inhibit the calcium–calmodulin-dependent phosphatase calcineurin in T cells, thereby preventing the activation of T cell-specific transcription factors such as NF-AT involved in lymphokine gene expression (Fig. 31.6). Although this may, at least in part, explain the mechanism of cyclosporine and FK506 immunosuppression, additional mechanisms have to be invoked to explain the pharmacologic properties and toxic effect of these drugs such as nephrotoxicity and neurotoxicity. Schwaninger and coworkers[613] studied the effect of cyclosporine and FK506 on calcineurin phosphatase activity and gene transcription mediated by the cyclic adenosine monophosphate-responsive element (CRE), a binding site of the ubiquitous transcription factor CREB. An imported gene was placed under the transcriptional control of the CRE of the rat glucagon gene and transiently transfected into the glucagon expressing cell line αTC2. Cyclosporine and FK506 inhibited depolarization-induced gene transcription in a concentration-dependent manner. Both cyclosporine and FK506 inhibited calcineurin phosphatase activity at the drug concentrations that inhibited gene transcription. The FK506 analog rapamycin had no effect on calcineurin activity and gene transcription, but excess concentrations of rapamycin prevented the effect of FK506 on both calcineurin activity and gene transcription. These results further support the notion that the interaction of drug-immunophilin complexes with calcineurin may be the molecular basis of cyclosporine- and FK506-induced inhibition of CREB/CRE-mediated gene transcription. The ability to interfere with CREB/CRE-mediated gene transcription represents a new mechanism of cyclosporine and FK506 action that may underlie pharmacologic effects and toxic manifestations of these potent immunosuppressive drugs.[613]

A recent report demonstrated that in vivo FK506 treatment eliminated antigen-stimulated T cells through DNA fragmentation (apoptosis), representing one of the mechanisms of immunologic tolerance.[614]

Experimental Studies

Cell Culture

McCauley and colleagues[615] demonstrated a cyclosporine- and FK506-mediated, dose-dependent inhibition of renal cell proliferation using LLC-PK1 cells (an established cell line derived from the pig proximal tubule) in culture. Although FK506 inhibited renal cell proliferation to a greater degree than cyclosporine at the same concentration, when clinically relevant concentrations were compared, FK506 was significantly less inhibitory than cyclosporine. Moutabarrik and associates[616] observed similar effects in the same cell line but could not make a clear distinction between the FK506 and the cyclosporine effects on release of 3H thymidine from prelabeled cells, N-acetyl-β-D-glucosaminidase release, and cell detachment. Ultrastructural changes such as vacuolization, swelling, and mitochondrial enlargement and inhibition of the growth of the cultured tubular cells were also observed at high concentrations of FK506 and cyclosporine. Low concentrations of FK506 and cyclosporine were not cytotoxic and induced only a minimal inhibitory effect on the growth of tubular cells in vitro. Cyclosporine and FK506 also induced a time-dependent stimulation of the secretion of endothelin by cultured tubular cells. The concentration of cyclosporine that induced these effects was 10 to 100 times higher than that required for FK506. The concentrations of FK506 and cyclosporine inducing endothelin secretion were not cytolytic for tubular cells in vitro. Yatscoff and coworkers[617] compare the effect of rapamycin and FK506 on the release of prostacyclin and endothelin in vitro using cultured rabbit mesangial and endothelial cells. The effects of both rapamycin and FK506 on the basal or stimulated release of prostacyclin or endothelin from mesangial cells and endothelial cells are similar with the following exceptions: Rapamycin results in a significant increase in the release of prostacyclin, whereas FK506 results in a significant decrease in the release of prostacyclin from the endothelial cells. Benigni and colleagues[618] review the vascular effects of FK506 as compared to cyclosporine in endothelial cell culture and intact organ. FK506, unlike cyclosporine, is without significant effect on thromboxane B_2, 6-ketoprostaglandin $F_1\alpha$, or endothelin release in bovine aortic endothelial cells grown in culture and does not alter the renal vascular resistance in vivo. These findings suggest that FK506 causes much less pronounced endothelial cell injury, at least in vitro.

Atcherson and Trifillis[619] examine in vitro cytotoxicity of FK506 on normal human proximal tubule cells. They find that FK506 is reversibly and mildly toxic to monolayers of human renal proximal tubule cells.

Edkins and associates[620] compare the effect of FK506 (2.5 mg per kg for 7 days) and cyclosporine (50 mg/kg/day) on renal and hepatic brain and cochlear-reduced glutathione content. Both cyclosporine and FK506 increase glutathione levels in kidney to approximately equivalent levels after 5 days of treatment. Only FK506 increases glutathione levels in liver, and neither drug changes levels in other tissues.

Shah and coworkers[621] show that FK506 exhibits a broad, powerful inhibitory effect on human hepatic microsomal cytochrome P-450-dependent drug metabolism. However, the full potential for drug interactions can only be determined by investigating its effects on other P-450 families using both in vivo and in vitro studies. On the other

hand, Yoshimura and coworkers[622] recently report that, in rats, both FK506 and rapamycin are without significant effects in contrast to cyclosporine on renal microsomal P-450- dependent drug metabolism.

Yoshimura and coworkers[623] review the effect of FK506 and rapamycin on renal P-450 systems in rat models. They find that although cyclosporine has a strong effect on renal P-450 systems and induces such a system in kidney cortex (microsomal P-450), FK506 and rapamycin have no substantial effect on the induction of renal P-450.

The role of intracellular calcium in the pathogenesis of cyclosporine nephrotoxicity has received great attention[624,625] and has resulted in therapeutic implications to prevent nephrotoxic effects of the drug. The effect of cyclosporine and FK506 on microsomes and mitochondria of rabbit renal cortex tissue has been studied by Prasad and associates.[626] Both drugs decrease calcium uptake and A23187-induced calcium release from microsomes and mitochondria in a dose-dependent manner (0.5 to 10.0 μg per mL). The effect of FK506 is significantly less at equivalent concentrations, and microsomal calcium-stimulated ATPase is not changed by either drug.

The potential role of the FK506 binding protein (FKBP12) in cellular calcium homeostasis has been suggested. Indeed, Jayaraman and colleagues[627] find that a 12-kd protein tightly bound to the calcium release channel in skeletal muscles of rabbit is FKBP12. Obviously, if this observation can be confirmed in vascular smooth muscle, it may explain the mechanism of FK506-induced vasoconstriction in renal vasculature. This process also is probably calcineurin-drug complex mediated. A further role of calcineurin in α-adrenergic stimulation of Na^+-K^+-ATPase activity in renal tubular cells is illustrated by Aperia and coworkers.[628] They demonstrate that FK506 inhibited Na^+-K^+-ATPase activity induced by oxymetazoline, an α-adrenergic agonist. This study may suggest a role for FK506-mediated renal nerve changes in sodium and potassium homeostasis. In this context, Palevsky and colleagues[629] report a resistance to the effect of aldosterone on renal cells in cultures exposed to FK506.

Animal Studies

Animal studies have shown both acute and chronic nephrotoxicity produced by FK506.[630] Somewhat different than cyclosporine, FK506 produces toxicity at blood levels that are clinically relevant; however, the doses necessary to achieve these blood levels on a weight basis are at least 10-fold larger than those used clinically. This contrasts with cyclosporine, with which acute and chronic nephrotoxicity can be produced with doses on a weight basis that are very close to those clinically used, particularly in the salt-depleted rat model; however, the blood levels achieved with these doses are at least three to four times those achieved clinically.[631]

Preclinical animal studies gave few hints of nephrotoxicity.[632] However, a troubling series of side effects soon appeared including vasculitis, myocardial necrosis, and severe weight loss. Fortunately, most of these side effects turned out to be species-specific. Nephrotoxicity of FK506 became apparent from the initial series of rescue patients treated with the drug.[633]

Several studies have documented reduction in effective renal plasma flow and GFR in animal models. Ueda and colleagues[634] have measured renal cortical blood flow, using a hydrogen ion clearance method, serum creatinine, and juxtaglomerular cell cross-sectional area in mice treated with FK506, 3 mg/kg/day given subcutaneously as compared with saline-treated control animals. Cortical blood flow is significantly reduced in FK506-treated animals as compared with control animals, as is juxtaglomerular cell area. Kumano and coworkers[635] also note a reduction in GFR and effective renal plasma flow using inulin and p-aminohippuric acid in a heminephrectomized rat model in response to an acute infusion of FK506 and after 21 days of treatment. Proximal tubular vacuolization typical of cyclosporine nephrotoxicity is noted, and diltiazem improves both the functional and morphologic changes caused by FK506. Lieberman and associates[613] note a significant volume reduction in both cyclosporine-treated and FK506-treated glomeruli that are inhibited by verapamil. Mitamura and colleagues[637] review the FK506-induced nephrotoxicity in spontaneous hypertensive rats. These results indicate that the acute nephrotoxicity of FK506 is derived from impaired glomerular function associated with renal arteriolar constriction brought about by the drug. All of these renal disorders induced by FK506 recover completely or partially when the drug is withdrawn for 2 or 4 weeks. Thus, the acute nephrotoxicity of FK506 in spontaneous hypertensive rats is reversible.

Ryffel and colleagues[638] explore the nephrotoxicity of immunosuppressants in rats. Specifically, they compare the nephrotoxic effects of FK506 and rapamycin with that of cyclosporine in male Wistar rats. FK506 causes proximal tubular epithelial changes consisting of atrophy, vacuolization, inclusion bodies, microcalcification, and focal mononuclear interstitial infiltrate as described for cyclosporine. The most striking alteration is hypertrophy of the juxtaglomerular apparatus. The percentage of renin-containing juxtaglomerular apparatus and the extent of renin immunoreactivity along afferent vessels are significantly increased in FK506-treated and CsA-treated rats. By contrast, no renal morphologic lesions are found in rapamycin-treated animals. Renal cortical extracts contain abundant cyclophilin and FK506-binding protein, the main intracytoplasmic receptors for cyclosporine and FK506, respectively. The authors hypothesize that both the immunosuppressive and toxic effects of FK506 and cyclosporine, but not of rapamycin, are mediated through an immunophilin–drug–calcineurin complex. The renal substrate of calcineurin, which mediates renal vasoconstriction, is yet to be identified.

Andoh and associates[639] also compare the acute rapamycin nephrotoxicity with cyclosporine and tacrolimus. They find that cyclosporine and FK506 strikingly decrease

urinary excretion of nitric oxide, renal blood flow, and GFR, whereas rapamycin does not. In contrast, all three of these drugs cause significant hypomagnesemia associated with inappropriately high fractional excretion of magnesium, suggesting renal magnesium wasting. In addition, with all three drugs there are lesions in the rat kidneys consisting of tubular collapse, vacuolization, and nephrocalcinosis. These researchers show that only the calcineurin inhibitors produce glomerular dysfunction in an acute experimental model of nephrotoxicity.

Of interest is the experiment of Hara and colleagues[640] that shows that FK506 is effective in the prevention of the development of rapid glomerular injury in rats with accelerated nephrotoxic serum glomerulonephritis.

Abnormalities in mineral metabolism are common complications of organ transplantation. The role of immunosuppressive agents in alteration of mineral metabolism is not clear. An animal study was conducted to investigate the effects of cyclosporine A (CsA), tacrolimus, and sirolimus on renal calcium, magnesium, and vitamin D metabolism.[641] CsA and tacrolimus induced a two- to threefold and 1.6- to 1.8-fold increase in urinary calcium and magnesium excretion, respectively, whereas rapamycin had no effects on calcium, but doubled the urinary magnesium excretion. CsA and tacrolimus, but not rapamycin, elevated serum 1,25(OH)(2) vitamin D without affecting the parathyroid hormone level. CsA and tacrolimus reduced mRNA abundance in TRPV5 (CsA: 64 ± 3% of control; tacrolimus: 50 ± 3%) calbindin-D28k (CsA: 62 ± 4%; tacrolimus: 43 ± 3%), and vitamin D receptor (CsA: 52 ± 3%; tacrolimus: 58 ± 2%, all $P < .05$). Rapamycin did not affect gene expression in any of studied proteins. The immunofluorescence staining study demonstrated a 50% reduction of TRPV5 and calbindin-D28k by CsA and tacrolimus. The suppression of VDR by calcineurin inhibitors is probably the underlying mechanism of renal calcium wasting. In spite of an increased 1,25(OH)(2) vitamin D level, the kidney is not able to reserve calcium, suggesting a role of vitamin D resistance that may be related to bone loss.

Clinical Studies

Since the initial reports on the use of tacrolimus in clinical transplantation by Starzl and Shapiro,[642,643] numerous large scale trials compared the efficacy and safety of tacrolimus and cyclosporine mainly in liver[644,645] and kidney[646–648] transplantation. According to five out of six of these large trials, renal function and the incidence of renal impairment were comparable in both treatment arms at 1 year posttransplantation. Similar results were reported in a long-term comparison of nephrotoxicity between tacrolimus and cyclosporine in pediatric heart transplant recipients.[649] In contrast, Ashan and coworkers reported a significantly better renal allograft function at 2 and 3 years under tacrolimus compared to cyclosporine, both in combination with steroids and mycophenolate mofetil.[648,650] However, graft survival at 2 and 3 years was comparable in both groups. In an intention-to-treat analysis, graft survival at 5 years was comparable between patients, initially randomized to tacrolimus or cyclosporine in the large U.S. multicenter trial.[646,651]

In a recent study, once daily administration of tacrolimus may be a good option, considering its nephrotoxic effects for kidney transplant patients. Indeed, the trough levels of tacrolimus showed a slight significant reduction after the conversion from the twice daily to the once daily extended release tacrolimus formulations. Serum creatinine and glomerular filtration rate showed a significant improvement without an association with the tacrolimus trough levels.[652]

Ekberg et al.[653] asked the question if in view of the most common immunosuppressive treatment in de novo renal transplantation being a triple regimen that includes tacrolimus, mycophenolate mofetil (MMF), and corticosteroids, and that may also include antibody induction. Whether nephrotoxicity is an issue with tacrolimus at the currently used dosages remains an open question. Data from three large, randomized, de novo renal transplantation studies (Symphony, Fixed Dose Concentration Controlled [FDCC], and OptiCept) that used variations of the triple regimen with respect to tacrolimus target levels, MMF dosing, and antibody induction were pooled. The analysis population consisted of 998 patients. On average, tacrolimus levels were in a range considered low (mean ± standard deviation 7.2 ± 2.54 ng per mL), and MMF dose was 1.5 ± 0.61 g per day. Lower tacrolimus levels and higher MMF doses were associated with significantly better renal function. There were other variables associated with renal function, most notably acute rejection, donor age, and delayed graft function. Subanalyses in each of the three studies gave a consistent picture. There was no overt difference in the effect sizes when patients with stage II (estimated glomerular filtration rate 60–89 mL per min) or stage III (30–59 mL per min) chronic kidney disease were assessed separately. Tacrolimus seems to have a moderate but consistent nephrotoxic effect even in modern efficient immunosuppressive regimens where it is used at lower doses than in previous years.

In all these large trials, the incidence of acute rejection was significantly lower in the tacrolimus treated patients, compared to the cyclosporine-treated patients. Similarly there was a different profile of adverse effects with higher incidence of posttransplant diabetes mellitus and neurotoxicity under tacrolimus, compared to a higher incidence of hypertension, hyperlipidemia, hirsutism, and gum hyperplasia in cyclosporine treated patients.

According to three studies, the intrarenal hemodynamics are less affected by tacrolimus compared to cyclosporine, with better preservation of the renal plasma flow.[559,560,654]

The histopathologic changes, induced by tacrolimus, in the (transplanted) kidney are entirely comparable to those induced by cyclosporine (i.e., arteriolar hyalinosis and striped interstitial fibrosis).[580,655–658] The intrarenal expression of TGF-β, collagen, fibronectin, MMP-2, TIMP-1, and osteopontin was assessed by RT-PCR, and proved to be similar in kidneys treated with either tacrolimus or cyclosporine.[659]

A recent study in children with liver transplantation investigated the influence of genetic polymorphisms in ABCBA on the incidence of nephrotoxicity and tacrolimus dosage requirements in pediatric patients following liver transplantation.[660] Haplotype analysis showed a significant association between T-T-T haplotypes and an increased incidence of nephrotoxicity at 6 months posttransplantation (haplotype-frequency = 52.9% in nephrotoxic patients vs. 29.4% in controls; P = .029). Furthermore, G2677→T and C3435→T polymorphisms and T-T-T haplotypes were significantly correlated with higher tacrolimus dose-adjusted predose concentrations at various time points examined long after drug initiation. The findings suggest that ABCB1 polymorphisms in the native intestine significantly influence tacrolimus dosage requirement in the stable phase after transplantation. In addition, ABCB1 polymorphisms in pediatric liver transplant recipients may predispose them to nephrotoxicity over the first year posttransplantation. Genotyping future transplant recipients for ABCB1 polymorphisms (G2677→T and C3535→T), therefore, could have the potential to individualize better tacrolimus immunosuppressive therapy and enhance drug safety.

In conclusion, the nephrotoxicity of tacrolimus is functionally and morphologically comparable to the nephrotoxicity of cyclosporine as well in recipients of a renal allograft, as in recipients of a solid nonrenal organ. However, there is evidence that tacrolimus is a more powerful immunosuppressive agent, with a different toxicity profile.

CNI nephrotoxicity was recognized in Cambridge in the late 1970s. The vasoconstrictor impact of CsA, and to a lesser extent tacrolimus, in both acute and chronic settings, results from a decrease in vasodilators and increase in vasconconstrictors whereas direct tubular toxicity results from blockade of mitochondrial permeability transition pores and inhibition of prolyl isomerase. It is thus apparent that we must revisit the data and again question the basis for chronic CNI nephrotoxicity in current clinical practice. This contribution to the debate will focus on the evidence that CNIs are nephrotoxic and that their impact needs to be limited if we are to improve long-term outcomes after transplantation, leaving others to promote the contrary perspective and perhaps also to reflect on the largely unproven impact of the steroid avoidance and other minimization strategies so prevalent today.[661]

MYCOPHENOLATE MOFETIL

MMF, the morpholinoethyl ester of mycophenolic acid (Fig. 31.5), has been developed as an immunosuppressant for prevention of rejection in renal transplantation. In vivo, MMF is deesterified to mycophenolic acid (the active immunosuppressive component), which is a potent and specific inhibitor of the synthesis of guanosine nucleotides and thus a selective suppressor of proliferation of both T and B lymphocytes. MMF, given alone or with corticosteroids or cyclosporine, lowers the frequency of acute rejection after allogeneic organ transplantation in animals.[662,663]

The immunosuppression of MMF appears to be additive with that of cyclosporine and tacrolimus, and MMF does not promote nephrotoxicity.[664] Initial studies indicated that MMF, in combination with cyclosporine and steroids, reduces the incidence of acute rejection in renal transplantation.[665–667]

The Mycophenolate Steroids Sparing (MYSS) study found that in renal transplant recipients who were on immunosuppressive therapy with the cyclosporine microemulsion Neoral, MMF was not better than azathioprine in preventing acute rejection at 21 months after transplantation and was 15 times more expensive. The MYSS Follow-up Study, an extension of MYSS, was aimed at comparing long-term outcome of 248 MYSS patients according to their original randomization to MMF (1 g twice daily) or azathioprine (75 to 100 mg per d). In kidney transplantation, the long-term risk/benefit profile of MMF and azathioprine therapy in combination with cyclosporine Neoral is similar. In view of the cost, standard immunosuppression regimens for kidney transplantation should perhaps include azathioprine rather than MMF.[668]

In the meantime, MMF has been used under several clinical conditions. In cardiac, liver, lung, and pancreas transplantation the use of MMF in association with reduced doses of cyclosporine has resulted in improved renal function and maintained immunosuppression.[669–672] In renal transplantation, Halloran and others[673] summarize the three multicenter trials that confirm, at 1-year posttransplant, MMF is effective in preventing acute renal allograft rejection.[665–667] Two studies address patients with chronic kidney graft dysfunction in whom MMF is introduced and cyclosporine exposure reduced.[674,675] The rationale is that the increased immunosuppressive potency of MMF would allow for a safe reduction of CsA doses. The conclusion from these two studies is that cyclosporine dose reduction in patients on MMF results in an improved graft function with no increased risk of rejection. It must be noted, however, that follow-up was short—less than 1 year—in both studies. In addition, whether MMF does better than azathioprine (AZA) in this setting remains an open question. Indeed, a similar improvement of chronic graft dysfunction is reported when AZA is introduced and cyclosporine doses reduced.[676]

Is there a role for MMF in the attempt to withdraw calcineurin inhibtors in patients with stable renal transplantation? Several randomized,[677–679] as well as nonrandomized,[690] clinical trials in renal transplantation examined the efficacy and safety of calcineurin inhibitors in patients with stable graft function under triple immunosuppressive regimen, consisting of prednisolone, cyclosporine or tacrolimus, and MMF. All these studies reported a significant improvement of the graft function, as well as lower blood pressure, and an improved lipid profile after CNI withdrawal. In contrast, the incidence of acute rejection was higher in the CNI withdrawal group, without any impact on graft survival. Therefore, these studies provide evidence that CNI withdrawal is achievable in renal transplant recipients with stable graft function. CNI withdrawal appears to improve graft function,

hypertension, and hyperlipidemia. However, caution should be paid to the increased incidence of acute rejection after CNI withdrawal, and the short term of follow-up, reported in these studies (6 to 32 months).Whether CNI withdrawal will result in improved graft survival is not yet known.

Because MMF has multiple immunosuppressive and anti-inflammatory modes of actions—including the inhibition of humoral and cellular immunity, antimutagenesis, reduction of mononuclear cell infiltration, and inhibition of vascular smooth muscle and mesangial cell proliferation—it is not surprising that the drug is now used in autoimmune-mediated renal disease.[681] Briggs and colleagues[682,683] report their limited experience in eight patients with different types of nephrotic-type glomerulonephritis and unsatisfactory response to steroids and cyclosporine. Controlled prospective studies are under way to clarify the potential advantages of MMF compared with other immunosuppressive agents in these disease entities.

In conclusion, MMF is a potent, nonnephrotoxic immunosuppressive drug, which significantly reduced the incidence of acute rejection under tripple immunosuppressive regimens with prednisolone and cyclosporine or tacrolimus. In addition, MMF appears to allow dose reduction or even withdrawal of CNI in renal transplant recipients with stable graft function, thereby avoiding the long-term nephrotoxicity, induced by calcineurin inhibtors. Because immunosuppressant-induced nephrotoxicity has been associated with significant financial costs, cyclosporine-sparing and FK506-sparing regimens should result in substantial savings in health care costs (Fig. 31.5).[684] It is important to emphasize here that there are no long-term data for these experimental regimens, but they offer a new direction if these short-term results are confirmed over a more sufficient period of time.

RAPAMYCIN

Rapamycin (sirolimus/SRL) is a macrocyclic fermentation product of Streptomyces hygroscopicus, and was first isolated in 1975.[685] SRL has a similar molecular structure to FK506 and also binds to FKBP12.[686] However, the SRL-FKBP12 complex does not affect the calcineurin phosphatase, but instead binds to a protein, called the mammalian target of rapamycin (mTOR).[687] This binding of the SRL-FKBP12 complex to mTOR inhibits both DNA and protein synthesis, resulting in arrest of the cell cycle in late G1, as it progresses to the S phase.[688]

SRL blocks T-cell proliferation, induced by cytokines, alloantigens, and mitogens in a dose-dependent manner.[689] In addition, SRL acts on B-cells, causing an inhibition of antigen and cytokine driven B-cell proliferation.[690] In vitro studies have demonstrated the synergistic immunosuppressive interaction of CsA and SRL,[691] in contrast to the combination of FK506 and SRL, which produced an antagonistic effect at low doses.[692] Animal studies have confirmed the immunosuppressive potential of SRL,[693] as well as its synergistic interaction with CsA.[694] In contrast to the in vitro studies, FK506 interacted synergistically with SRL in animal studies.[695]

Treatment with CsA or FK alone significantly decreased KLOTHO expression and increased urinary 8-hydroxy-2′-deoxyguanosine (8-OHdG) excretion compared with vehicle treatment but sirolimus treatment did not. Treatment SRL+CsA or SRL+FK further decreased KLOTHO expression and increased urinary 8-OHdG excretion compared with treatment of CsA or FK alone. There was a strong correlation between KLOTHO expression and urinary 8-OHdG excretion ($r = -0.893$; $P < .001$). Treatment of CsA or FK alone increased renal ectopic calcification and serum intact parathyroid hormone level and decreased renal FGF23 expression compared with VH treatment ($P < .05$) but SRL treatment did not. Treatment with SRL+CNI aggravated these parameters compared with CNI alone. Sirolimus accelerates the calcineurin inhibitor-induced oxidative process by down-regulating the renal antioxidant KLOTHO expression in the kidney.[696]

Clinical Efficacy of Sirolimus in Renal Transplantation

Based on the results from several multicenter, prospective, randomized trials—including studies based in the United States, globally, a combined European-United States, and two in Europe—SRL was approved in 1999 by the U.S. Food and Drug Administration (FDA) for the prevention of acute rejection in renal transplant recipients. SRL was used in combination with CsA and prednisolone in these studies, and reduced the incidence of acute rejection at 1 year to 10%.[697]

Three prospective, randomized trials in renal transplant recipients compared CsA to SRL in combination with prednisolone and azathioprine or mycophenolate mofetil.[698–700] All these trials showed a comparable incidence of acute rejection in both treatment arms and, more importantly, a superior graft function at 1 year in the SRL-treated patients. In one study, graft function remained significantly better at 3 years in the SRL-treated patients.[701] In addition, the incidence of normal histology in protocol biopsies at 2 years was significantly higher in SRL-treated patients, compared to CsA-treated patients (66.6% vs. 20.8%).[701] These results from three trials provide evidence that avoidance of the long-term nephrotoxicity, induced by calcineurin inhibitors, is achievable in renal transplant recipients.

Several randomized trials in renal transplantation investigated the feasibility and the outcome of early calcineurin inhibitor withdrawal, in triple regimens with SRL and prednisolone.[702–705] Overall, patient and graft survival, as well as the incidence of acute rejection at 1 year, were comparable in both treatment arms (CsA+SRL+ P vs. SRL+P). In contrast, graft function was superior, and the incidence of hypertension was reduced in the patients weaned from CsA. Similarly, the incidence of chronic allograft nephropathy was significantly lower in protocol biopsies at 1 year from patients on SRL+P alone.[705] Again, these data provide strong

evidence that early witdrawal of calcineurin-inhibitors can safely be achieved in renal transplant recipients under SRL, and may avoid long-term nephrotoxicity.

In a recent study of Heilman and colleagues, it was concluded that conversion from tacrolimus-MMF to sirolimus-MMF at 1 month posttransplant in kidney recipients on rapid steroid withdrawal is poorly tolerated and does not improve GFR at 1 year.[706]

The use of SRL in organ transplantation is still a matter of debate as demonstrated by recent pro and contra back-to-back publications.[707] Sirolimus therapy is burdened by a concerning safety profile including high risk of delayed graft function and onset of proteinuria. In addition, several other side effects such as dyslipidemia, diabetes, myelosuppression, delayed wound-healing, infertility, ovarian cysts, and mouth ulcers further limit its use.[708]

A feature of increasing importance is that the mTOR pathway is central for vital aspects of tumor development, including angiogenesis and cell growth; rapamycin, therefore, has anticancer activities, which may prove critical in the fight against high cancer rates in transplant recipients.[707]

Large trials showed that SRL therapy is associated with an increased risk of acute rejections and worse graft function as compared with cyclosporine or tacrolimus.[709] Boosting memory T-cell response by mTOR inhibitor therapy might help induce long-lasting protective immune memory against bacterial or viral pathogens strong enough to prevent their replication,[710] especially in transplant recipients and other immunosuppressed patients with autoimmune disorders. Conversion to mTOR inhibitors may represent a valuable option in those cases with persistent infection resistant to antiviral therapy.[711,712]

A recent intriguing observation[713] adds to the interest of this molecule. Inoki et al. have shown that activity of mTOR complex 1 (mTORC1), a kinase that senses nutrient availability, was enhanced in the podocytes of diabetic animals. Further, podocyte-specific mTORC1 activation induced by ablation of an upstream negative regulator (PcKOTsc1) recapitulated many DN features, including podocyte loss, glomerular basement membrane thickening, mesangial expansion, and proteinuria in nondiabetic young and adult mice. Abnormal mTORC1 activation caused mislocalization of slit diaphragm proteins and induced an epithelial-mesenchymal transition-like phenotypic switch with enhanced ER stress in podocytes. Conversely, reduction of ER stress with a chemical chaperone significantly protected against both the podocyte phenotypic switch and podocyte loss in PcKOTsc1 mice. Finally, genetic reduction of podocyte-specific mTORC1 in diabetic animals suppressed the development of DN. These results indicate that mTORC1 activation in podocytes is a critical event in inducing DN and suggest that reduction of podocyte mTORC1 activity is a potential therapeutic strategy to prevent DN.

One may suggest that no renal transplant patient should receive de novo SRL therapy and that the use of SRL should be restricted to very selected patients, such as those with posttransplant malignancies or, probably, treatment-resistant viral infection. In such patients, the risk/benefit profile of SRL therapy should be carefully considered on a case-by-case basis. On the other hand, in subjects with stable kidney function and no evidence of treatment-related side effects, there is no reason to stop mTOR inhibitor therapy.

Nephrotoxicity of Sirolimus

Studies in pigs and rats have shown that sirolimus has no deleterious effects on GFR or renal blood flow, and caused minimal morphologic signs of toxicity.[714,715] Sirolimus reduced medullary concentrating ability and increased tubular enzymuria in rat kidneys, suggesting that mild tubular injury may occur.[716] In a salt-depleted rat model of CsA toxicity, the combination of CsA with SRL produced a functional and morphologic deterioration.[717]

In clinical studies in renal transplant recipients, sirolimus proved to be an effective immunosuppressive drug, devoid of intrinsic nephrotoxicity (see "Clinical Efficacy of Sirolimus in Renal Transplantation"). However, sirolimus may prolong delayed graft function in renal transplant recipients.[718] In addition, thrombotic microangiopathy has been described under the combination of sirolimus and tacrolimus, after intestinal transplantation.[719] Of concern are the reports on de novo proteinuria, occurring after conversion from a calcineurin inhibitor to sirolimus in renal transplant recipients.[720] Although the exact mechanism for the development of this proteinuria is currently putative, the increased intraglomerular pressure, resulting from the withdrawal of the intrarenal vasoconstriction, induced by CNIs, could be one reasonable explanation.

Recent evidence of a high incidence of proteinuria among de novo sirolimus-based regimens has been reported among renal transplant patients at short-term follow-up. Proteinuria has become a recognized, serious event (5 years incidence of 29%–38%) of primarily sirolimus-treated renal transplants patients, which is most probably of glomerular origin. It has been shown that proteinuria exerts a bad prognostic effect on graft function and subsequent graft survival at 5-year follow-up.[721]

The mechanisms underlying the development of proteinuria in renal transplant recipients converted from calcineurin inhibitors to sirolimus are still unknown. The data suggest that sirolimus-induced proteinuria in humans may be a dose-dependent effect of the drug on key podocyte structures.[722]

In a recent single center experience[723] and confirmed by many other observations, mTORi sirolimus and everolimus associated–pneumonitis is not a rare disease. Pneumonitis is not apparently dependent on the drug dose or the blood levels. Discontinuation of mTORi seems to be the safest treatment option to avoid pulmonary fibrosis or a fatal outcome.

New-onset diabetes after transplantation (NODAT) is a multifactorial, complex metabolic disorder associated with impaired long-term graft function, reduced recipient survival, and increased risks of cardiovascular disease and

infectious complications. Neither calcineurin inhibitor nor SRL or steroids seems to be innocent of contributing to it. Immunosuppressants account for 74% of the occurrence of NODAT. Among modifiable risk factors, obesity is independent and significant, with great prevalence in the population. In additional to lifestyle modifications, the role of bariatric surgery (BS) either before or after transplantation is highlighted herein as a strategy to reduce disease in the view of the results among overweight, nontransplanted patients.[724] Because of the strong association between high glucose values in the early posttransplant period and the development of NODAT, the condition must be recognized early after (or even before) transplantation by intensive screening. Patients at risk for NODAT must modify appropriate risk factors and particularly undergo pretransplant planning and/or posttransplant adjustment individualizing immunosuppressive therapy to mitigate the risk of this serious complication.

CHAPTER

32 Nephrotoxicity of Nonsteroidal Anti-inflammatory Agents, Analgesics, and Inhibitors of the Renin-Angiotensin System

Biff F. Palmer

NEPHROTOXICITY OF NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are some of the most widely used therapeutic agents in clinical practice today. Although the gastrointestinal toxicity of these medications is well known, it has become increasingly apparent that the kidney is also an important target for untoward clinical events. The renal toxicity associated with the use of NSAIDs can be divided into one of several distinct clinical syndromes. These include a form of vasomotor acute renal failure, nephrotic syndrome associated with interstitial nephritis, chronic renal injury, and abnormalities in sodium, water, and potassium homeostasis. The common link in these syndromes is a disruption in prostaglandin metabolism, the class of compounds whose synthesis is inhibited by these agents.

PROSTAGLANDIN BIOSYNTHESIS AND COMPARTMENTALIZATION

Prostaglandins are members of a class of compounds termed eicosanoids. Eicosanoids are biologically active fatty acids that are all derived from the oxygenation of arachidonic acid. The particular enzyme involved in the oxygenation process dictates which class of eicosanoid will be synthesized. Oxygenation of arachidonic acid by the enzyme cyclooxygenase is responsible for prostaglandin and thromboxane synthesis (Fig. 32.1). The enzyme lipoxygenase converts arachidonic acid to leukotrienes, lipoxins, and eventually, to hydro fatty acid derivatives such as hydroxyeicosatetraenoic acid (HETE). Finally, oxygenation by the cytochrome P-450 system generates epoxyeicosatrienoic acids (EETs).

The availability of free arachidonic acid is the rate-limiting step in eicosanoid biosynthesis. Normally, arachidonic acid is found esterified to membrane phospholipids, where it undergoes deacylation primarily under the influence of phospholipase A_2. Phospholipase A_2–mediated arachidonic acid release is a calcium-calmodulin–dependent step that is stimulated by vasopressin, bradykinin, angiotensin, and norepinephrine.[1] Once released, free arachidonic acid is either re-esterified back into membrane lipids or is converted into one of the biologically active eicosanoids.

The first step in the synthesis of prostaglandins and thromboxanes is a cyclooxygenase reaction in which arachidonic acid is converted into the cyclic endoperoxide prostaglandin G_2 (PGG_2). PGG_2 then undergoes a peroxidase reaction to form a second endoperoxide called PGH_2, which is accompanied by the formation of a superoxide radical. Both of these reactions are catalyzed by the enzyme cyclooxygenase (COX), also known as prostaglandin endoperoxide H synthase.[2,3] The cyclooxygenase and peroxidase reactions occur on distinct but neighboring sites on the COX enzyme. Once formed, PGH_2 has a short half-life and is rapidly acted on by a series of enzymes that produce biologically active prostaglandins or thromboxane. Prostacyclin synthase acts to form prostacyclin (PGI_2), thromboxane synthase forms thromboxane A_2, and isomerases are responsible for the formation of PGE_2, PGD_2, and $PGF_{2\alpha}$.

Prostaglandins are synthesized on demand and exert physiologic effects in discrete microenvironments along the nephron in close proximity to their points of synthesis (Table 32.1). Due to the virtual absence of distant effects, these compounds are best regarded as autacoids rather than hormones. Variations in the synthetic and degradative machinery along the length of the nephron account for the differing types and amounts of prostaglandins found in any given segment.[4] PGI_2 is the most abundant prostaglandin produced in the cortex and is primarily synthesized in cortical arterioles and glomeruli.[5] This location corresponds to the known effects of PGI_2 in regulating renal vascular tone, the glomerular filtration rate (GFR), and renin release. PGE_2 and thromboxane A_2 are also produced in the glomerulus and therefore may exert effects at this site.

The most abundant prostaglandin found in the tubules is PGE_2.[5] The cortical and especially the medullary portion of the collecting duct are the dominant sites of PGE_2 synthesis. Lesser amounts are found in the thin descending

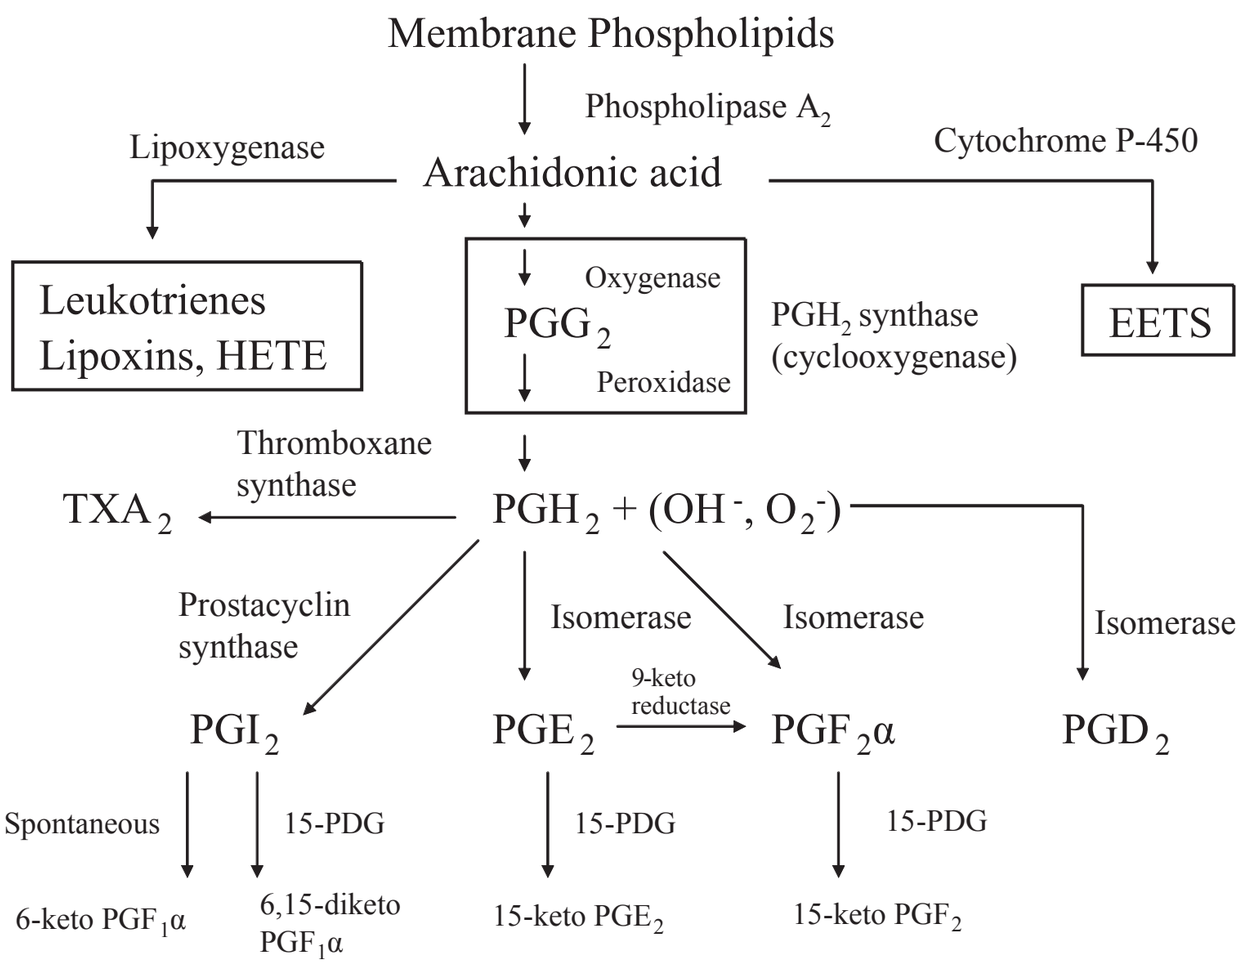

FIGURE 32.1 Synthetic and degradative pathways for the different types of eicosanoids. 15-*PDG*, 15 prostaglandin dehydrogenase; *EETs*, epoxyeicosatrienoic acids; *HETE*, hydroxyeicosatetraenoic acid; *TXA_2*, thromboxane A_2.

and thick ascending limb with the least amount of synthesis found in the proximal tubule. Medullary interstitial cells are also a rich source of PGE_2 production. This distribution provides the anatomic basis for PGE_2 to modulate sodium and chloride transport in the Henle loop, regulate arginine vasopressin-mediated water transport, and control vasa recta blood flow. $PGF_{2\alpha}$ is synthesized primarily by medullary interstitial cells and less by the papillary collecting tubule and glomeruli. Prostaglandin-degradative enzymes are found in both the cortex and medulla but are most abundant in the cortex. Except for PGI_2, which undergoes spontaneous hydrolysis to 6-keto-$PGF_{2\alpha}$, prostaglandins are rapidly metabolized into inactive products by a 15-prostaglandin dehydrogenase. An increased concentration of this enzyme in the proximal nephron may facilitate the degradation of prostaglandins delivered to the proximal tubule by glomerular filtration.[6]

32.1 Compartmentalization and Function of Renal Prostaglandins

Site	Eicosanoid	Action
Arterioles	PGI_2, PGE_2	Vasodilation
Glomeruli	$PGI_2 > PGE_2$ (human)	Maintain GFR
	$PGE_2 > PGI_2$ (rat)	Vasoconstriction
	TXA_2	
Tubules	PGE_2, $PGF_{2\alpha}$	Enhance NaCl and water excretion
Interstitial cells	PGE_2	Enhance NaCl and water excretion, influences regional blood flow
Juxtaglomerular apparatus	PGI_2, PGE_2	Stimulate renin release

PGI, prostaglandin I; PGE, prostaglandin E; PGF, prostaglandin F; TXA, thromboxane A; GFR, glomerular filtration rate.

BIOLOGIC ACTIONS OF PROSTAGLANDINS IN THE KIDNEY

Under baseline euvolemic conditions, prostaglandin synthesis is negligible, and as a result, these compounds play little to no role in the minute-to-minute maintenance of renal function. However, a major role occurs in the setting of a systemic or intrarenal circulatory disturbance. This interaction is best illustrated when examining the renal function under conditions of volume depletion (Fig. 32.2). In this setting, renal blood flow is decreased while sodium reabsorption, renin release, and urinary concentrating ability are increased. To a large extent, these findings are mediated by the effects of increased circulating levels of angiotensin II (AII), arginine vasopressin (AVP), and catecholamines. At the same time, these hormones stimulate the synthesis of renal prostaglandins, which in turn act to dilate the renal vasculature, inhibit salt and water reabsorption, and further stimulate renin release. Prostaglandin release under these conditions serves to dampen and counterbalance the physiologic effects of the hormones that elicit their production. As a result, renal function is maintained near normal levels despite the systemic circulation being clamped down. Predictably, the inhibition of prostaglandin synthesis will lead to unopposed activity

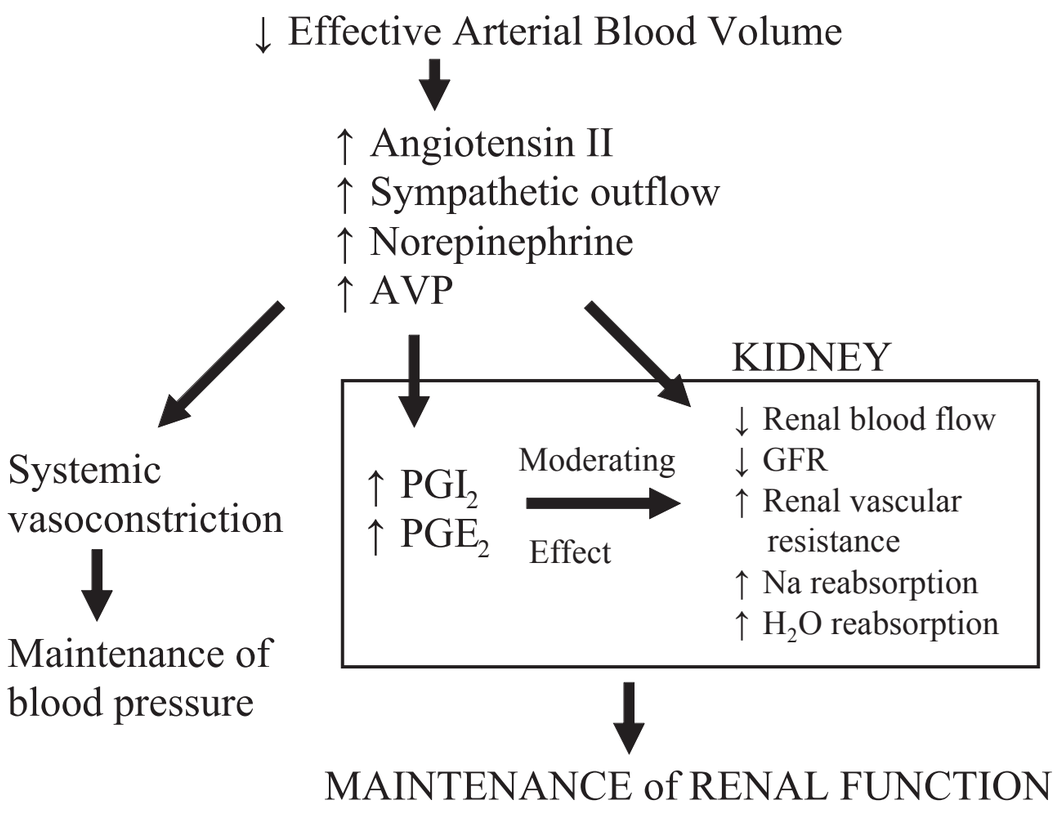

FIGURE 32.2 In the setting of absolute or effective volume depletion, a number of effectors are activated that serve to defend the circulation and, at the same time, stimulate the synthesis of renal prostaglandins. In turn, renal prostaglandins function to moderate the effects of these hormonal systems such that renal function is maintained in the setting of systemic vasoconstriction. *AVP*, arginine vasopressin; *GFR*, glomerular filtration rate.

of these hormonal systems, resulting in exaggerated renal vasoconstriction and magnified antinatriuretic and antidiuretic effects. In fact, many of the renal syndromes that are associated with the use of NSAIDs can be explained by the predictions of this model.

EEXPRESSION AND REGULATION OF CYCLOOXYGENASE-1 AND -2 IN THE KIDNEY

Aspirin and other NSAIDs exert their prostaglandin-inhibitory effects by inhibiting the COX enzyme. The COX enzyme exists as two isoforms termed COX-1 and COX-2. These enzymes are encoded by two different genes and differ significantly in their regulation. The COX-1 enzyme is constitutively expressed in most tissues and is responsible for producing prostaglandins involved in maintaining normal tissue homeostasis. The COX-2 enzyme is principally an inducible enzyme rapidly upregulated in response to a variety of stimuli such as growth factors and cytokines typically found in the setting of inflammation.[3] With the discovery of COX-2, a great deal of effort was put forth to develop compounds to selectively block the activity of this isoform without affecting the activity of COX-1. The availability of a COX-2–specific inhibitor would provide a therapeutic tool to inhibit the synthesis of arachidonic acid metabolites at sites of inflammation and yet leave unperturbed COX-1–derived prostanoids involved in normal homeostasis. In this manner the analgesic, anti-inflammatory, and antipyretic effects of an NSAID could be obtained with minimal to no side effects. Although the initial experience with specific COX-2 inhibitors has been associated with a reduction in gastrointestinal complications, this paradigm is not applicable to the kidney.

COX-1 and COX-2 are both constitutively expressed in the kidney. COX-1 is localized to mesangial cells, arteriolar endothelial cells, parietal epithelial cells of the Bowman capsule, and throughout the cortical and medullary collecting duct.[7] COX-2 is primarily expressed in the macula densa and the adjacent cells in the cortical thick ascending limb with lesser amounts in the podocytes and the arteriolar smooth muscle cells.[8–9] COX-2 is also abundantly expressed in interstitial cells in the inner medulla and the papilla.

The expression of COX-2 in different regions of the kidney varies in response to alterations in intravascular volume. This variation is particularly evident in the macula densa, where studies show COX-2 plays an important stimulatory role in the release of renin via the tubuloglomerular feedback mechanism. Under conditions of low renal perfusion when the chloride concentration at the level of the macula densa is low, renin release is inhibited by a COX-2 selective inhibitor but unaffected by a COX-1 inhibitor.[10] In genetically engineered mice lacking COX-2, there is a failure of renin release in response to a low salt diet, whereas renin release is intact in animals lacking COX-1.[11,12]

Stimulation of renin with the subsequent formation of angiotensin II is part of a feedback loop because angiotensin II exerts an inhibitory effect on COX-2 synthesis in the macula densa via the angiotensin type 1 (AT_1) receptor.[13] In contrast to effects at the macula densa angiotensin II upregulates COX-2 and prostaglandin synthesis in vascular smooth muscle cells and mesangial cells.[14] This latter effect provides a mechanism for COX-2 to both facilitate the tubuloglomerular feedback response to low salt delivery to the macula densa by increasing angiotensin II levels and preserve the glomerular filtration rate through the generation of vasodilatory prostaglandins to antagonize the vasoconstrictive effect of angiotensin II.[15]

The expression of COX-2 is also responsive to changes in volume. COX-2 expression decreases with salt depletion and increases with a high salt diet and dehydration.[9] COX-2–derived prostaglandins may play an important role in facilitating a natriuretic response to salt loading and may help protect against volume overload. The increase in COX-2 in response to dehydration is thought to provide a cytoprotective effect in the setting of hypertonic stress.[16,17] Treatment of water-deprived animals with a selective COX-2 inhibitor is associated with apoptotic patches of renal medullary interstitial cells. By contrast, no such changes are seen in animals treated with the inhibitor alone or in animals undergoing water deprivation without pharmacologic treatment.

In summary, COX-2 is constitutively expressed in the kidney and is highly regulated in response to physiologic perturbations in intravascular volume. The majority of experimental and clinical studies to date suggest that the specific COX-2 inhibitors may not offer any distinct advantage

over traditional NSAIDs with regard to renal toxicity. In fact, most of the renal syndromes that have been linked to nonselective COX inhibitors have now been described with the selective COX-2 inhibitors. The only exception is the development of chronic kidney disease and papillary necrosis. The failure to link COX-2 inhibitors use to these complications is not surprising because these agents have only been available for clinical use for a relatively short time. As with traditional NSAIDs, the COX-2 inhibitors need to be used cautiously and require close monitoring of renal function in patients at high risk for adverse renal outcomes.

EFFECTS OF PROSTAGLANDINS ON THE RENAL CIRCULATION

Prostaglandins primarily exert a vasodilatory effect on the renal vasculature. This vasodilatory effect alters the renal circulation in two major ways. First, these compounds influence the distribution of renal blood flow to different regions of the kidney. Prostaglandin stimulation results in a preferential increase in blood flow to the more juxtamedullary nephrons.[18,19] By contrast, the inhibition of prostaglandin synthesis results in a selective reduction of flow to the inner cortical nephrons while flow remains well preserved in the outer cortex.[20] Second, prostaglandins exert a vasoregulatory effect on the renal microcirculation to include the interlobular, afferent, and efferent arterioles as well as the glomerular mesangium. In isolated renal arterioles, both PGE_2 and PGI_2 attenuate AII-induced and norepinephrine-induced afferent arteriolar vasoconstriction. On the efferent side of the circulation, PGI_2 similarly antagonizes AII-induced and norepinephrine-induced vasoconstriction, but PGE_2 is without effect.[21] In addition to local production, vascular reactivity of the efferent arteriole appears to be influenced by prostaglandins produced in the upstream glomerulus. In this regard, Arima and associates[22] find that the orthograde infusion of AII (afferent arteriole-glomerulus-efferent arteriole) results in less vasoconstriction of the efferent arteriole as compared to when infused in a retrograde fashion (efferent arteriole-glomerulus-afferent arteriole). Pretreatment with indomethacin markedly increases the vasoconstrictive effect during an orthograde infusion but is without effect during the retrograde infusion.

Prostaglandins have also been shown to attenuate mesangial cell contraction induced by AII, endothelin, AVP, and platelet-activating factor.[23,24] Contraction of these cells will normally cause a decrease in the total glomerular capillary surface area and result in a fall in the GFR. Mesangial cell synthesis and the release of PGI_2 in humans and PGE_2 in rats dampen the constrictor effects of these hormones such that the glomerular capillary surface area is maintained, thereby minimizing any fall in GFR. Thus, in the setting of enhanced hormonal constrictor activity, prostaglandins play a major role in maintaining glomerular hemodynamics by exerting a vasodilatory effect at the level of the afferent and efferent arteriole as well as within the glomerular mesangium.

RENAL SYNDROMES ASSOCIATED WITH NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Vasomotor-Induced Acute Renal Failure

Prostaglandins appear to play a negligible role in the maintenance of renal function under normal circumstances. This conclusion is based on studies in both experimental animals as well as humans. In conscious, sodium-replete dogs and rats, the inhibition of renal prostaglandin synthesis with a variety of NSAIDs does not alter baseline renal blood flow or GFR.[25,26] Similarly, renal hemodynamics are unaffected in healthy humans after both the short-term[27,28] and the long-term administration of aspirin.[29] In related studies, the administration of indomethacin to healthy volunteers was also found to produce no change in renal hemodynamics.[30]

A sharply different effect of COX inhibition is observed when systemic hemodynamics are compromised. Under conditions of circulatory distress, renal blood flow represents a balance between vasoconstrictor influences on the one hand and vasodilatory prostaglandins on the other. Predictably, the administration of NSAIDs in this setting will shift this balance toward unopposed vasoconstriction and will potentially result in a precipitous decline in renal function.

This interplay between vasoconstrictive effectors and vasodilatory prostaglandins is particularly well illustrated in a series of studies using a model of hemorrhage in dogs.[31,32] In animals subjected to a hemorrhage, prostaglandin synthesis inhibition was associated with a marked reduction in renal blood flow as compared to prostaglandin-intact dogs. This renal ischemic response was found to be partly reversed after the infusion of an AII antagonist or after renal denervation. When renal denervation was combined with the AII antagonist, renal blood flow was restored to values comparable to that in the nonprostaglandin-inhibited animals. These findings illustrate the pivotal role that prostaglandins play in opposing the renal ischemic effects of AII and renal nerves.

The modulating effect of vasodilatory prostaglandins on renal hemodynamics can be expected to roughly parallel the extent to which vasoconstrictor effectors are activated. In turn, the activity of these effectors will reflect the degree of circulatory distress. With only mild perturbations in the circulation, one can begin to detect a discernible effect of prostaglandins on renal blood flow. For example, unlike subjects ingesting an ad lib sodium diet, normal subjects placed on a salt-restricted diet will demonstrate a modest fall in creatinine clearance and renal blood flow following the administration of aspirin or indomethacin.[33,34]

Diuretic therapy is a common clinical situation where NSAIDs may exert a deleterious effect on renal function in otherwise healthy subjects.[35] Like sodium restriction, diuretics

increase the dependence of renal blood flow and GFR on vasodilatory prostaglandins and potentiate the deleterious effects of prostaglandin inhibition with COX inhibitors. The degree to which renal function is disturbed, however, appears to vary depending on which diuretic–NSAID combination is used. In this regard, Favre and colleagues[35] found that the combination of triamterene and indomethacin given to healthy subjects results in a marked decline in creatinine clearance. By contrast, only a mild decrease in creatinine clearance is found when indomethacin is given in combination with furosemide, hydrochlorothiazide, or spironolactone. Interestingly, triamterene is the only diuretic associated with a marked increase in urinary prostaglandin secretion. Although there is little evidence to suggest that the renal failure patients in this study were volume-depleted, it appears that triamterene, by some unknown mechanism, renders the renal circulation critically dependent on vasodilatory prostaglandins. As a result, triamterene in combination with an NSAID should only be used with extreme caution.

As alterations in the circulation become more pronounced, rendering the renal circulation more dependent on vasodilatory prostaglandins, COX inhibition can be expected to result in more profound changes in renal hemodynamics. In congestive heart failure, a decrease in effective arterial circulatory volume is the proximate cause for activation of neurohumoral vasoconstrictor forces that participate in the maintenance of systemic arterial pressure and result in increased total peripheral vascular resistance. Important to note, the rise in renal vascular resistance is less than that seen in the periphery. Vasodilatory prostaglandins function in a counterregulatory role, attenuating the fall in renal blood flow and GFR that would otherwise occur if vasoconstrictor forces were left unopposed.[36]

Cirrhosis is another clinical condition in which the integrity of the renal circulation can become critically dependent on vasodilatory renal prostaglandins. Cirrhotic patients with a low urinary sodium concentration tend to be the most susceptible to develop acute decrements in renal function following the administration of NSAIDs.[37] These patients have a more marked decrease in effective arterial circulatory volume, primarily due to splanchnic vasodilation, which in turn leads to higher levels of circulating catechols, AII, and AVP.[38,39] As a result, the renal circulation in this subset of patients is more critically dependent on the effect of vasodilatory prostaglandins. As seen in patients with congestive heart failure, these patients have high urinary concentrations of PGE_2, which decline in parallel with the fall in GFR.[37]

Renal prostaglandins may play an important role in the maintenance of renal hemodynamics in nephrotic syndrome. GFR and filtration fraction are moderately decreased in most patients with the nephrotic syndrome.[40,41] Micropuncture studies in an experimental model of the nephrotic syndrome have indicated that the relative preservation of renal plasma flow may serve an important role in attenuating the fall in GFR that would otherwise occur due to a reduction in the ultrafiltration coefficient.[42] In this setting, locally produced vasodilatory prostaglandins may serve to reduce afferent arteriolar resistance, thereby increasing renal plasma flow and increasing filtration pressure.[43,44] The administration of NSAIDs in this setting would lead to increased afferent arteriolar tone. The resulting fall in renal plasma flow and filtration pressure combined with the already decreased ultrafiltration coefficient would result in a dramatic fall in GFR.[43] Indeed, the administration of prostaglandin synthesis inhibitors to nephrotic subjects is commonly associated with a fall in GFR and may precipitate acute renal failure in some patients.[45] Other settings in which there is an increased vasoconstrictive input focused on the kidney rendering it particularly vulnerable to the deleterious effects of NSAIDs include endotoxic shock[46] and anesthesia.[47]

Risk factors for the development of NSAID-induced acute kidney injury are not necessarily confined to conditions characterized by decreases in absolute or effective arterial circulatory volume (Table 32.2). One such example is the presence of underlying chronic kidney disease. In this setting, increased vasodilatory prostaglandins are thought to play an adaptive role in minimizing the decline in global renal function by increasing GFR in surviving nephrons through increased renal blood flow. The signal for increased prostaglandin production is generally not a disturbance in the systemic circulation leading to increased circulating levels of AII and catecholamines but rather intrarenal mechanisms leading to the generation of vasoactive compounds within the glomerular microcirculation.[48]

32.2 Risk Factors for NSAID-Induced Acute Vasomotor Renal Failure

Decreased EABV	Normal or ↑ EABV
Congestive heart failure	Chronic renal failure
Cirrhosis	Glomerulonephritis
Nephrotic syndrome	Elderly
Sepsis	Contrast-induced nephropathy
Hemorrhage	Obstructive uropathy
Diuretic therapy	Cyclosporin A
Postoperative patients with "third space" fluid	
Volume depletion/ hypotension	

EABV, effective arterial blood volume.

32.3 Predisposing Factors for NSAID-Induced Nephrotoxicity in the Elderly

Age-related changes in renal function
↓ in glomerular filtration rate ↓ in renal blood flow ↑ in renal vascular resistance
Age-related changes in pharmacokinetics
↑ free drug concentration - Hypoalbuminemia - Retained metabolites ↓ total body water ↓ hepatic metabolism resulting in longer drug half-life

Increasing age is a risk factor for the development of nephrotoxicity when using NSAIDs.[49,50] This susceptibility, in part, may be related to changes in kidney function that normally accompany the aging process (Table 32.3).[51] Aging is associated with a progressive decline in the GFR and total renal blood flow. In addition, there is an increase in renal vascular resistance. Important to note, the renal vasculature becomes less responsive to vasodilators, whereas the response to vasoconstrictors remains intact. In an analysis of 1,908 patients treated with ibuprofen, renal impairment was found to occur in 343 (18%) patients.[49] The two most important risk factors identified for the development of toxicity is an age greater than 65 years and preexisting renal insufficiency. In a prospective study of 114 older patients (mean age 87 years) started on NSAID therapy, a greater than 50% increase in the serum urea nitrogen concentration was found in 15 (13%) patients.[50] In this study, the concurrent use of a loop diuretic and large doses of NSAIDs were found to be predictive of those who developed significant azotemia.

In addition to age-related changes in kidney function, age-related changes in the pharmacokinetics of NSAIDs may also make this population more susceptible to renal toxicity.[52,53] Older patients, particularly those with chronic illness, often have lower albumin levels, which reduce the protein binding of the drugs and result in higher free-drug concentrations. This binding of the parent compound to circulating albumin is further impaired by retained metabolites, which accumulate as a result of the normal age-related impairment in renal function. Increased drug levels also occur as a result of the age-related decrease in total body water. Finally, decreased hepatic metabolism, which is often present in older adults, contributes to a longer half-life of the parent compound and can result in unexpectedly high drug levels.

Other conditions in which effective arterial circulatory volume is normal or increased and yet renal function is critically dependent on increased synthesis of prostaglandins include immune mediated glomerular injury, urinary obstruction,[54] radiocontrast-induced injury,[55] and the administration of calcineurin inhibitors.[56] In these conditions, the increased production of vasodilatory prostaglandins has been shown to counterbalance the effects of intrarenally generated vasoconstrictors such as thromboxane, leukotrienes, platelet-activating factor, and endothelin. The administration of NSAIDs in each of these settings can be expected to result in an exaggerated fall in renal function.

NSAID-induced acute kidney injury is most commonly an oliguric form of renal failure that begins within several days after the initiation of the drug (Table 32.4). The urinalysis is unremarkable in the majority of cases. Unlike other causes of acute kidney injury, the fractional excretion of sodium is often less than 1%. This low fractional excretion of sodium reflects the underlying hemodynamic nature of the renal failure. Hyperkalemia out of proportion to the decrement in renal function is also a typical feature of this lesion. If recognized early, the renal failure is reversible with the discontinuation of the NSAID. As a result, dialysis is usually not required.

Glomerular and Interstitial Disease

The use of NSAIDs can be associated with the development of a distinct syndrome characterized by the development of interstitial nephritis and nephrotic range proteinuria. The incidence of this lesion is unknown but is thought to be rare. One estimate for fenoprofen-induced interstitial nephritis was 1 case per 5,300 patient-years of treatment.[57] Although virtually all NSAIDs have been reported to cause this syndrome, the vast majority of cases have been reported in association with the use of propionic acid derivatives (fenoprofen, ibuprofen, and naproxen). Of these, fenoprofen has been implicated in greater than 60% of cases.[58] Interstitial nephritis with and without nephrotic syndrome has also been reported with the COX-2 inhibitors, rofecoxib and celecoxib.[59–63]

Unlike hemodynamically mediated ARF, there are no clear-cut risk factors that serve to identify those at risk for

32.4 Clinical Features of NSAID-Induced Vasomotor Renal Failure

• Oliguria
• Usually occurs within a few days of beginning medicine
• Hyperkalemia out of proportion to renal failure
• Low fractional excretion of Na
• Usually does not require dialysis
• Usually reversible

the development of this syndrome. The mean age of patients is 65 years.[58] The presence of an underlying renal disease prior to the exposure of the NSAID has been notably absent. This syndrome has generally been referred to as an example of acute interstitial nephritis. There are, however, a number of features that distinguish this form of interstitial renal disease from that observed with other pharmacologic agents (Table 32.5).[58] First, the average duration of exposure prior to the onset of the disease is typically measured in months and can be as long as a year. By contrast, allergic interstitial nephritis due to other drugs usually presents within several days to weeks after exposure to the drug. Second, nephrotic range proteinuria is found in >90% of cases of NSAID-induced interstitial disease, a degree of proteinuria that is distinctly uncommon in acute allergic interstitial nephritis due to other drugs. Third, symptoms of hypersensitivity that are commonly seen in acute allergic interstitial nephritis such as rash, fever, arthralgias, or peripheral eosinophilia are uncommon in NSAID-associated disease. Fourth, the vast majority of cases associated with NSAIDs have been reported in older patients. On the other hand, allergic interstitial nephritis is seen in all age groups.

Renal biopsy findings typically show a diffuse or focal lymphocytic infiltrate. The number of eosinophils in the infiltrate is variable but generally is not marked. The glomerular changes are most commonly those seen in minimal change disease. In particular, the glomeruli are normal by light microscopy, whereas fusion of the podocytes is seen with electron microscopy. In some cases there is evidence of glomerulosclerosis. Because most patients who develop this syndrome are older, this latter finding may simply represent the normal age-related increase in glomerulosclerosis. Immunofluorescent studies are typically nonspecific. There has been an occasional report of weak and variable staining for immunoglobulin G and C_3 along the tubular basement membrane. Electron microscopy typically shows a diffuse fusion of the podocytes in cases with heavy proteinuria. Mesangial, electron-dense deposits have been observed only rarely, suggesting that this is not an immune-mediated disease.

32.5 Clinical Characteristics of NSAID-Induced Tubulointerstitial Nephritis (TIN) Versus Typical Drug-Induced TIN

Characteristic	NSAID-Induced TIN	Typical Drug-Induced TIN
Duration of exposure	5 days to >1 year	5–26 days
Hypersensitivity symptoms	7%–8%	80%
Eosinophilia	17%–18%	75%–80%
Proteinuria >3.5 gms/24 hours	>90%	<10%
Eosinophiluria	0%–5%	80%–85%
Peak serum creatinine	1.5– >10 mg%	1.5– >10 mg%

Although the combination of interstitial nephritis and nephrotic syndrome is the most common clinical manifestation, a second presentation is the development of nephrotic syndrome without evidence of interstitial renal disease.[64] Once again, the glomerular histology is typical of minimal change disease, although a few patients have been described with changes typical of membranous glomerulopathy.[59,65] It is likely that the pathophysiologic mechanism that underlies the development of glomerular disease in the absence of interstitial disease is similar, if not identical, to the more common finding of combined nephrotic proteinuria and interstitial nephritis.

A third presentation that has uncommonly been reported is the development of interstitial nephritis without nephrotic proteinuria.[66,67] The onset of disease following the initiation of drug therapy tends to be much shorter and, in this respect, resembles the more common form of drug-induced allergic interstitial nephritis. In addition, these patients are more likely to exhibit a systemic hypersensitivity reaction. Given the closer temporal relationship between the administration of the offending NSAID and the development of renal insufficiency, one may confuse this latter presentation with that of NSAID-induced vasomotor ARF. Symptoms of hypersensitivity as well as histopathologic changes typical of interstitial renal disease should allow one to distinguish this lesion from hemodynamically mediated ARF.

Finally, NSAID toxicity may present as an exacerbation of an underlying disease. In a case report of a patient with systemic lupus erythematosus, the development of interstitial nephritis and nephrotic syndrome after the administration of naproxen clinically appeared as a rapidly progressive lupus glomerulonephritis.[68]

The clinical course of patients who present in any one of these manners is to develop a spontaneous remission after the removal of the offending NSAID. The time until resolution is variable but can range from a few days to several weeks. In some patients, the degree of renal insufficiency can be severe enough that dialytic support is required. Steroid therapy has been used in many of the reported cases; however, the efficacy and necessity of this therapy are unknown. It should be noted that relapses have been reported after inadvertent exposure to the same NSAID or after exposure to a different NSAID.[69]

Renal Sodium Retention

Sodium retention is a characteristic feature of virtually all NSAIDs, occurring in as many as 25% of patients who use them. The physiologic basis of this effect is directly related to

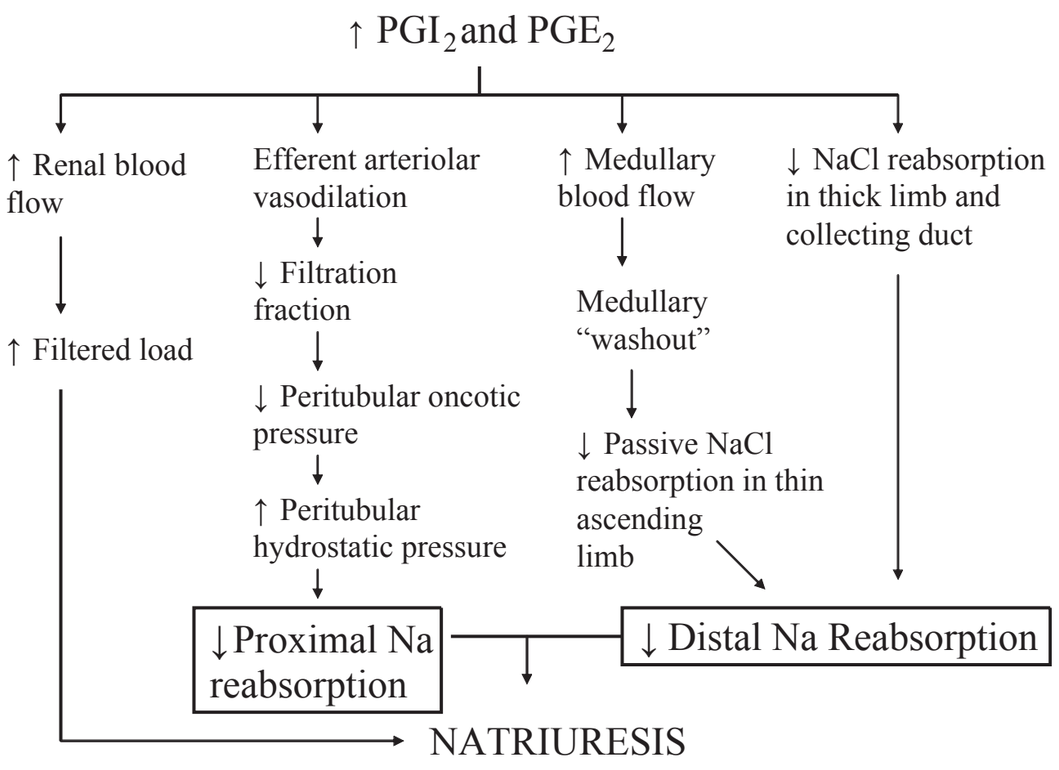

FIGURE 32.3 The direct and indirect mechanisms by which renal prostaglandins exert a natriuretic effect.

the natriuretic properties of prostaglandins. Prostaglandins increase urinary sodium excretion by both indirect and direct mechanisms (Fig. 32.3). Through their activity as renal vasodilators, prostaglandins may cause an increase in the filtered load of sodium. In addition, these compounds preferentially shunt blood flow to the inner cortical and medullary regions of the kidney.[19–21] As a result of increased medullary blood flow, there is a fall in the medullary interstitial solute concentration. Processes that reduce the degree of medullary hypertonicity lead to a concomitant reduction in the osmotic withdrawal of water from the normally sodium-impermeable thin descending limb of Henle. This in turn decreases the sodium concentration of fluid at the hairpin turn. The net effect is less passive reabsorption of sodium across the normally water-impermeable thin ascending limb of Henle. Consistent with this mechanism, the infusion of PGE_1 lowers and the prostaglandin synthesis inhibition raises sodium chloride and total solute concentration in the medulla.[70]

Finally, prostaglandins can affect sodium reabsorption in the proximal tubule by virtue of their ability to influence the tone of the efferent arteriole. Changes in the tone of this vessel play a central role in determining the Starling forces that govern fluid reabsorption in this nephron segment. Increased resistance of this vessel, as that which occurs in the setting of high concentrations of AII, leads to a decrease in the downstream peritubular hydrostatic pressure. In addition, efferent constriction increases the filtration fraction by reducing glomerular plasma flow and increasing the upstream glomerular pressure. The increased filtration fraction leads to an increase in the peritubular oncotic pressure. A decrease in hydrostatic pressure and the increase in oncotic pressure in the peritubular vessel favor fluid reabsorption in the proximal tubule. By modulating the degree to which the efferent arteriole is constricted and thus altering peritubular Starling forces acting on the proximal tubule, prostaglandins can decrease proximal tubular sodium reabsorption. Predictably, in a model of high circulating levels of AII induced by suprarenal aortic constriction, the inhibition of prostaglandin synthesis was found to increase efferent arteriole oncotic pressure and decrease peritubular hydrostatic pressure, resulting in a significant increase in proximal fluid reabsorption.[71]

In addition to these hemodynamically mediated changes in renal sodium handling, prostaglandins have direct effects on tubular sodium transport. In the isolated perfused tubule, PGE_2 has been shown to inhibit sodium transport in the cortical and outer medullary collecting duct.[72,73] Using the same technique, PGE_2 has also been shown to decrease chloride transport in the thick ascending limb of Henle.[74] In vivo studies also support a direct inhibitory effect of prostaglandins on the sodium transport in the loop of Henle, the distal nephron, and the collecting duct.[75,76] The mechanism of this direct inhibitory effect is unclear but may involve decreased activity of the Na^+-K^+-ATPase pump.[77] Prostaglandins have also been shown to mediate the natriuretic response to increased renal interstitial hydrostatic pressure that occurs during renal interstitial volume expansion.[78,79] In addition, these compounds play a permissive role in the sodium excretion that follows volume expansion and an increase in renal perfusion pressure.[80]

It would at first seem paradoxical that under conditions of volume depletion the kidney would elaborate a compound that would have further natriuretic properties. The role of prostaglandins in this setting, however, is to moderate the avid salt retention that would otherwise occur in the setting of unopposed activation of the renin–angiotensin–aldosterone and adrenergic systems. By virtue of their natriuretic properties, prostaglandins play a role in ensuring adequate delivery of filtrate to more distal nephron segments under conditions in which distal delivery is threatened (e.g., renal ischemia, hypovolemia). In addition, diminished NaCl reabsorption in the thick ascending limb of Henle reduces the energy requirements of this segment. This reduction in thick ascending limb workload in conjunction with a prostaglandin-mediated reallocation in renal blood flow helps to maintain an adequate oxygen tension in the medulla under conditions that would otherwise have resulted in substantial hypoxic injury.[81,82]

NSAIDs are thought to cause salt retention primarily by inhibiting prostaglandin synthesis and therefore disrupting the foregoing mechanisms. The extent to which salt retention becomes clinically manifest depends on the degree of baseline prostaglandin production. In normal healthy humans, baseline prostaglandin production is minimal. As a result, NSAID-induced positive sodium balance is transient and usually of no clinical importance. By contrast, NSAID administration in clinical conditions such as congestive heart failure, cirrhosis, or nephrotic syndrome can result in marked sodium retention and potentially adverse clinical consequences.

In addition to causing sodium retention, NSAIDs have been shown to attenuate the natriuretic effect of diuretics.[83] The mechanism of this resistance is multifactorial. The natriuretic effects of loop diuretics have, in part, been linked to

the ability of these drugs to increase renal blood flow, an effect mediated by the stimulation of vasodilatory prostaglandins.[84,85] By inhibiting prostaglandin synthesis, NSAIDs limit sodium excretion by preventing the increase in renal blood flow normally seen after the administration of the diuretic.[85] In addition to this hemodynamic effect, micropuncture and microperfusion studies have shown that prostaglandin inhibition also blunts the effect of furosemide at the level of the thick ascending limb of Henle.[86,87] This latter effect may be related to the inhibition of furosemide-induced stimulation of natriuretic prostaglandins that act within this tubular segment. Finally, NSAIDs may limit the diuretic response to loop diuretics by competing for tubular secretion, thereby limiting the delivery of the drug to the luminal surface of the thick ascending limb.

Indomethacin has also been shown to attenuate the diuretic response to hydrochlorothiazide.[88] The mechanism of this interaction may result from enhanced salt absorption in the loop of Henle, which would then limit the delivery of chloride to the site of the thiazide action in the distal nephron. A similar explanation may underlie the resistance that has been described with NSAIDs and spironolactone.[89]

Sodium Balance and Hypertension

In considering the natriuretic and vasodilatory properties of prostaglandins, it is not surprising that the administration of NSAIDs has been shown to interfere with blood pressure control. In pooled studies, the administration of NSAIDs has been associated with an average increase in blood pressure of between 5 and 10 mm Hg.[90,91] Of the various subgroups examined, this effect is most pronounced in patients who are already hypertensive and much less so in those who are normotensive. Of the hypertensive patients, those treated with β-blockers seem to be the most vulnerable to the hypertensive effect of NSAIDs.[91] In this regard, it is particularly interesting to note that propranolol has been shown to increase prostacyclin formation.[92] There is less of an interaction with diuretics and angiotensin-converting enzyme inhibitors, whereas no effect is seen with calcium channel blockers.

Subgroup analysis shows that patients with low renin hypertension (older adults and blacks) are at higher risk for worsening hypertension in association with NSAID use. Older hypertensive patients have reduced urinary PGE_2 excretion when compared to younger hypertensive patients.[93] The pathogenesis of NSAID-induced hypertension is not known with certainty. In a recent meta-analysis, NSAIDs were found to not alter body weight or urinary sodium excretion significantly, implying that mechanisms other than salt retention were responsible for the increased blood pressure.[91] In this regard, elimination of the vasodilator prostacyclin from the resistance blood vessels is believed to play some role in the development of hypertension in individuals at risk.[93,94]

The use of COX-2 inhibitors is complicated by the development of peripheral edema with a frequency similar to that seen with traditional NSAIDs. In addition, the majority of data suggest no difference between the various COX-2 inhibitors and the tendency to develop increased blood pressure.[95]

Potassium Metabolism

The use of NSAIDs has been associated with the development of hyperkalemia in the setting of chronic kidney disease as well as with normal renal function.[96,97] The physiologic basis for this effect is inhibition of prostaglandin-mediated renin release with the subsequent development of hypoaldosteronism. Both in vivo and in vitro studies have shown a direct stimulatory effect of prostaglandins (primarily PGI_2 and PGE_2) on renin release from the juxtaglomerular cells.[98,99] Clinical studies in salt-restricted subjects have shown the COX-2 selective inhibitors reduced urinary potassium excretion to a similar extent as traditional NSAIDs. Both celecoxib and rofecoxib have been reported to cause significant hyperkalemia in case reports. These findings are consistent with COX-2 in the macula densa playing an important role in stimulating renin release.

In addition to direct effects, these compounds play an essential intermediary role in those pathways that are of primary importance in the regulation of renin release. In particular, renin release stimulated by both decreased perfusion pressure and decreased delivery of filtrate to the macula densa is dependent on an intact cyclooxygenase system.[100] By contrast, β-adrenergic stimulation of renin release can occur independently of prostaglandin synthesis.[101]

NSAID-induced suppression of renin release with the subsequent development of a hyporenin–hypoaldosterone state is thought to be the primary mechanism of hyperkalemia. Decreased renin release leads to decreased circulating levels of angiotensin I, which in turn results in low levels of AII. Because AII normally stimulates aldosterone release from the zona glomerulosa cells in the adrenal gland, serum aldosterone levels fall. In addition to low circulating levels, the effect of any given level of AII on aldosterone release is impaired because prostaglandins have been shown to play an intermediary role in this stimulatory effect.[102] Low circulating levels of AII further contribute to the development of hypoaldosteronism because adequate levels of AII are required for the stimulatory effect of hyperkalemia on aldosterone release at the level of the adrenal gland.[103] In addition to interfering with the renin–angiotensin–aldosterone cascade, NSAIDs favor positive potassium balance in other ways. As discussed earlier, the inhibition of prostaglandin synthesis is associated with increased sodium reabsorption in the loop of Henle and thus decreased distal delivery. A reduction in sodium delivery to the aldosterone-sensitive cortical collecting tubule is a known factor impairing potassium excretion. In addition, tubular flow rates are an important determinant of potassium excretion. Because NSAIDs increase the hydroosmotic effect of AVP, flow rates can fall, further impairing potassium excretion. Finally, decreased synthesis of prostaglandins may have effects of decreasing potassium secretion at the level of the potassium channel.[104]

The development of hyperkalemia in patients receiving an NSAID is most likely to occur in the setting of renal insufficiency or those with baseline abnormalities in the renin–angiotensin–aldosterone system.[98] Diabetic patients are at risk due to the increased incidence of hyporeninemic hypoaldosteronism that occurs in this patient population.[105,106] Similarly, older adults are at higher risk by virtue of the normal age-related decrease in circulating renin and aldosterone levels. Particular caution should be used when NSAIDs are combined with other pharmacologic agents known to interfere with the renin–angiotensin–aldosterone cascade.[107] Examples would include β-blockers, calcineurin inhibitors, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, heparin, ketoconazole, high-dose trimethoprim, and potassium-sparing diuretics.

Water Metabolism

Prostaglandins have important modulatory effects on renal water metabolism. Their primary effect is to impair the ability to maximally concentrate the urine. In doing so, two processes that are central in the elaboration of concentrated urine are interfered with; namely, the generation of a hypertonic interstitium and maximal collecting duct water permeability. The decrease in interstitial hypertonicity is due to a washout effect that results from the ability of prostaglandins to shunt blood flow to the inner cortical and medullary regions of the kidney. In addition, prostaglandins decrease sodium absorption in the thick ascending limb and decrease AVP-induced urea permeability in the medullary collecting duct. The decreased accumulation of sodium and urea in the interstitium further reduces the interstitial osmolality. The impairment in the collecting duct water permeability is the result of prostaglandins opposing the hydro-osmotic effect of AVP.[108] Interesting to note, AVP is known to stimulate PGE_2 synthesis in collecting duct cells; by doing so, AVP induces its own antagonist. This interaction is another example in which prostaglandins exert a moderating effect on an effector mechanism that elicited their synthesis. In this case, prostaglandins play an important role in minimizing the water retention that would otherwise occur if the activity of AVP was unopposed. By opposing the vasoconstrictive action of AVP, prostaglandins also contribute to the maintenance of glomerular perfusion and filtration.

Based on the foregoing discussion, the administration of NSAIDs would predictably impair solute-free water excretion by increasing the hydro-osmotic effect of any given level of circulating AVP and increasing the degree of interstitial hypertonicity (Fig. 32.4). In most circumstances, however, hyponatremia is not associated with the use of NSAIDs. Under normal conditions, any decrease in serum osmolality would be sensed in the hypothalamus and result in the inhibition of AVP release. As a consequence, excess solute-free water would be promptly excreted, restoring the serum osmolality back to normal. On the other hand, the administration of NSAIDs in the setting of nonsuppressible AVP release may result in dramatic falls in the serum sodium concentration. Patients at risk for this complication would include those with high circulating levels of AVP driven by a decreased effective arterial circulatory volume such as congestive heart failure or cirrhosis.[109] Patients with syndrome of inappropriate antidiuretic hormone secretion (SIADH) or those taking medications capable of stimulating AVP secretion or impairing urinary dilution by other mechanisms are also at risk for the development of hyponatremia.[47]

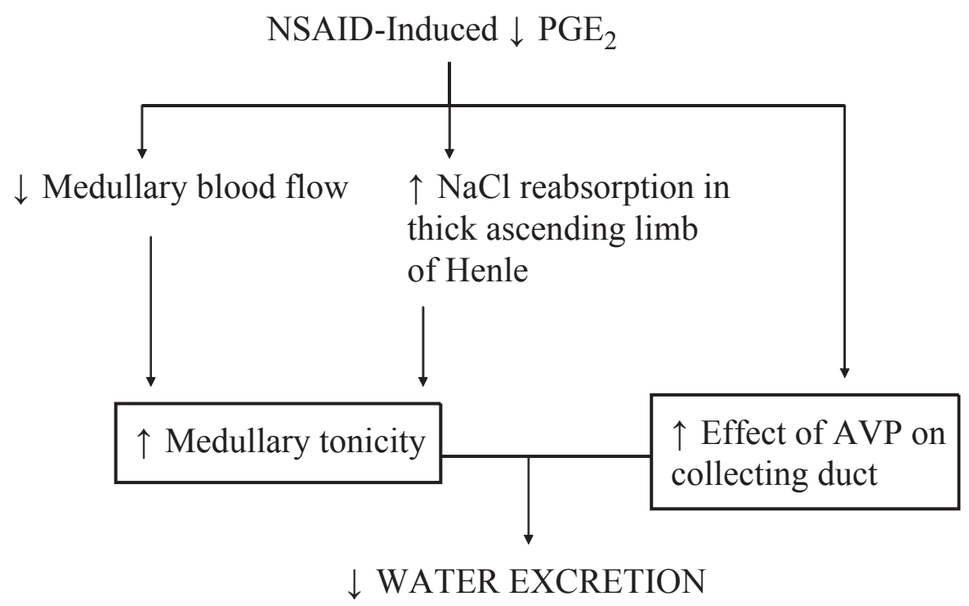

FIGURE 32.4 The mechanisms by which nonsteroidal anti-inflammatory drugs lead to decreased renal water excretion. *AVP*, arginine vasopressin.

In this regard, a recent study examined the effects of ibuprofen and a thiazide diuretic on renal water handling in otherwise healthy young and older volunteers subjected to a water load.[110] Three days of hydrochlorothiazide (100 mg per day) was found to impair both solute-free water clearance and the ability to elaborate a maximally dilute urine. A delay in the recovery of serum osmolality was noted in both the young and older subjects but to a significantly greater extent in the older subjects. When the young subjects were then given a water load after treatment with ibuprofen together with the thiazide, solute-free water clearance and serum osmolality were reduced further and to a degree similar to that seen in the older subjects on the thiazide regimen alone. It was postulated that the susceptibility to thiazide-induced hyponatremia known to occur in some elderly patients may, in part, be related to lower renal prostaglandin production. It can be expected that a greater number of older patients will be taking a combination of NSAIDs and hydrochlorothiazide given the efficacy of thiazide diuretics in the treatment of systolic hypertension.

NONSTEROIDAL ANTI-INFLAMMATORY DRUG-INDUCED CHRONIC KIDNEY DISEASE AND ANALGESIC NEPHROPATHY

The most common form of drug-induced chronic kidney disease is analgesic nephropathy. This lesion has most commonly been linked to the chronic ingestion of compound analgesics containing aspirin, phenacetin, and caffeine.[111]

A still unresolved question is whether long-term use of NSAIDs alone can similarly result in a progressive and irreversible form of chronic kidney disease. In this regard, a number of observations have emerged that would appear to substantiate the belief that long-term use of NSAIDs can lead to a chronic form of renal injury. Furthermore, the clinical characteristics of NSAID-induced chronic kidney disease are sufficiently different from those in analgesic nephropathy to suggest that this is a distinct clinical entity. Before reviewing the data linking chronic NSAID use and renal insufficiency, a brief description of analgesic nephropathy will be provided.

Analgesic nephropathy is a chronic kidney disease characterized by renal papillary necrosis and chronic interstitial nephritis.[111–113] The early reports linking analgesics and renal disease were generally found in patients who consumed combination products containing phenacetin. This fact focused attention on phenacetin as the primary cause of the syndrome and prompted many countries to officially remove the drug from nonprescription analgesics. Significantly, the removal of phenacetin has not been uniformly followed by the expected reduction in the incidence of the syndrome.[114] Given that other agents such as acetaminophen or salicylamide have been substituted for phenacetin in many combination products, the lack of decline in incidence of analgesic nephropathy suggests that the use of combination products is as important as whether the compound contains phenacetin.[114,115] This conclusion is further supported by the experience in Belgium where a strong geographic correlation exists between the prevalence of analgesic nephropathy and sales of analgesic mixtures containing a minimum of two analgesic components.[116,117]

Numerous epidemiologic studies performed in the past demonstrated a wide variation in the geographic incidence of analgesic nephropathy.[114,115,118–121] Much of this variability could be explained by differences in the annual per capita consumption of phenacetin.[113,114] In those countries with the highest consumption such as Australia and Sweden, analgesic nephropathy was found responsible for up to 20% of cases of end-stage renal disease. In Canada, which had the lowest per capita consumption, analgesic nephropathy accounted for only 2% to 5% of end-stage renal disease patients. It has been estimated that between 2% and 4% of all end-stage renal disease cases in the United States can be attributable to habitual analgesic consumption. Within the United States, there are also regional differences in the reported incidence of analgesic nephropathy, which are thought to be reflective of differences in analgesic consumption.[114,115,118,119] For example, the use of combination analgesics is more common in the southeastern United States, and the incidence of analgesic nephropathy is three to five times as common a cause of end-stage renal disease in North Carolina compared to Pennsylvania.[114,115,118,119]

The development of analgesic nephropathy is associated with a number of well-defined clinical characteristics.[122] The disease is more common in women by a factor of 2 to 6 and has a peak incidence at age 53 years. Patients typically consume compound analgesics on a daily basis, often for chronic complaints such as headache, dyspepsia, or to improve work productivity. It has been estimated that nephropathy occurs after the cumulative ingestion of 2 to 3 kg of the index drug. Often, patients will exhibit a typical psychiatric profile characterized by addictive behavior. Gastrointestinal complications, such as peptic ulcer disease, are common. The patients are frequently anemic as a result of gastrointestinal blood loss as well as renal insufficiency. Ischemic heart disease and renal artery stenosis have both been reported to occur with higher frequency in these patients.[113] In fact, regular use of analgesic drugs containing phenacetin is associated with an increased risk of hypertension and mortality and morbidity due to cardiovascular disease.[121,123] Finally, long-term use of analgesics is known to be a risk factor for the subsequent generation of uroepithelial tumors.[124]

Patients with analgesic nephropathy predominantly have tubulomedullary dysfunction characterized by an impaired concentrating ability, acidification defects, and occasionally a salt-losing state. Proteinuria tends to be low to moderate in quantity. Interesting to note, the pattern of proteinuria is typically a mixture of glomerular and tubular origin. Pyuria is common and is often sterile. Occasionally, hematuria is noted, but if persistent should raise the possibility of an uroepithelial tumor.

There are several features of analgesic nephropathy that make it difficult to diagnose. The disease is slowly progressive and the symptoms and signs are nonspecific. Patients are often reluctant to admit to a heavy usage of analgesics and therefore are either misdiagnosed or not diagnosed at all until the renal failure is far advanced. In addition, the lack of a simple and noninvasive test that reliably implicates analgesics as the cause of the renal injury has been an important limiting factor. Noncontrast abdominal computed tomography (CT) may emerge as a useful diagnostic tool in this setting given its usefulness in the diagnosis of papillary necrosis.[125] Characteristic findings by CT suggesting the diagnosis include small kidneys with an irregular contour and intrarenal calcifications, particularly in the medulla.

As mentioned earlier, there are a number of reports that suggest that chronic use of NSAIDs alone may also lead to renal injury. In this regard, several NSAIDs have been associated with the development of papillary necrosis either when administered alone or in combination with aspirin.[126] In addition to inhibiting prostaglandin synthesis, the ability of these agents to redistribute blood flow to the cortex, thus rendering the renal medulla ischemic, may underlie this association. Although the reports linking papillary necrosis and NSAIDs are predominantly anecdotal in nature, more recent observations would suggest that chronic renal failure resulting from long-term use of NSAIDs may be more prevalent than once thought.[127,128] In a multicenter case-control study, Sandler and associates[127] reported a twofold increase in the risk for chronic kidney disease associated with the previous daily use of NSAIDs. Chronic kidney disease in these patients was newly diagnosed and was defined as a serum creatinine concentration of 1.5 mg per deciliter or greater. This increased risk was primarily limited to older men. An

additional report linking the chronic use of NSAIDs with the development of chronic kidney disease described 56 patients from Australia.[113] These patients had taken only NSAIDs over a period of 10 to 20 years for treatment of varying rheumatic diseases. In 19 patients (34%), radiographic evidence of papillary necrosis was found. In 37 patients, renal biopsy material was available that disclosed evidence of chronic interstitial nephritis. The clinical characteristics of these patients were quite different from those with analgesic nephropathy, suggesting that NSAID-induced chronic kidney disease is indeed a distinct entity. In particular, patients with NSAID-associated renal disease were older, had an equal female-to-male ratio, a lower incidence of papillary necrosis, less severe renal insufficiency, and a lower incidence of urinary tract infections.[113] In addition, an increased risk of uroepithelial tumors has not been described in these patients.

Further evidence of chronic toxicity has been reported in a preliminary communication in which patients treated with NSAIDs for rheumatoid arthritis and osteoarthritis were compared to a matched control arthritis population.[129] In this study, the NSAID-treated patients had a rise in the serum creatinine concentration from 1.28 to 2.58 mg per deciliter over a mean period of 47.5 months. The control group not taking NSAIDs had stable renal function. Finally, Segasothy and colleagues[128] report on the risk of chronic renal disease in a prospective study of 259 heavy analgesic abusers. In this study, 69 patients developed radiographic evidence of papillary necrosis. Of these, 29 used NSAIDs either singularly (17 patients) or in combination with another NSAID (12 patients). Another 9 patients used NSAIDs in combination with paracetamol, aspirin, caffeine, or a traditional herbal medicine. Renal insufficiency (serum creatinine concentration 1.4 to 8.8 mg per deciliter) was noted in 26 of the 38 patients who had used an NSAID chronically. Similar to the patients from Australia,[113] this disorder was more common in males (1.9:1.0), distinguishing this disorder from classic analgesic nephropathy, which typically occurs in females. Similarly, these patients did not exhibit the usual psychological profile associated with analgesic abuse.

Thus, although further studies are needed to definitely assess the question of cumulative toxicity, it appears that some chronically treated patients may develop a change in renal function over a long-term period. Given the abuse potential of powerful NSAIDs and the fact that ibuprofen, naproxen, and ketoprofen are now available on an over-the-counter basis, it is possible that chronic NSAID abuse may become a more common cause of chronic kidney disease in the future.

In considering the definite association of compound analgesic abuse and the possible linkage of chronic NSAID use to the development of chronic kidney disease, it has become common clinical practice to recommend acetaminophen whenever possible for analgesia. In this regard, a recent case-control study examining the use of over-the-counter analgesics as a risk factor for end-stage renal disease found that acetaminophen may also cause chronic kidney disease when used on a continual basis.[130] In this study, heavy average use of acetaminophen (>1 pill per day) and medium- to high-cumulative intake (1,000 or more pills in a lifetime) each doubled the odds of end-stage renal disease. These authors conclude that a reduced consumption of acetaminophen could decrease the overall incidence of end-stage renal disease approximately 8% to 10%. The findings in this study confirmed an earlier report that also concluded that long-term daily use of acetaminophen is associated with an increased risk of chronic kidney disease.[118] Although these studies do not establish a cause-and-effect relationship between acetaminophen ingestion and chronic kidney disease, the data do suggest that the ingestion of acetaminophen on a continual and chronic basis should be discouraged.

An organized review was conducted by a consensus panel of the National Kidney Foundation (NKF) in which over 600 articles were surveyed. This review studied the implications of several different kinds of analgesic ingestion and renal failure risks.[131,132] The highlights of the recommendations from the NKF consensus panel based on this review are that:

1. The ingestion of aspirin and nonsteroidal combinations are not encouraged because of an increased risk of renal failure when those combinations are ingested together.
2. The habitual consumption of analgesics is discouraged, and monitoring is recommended when such use is mandatory.
3. Combination analgesics are recommended to be available by prescription only with an explicit warning to physicians that the habitual consumption of these combination products could lead to the insidious development of chronic kidney disease.
4. There should be an explicit warning to consumers regarding NSAID ingestion.

The panel concluded that there is negligible clinical evidence that suggests the habitual use of acetaminophen alone causes the clinical entity of analgesic nephropathy and that there is no evidence that the occasional use of acetaminophen causes renal injury. Finally, the panel points out that there is no risk from the regular use of aspirin in the relatively small doses recommended for the prevention of cardiovascular events.

NEPHROTOXICITY OF INHIBITORS OF THE RENIN-ANGIOTENSIN SYSTEM: ANGIOTENSIN CONVERTING ENZYME INHIBITORS, ANGIOTENSIN RECEPTOR BLOCKERS, AND DIRECT RENIN INHIBITORS

The most common form of nephrotoxicity associated with inhibitors of the renin-angiotensin system is an increase in the serum creatinine concentration occurring in the setting

of antihypertensive therapy.[133] This complication is becoming more common in clinical practice because guidelines governing adequate blood pressure control have been made more stringent. This decline in renal function is hemodynamic in origin and not secondary to structural injury to the kidney and can be traced to changes in renal autoregulation that accompany chronic kidney disease.

Normal renal autoregulation enables the kidney to maintain fairly constant renal blood flow and glomerular filtration rates in the setting of varying systemic blood pressure. One component of this process is an intrinsic property of the afferent arteriole called the myogenic reflex. The myogenic reflex causes this vessel to either constrict or dilate in response to changes in intraluminal pressure. An increase in arterial pressure elicits a vasoconstrictive response, whereas decreased arterial pressure results in vasodilation. These changes in afferent tone provide an immediate response to maintain intraglomerular pressure and glomerular filtration rate relatively constant in the face of everyday fluctuations in systemic blood pressure.[134]

In the setting of chronic hypertension, the small arteries of the kidney, including the afferent arteriole, undergo a number of pathologic changes that give rise to alterations in the way the kidney autoregulates.[135] As with vessels elsewhere, the afferent arteriole initially demonstrates evidence of endothelial dysfunction leading to impaired vasodilation. Over time, this impairment is exaggerated by histologic changes of hyaline arteriosclerosis and myointimal hyperplasia. These changes lead to a blunted ability of the preglomerular circulation to either constrict or dilate in response to changes in renal perfusion pressure. In essence, these vessels take on the characteristics of a pressure-passive vasculature where changes in mean arterial pressure are matched by proportional change in GFR (Fig. 32.5).[135,136]

A blunted ability of the preglomerular circulation to dilate in response to a drop in the mean arterial pressure will cause an exaggerated decrease in the intraglomerular pressure and GFR. This impairment in autoregulation explains why patients with hypertension and chronic kidney disease are more likely to have an increase in the serum creatinine concentration when blood pressure is lowered. Any drug that lowers blood pressure can cause an increase in the serum creatinine concentration through this mechanism but inhibitors of the renin-angiotensin system are more commonly associated with this complication. Angiotensin-converting-enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and the direct renin inhibitor will exaggerate the decline in intraglomerular pressure due to blood pressure reduction by concomitant vasodilation of the efferent side of the glomerular circulation.

As long as the increase in serum creatinine concentration is not excessive (>30% above the baseline value) or progressive, discontinuation of these drugs is not necessarily warranted particularly considering the potential benefit these agents have in slowing the progression of chronic kidney disease. Long-term trials in both diabetic and nondiabetic patients have shown that the initial decline in renal function reaches a plateau within several weeks and is reversible with discontinuation of the blocker even after several years of therapy.[138,139] Thus a small, stable increase in the serum creatinine concentration after the start of an ACE inhibitor, ARB, or the direct renin inhibitor is hemodynamic in nature and reflects a fall in intraglomerular pressure.

If the rise in serum creatinine is >30% or the repeat value shows a progressive rise, then the appropriate response is to discontinue the drug and initiate a search for other causes of renal dysfunction. There are several conditions in which use of renin-angiotensin blockers may cause exaggerated or progressive declines in renal function. The first setting involves significant (usually >70%) bilateral renal artery obstruction or unilateral renal artery obstruction to a solitary functioning kidney. Under these conditions, increased tone of the efferent arteriole acts to attenuate the decline in intraglomerular pressure that results from the arterial obstruction. The trade-off is that renal function and glomerular filtration rate become dependent upon sustained constriction of the efferent vessel by AII. A similar physiology can develop in patients with polycystic kidney disease where the renal arteries become extrinsically compressed by large cysts.[140] Unless the underlying obstruction can be treated, other classes of antihypertensive agents will have to be used.

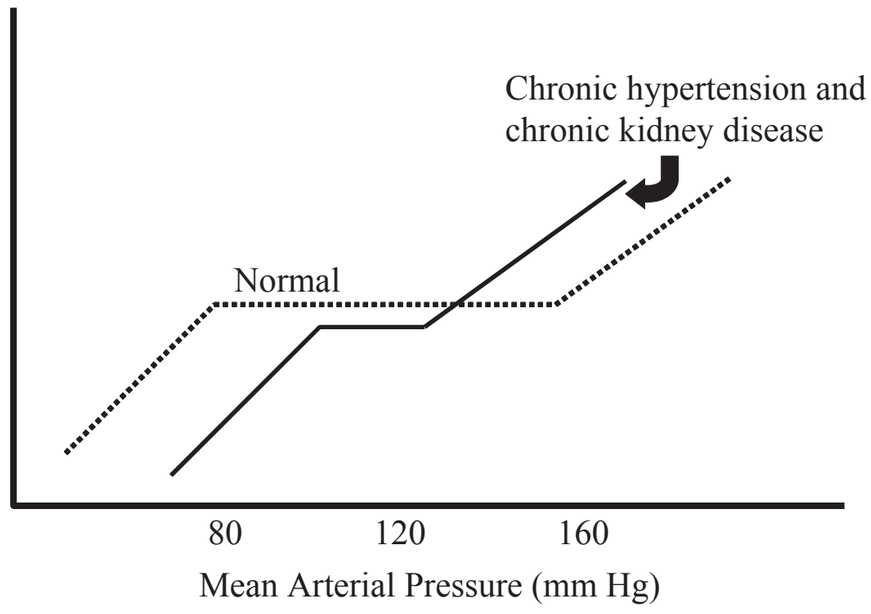

FIGURE 32.5 Renal autoregulation normally maintains relatively constant intraglomerular pressure despite variations in renal perfusion pressure. In patients with chronic hypertension or mild chronic kidney disease renal autoregulation changes in such a way that intraglomerular pressure begins to vary more directly with changes in mean arterial blood pressure. One can conceptualize this change as if the normal sigmoidal relationship between systemic blood pressure and intraglomerular pressure becomes progressively more linear. As a result, increases in mean pressure cause exaggerated rises in intraglomerular pressure, whereas declines in mean pressure will cause exaggerated falls in intraglomerular pressure. The decline in intraglomerular pressure accompanying more stringent levels of blood pressure control will manifest itself by an increase in the serum creatinine concentration. Renal dysfunction that occurs in this setting is hemodynamic in origin and is reflective of a lower intraglomerular pressure.

Blockade of the renin-angiotensin system can also cause an azotemic response under conditions of an absolute (gastroenteritis, aggressive diuresis, poor oral intake) or effective reduction in arterial circulatory volume (moderate to severe congestive heart failure). In these settings, AII–mediated constriction of the efferent arteriole serves to minimize the decline in glomerular filtration rate that would otherwise occur as a result of the fall in renal perfusion pressure. In the volume-contracted patient, the appropriate response is to hold the drug and then restart the medication once the extracellular fluid volume has been replenished. In a patient with congestive heart failure, renin-angiotensin blockade will increase the serum creatinine when the decrease in intraglomerular pressure resulting from efferent vasodilation is not offset by an increase in renal perfusion. This can occur in patients with severely depressed cardiac function in which afterload reduction can no longer increase cardiac output or in the setting of aggressive diuresis.

A similar mechanism is responsible for renal dysfunction that occurs in patients given renin-angiotensin system blockers in the setting of NSAIDs, cyclosporin A, or early sepsis.[141–143] In these settings, there is increased vasoconstriction of the renal vasculature. Inhibiting AII-mediated efferent vasoconstriction in the face of decreased renal perfusion pressure accounts for the fall in GFR.

A few cases of membranous nephropathy have been attributed to the use of ACE inhibitors,[144,145] but the overall incidence of this complication and that of tubulointerstitial nephritis are believed to be low. To date, there are no such reports linking ARBs or the direct renin inhibitor to the development of glomerular or interstitial renal disease.

CHAPTER

33 Contrast-Induced Acute Kidney Injury

Steven D. Weisbord • Paul M. Palevsky

Acute kidney injury is a well-recognized complication of intravascular iodinated contrast administration.[1–4] Epidemiologic trends and clinical factors suggest that contrast-induced acute kidney injury (CIAKI), which is associated with serious adverse short- and long-term outcomes, will continue to be an important clinical entity for the foreseeable future. First, patients are living longer with a greater burden of chronic illness, suggesting that there will be an increasing demand for radiographic procedures that use intravascular (IV) radiocontrast. Second, chronic kidney disease (CKD), which is the principal risk factor for CIAKI, and diabetes mellitus, which amplifies the risk for CIAKI in patients with baseline renal impairment, are increasing in prevalence.[5] Third, recent studies linking gadolinium-containing contrast agents used to enhance the diagnostic accuracy of magnetic resonance imaging (MRI) studies with nephrogenic systemic fibrosis, a potentially severe fibrosing disorder in patients with advanced CKD, has led to the performance of fewer contrast-enhanced MRI procedures in patients with kidney disease and is likely to result in a greater reliance on imaging modalities that use iodinated radiocontrast in patients at risk for CIAKI.[6–8] Lastly, advancements in modern imaging technology have led to an increasing array of diagnostic and therapeutic procedures that employ iodinated contrast. As a result of these factors, CIAKI is likely to remain a common iatrogenic complication.

This chapter reviews the pathophysiology, risk factors, clinical presentation, and incidence of CIAKI; discusses the adverse outcomes associated with the development of CIAKI; and summarizes the data regarding interventions to prevent this iatrogenic condition.

THE PATHOPHYSIOLOGY OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

Our current understanding of the pathophysiology of CIAKI principally derives from animal studies examining the effect of contrast media on renal hemodynamics, oxygen delivery, and kidney function. These studies suggest that multiple overlapping pathophysiologic processes triggered by contrast administration collectively contribute to renal injury. These include mismatched oxygen supply and demand resulting in medullary hypoxia, direct toxic effects of contrast on tubular epithelial cells, and the generation of cytotoxic oxygen free radicals within the kidney that intensify renal injury (Fig. 33.1). Animal models used to investigate the pathophysiology of CIAKI have relied upon additional nephrotoxic insults such as volume depletion or concomitant nonsteroidal anti-inflammatory administration to enhance the susceptibility of the kidneys to contrast-induced injury. For example, Heyman et al.[9] compared the effect of contrast media on renal vasoconstriction in intact rats and uninephrectomized, salt-depleted rats that were injected with intravenous indomethacin. Renal blood flow dropped to a substantially greater degree following contrast administration in the preconditioned rats. Similarly, Agmon and colleagues[10] pretreated rats with indomethacin and nitro-L-arginine methyl ester (L-NAME), an inhibitor of nitric oxide synthesis to examine the effect of iodinated contrast on renal medullary blood flow. Whether such additional nephrotoxic insults in animals accurately reflect the mechanisms underlying the increased susceptibility of the human kidney to iodinated contrast from renal impairment is not clear. Nonetheless, such studies form much of the basis for our current understanding of the pathophysiology of CIAKI.

Vasoconstriction and Medullary Hypoxia

Multiple studies have demonstrated that the administration of iodinated contrast media induces vasoconstriction of the renal vasculature.[11–13] However, this effect is not uniform throughout the kidney but rather regional because blood flow to the cortex appears to be maintained but decreases significantly in the renal medulla. Oxygen delivery to the renal cortex is high, yet delivery to the medulla is considerably lower, resulting in low medullary tissue oxygen tension, with values as low as 30 mm Hg detected under normal physiologic conditions in rats, dogs, and humans. At baseline, oxygen extraction by the renal medulla is near maximal, reaching 79% of regional oxygen delivery. Thus, medullary oxygen

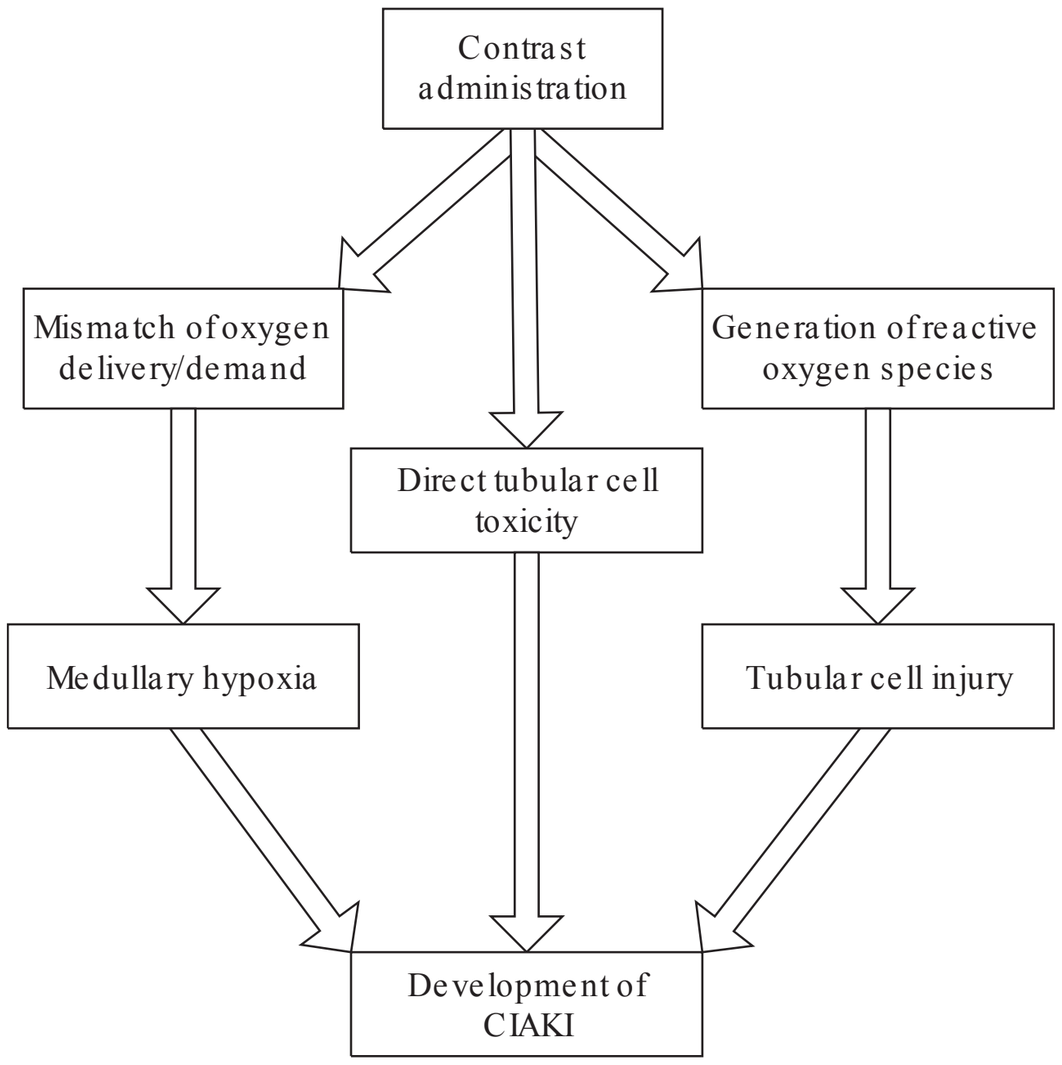

FIGURE 33.1 Pathophysiology of contrast-induced acute kidney injury.

reserve is marginal under normal conditions.[14,15] In the intact kidney, medullary blood flow is usually maintained, even in the presence of systemic and local vasoconstrictive stimuli, by the combined effects of vasodilators including nitric oxide and prostaglandin E_2, as well as the unique regional vasodilatory effects of renal vasoconstrictors.[16] However, in certain settings, including altered renal reserve, vasoconstriction can overwhelm the kidney's capacity to preserve oxygen delivery, leading to medullary hypoxia. In particular, the vasoconstrictors endothelin and adenosine have been implicated in the reduction in outer medullary blood flow following the administration of iodinated contrast.[17–20] However, the precise role of and degree to which renal injury from contrast is directly attributable to these vasoconstrictors is unknown. Nonetheless, a series of studies have examined the role of medullary hypoxia in the pathogenesis of CIAKI.[21,22] Liss and colleagues[22] demonstrated a fall in medullary oxygen tension from approximately 30 mm Hg to 15 mm Hg after the administration of low-osmolal and iso-osmolal contrast agents. The contrast-induced exacerbation of medullary hypoxemia has also been suggested by noninvasive blood-oxygen level dependent magnetic resonance imaging (BOLD MRI), which detects an increased unsaturated hemoglobin concentration within the renal medulla and by the detection of increased levels of hypoxia-inducible factors (HIF) shortly after contrast administration.[23,24] Systemic effects of iodinated contrast media may also contribute to the decline in renal medullary oxygen tension. Contrast administration is associated with the induction of pulmonary ventilation–perfusion mismatch, reduced cardiac output with a secondary decrease in renal perfusion pressure, rheologic alterations of blood, and a leftward shift of the oxygen-hemoglobin dissociation curve.[25–29] However, these systemic effects appear to play a less prominent role in the reduction in medullary oxygen tension than the intrarenal mechanisms.

Simultaneous with its effect on medullary oxygen tension, iodinated contrast increases oxygen demand within the kidney. The administration of contrast media induces an abrupt and transient natriuresis and increases glomerular filtration and urinary output, effects that are mediated, at least in part, by an increase in plasma volume and the release of natriuretic peptides.[17,30,31] These effects, along with the increased osmotic load following contrast media administration, lead to enhanced solute delivery to the distal nephron. The increased active transport in the distal nephron increases oxygen demand. Thus, the contrast-induced decrease in medullary oxygen tension is accompanied by a concomitant increase in oxygen demand, particularly at the corticomedullary junction, resulting in a mismatch between oxygen supply and demand, tissue hypoxia, and cellular injury.

Direct Tubular Toxicity and Generation of Reactive Oxygen Species

Radiocontrast agents result in tubular cell injury directly through direct cytotoxicity and indirectly through the generation of reactive oxygen species (ROS).[32–37] Following filtration at the glomerulus, iodinated contrast enters the urinary space and increases the viscosity of the tubular fluid. The increased urine viscosity combined with intratubular cast formation by cellular debris and the precipitation of contrast medium with urinary proteins may increase exposure of the tubules to the contrast medium, thus increasing the risk for direct cytotoxicity. Evidence supporting the role of direct tubular cell toxicity in the pathogenesis of CIAKI derives from renal biopsy specimens demonstrating vacuolization and necrosis of tubular cells in patients who recently underwent contrast-enhanced procedures.[38] Additionally, data from in vitro studies of renal epithelial cells demonstrate contrast-associated DNA fragmentation, altered cell polarity, inhibition of mitochondrial function, increased brush border marker enzyme activity, and apoptosis—effects that support the direct nephrotoxic effects of contrast.[34–36]

In vitro studies demonstrate that iodinated contrast agents also induce oxygen free radical mediated injury through the oxidation of cell membranes, cellular proteins, and nucleic acids.[39–43] Secondary activation of reparative processes, such as the DNA mending poly-(ADP-ribose) polymerase (PARP) may, in turn, precipitate additional depletion of intracellular energy stores and tubular damage.[44,45] Endothelial cells may also be injured by the evolving hypoxic stress. Following exposure to contrast media, HIF-2α accumulates in medullary endothelial capillaries.[46] Resultant endothelial damage, induced by reactive oxygen species and energy consuming reparative mechanisms, such as PARP, leads to endothelial dysfunction, further exacerbating regional tissue hypoxia.[40,47–49] Thus, the hemodynamic and toxic effects of

iodinated contrast media are synergistic, leading to the amplification of kidney injury.

RISK FACTORS FOR CONTRAST-INDUCED ACUTE KIDNEY INJURY

Patient-Related Risk Factors

Risk factors for CIAKI can be categorized as patient related or procedure related (Table 33.1). CIAKI rarely develops in the absence of patient-related risk factors, which are collectively characterized by functional and structural changes impairing the capacity of the kidneys to adequately compensate for the hemodynamic and microcirculatory stresses caused by iodinated contrast media. Preexisting disease of the renal parenchyma (i.e., CKD) is characterized by an abnormal medullary microcirculation and a diminished capacity to compensate for hemodynamic perturbation. Clinical studies confirm that underlying renal impairment is the major patient-related risk factor for CIAKI, with increasing levels of dysfunction associated with escalating levels of risk.[50] In a study of 378 hospitalized patients undergoing nonrenal angiography, D'Elia et al.[51] found that preexisting renal insufficiency was the only risk factor predisposing to CIAKI. In an analysis of nearly 3,700 patients, McCullough and colleagues[52] found a strong inverse relationship between the baseline kidney function and a risk of both CIAKI and the need for acute dialysis. Schemata outlining the risk associated with varying levels of CKD have been proposed. For patients with mild to moderate underlying renal insufficiency, the incidence of CIAKI is approximately 5% to 10%. Superimposition of diabetes mellitus on mild to moderate renal insufficiency heightens this risk, whereas the incidence of CIAKI increases to as much as 50% or more in patients with very advanced CKD.

Although diabetes mellitus substantially amplifies the risk of CIAKI in patients with underlying renal impairment, the presence of diabetes in the setting of intact kidney function does not appear to be associated with an increased risk of CKAKI.[51–55] For example, in a study by Rudnick et al.[53] that compared the effects of high- and low-osmolal contrast agents in 1,196 patients undergoing coronary angiography, CIAKI—defined by a postprocedure increase in serum creatinine (SCr) of ≥1.0 mg per deciliter—occurred in none of 359 patients without diabetes or underlying CKD and in just 2 of 315 (0.6%) patients with diabetes but no underlying CKD. However, in study participants with baseline renal impairment, 17 of 296 nondiabetics (6%) and 42 of 213 diabetics (20%) developed CIAKI. Thus, diabetes substantially amplifies the risk of CIAKI in patients with impaired kidney function, but does not appear to represent a notable risk factor in the setting of intact kidney function.

Patients with absolute or effective intravascular volume depletion have increased susceptibility to renal injury from iodinated radiocontrast media.[56] Both clinical states are associated with reduced renal blood flow, which can exacerbate the impact of renal vasoconstriction following intravascular radiocontrast administration. Absolute extracellular volume depletion due to gastrointestinal (GI) losses or diuresis and effective intravascular volume depletion due to advanced heart failure or end-stage liver disease, which are associated with an increased reliance on the vasodilatory effects of prostaglandins to maintain renal microperfusion, also augment the risk for CIAKI.[56,57] Similarly, nephrotoxic medications, specifically nonselective and cyclo-oxygenase-2 selective nonsteroidal anti-inflammatory medications, which inhibit vasodilatory prostaglandins in the kidney, are associated with an increased risk of CIAKI.[58] Other medications that may also increase the likelihood of contrast-associated renal injury include aminoglycosides and calcineurin inhibitors.

Additional factors that have been reported to increase the risk of CIAKI include older age, hypertension, and anemia.[59,60] However, the independent impact of these factors on the risk for CIAKI is uncertain because each is strongly correlated with the presence of underlying CKD. Recent studies suggest that an elevated serum glucose concentration at the time of contrast administration may confer an added risk of CIAKI, particularly among nondiabetics.[61] Likewise, elevated urinary protein excretion has been shown to be associated with increased risk of AKI in several clinical settings, although its role in the context of contrast administration is currently unknown.[62] In animal studies, intratubular light chains, particularly if accompanied by intravascular volume depletion, augment the nephrotoxic potential of radiocontrast media.[34] However, more recent studies in humans do not support an association of multiple myeloma with an increased risk for CIAKI.[63] An analysis of 476 patients with multiple myeloma who received iodinated contrast revealed

33.1 Risk Factors for Contrast-Induced Acute Kidney Injury

Patient Related	Procedure Related
Renal impairment	High-osmolal contrast media
Diabetes mellitus[a]	Large contrast volume
Absolute intravascular volume depletion	Multiple sequential procedures
Effective intravascular volume depletion	Intra-arterial administration
Concomitant nephrotoxic medication use	

[a]Amplifies risk in the setting of renal impairment; not a strong independent risk factor.

an incidence of CIAKI of just 0.6% to 1.25%.[64] Early reports of CIAKI following contrast exposure in patients with multiple myeloma may not have fully accounted for other comorbid factors such as sepsis and volume depletion.

In summary, the administration of iodinated contrast media leads to hemodynamic and toxic effects that, in healthy subjects, are balanced by protective regulatory systems that maintain renal parenchymal oxygenation, function, and integrity. These protective regulatory systems are impaired in the setting of patient-related risk factors, particularly preexisting CKD, leading to an increased susceptibility to renal injury and the development of CIAKI.

Procedure-Related Risk Factors

A series of procedure-related factors have been identified that increase the risk for CIAKI. The dose of contrast has been the subject of considerable attention, with some studies demonstrating an association of higher volumes of contrast with greater risk and other studies showing no such association.[65–67] Miller and colleagues[67] prospectively evaluated 200 patients undergoing procedures with intravenous or intra-arterial contrast and reported no consistent change in renal function with increasing doses of contrast media. Conversely, Cigarroa et al.[65] demonstrated that decreasing the volume of contrast administered during coronary angiography was associated with a reduction in the incidence of CIAKI. Although a specific threshold volume of contrast above which the risk for CIAKI increases substantially has not been definitively determined, multiple sequential procedures or procedures employing larger volumes of contrast appear to pose a greater risk. Similarly, higher doses of iodine have also been associated with a greater risk for CIAKI, which has led to the development of formulas that incorporate the dose of iodine to estimate risk.[68,69] However, the role and importance of an iodine dose relative to the overall volume of contrast requires further study.

The type of contrast agent has also been strongly associated with risk for CIAKI. The first iodinated contrast media widely used in clinical practice were high-osmolal ionic derivatives of triiodobenzene, such as diatrizoate, meglumine, or metrizoate.[70] These high-osmolal contrast media (HOCM) were characterized by osmolalities that were five to eight times greater than blood (approximately 1,500 to 2,000 mOsm per kilogram of water). A series of studies in the early 1990s demonstrated that contrast agents with osmolalities of approximately 600 to 850 mOsm per kilogram (low-osmolal contrast media [LOCM]) were less nephrotoxic than conventional HOCM.[53,71] A third-generation iso-osmolal agent (approximately 300 mOsm per kilogram), iodixanol, was introduced in the late 1990s. Several clinical trials and meta-analyses have compared the nephrotoxicity of this agent with various LOCM, with conflicting results (see section on prevention).[72–75]

Iodinated contrast media are administered intra-arterially in the setting of an angiography and intravenously with computed tomography (CT). Direct comparisons of the incidence of CIAKI across different procedure types have been scarce. In a study of 660 patients with CKD, Weisbord et al.[76] demonstrated that the incidence of CIAKI, defined by an increase in SCr ≥25%, was higher following noncoronary angiography (13.2%) than both coronary angiography (8.5%) and CT imaging (6.5%). However, these analyses did not account for variation in baseline clinical risk factors such as diabetes mellitus, heart failure, and the severity of CKD or in differential application of preventive interventions such as IV fluids. Differences in such factors may account for the higher observed rate of CIAKI following angiography in this study and may also underlie the perception that procedures involving intra-arterial contrast administration are associated with a higher risk of CIAKI than procedures that use IV injection.

THE CLINICAL PRESENTATION OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

CIAKI presents as an acute decline in renal function that characteristically develops within 72 hours following contrast administration. Serum creatinine typically peaks within 3 to 5 days and returns toward baseline levels within 7 to 10 days. Most patients with CIAKI remain nonoliguric, although oliguric acute kidney injury (AKI) may occur. CIAKI is a form of acute tubular necrosis (ATN), for which the principal differential diagnoses include ischemic ATN and renal atheroembolic disease.[77] Differentiation from ischemic ATN is generally based on the clinical setting, although distinguishing between these two forms of AKI may be difficult in hemodynamically unstable patients who sustain episodes of hypotension contemporaneous with contrast administration. The urine sediment in CIAKI commonly demonstrates coarsely granular "muddy brown" casts, as is seen in other etiologies of ATN. The fractional excretion of sodium in CIAKI is often less than 1%, although this does not have sufficient diagnostic reliability to definitively differentiate CIAKI from ischemic or other forms of ATN.

Renal atheroembolic disease, which is considerably less common than CIAKI and ischemic ATN, results from the release of cholesterol crystals and other atheromatous debris into the systemic circulation from ulcerated atherosclerotic plaques.[78] Although renal atheroembolic disease can occur spontaneously, it is more common following angiographic procedures.[78] The time course of angiography-associated atheroembolic disease and CIAKI differ; although acute atheroembolism can occur immediately following vascular catheterization, more commonly it is delayed, typically developing days to weeks following vascular instrumentation.[78] Unlike CIAKI, atheroembolic disease is generally associated with specific systemic manifestations including mesenteric ischemia, digital ischemia ("blue toe" syndrome) and livedo reticularis, and laboratory abnormalities that include eosinophilia, eosinophiluria, and hypocomplementemia.[79]

In clinical practice, the identification of patients with CIAKI is based on observing a rise in SCr that occurs in the characteristic time frame following contrast administration. Because clinically detectable elevations in SCr are not evident for many hours to days after renal injury, the diagnosis and implementation of supportive care are typically delayed. Earlier identification of renal injury in the incipient stage of AKI could lead to more immediate implementation of supportive care in the postprocedure period. A series of candidate urinary and serum biomarkers have been identified for the early diagnosis of AKI, including neutrophil gelatinase-associated lipocalin (NGAL), interleukin-18 (IL-18), and kidney injury molecule-1 (KIM-1).[80,81] In addition, these biomarkers have the potential to differentiate volume responsive AKI (prerenal azotemia) from intrinsic AKI. Given their early expression in the urine following tubular injury, these or other biomarkers may ultimately assist in the diagnosis of CIAKI prior to a change in SCr.

THE INCIDENCE OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

The reported incidence of CIAKI is highly dependent on the patient population studied and on the criteria employed to define renal injury. Serologic criteria that have been used in past studies to define CIAKI include an increase in SCr of at least 0.3 mg per deciliter, 0.5 mg per deciliter, 1.0 mg per deciliter, or 2.0 mg per deciliter, or a relative increase of at least 10%, 25%, or 50% within 5 days following contrast administration.[51,65,72,82–91] D'Elia and coworkers[51] reported that 0.68% of nonazotemic patients and 17.4% of azotemic patients experienced a 1.0 mg per deciliter rise in SCr following nonrenal angiography. A 12% incidence of CIAKI was reported in seriously ill, hospitalized patients, using an elevation in SCr of ≥1 mg per deciliter within 48 hours as the criterion for nephrotoxicity.[92] A study of 537 patients undergoing angiography that defined CIAKI as an increase in SCr of at least 1.0 mg per deciliter within 24 hours demonstrated no episodes of CIAKI.[93] More recently, an observational cohort study by Weisbord and colleagues[76] enrolled patients with baseline estimated glomerular filtration rate (eGFR) less than 60 mL/min/1.73m^2 who were undergoing nonurgent coronary or noncoronary angiography or CT, and reported on the rates of CIAKI with these procedures. The incidence of CIAKI, defined by an increase in SCr of ≥25%, was 13.2% following noncoronary angiography, 8.5% following coronary angiography, and 6.5% following CT scans.[76] Using more robust increments in SCr to define CIAKI resulted in considerably lower rates of renal injury with less than 1% of patients overall experiencing a rise in SCr of ≥1.0 mg per deciliter. In a recent observational study of 1,111 hospitalized patients who underwent procedures with intravascular contrast, the incidence of CIAKI, defined as an increase in SCr of ≥0.5 mg per deciliter within 1 to 5 days, was as high as 44% among patients with baseline renal insufficiency and concomitant diabetes.[94]

The substantial variability in the reported rates of CIAKI across these and other studies highlights the important impact that patient population, procedure type, and criteria used to define renal injury have on the reported disease incidence. Determining accurate estimates of the incidence of CIAKI, particularly if defined by diminutive increments in SCr, is further confounded by the underlying fluctuation in SCr that occurs independently of iodinated contrast administration. Bruce et al.[95] studied the incidence of AKI, defined by an increase in SCr ≥0.5 mg per deciliter or a decrease in eGFR ≥25%, among 11,588 patients who underwent a total of 13,274 CT scans either with iodinated contrast (n = 5,790) or without iodinated contrast (n = 7,484). Among patients with baseline CKD, the overall incidence of renal injury in patients who did not receive iodinated contrast (8.8%) was comparable to that of patients who received iodinated contrast (9.7% with iso-osmolal iodixanol and 9.9% with low-osmolal iohexol). Thus, baseline variability in SCr and factors other than iodinated contrast should be considered when estimating the incidence of acute kidney injury from contrast administration.

OUTCOMES ASSOCIATED WITH CONTRAST-INDUCED ACUTE KIDNEY INJURY

Short-Term Outcomes Associated with Contrast-Induced Acute Kidney Injury

Several studies have demonstrated that CIAKI is associated with increased short-term mortality (Table 33.2).[52,96–100] In a retrospective study of 183 hospitalized patients, Levy et al.[96] demonstrated that CIAKI was associated with an increased risk of in-hospital mortality after adjustment for underlying level of comorbid illness (odds ratio [OR] = 5.5, P< .001). McCullough et al.[52] evaluated 1,826 patients who had undergone percutaneous coronary intervention and documented an in-hospital mortality rate of 7.1% among patients with CIAKI (defined by an increase in SCr of >25%) compared to 1.1% in those without CIAKI (P< .0001). Patients who developed CIAKI that required renal replacement therapy experienced an in-hospital mortality rate greater than 35%. In a retrospective study, Rihal et al.[100] examined outcomes in 7,586 patients undergoing percutaneous coronary intervention and reported that patients who developed CIAKI had a marked increased risk for in-hospital mortality (OR = 10.8, P< .0001). Among more than 20,000 patients who underwent percutaneous coronary intervention, Bartholomew and colleagues[97] demonstrated that CIAKI, defined by increases in SCr ≥1.0 mg per deciliter, was associated with a striking increase in in-hospital mortality (OR = 22, 95% confidence interval [CI]: 16 to 31). In a recent analysis, Shema et al.[94] demonstrated that among over 1,100 hospitalized patients who underwent contrast-enhanced radiographic procedures, CIAKI was independently associated with a nearly 10-fold increase in in-hospital mortality (OR = 9.8, 95% CI: 4.4 to 22.0).

33.2 Association of Contrast-Induced Acute Kidney Injury with Short-Term Risk of Mortality

Study Authors	# Study Patients	Definition of CIAKI	Adjusted OR for Death	95% CI
Levy et al.	357	↑ SCr ≥25% to ≥2.0 mg/dL	5.5	2.9–13.2
Gruberg et al.	439	↑ SCr >25%	3.9	2.0–7.6
Shema et al.	1,111	↑ SCr ≥50% or ↓ eGFR ≥25%	3.9	1.2–12.0
McCullough et al.	1,826	↑ SCr >25%	6.6	3.3–12.9
From et al.	3,236	↑ SCr ≥25% or ≥0.5 mg/dL	3.4	2.6–4.4
Rihal et al.	7,586	↑ SCr >0.5 mg/dL	10.8	6.9–17.0
Bartholomew et al.	20,479	↑ SCr ≥1.0 mg/dL	22	16–31
Weisbord et al.	27,608	↑ SCr 0.25–0.5 mg/dL	1.8	1.4–2.5

CIAKI, contrast-induced acute kidney injury; OR, odds ratio; CI, confidence interval; SCr, serum creatinine; eGFR, estimated glomerular filtration rate.

Finally, in a retrospective analysis of over 27,000 patients who underwent coronary angiography, Weisbord et al.[99] found that postangiography increases in SCr greater than 0.25 mg per deciliter but no higher than 0.5 mg per deciliter were independently associated with increased in-hospital mortality (OR = 1.83, 95% CI: 1.35 to 2.49).

Prospective observational studies and clinical trials reveal comparable findings. In a study of 439 patients with CKD undergoing percutaneous coronary intervention, Gruberg et al.[101] found that in-hospital mortality occurred more frequently among patients who developed CIAKI than in comparable patients without CIAKI (14.9% versus 4.9%, P= .001). In a clinical trial, Marenzi et al.[102] also found that patients who developed CIAKI had a significantly increased incidence of in-hospital mortality compared to patients who did not sustain a postangiography decline in renal function (26% versus 1.4%, P< .001). Finally, Maioli et al.[103] demonstrated that in-hospital mortality among patients who developed CIAKI was markedly higher than among patients who did not develop this postprocedure complication (11.1% versus 0.2%, P= .001).

CIAKI is also associated with prolonged hospitalization.[97,99,104–107] Bartholomew et al.[97] found that patients who developed CIAKI after percutaneous coronary intervention (PCI) were 15 times more likely to have their hospitalization prolonged more than 4 days. In the aforementioned study by Shema et al.,[94] CIAKI was associated with a marked increase in hospital length of stay (24 days with CIAKI versus 13 days without CIAKI, P< .001). Adolph et al.[104] demonstrated that the development of CIAKI resulted in an increased mean duration of hospitalization of 2 days. The extended length of a hospital stay associated with CIAKI translates into increased health care expenditures. Using decision analytic techniques, Subramanian et al.[105] reported that a single episode of CIAKI results in an average increase in hospital-related costs of more than $10,000.

Notwithstanding the findings of these studies that demonstrate that CIAKI is associated with increased short-term mortality and a prolonged duration of hospitalization, it is important to note that the causal nature of such associations has not been established. Risk factors that increase the risk for CIAKI (i.e., CKD, heart failure) are also independently associated with these adverse short-term outcomes.

Long-Term Outcomes Associated with Contrast-Induced Acute Kidney Injury

In several recent analyses, CIAKI has also been linked with increased longer term mortality (Table 33.3).[100,108–112] Solomon et al.[111] demonstrated that the development of CIAKI following angiography was associated with a greater than threefold increased risk of death, stroke, myocardial infarction, and end-stage renal disease at 1 year of follow-up. In a study of 985 patients, Harjai et al.[109] demonstrated that CIAKI following coronary angiography was independently associated with an increased likelihood of death at 24 months (hazard ratio [HR] = 2.6; 95% CI: 1.5 to 4.4). A study by Brown et al.[112] that examined long-term outcomes among 7,856 patients found that patients with either transient or persistent postangiography decrements in kidney function had a two- to threefold increase in long-term mortality. In a smaller study of 78 patients, Goldenberg and colleagues[108] documented that CIAKI that fully recovered within 7 days of angiography was associated with a greater than twofold increase in the 5-year mortality (HR = 2.66, 95% CI: 1.72 to 4.46). The previously described study by Rihal et al.[100] also demonstrated that the

33.3 Association of Contrast-Induced Acute Kidney Injury with Long-Term Risk of Mortality

Study Authors	# Study Patients	Definition of CIAKI	Follow-Up (Months)	Adjusted HR	95% CI
Goldenberg et al.	78	↑SCr ≥0.5 mg/dL or ≥25%	60	2.7	1.7–4.5
Solomon et al.	294	↑SCr ≥0.3 mg/dL	12	3.2[a]	1.1–8.7
Harjai et al.	985	↑SCr ≥0.5 mg/dL	24	2.6	1.5–4.4
Roghi et al.	2,860	↑SCr ≥0.5 mg/dL	24	1.8	1.0–3.4
Rihal et al.	7,075	↑SCr >0.5 mg/dL	6	[b]	[b]
Brown et al.	7,856	↑SCr ≥0.5 mg/dL	90	3.1	2.4–4.0

[b]Six-month mortality of 9.8% with CIAKI versus 2.3% without CIAKI ($p < 0.0001$).
CIAKI, contrast-induced acute kidney injury; HR, hazard ratio; CI, confidence interval; SCr, serum creatinine.

5-year mortality rate among patients who underwent coronary angiography and survived to hospital discharge was significantly higher in those who had experienced CIAKI (44.6% versus 14.5%). Finally, James et al.[113] recently demonstrated that patients sustaining a 50% to 100% increase in SCr following coronary angiography doubled their risk of death (HR = 2.0; 95% CI: 1.69 to 2.36) over the ensuing 3 years, whereas patients sustaining an acute increase in SCr >100% experienced a nearly fourfold increased risk of death (HR = 3.72; 95% CI: 2.92 to 4.76).

Past studies have also demonstrated a relationship between CIAKI and accelerated progression of CKD.[103,108,113,114] In a study of 78 patients, Goldenberg et al.[108] found that patients with a transient postprocedure rise in SCr ≥25% or ≥0.5 mg per deciliter following coronary angiography experienced a larger decrement in eGFR 2 years following the procedure than patients without these transient elevations in SCr (Δ eGFR of −20 ± 11 mL/min/1.73 m^2 versus −6 ± 16 mL/min/1.73 m^2, P= .02). Maioli et al.[103] reported that patients with CIAKI had a 0.2 mg/dL higher mean SCr 1 month postangiography than did patients without CIAKI (P= .001). Finally, James et al.[114] recently documented that patients who developed an increase in SCr ≥0.3 mg/dL or between 50% and 99% following coronary angiography experienced a more rapid loss of kidney function compared to patients without such changes in kidney function (loss of eGFR 0.8 mL/min/1.73m^2 per year versus 0.2 mL/min/1.73m^2 per year). For patients sustaining increases in SCr ≥100%, the long-term rate of loss of eGFR was even more marked (2.8 mL/min/1.73m^2 per year).[114] These investigations also demonstrated an increased risk of mortality and end-stage renal disease during 3 years of follow-up in patients who developed CIAKI with graded risks based on the severity of AKI (P< .001 for the trend in mortality and ESRD) (Fig. 33.2).[113] As was noted with the associations of CIAKI with shorter term outcomes, although there is a strong association of CIAKI with longer term mortality and more rapid progression of CKD and ESRD, the causality of this association has not been determined.

THE PREVENTION OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

Overview of Prevention

With a large body of evidence demonstrating associations of CIAKI with adverse short and longer term adverse outcomes, there has been a substantial emphasis placed on identifying interventions to prevent this form of renal injury. CIAKI is one of the few forms of AKI that is potentially preventable because patients at high risk are easily identifiable and most procedures that involve the intravascular administration of iodinated contrast are scheduled sufficiently in advance to allow implementation of prophylactic measures.

The initial step in the prevention of CIAKI is the identification of patients at an increased risk. Alternative imaging procedures that do not require the use of iodinated contrast media, including ultrasonography, nonenhanced CT scans, and MRIs and nuclear imaging, should be considered in patients at increased risk for CIAKI. This involves a careful assessment of both the risk of CIAKI and any potential loss of diagnostic yield with alternative imaging procedures. The use of gadolinium enhancement of MRI procedures is particularly problematic in patients with advanced CKD or ongoing AKI because gadolinium-containing agents are associated with the development of nephrogenic systemic fibrosis in patients with markedly decreased GFR—the subset of patients at highest risk of developing CIAKI.[6,7]

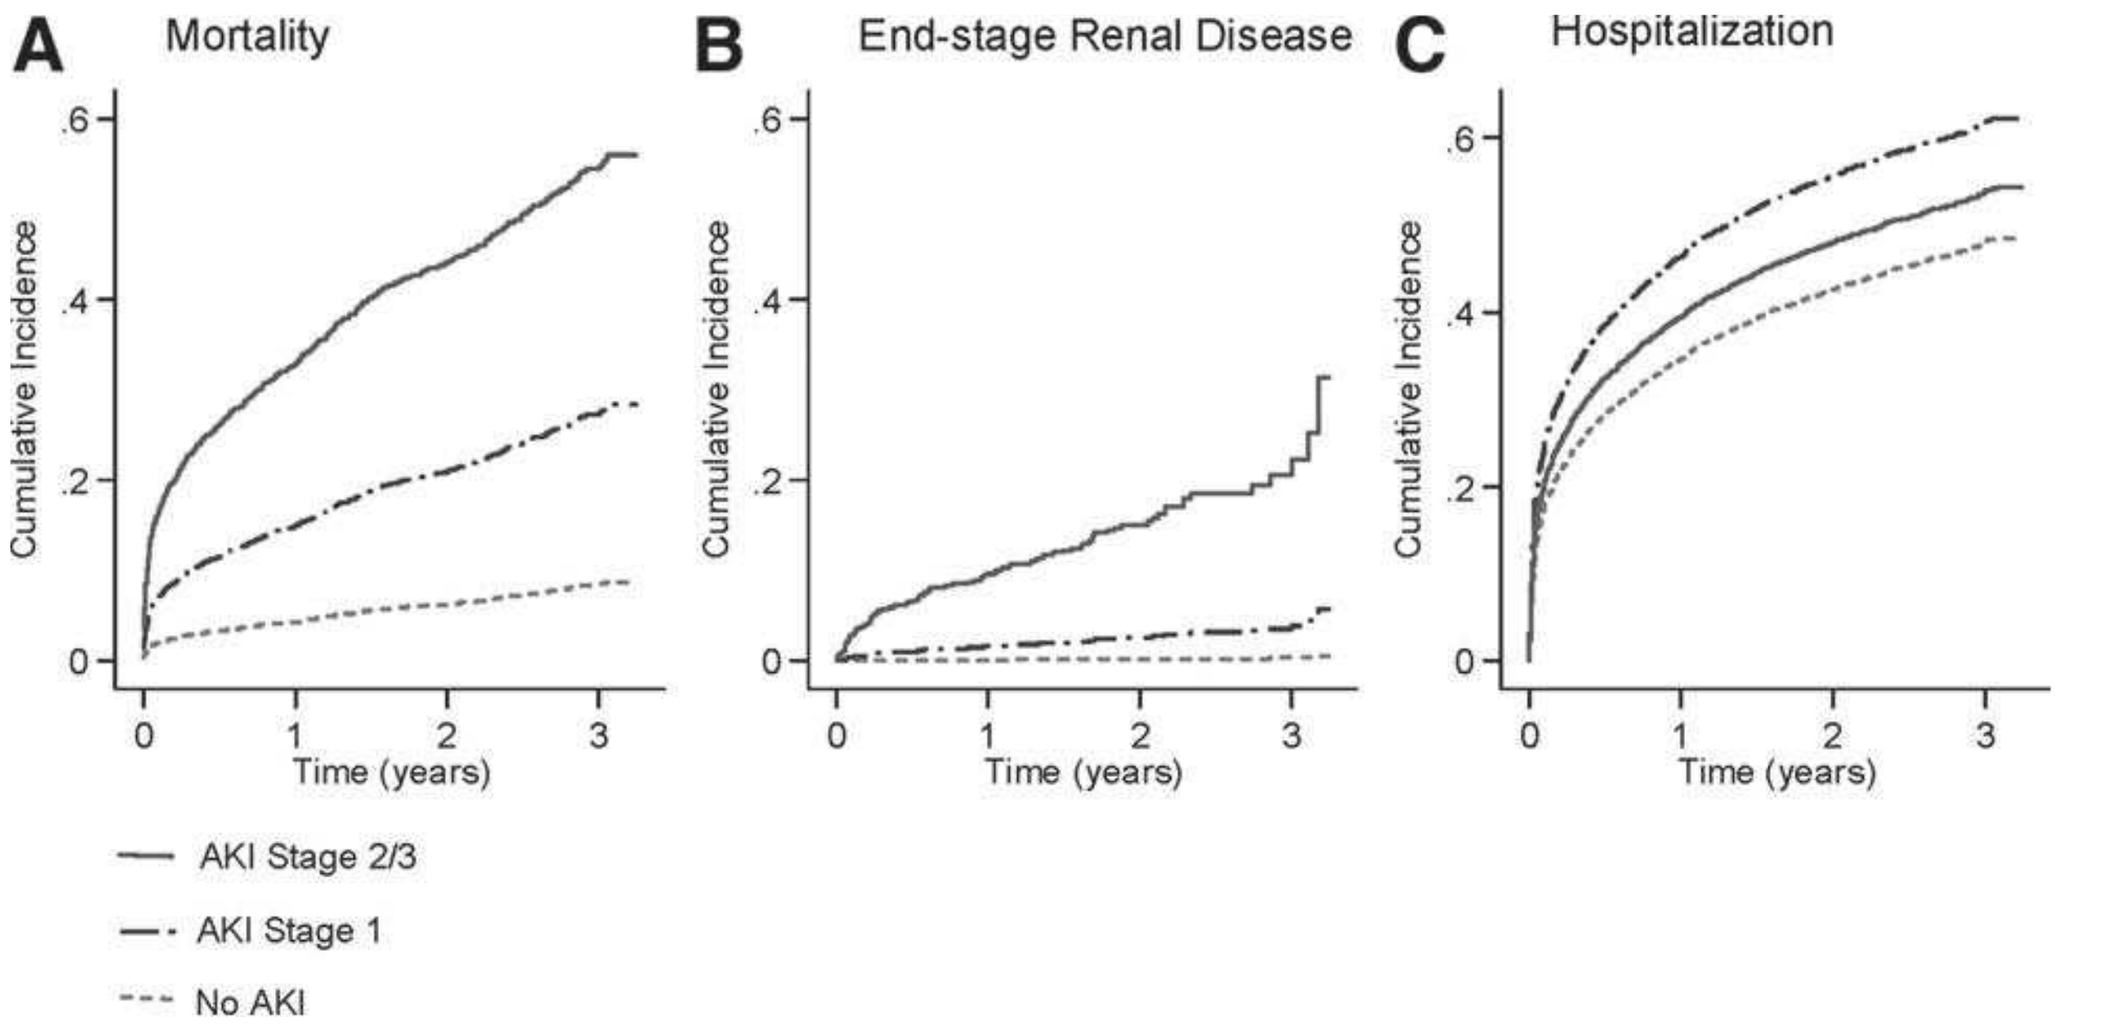

FIGURE 33.2 Cumulative incidence of **(A)** mortality, **(B)** end-stage renal disease (ESRD), and **(C)** hospitalization for all causes according to stage of acute kidney injury (AKI) defined according to the Acute Kidney Injury Network criteria (AKI stage 1: ≥0.3 mg/dL absolute or 1.5- to twofold relative increase in serum creatinine; AKI stage 2: >two- to threefold increase in serum creatinine; AKI stage 3: >threefold increase in serum creatinine or serum creatinine ≥4.0 mg/dL with an acute rise of >0.5 mg/dL). Reprinted with permission from James MT, et al. Associations between acute kidney injury and cardiovascular and renal outcomes after coronary angiography. *Circulation*. 123(4):409–416.

Preventive measures for CIAKI can be categorized into four principal strategies: (1) the use of less nephrotoxic contrast agents; (2) the provision of preemptive renal replacement therapy to remove contrast from the circulation; (3) the use of pharmacologic agents to counteract the nephrotoxic effects of contrast media; and (4) the administration of IV fluids to expand the intravascular space and enhance diuresis.

The Choice of Contrast Agent

Various physicochemical properties of iodinated contrast media, including ionicity, osmolality, and viscosity, have been implicated in the development of CIAKI. All iodinated contrast agents contain either a single triiodobenzene ring or are dimeric structures with two triiodobenzene rings (Fig. 33.3).[70] The initial contrast media were monomeric sodium or meglumine salts of triiodobenzoic acid derivatives. These agents are characterized as ionic because they dissociate in aqueous solution, and as high osmolal, with osmolalities ranging from approximately 1,500 mOsm per kilogram to greater than 2,000 mOsm per kilogram. The next generation of contrast media included nonionic derivatives of triiodobenzene. Because these agents do not dissociate in an aqueous solution, an equivalent dose of iodine is provided with approximately half the osmolal load (approximately 600 mOsm per kilogram to 1,000 mOsm per kilogram), resulting in these agents being characterized as low osmolal, although they still have a much higher osmolality than plasma. Low-osmolal agents can also be ionic, consisting of a dimeric structure derived from triiodobenzene and triiodobenzoic acid. Most recently, nonionic, iso-osmolal (osmolality approximately 300 mOsm per kilogram) agents have been synthesized as dimeric derivatives of triiodobenzene. Although these newer

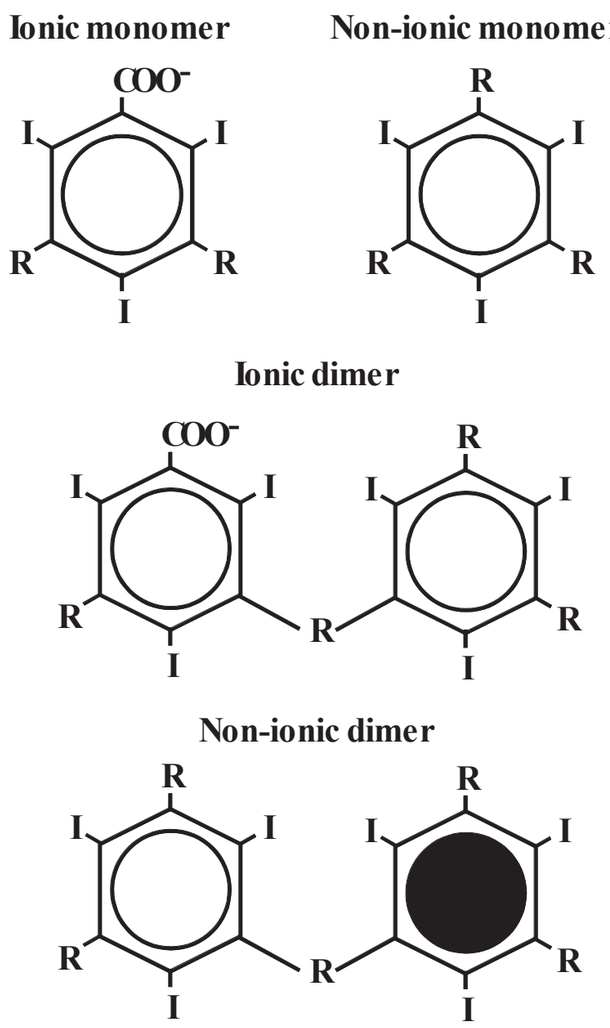

FIGURE 33.3 The molecular structure of iodinated contrast agents.

agents have a lower osmolality than "low-osmolal contrast media," which is thought to decrease their toxicity, their larger molecular size results in increased viscosity. Studies in animal models demonstrate that higher viscosity increases the transit time of contrast in the renal tubular fluid, raises hydrostatic pressure, and reduces glomerular filtration.[115] It has also been suggested that higher viscosity leads to a more pronounced aggregation of red blood cells and decreased red blood cell velocity in the medullary vessels.[116] Although HOCM and LOCM have lower viscosities than iso-osmolal contrast media (IOCM) particularly at room temperature, preheating may represent a means to reduce viscosity prior to administration.[117]

A substantial body of research has been devoted to discerning the relationship between the osmolality of various contrast media and the risk for CIAKI. Early studies focused on the comparative nephrotoxicity of HOCM and LOCM.[53,71] Following the performance of a series of small studies, Rudnick et al.[53] reported the results of the Iohexol Cooperative Study, a multicenter clinical trial comparing high-osmolal diatrizoate with low-osmolal iohexol in 1,196 patients undergoing nonemergent coronary angiography. Overall, CIAKI was less common with iohexol than with diatrizoate (3.2% versus 7.1%, $p=0.002$). The lower risk of CIAKI with iohexol was particularly notable among the subset of patients with both diabetes mellitus and baseline renal impairment. Using data from this and several other trials, Barrett and Carlisle[71] conducted a meta-analysis demonstrating a lower risk of CIAKI, defined by a rise in SCr >0.5 mg per deciliter, with LOCM compared to HOCM (OR = 0.61; 95% CI: 0.48 to 0.77). Among patients with underlying renal impairment, the odds of CIAKI with LOCM decreased further to 0.5 (95% CI: 0.36 to 0.68). These studies helped establish a sound evidence basis for the preferential use of LOCM rather than HOCM in patients with impaired kidney function.

More recently, clinical trials have examined the relative nephrotoxicity of LOCM and the iso-osmolar agent iodixanol. Although some of these studies demonstrated a lower incidence of CIAKI associated with iodixanol than with certain LOCM (i.e., iohexol, ioxaglate), the results have not been consistent across studies, with other studies demonstrating comparable rates of CIAKI with iodixanol and LOCM.[72,75,90,118–122] Meta-analyses of these data suggest that although iodixanol may be associated with a lower risk of CIAKI than specific low-osmolal agents (e.g., iohexol, ioxaglate), this benefit is not seen across the entire spectrum of LOCM.[73,74,123–125] The composite findings of the clinical trials and meta-analyses to date are reflected in clinical practice guidelines issued by the American College of Cardiology/American Heart Association in 2009, which recommend the use of iso-osmolal iodixanol or LOCM exclusive of iohexol or ioxaglate in patients with chronic kidney disease undergoing angiography.[126] The European Society of Urogenital Radiology has recommended the use of either LOCM or IOCM in patients at an increased risk of CIAKI.[127]

Use of Renal Replacement Therapies to Prevent Contrast-Induced Acute Kidney Injury

Because of their water solubility, limited protein binding, and restriction of distribution to the extracellular space, iodinated contrast media are efficiently cleared by hemodialysis, an observation that has led to studies investigating the role of prophylactic renal replacement therapy for the prevention of CIAKI. These studies were based on the hypothesis that accelerated removal of iodinated contrast from the circulation will reduce renal exposure and minimize the development of CIAKI. Lee et al.[128] found a smaller decrement in creatinine clearance and a less frequent requirement for chronic hemodialysis among 82 patients with advanced CKD undergoing a coronary angiography who were randomized to receive prophylactic hemodialysis compared to patients who did not receive prophylactic hemodialysis. However, the small sample size, inaccuracy of the primary endpoint that was based on 24-hour urine collection for the calculation of creatinine clearance, and paucity of patients who progressed to ESRD preclude meaningful conclusions from this trial. However, the benefit seen in this study has not been supported by the majority of other trials conducted over the past 2 decades, which found either no benefit or increased rates of CIAKI in patients who received prophylactic hemodialysis.[129–134] Collectively, available data to date indicate that prophylactic hemodialysis does not reduce the incidence of CIAKI and may be associated with potential harm and increased cost.[135,136]

Continuous renal replacement therapy (CRRT) also effectively removes iodinated contrast from the circulation, albeit at a slower rate than conventional intermittent hemodialysis. Two trials conducted by Marenzi and colleagues[137,138] studied the role of continuous veno-venous hemofiltration (CVVH) for the prevention of CIAKI, and both studies reported that this therapy reduces the risk for CIAKI and death. However, the primary endpoint in both trials was defined by small increases in SCr, an endpoint of questionable validity given that CVVH directly lowers the serum creatinine concentration. Therefore, given the level of existing evidence as well as issues related to cost and risks of CRRT, the preemptive use of this therapy to prevent the development of CIAKI or its attendant complications cannot be recommended.

Pharmacologic Agents to Prevent Contrast-Induced Acute Kidney Injury

A large number of pharmacologic agents have been investigated for the prevention of CIAKI. Although none have been definitively shown to be effective, these agents can be categorized into those that have been shown to be ineffective (and in some cases harmful) and those for which the evidence basis upon which to determine effectiveness is inadequate (Table 33.4).

33.4 Pharmacologic Agents for the Prevention of Contrast-Induced Acute Kidney Injury

Ineffective	Indeterminate Effectiveness
Loop diuretics[a]	Atrial natriuretic peptide
Dopamine[a]	Theophylline/aminophylline
Fenoldopam[a]	Statins
Calcium channel blockers	Prostaglandin analogs N-acetylcysteine Bosentan Allopurinol Acetazolamide

[a]Potentially deleterious.

Diuretics

By virtue of its inhibition of active sodium transport in the ascending limb of the Henle loop, furosemide was proposed as a potential intervention that would reduce oxygen use and, hence, decrease the risk of nephrotoxicity of iodinated contrast. This theoretical benefit of furosemide has not been borne out in clinical trials. In a study by Solomon et al.,[17] the addition of furosemide to hypotonic sodium chloride was associated with a higher incidence of CIAKI than periprocedural hypotonic saline alone (40% versus 11%, P≤ .02). The ineffectiveness of furosemide was consistent with an earlier report that also demonstrated furosemide to be associated with a higher risk of CIAKI.[139] Several studies have also investigated the role of mannitol for the prevention of CIAKI.[84,140,141] Mannitol results in an osmotic dieresis, increases medullary blood flow, and serves as a scavenger of reactive oxygen species. However, clinical studies have failed to demonstrate a beneficial effect of mannitol for this purpose. In the aforementioned trial by Solomon et al.,[17] patients who received mannitol in combination with hypotonic saline had a greater risk of developing CIAKI than did patients who received hypotonic saline alone (relative risk [RR] 2.61, 95% CI: 0.76 to 9.03). In a subsequent study, Majumdar et al.[142] evaluated the effect of forced isovolemic diuresis with a combination of furosemide and mannitol to volume administration with hypotonic saline. Similar to the results in the prior study, the use of mannitol and saline was associated with a significantly increased risk of CIAKI despite the use of a protocol to ensure that intravascular volume was maintained. The carbonic anhydrase inhibitor acetazolamide was shown to be renoprotective in a rat model of CIAKI, perhaps by means of attenuating oxygen free radical formation through alkalinization of the urine.[143] Two studies demonstrated lower rates of CIAKI among patients who were administered acetazolamide, but the studies were insufficient in size to permit meaningful conclusions on the effectiveness of this agent.[144,145]

Calcium Channel Blockers

Calcium channel blockers have vasodilatory effects, which have led to their evaluation for the prevention of CIAKI. Cacoub and colleagues[146] retrospectively studied 26 patients, 11 of whom received nifedipine before and after iodinated contrast administration, and reported comparable rates of CIAKI among patients who had and had not received this agent. Khoury et al.[147] randomized 85 patients to receive IV fluids with or without nifedipine and failed to demonstrate a reduced incidence of CIAKI in patients who received this calcium channel blocker.

Dopamine and Fenoldopam

At low doses, dopamine increases renal blood flow and inhibits sodium reabsorption in the proximal tubule.[148] Several studies have investigated the use of prophylactic dopamine to reduce the propensity for iodinated contrast media to induce renal injury.[148–150] Although small studies suggested a beneficial effect, larger clinical trials have failed to confirm these findings.[148–151] In a study of patients with CKD undergoing coronary angiography, Weisberg and colleagues[148] compared renal blood flow and the incidence of CIAKI between subjects treated with low dose dopamine coupled with 0.45% saline and patients who received 0.45% saline alone. Despite observing a sustained increase in renal blood flow with dopamine, overall rates of CIAKI between the two groups were similar (6 out of 15 versus 5 out of 15, p=1.0). Of note, diabetics treated with dopamine experienced more CIAKI than diabetics treated with saline alone. More recently, Abizaid et al.[152] conducted a randomized trial comparing the effects of dopamine added to IV saline on rates of CIAKI following coronary angiography. No benefit was observed for subjects who received dopamine. Thus, although low dose dopamine increases renal blood flow, this hemodynamic effect has no impact on diminishing the nephrotoxic effect of iodinated contrast and may be detrimental to patients with underlying diabetes mellitus.

Fenoldopam is a selective dopamine receptor agonist and vasodilator that is used for the treatment of hypertensive emergency. Studies in humans have shown that fenoldopam dilates renal vessels and augments renal perfusion, properties that informed studies investigating its potential to prevent CIAKI.[153–156] Several studies reported that periprocedural fenoldopam administration reduced the incidence of CIAKI.[155–160] However, most were uncontrolled, nonrandomized or of limited sample size. Two randomized controlled trials found no benefit to fenoldopam for the prevention of CIAKI. In a randomized trial of 123 patients, Allaqaband et al.[161] compared half-isotonic saline alone to either half-isotonic saline plus fenoldopam or half-isotonic

saline plus N-acetylcysteine. There was no difference in the incidence of CIAKI across the three treatment arms (P= .92). In a subsequent study, Stone et al.[162] randomized 315 patients with CKD to receive IV fluids with or without IV fenoldopam before and after coronary angiography. The incidence of CIAKI, defined as an increase in SCr of at least 25% within 96 hours, was 33.6% in patients assigned to receive fenoldopam as compared to 30.1% in patients assigned to placebo (P= .61). There were also no significant differences in the rates of rehospitalization, the need for dialysis, or 30-day mortality. The data therefore do not support the use of fenoldopam for the prevention of CIAKI.

Atrial Natriuretic Peptide

The renal vasodilatory properties of atrial natriuretic peptide (ANP) have led to interest in this agent for the prevention and treatment of many etiologies of AKI, including CIAKI. Although early studies using animal models suggested a benefit with ANP, clinical trials of ANP in CIAKI have yielded conflicting results.[31,55,163–165] In a multicenter, randomized controlled trial, Kurnik et al.[163] assigned 247 patients with baseline CKD to placebo or one of three doses of ANP (0.01 mcg per kilogram per minute, 0.05 mcg per kilogram per minute, or 0.1 mcg per kilogram per minute) beginning 30 minutes prior to and continuing until 30 minutes after radiocontrast administration. There was no beneficial effect of ANP on the development of CIAKI, with an incidence of CIAKI of 19% in patients receiving placebo as compared to 25% in patients receiving the highest dose of ANP. In a more recent study, Morikawa and colleagues[164] randomized 254 patients with CKD undergoing coronary angiography with or without PCI in an unblinded fashion to ANP at a dose of 0.042 mcg per kilogram per minute and IV fluids or to IV fluids alone. CIAKI occurred less frequently among patients who received ANP than among patients in the control group (3.2% versus 11.7%, P= .015), and the incidence of persistent decline in kidney function at 1 month was lower among patients randomized to ANP. The difference in the results in these two trials may relate to differences in the study protocols; in the study by Morikawa et al., the ANP infusion rate was lower than the maximal rate in the Kurnik study, and the duration of infusion was more prolonged. Although these data suggest a potential benefit to ANP for the prevention of CIAKI, further study is required to establish the potential role for this agent.

Theophylline/Aminophylline

Research demonstrating that adenosine may be an important mediator in the pathogenesis of CIAKI prompted an investigation of theophylline, an adenosine antagonist, as a potential protective agent in patients receiving radiocontrast.[166,167] Initial human studies suggested that kidney function was preserved by IV theophylline in patients receiving contrast.[168] These observations led Erley et al.[166] to conduct a prospective randomized clinical trial of theophylline in combination with IV saline in 80 patients. In this study, theophylline offered no benefit in preventing CIAKI, although the incidence was low in both the theophylline and the placebo groups. Similarly, a randomized trial of patients undergoing angiography compared aminophylline, dopamine, and saline, and demonstrated no reduction in the incidence of renal injury with aminophylline.[69] In contrast, Huber et al.[134] observed a reduction in the incidence of CIAKI from 20% to 4% following pretreatment with oral theophylline in a study of 100 patients with CKD. In an effort to reconcile these conflicting studies, Ix et al.[169] conducted a meta-analysis that included seven randomized trials of theophylline or aminophylline encompassing 480 patients. In this pooled analysis, patients treated with theophylline or aminophylline experienced a smaller mean increase in SCr than did patients in the study control arms (0.13 mg per deciliter; 95% CI: 0.06 to 0.22 mg per deciliter; P= .004). Adverse effects of therapy and the incidence of longer term outcomes of CIAKI were not reported in the majority of studies. In a second meta-analysis of nine randomized controlled trials involving 585 patients, Bagshaw and Ghali[170] reported an odds ratio for the development of CIAKI of 0.40 (95% CI: 0.14 to 1.16; P= .09) associated with theophylline administration using a random-effects model. They cautioned, however, that there was significant heterogeneity across trials and that the pooled results required cautious interpretation. Kelly and colleagues[171] reached a similar conclusion in a meta-analysis of six studies that included 531 patients, with an odds ratio for the development of CIAKI associated with theophylline of 0.49 (95% CI: 0.23 to 1.06). Given the potential side effects of theophylline and the limited quality of existing data, it is premature to conclude that this agent is protective in the setting of contrast administration.

Statins

By virtue of their antioxidant and anti-inflammatory properties and their effects on endothelial function, statins have been hypothesized to be potentially protective against the development of CIAKI.[172–175] Preliminary observational analyses suggested that statins are effective at reducing the incidence of renal injury from contrast. However, a trial by Jo et al.[175] that randomized patients to four 40 mg doses of simvastatin or placebo at the time of coronary angiography failed to demonstrate a benefit to simvastatin therapy. A recent single-center trial by Toso et al.[176] randomized 304 patients with CKD to receive 80 mg of atorvastatin or placebo daily for 2 days prior to and 2 days following coronary angiography. CIAKI, defined as an increase in SCr $\geq$0.5 mg per deciliter within 5 days, developed in 10% of atorvastatin-treated patients and 11% of placebo-treated patients (P= .86). No differences were seen between the groups in the incidence of persistent renal injury at 30 days following angiography. Thus, data to date are insufficient to support the administration of statins for the prevention of CIAKI.

Prostaglandins

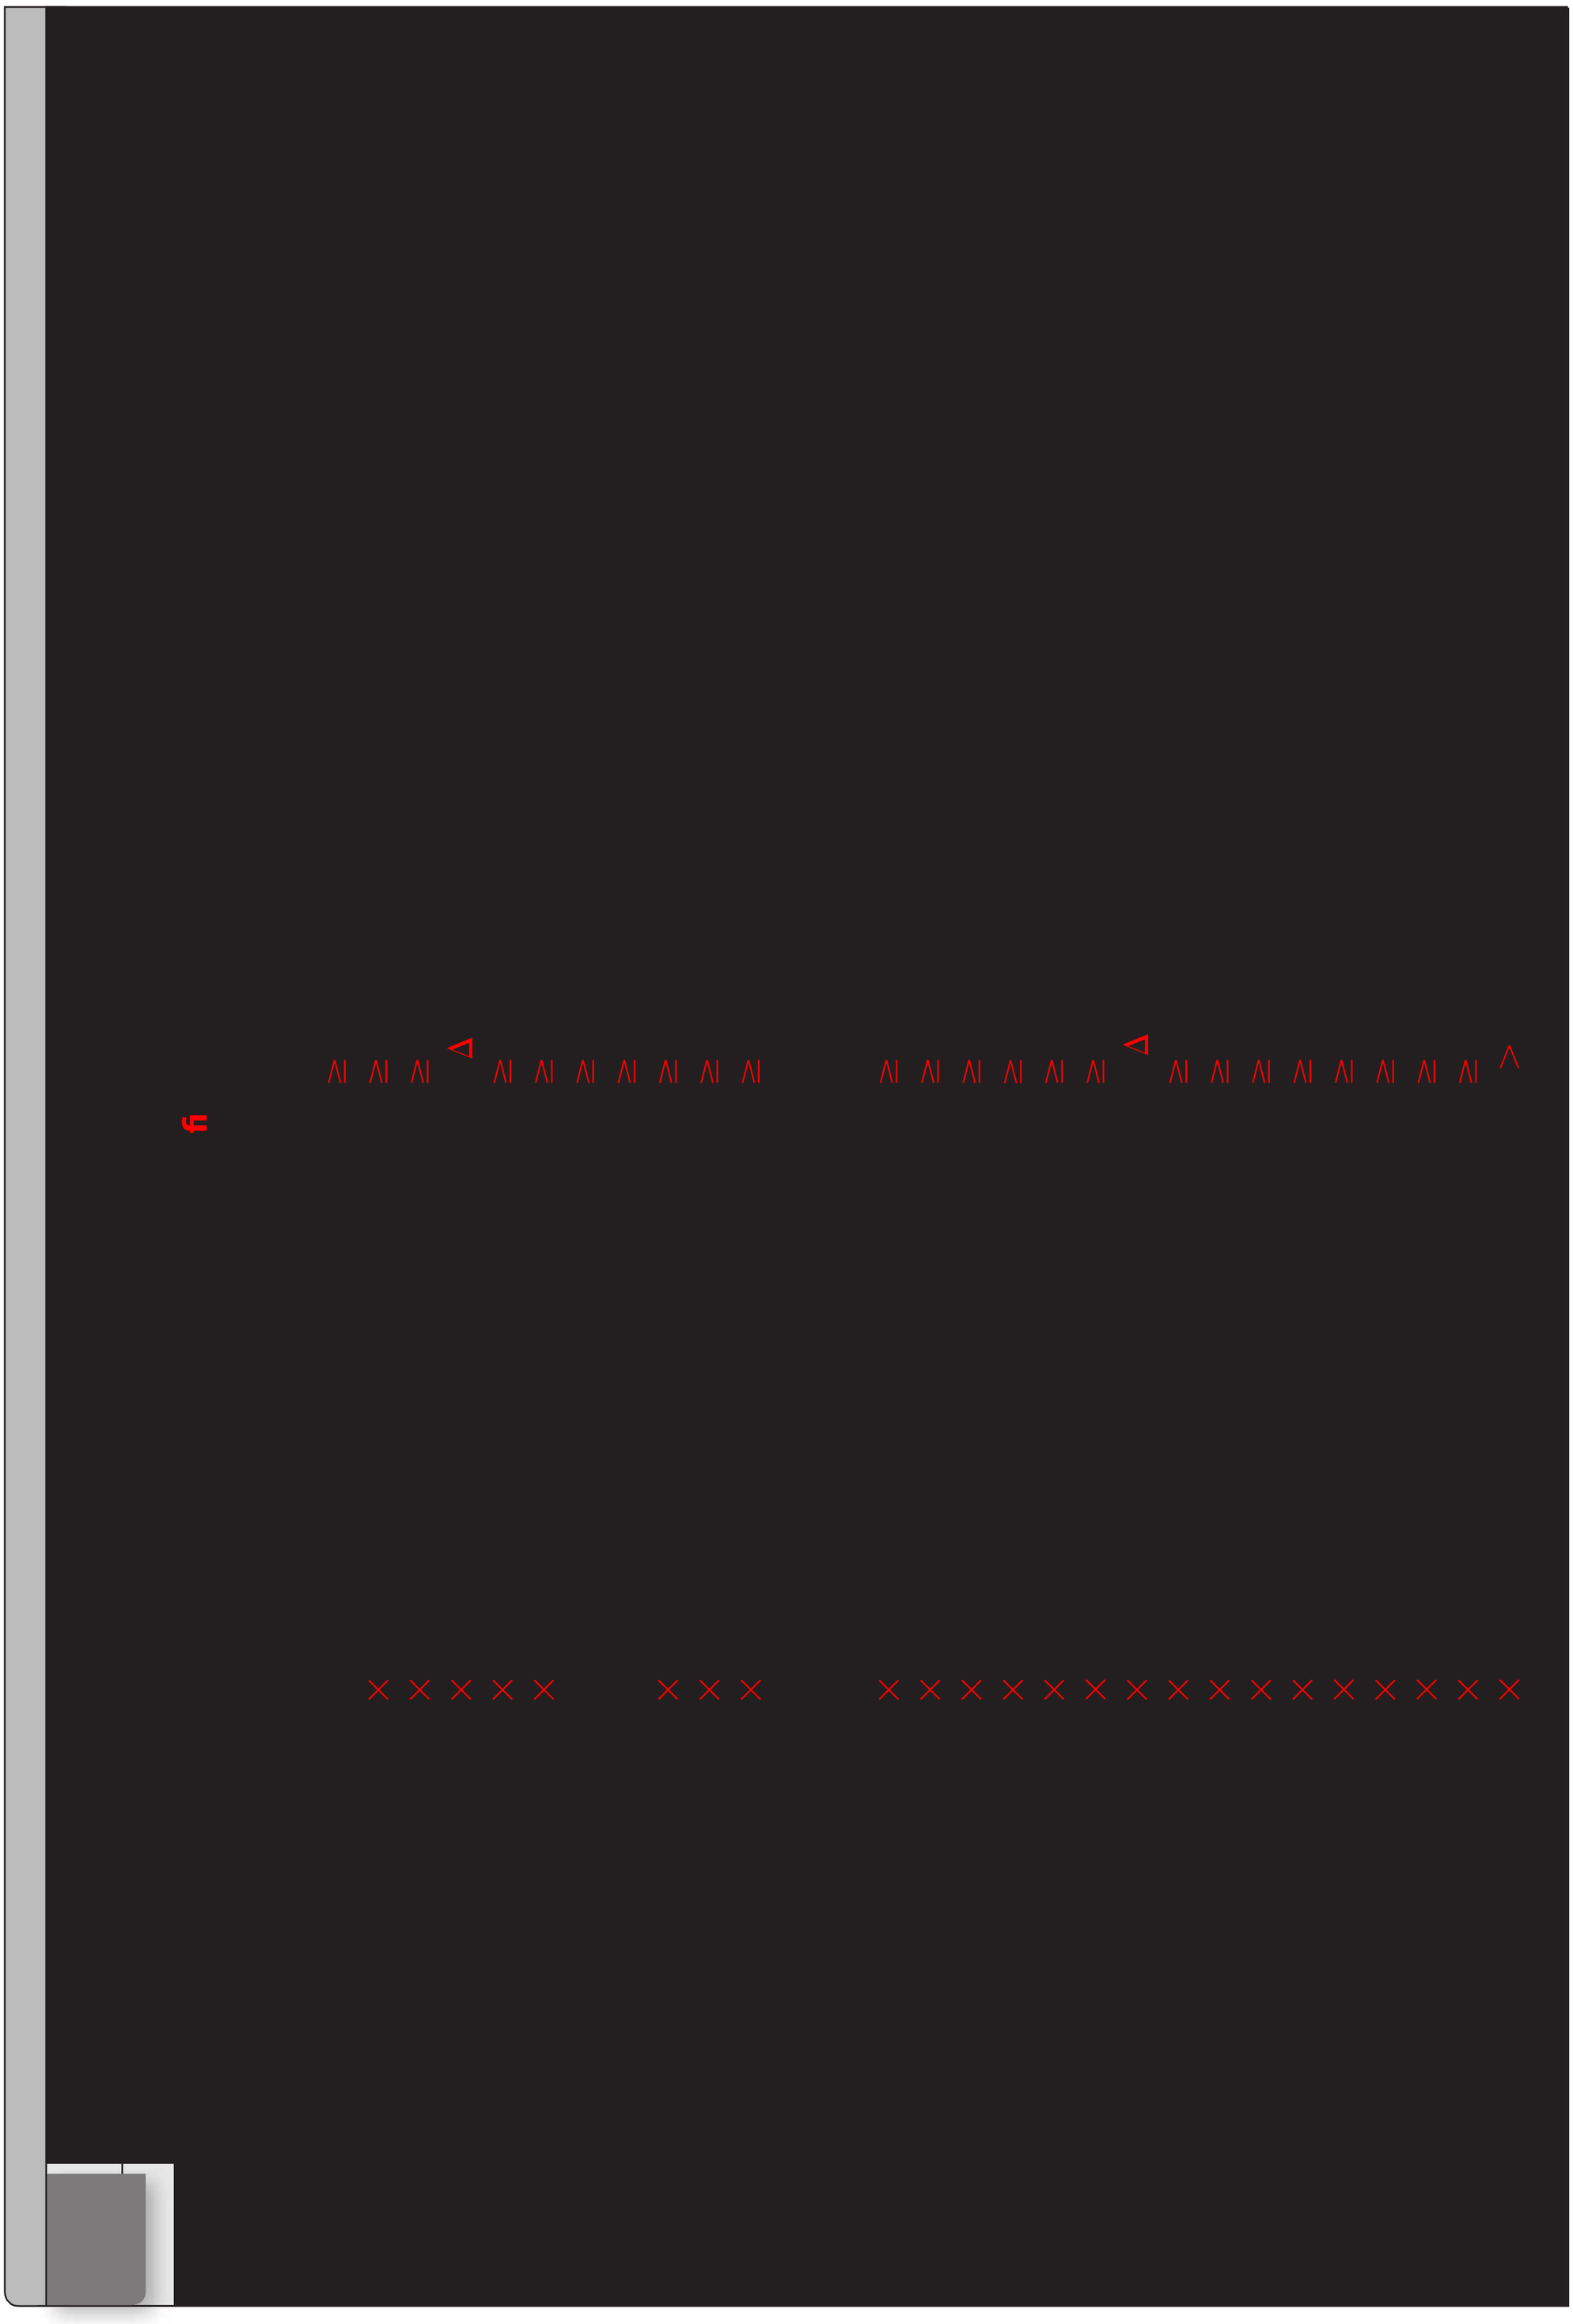
Prostaglandins (PGI_2 and PGE_2) have vasodilatory actions in the kidney and may attenuate the vasoconstrictive effects of iodinated contrast. Studies in animal models suggest a potential beneficial role of prostaglandins for the prevention of nephrotoxicity caused by iodinated contrast.[10,23] Spargias and colleagues[177] conducted a randomized clinical trial in 208 patients with CKD who were undergoing coronary angiography. Patients were randomized to receive placebo or iloprost, a PGI_2 analog, at a dose of 1 ng per kilogram per minute prior to and following the angiography. The investigators found a lower incidence of CIAKI, defined by an increase in SCr ≥0.5 mg per deciliter or ≥25% within 2 to 5 days, with iloprost compared to placebo (8% versus 22%, P= .005) with few adverse events. Notwithstanding the reasonably substantial reduction in the incidence of CIAKI, several caveats must be considered in interpreting the results of this trial. First, the study's power was based on the assumption of a 70% reduction in the incidence of the primary outcome with iloprost, a biologically and clinically implausible effect size. Second, the effects of iloprost on longer term adverse outcomes were not tracked. Until adequately powered studies that comprehensively investigate the short- and long-term risk/benefit ratio of prostaglandins, the routine use of these agents for the prevention of CIAKI cannot be recommended.

N-Acetylcysteine (NAC)

The rationale for the use of NAC for the prevention of CIAKI relates to its capacity to serve as a ROS scavenger, reduce the depletion of glutathione, and stimulate the production of vasodilatory agents such as nitric oxide.[178,179] Studies in animal models of AKI demonstrate that the administration of NAC reduces oxidative damage, attenuates renal medullary vasoconstriction, and decreases renal injury.[178,180] These animal models provided the scientific basis for human studies of NAC for the prevention of CIAKI. An initial trial by Tepel et al.,[181] published in 2000, described the efficacy of NAC for the prevention of CIAKI. In this study, 83 patients undergoing contrast-enhanced CT scans were randomized to receive 600 mg of NAC or placebo twice daily on the day prior to and the day of the procedure. A lower proportion of patients randomized to NAC developed CIAKI than did patients randomized to placebo (2% versus 21%, P= .01). Similar results were reported by Diaz-Sandoval et al.,[182] who randomized 54 patients undergoing coronary angiography to NAC or placebo and also demonstrated a markedly lower incidence of CIAKI among patients who had received NAC (8% versus 45%, P= .005). Similarly, Shyu and colleagues[183] randomized 121 patients with significant baseline CKD (SCr ≥2.8 mg per deciliter) who were undergoing coronary intervention to NAC or placebo and also demonstrated a lower rate of CIAKI among patients who had received NAC (3% versus 25%; P< .001). These initial positive findings were followed by multiple additional trials that yielded highly conflicting results (Table 33.5).[86,102,161,181–203] In an effort to reconcile the incongruent clinical trial findings, multiple meta-analyses have analyzed the pooled results of these studies.[204–221] In one of the larger meta-analyses, Kelly and colleagues[171] included 26 trials encompassing 3,393 patients and found a 38% reduction in the risk of CIAKI associated with NAC (RR=0.62; 95% CI: 0.44 to 0.88). Although the investigators reported heterogeneity among the pooled studies, they found no evidence of publication bias. In another meta-analysis of 22 trials that included 2,746 patients published nearly simultaneously with the Kelly study, Gonzalez et al.[211] found significant heterogeneity among the trials. Using cluster analyses, the investigators divided the trials into two groups that had minimal heterogeneity. One cluster included trials in which NAC was found to be protective, and was characterized by an observed decline in SCr following contrast administration among patients treated with NAC, whereas the other cluster consisted of studies in which there was no fall in SCr in the NAC-treated patients and no overall benefit for the prevention of CIAKI. The investigators concluded that NAC was not effective for the prevention of CIAKI. Trevidi and colleagues[219] performed a meta-analysis of 16 studies, encompassing 1,677 patients, in which the dose of NAC was greater than 1,200 mg. In this analysis of "high-dose" therapy, NAC was associated with an odds ratio for the development of CIAKI of 0.46 (95% CI: 0.33 to 0.63). Thus, the conclusions of multiple meta-analyses of NAC are as contrasting and inconclusive as the findings of the primary clinical trials. Since the publication of these meta-analyses, Berwanger and colleagues[221a] reported the results of a randomized clinical trial comparing NAC to placebo in 2,308 patients undergoing angiography. The study did not demonstrate a benefit to NAC; however, only a small minority of trial participants had abnormal baseline kidney function, rendering the study population at low overall risk for CIAKI. However, given the low cost and minimal risk associated with oral NAC, the Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guideline for Acute Kidney Injury suggests its use in conjunction with isotonic crystalloid administration in patients at high risk for CIAKI.[222]

Additional Pharmacologic Agents

A series of additional pharmacologic agents have been investigated for their capacity to prevent the development of CIAKI. Wang et al.[223] randomized 158 patients undergoing coronary angiography to receive the nonselective endothelin (ET_A/ET_B) receptor antagonist bosentan or placebo. The mean increase in SCr 48 hours following angiography was significantly higher in the treatment group than in the placebo group (0.7 ± 0.7 versus 0.4 ± 0.6 mg per deciliter; P= .002), and the incidence of CIAKI was also higher among patients who received bosentan (56% versus 29%; P= .002). Katholi et al.[224] studied the effect of allopurinol in 39 patients with mild kidney disease. Allopurinol-treated patients with low plasma Mg^{2+} had somewhat milder decrements in creatinine clearance following contrast administration than control, hypomagnesemic patients (33% versus 79%,



respectively). However, in normomagnesemic patients, allopurinol did not affect the decline in kidney function. At present, the data are insufficient to establish any role for either of these agents for the prevention of CIAKI.

Intravenous Fluids for the Prevention of Contrast-Induced Acute Kidney Injury

The principal intervention that has been shown to be effective in reducing the risk for CIAKI is the administration of IV fluid.[84,87,91,225] Intravascular volume expansion is believed to have two physiologic effects that protect against the development of CIAKI. First, expansion of the intravascular space may attenuate the vasoconstrictive effect of contrast by means of suppressing vasopressin, inhibiting the renin–angiotensin–aldosterone system, and inducing the synthesis of vasodilatory renal prostaglandins.[226] Second, intravascular volume expansion may counteract the direct toxicity of iodinated contrast on tubular epithelial cells by decreasing the concentration and viscosity of contrast media in the tubular lumen.[226]

Early animal studies provided preliminary, albeit indirect, support for the benefit of intravascular volume expansion. Larson and colleagues[227] evaluated the degree and duration of contrast-induced vasoconstriction in sodium-depleted and sodium-replete dogs. Renal blood flow was reduced to a considerably greater degree (42.2% versus 12.2%) and for a longer period of time (343 seconds versus 147 seconds, $P < .01$) in sodium-depleted compared to sodium-replete dogs. Yoshioka et al.[43] assessed the impact of contrast administration on glomerular filtration in water-deprived and non-water-deprived rats and in water-deprived rats that received sodium chloride. An early (24 hours) and a sustained reduction in glomerular filtration was observed in water-deprived rats, whereas non-water-deprived rats and water-deprived rats that were administered sodium chloride experienced no reduction in GFR. Finally, Erley et al.[20] studied the impact of contrast on rats, including a group that was administered L-NAME, which contributes to a nitric oxide–depleted state. Among volume-depleted rats administered L-NAME, iodinated contrast reduced GFR (1.25 mL per minute to 0.89 mL per minute, $P < .05$). This effect was diminished in volume-depleted rats in the absence of L-NAME and was absent in volume-expanded L-NAME rats. Collectively, these studies highlight the association of volume-depleted states with an increased risk for CIAKI.

Human data on the benefit of intravascular volume expansion derived initially from observational studies. In 1981, Eisenberg et al.[88] reported the results of a single arm observational study of 537 patients who received intravascular volume expansion with an average volume of 550 mL of isotonic NaCl during each hour of angiography. CIAKI did not develop in any study patients compared to 12% of patients in a historic cohort who had received 80 mL per hour of 5% dextrose in water. Subsequently, Kerstein and Puyau[228] studied the effect of 0.5% NaCl in 5% dextrose administered prior to and following noncoronary angiography in 150 patients. Study participants with baseline renal insufficiency received an additional 300 to 500 mL of IV fluid and 20 to 40 mg of furosemide prior to the procedure. None of the patients were observed to have developed CIAKI. However, this study had no control group and enrolled a relatively low-risk patient population. Nonetheless, these observational studies provided early insights into the potential benefit of IV volume expansion for the prevention of CIAKI.

Several randomized clinical trials over the past 2 decades have examined the effect of IV volume expansion in the prevention of CIAKI, and provide preliminary data on the comparative effects of IV fluid composition. In 1994, Solomon et al.[84] published the results of a three-armed clinical trial of patients undergoing coronary angiography comparing prophylactic IV 0.45% saline to prophylactic IV 0.45% saline with 25 g of IV mannitol or 80 mg of IV furosemide. Overall, 11% of patients who received IV fluid alone developed CIAKI compared to 28% of patients who also received mannitol and 40% in those who also received furosemide. The absence of a control group who received no IV fluid precluded a conclusion that IV fluids were definitively beneficial. However, Trivedi et al.[225] subsequently confirmed the benefit of IV volume expansion in a clinical trial that enrolled patients undergoing nonemergent coronary angiography. Patients were randomized to receive either IV isotonic sodium chloride for 12 hours prior to and 12 hours following angiography or unrestricted oral fluids. The study was stopped by the safety monitor after just 53 patients had been enrolled because the rate of CIAKI was markedly lower in the IV saline group than in the oral fluid group (3.7% versus 34.6%; $P = .005$).

Mueller et al.[87] compared the effects of hypotonic and isotonic saline in over 1,600 low-risk patients undergoing coronary angiography who were randomized to receive periprocedural IV 0.45% saline or 0.9% saline. The overall rate of CIAKI was greater in patients who received half-isotonic saline compared to those who were administered isotonic saline (2% versus 0.7%, $P = .04$). Notwithstanding the decidedly low-risk profile of this study's patient population, this trial has served as the justification for the widespread belief that isotonic saline is superior to hypotonic saline for the prevention of CIAKI.

Recent research on IV fluid composition has focused on the comparison of isotonic sodium bicarbonate with isotonic sodium chloride. The belief that the generation of ROS in the kidney, which is augmented by acidic urine and contributes to renal tubular cell injury, and that the alkalization of the urine with the administration of IV bicarbonate attenuates this process, forms the physiologic framework for clinical studies comparing isotonic IV fluids that differ in respect to the anion component (HCO_3^- v. Cl^-). Merten and colleagues[91] conducted the initial clinical trial comparing the benefits of isotonic bicarbonate to isotonic saline. One hundred and nineteen patients were randomized to one of two fluid regimens; 8 of 59 patients (13.6%) randomized to receive isotonic saline developed CIAKI as compared to

33.6 Clinical Trials of Intravenous Isotonic Sodium Bicarbonate and Saline for the Prevention of Contrast-Induced Acute Kidney Injury

Authors	# Study Patients	Diabetes (%)	Baseline SCr (mg/dL)	Definition of CIAKI	% CIAKI Bicarbonate	% CIAKI Saline
Positive studies						
Briguori et al.	219	52%	2.0	↑ SCr ≥25%	1.9%	9.9%

[b]Bicarbonate administered as 75 mL of 8.4% sodium bicarbonate added to 1 L isotonic saline.
CIAKI, contrast-induced acute kidney injury; SCr, serum creatinine; eGFR, estimated glomerular filtration rate.

1 of 60 patients randomized to receive isotonic bicarbonate (P = .02). Subsequently, at least nine other clinical trials comparing IV isotonic bicarbonate with IV isotonic saline have been published, slightly more than half of which have demonstrated a lower incidence of CIAKI with bicarbonate (Table 33.6).[103,104,144, 229–234]

In response to the disparate results of these clinical trials, nearly a dozen systematic reviews and meta-analyses comparing the effectiveness of bicarbonate and saline have been performed.[207,229,230,235–242] Zoungas et al.[235] pooled the findings of 23 published and unpublished trials that included more than 3,500 patients and found a reduction in the risk of CIAKI with IV bicarbonate compared to saline (RR = 0.62; 95% CI: 0.45 to 0.86). However, they also noted significant study heterogeneity and evidence of publication bias. Sensitivity analyses restricted to published studies demonstrated a significantly lower risk of CIAKI with bicarbonate (RR = 0.43, 95% CI: 0.25 to 0.75), whereas analyses focused on unpublished trials failed to demonstrate such a benefit (RR = 0.78, 95% CI: 0.52 to 1.17) (Fig. 33.4). Another recent meta-analysis by Kunadian et al.[242] included data from seven published trials that also demonstrated a lower risk of CIAKI with IV isotonic bicarbonate (OR = 0.33, 95% CI: 0.16 to 0.69). However, the investigators also reported study heterogeneity and publication bias, which impact the interpretation of benefit. Thus, based on the current level of evidence, there is considerable uncertainty regarding the true benefit of isotonic bicarbonate as compared to saline. Given this uncertainty, and the potential for medical errors in compounding isotonic bicarbonate solutions in the absence of commercially available preparations, the KDIGO Clinical Practice Guideline for Acute Kidney Injury did not make a recommendation favoring either isotonic bicarbonate or saline.[222]

Current Recommendations for the Prevention of Contrast-Induced Acute Kidney Injury

Once a determination has been made that a procedure using intravascular iodinated contrast is required in a patient at increased risk for CIAKI, steps to attenuate that risk should be implemented based on our current understanding of the preventive modalities discussed previously. Modifiable patient-related risk factors should be addressed. Overt intravascular volume depletion should be corrected in all patients prior to the administration of iodinated radiocontrast. Based on our understanding of the pathophysiology of CIAKI and data from animal studies, nonselective nonsteroidal anti-inflammatory medications and selective cyclooxygenase-2

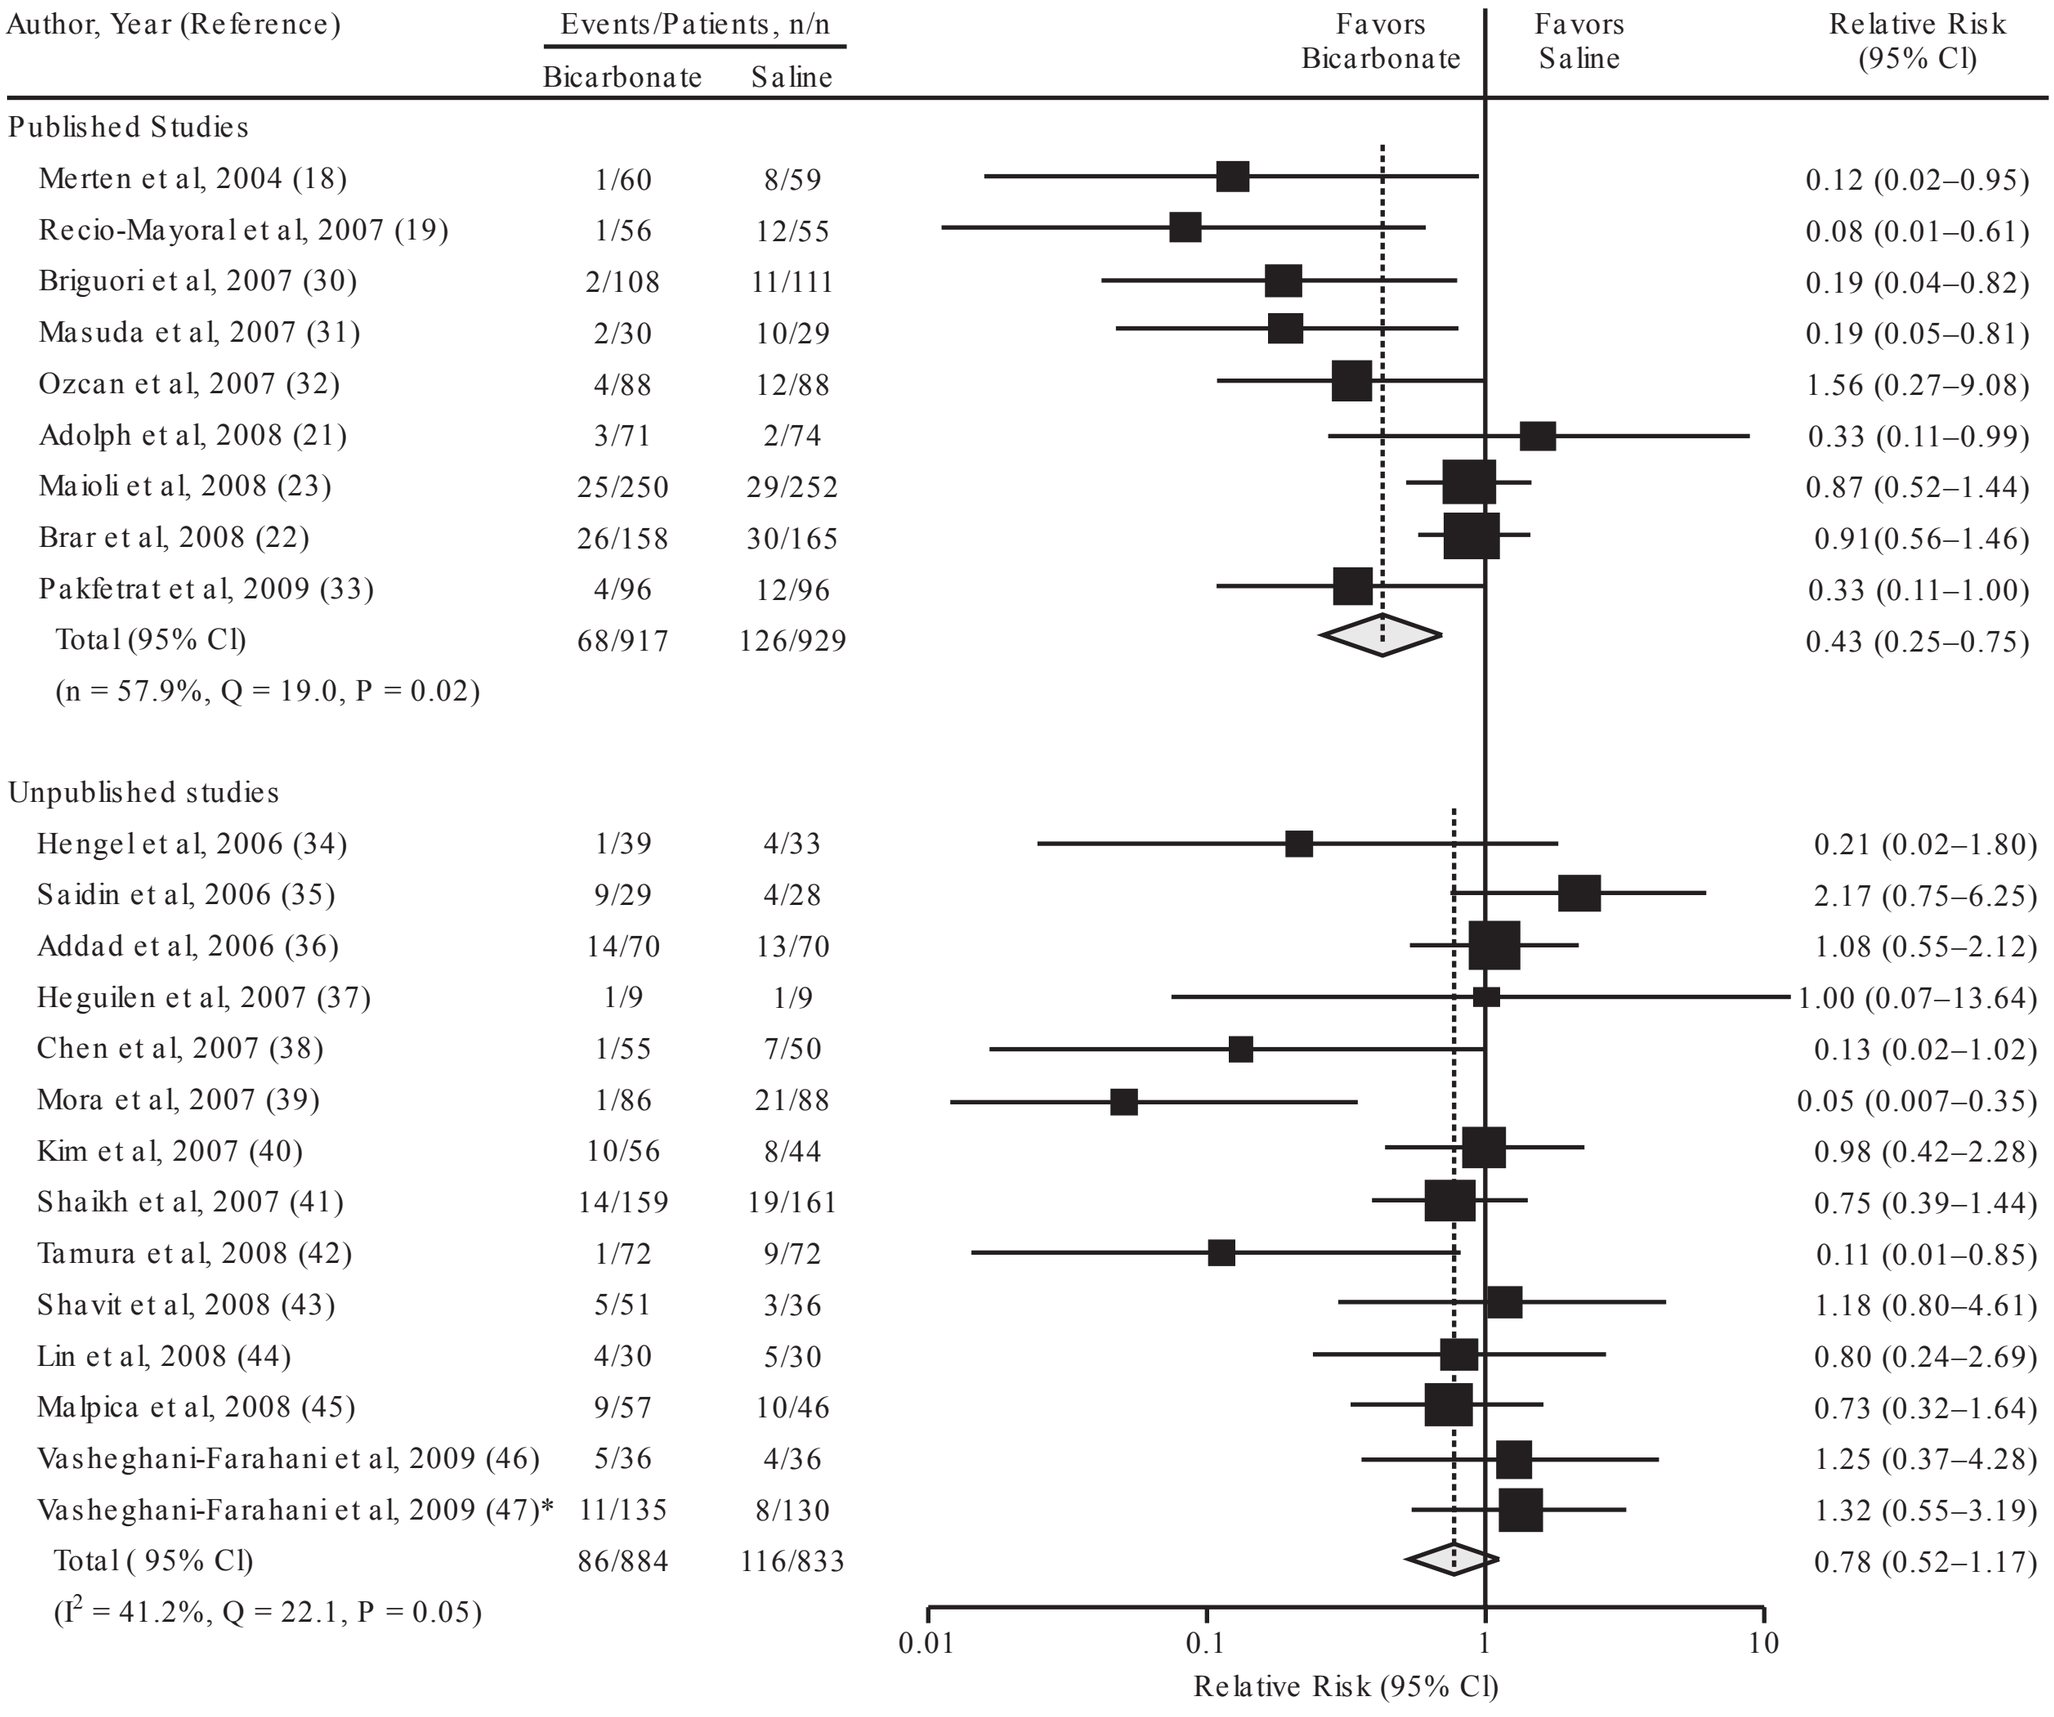

FIGURE 33.4 The forest plot of relative risks for contrast-induced nephropathy from 23 studies. Reprinted with permission from Zoungas S, et al. Systematic review: sodium bicarbonate treatment regimens for the prevention of contrast-induced nephropathy. *Ann Intern Med*. 2009;151(9):631–638.

inhibitors, which inhibit the production of vasodilatory prostaglandins, should be discontinued at least 24 hours prior to contrast administration and held until confirmation has been made that CIAKI has not developed. Additionally, modifiable procedure-related risk factors should be considered. The volume of contrast administered should be limited to the minimum required dose that does not compromise diagnostic accuracy. Iso-osmolal or nonionic, low-osmolality contrast other than iohexol or ioxaglate should be employed. IV fluids consisting of isotonic sodium chloride or sodium bicarbonate should be administered prior to and following the administration of contrast. Among inpatients undergoing nonemergent procedures, an IV fluid regimen of 1 mL per kilogram per hour for 6 to 12 hours preceding and 6 to 12 hours following the administration of iodinated contrast has been most rigorously validated and should be considered. For high-risk patients undergoing elective outpatient procedures or urgent inpatient studies, comparable volumes of isotonic saline or sodium bicarbonate, administered over 1 to 3 hours prior to and 4 to 6 hours following contrast administration, may provide a more practical alternative, although this approach has not been formally compared to more prolonged periods of IV fluid administration. Although IV volume expansion would be inappropriate in the setting of acute decompensated heart failure, fluids should not be withheld merely because of a history of heart failure or low cardiac ejection fraction; rather, cautious IV fluid administration should be accompanied by close monitoring for adverse pulmonary effects.

Although the role of N-acetylcysteine for the prevention of CIAKI remains unclear, this antioxidant agent has minimal toxicity and is inexpensive when administered orally. Certain studies that examined the effect of the dose demonstrated a potential benefit to a higher dose NAC. Therefore, oral NAC administered at a dose of 1,200 mg twice daily prior to and following contrast administration should be considered. However, NAC should not be used in lieu of

more effective proven preventative interventions such as isotonic IV fluids. There is currently no role for prophylactic renal replacement therapy for the prevention of CIAKI. Diuretics, dopamine, and fenoldopam have been shown to be ineffective and, in certain instances, may be deleterious and therefore should not be used. Until further evidence from large, methodologically rigorous clinical trials is available, atrial natriuretic peptides, theophylline, statins, and prostaglandin analogs are not recommended. There is currently no role for allopurinol or endothelin receptor antagonists.

There is little evidence that lactic acidosis develops in patients taking metformin who have normal renal function before receiving iodinated contrast. Concern arises for the development of metformin-induced lactic acidosis when diabetics with other risk factors for CIAKI develop renal injury and delayed excretion of the drug occurs. Therefore, current recommendations call for the discontinuation of metformin in patients at an increased risk of CIAKI with the reinstitution of the medication once postprocedure renal function has been confirmed to be stable. Additional steps to maintain serum glucose concentrations while metformin is being held may be necessary. There are no data to support the discontinuation of diuretics at the time of contrast administration. Small studies investigating the impact of discontinuing angiotensin converting enzyme (ACE) inhibitors/angiotensin receptor blockers prior to contrast administration have been conflicting.[243,244] Rosenstock and colleagues[244] randomized 220 patients who were on chronic ACE inhibitor or angiotensin receptor blocker therapy and who were scheduled to undergo coronary angiography to either continuation or discontinuation of renin-angiotensin-aldosterone system (RAAS) blockade. The incidence of CIAKI was 6.2% in the 113 patients who continued RAAS blockade and was 3.7% in the 107 patients who discontinued RAAS blockade (P= .66) as compared to 3.3% in 63 matched patients who were naïve to RAAS blockade. Therefore, no evidence-based recommendations to discontinue such agents can be made.

In patients at risk for CIAKI, the monitoring of renal function following the administration of iodinated radiocontrast is essential. Renal function should be measured between 48 and 72 hours following the procedure to assess for the development of renal injury and to permit timely implementation of supportive care.

CONCLUSION

Acute kidney injury resulting from the administration of intravascular iodinated contrast media is a leading cause of nephrotoxic ATN. It develops almost exclusively in patients with underlying risk factors. With multiple studies demonstrating an association of CIAKI with serious adverse short- and long-term outcomes, a careful evaluation of each patient who is to receive intravascular radiocontrast for the presence of underlying risk factors for CIAKI and implementation of evidence-based preventive measures will facilitate the prevention of this iatrogenic condition.

CHAPTER

34 Nephrotoxicity Secondary to Environmental Agents, Heavy Metals, Drug Abuse, and Lithium

Veronica Torres da Costa e Silva • Etienne Macedo • Luis Yu

Environmental kidney diseases are a consequence of occupational exposure, a particular form of environmental disease. Recognized chronic occupational renal diseases include those caused by exposure to heavy metals, organic solvents (aliphatic, aromatic, and halogenated hydrocarbons), and silica. Minamata disease from mercury and Itai-Itai disease from cadmium are two environmental diseases caused by industrial elements. Another disease is Balkan nephritis presumed to be of environmental origin and the nephropathy caused by the ingestion of germanium compounds.

Several heavy metals are generally recognized as nephrotoxic following environmental or occupational exposure, including: lead, cadmium, mercury, uranium, chromium, copper, and arsenic. However, chronic renal failure has been described only for lead, mercury, cadmium, uranium, and arsenic. Therapeutic forms of platinum, gold, lithium, and bismuth may also induce kidney damage and these aspects are explored in other chapters of this book. Other heavy metals with potentially nephrotoxic effects are barium, cobalt, manganese, nickel, silver, thallium, thorium, tin, and vanadium but there is no definitive evidence they can actually lead to renal disease.

URINARY BIOMARKERS

Urinary proteins and biochemical markers were associated with toxic renal injury. Urinary biomarkers may reflect specific sites of renal injury: (1) low molecular weight proteins and intracellular enzymes—proximal tubule damage; (2) Tamm-Horsfall glycoprotein and kallikrein—distal tubule injury; (3) high molecular weight proteins—increased glomerular permeability (if >200 mg per g creatinine); and (4) biochemical markers—eicosanoids suggesting vascular injury.

A group of urinary markers (human intestinal alkaline phosphatase [HIAP], total nonspecific alkaline phosphatase [TNAP], N-acetyl-β-D-glucosaminidase [NAG], retinol binding protein [RBP], Tamm-Horsfall glycoprotein [THG], β_2-microglobulin, microalbumin, thromboxane B_2 [TBX_2], and three prostaglandins [prostaglandin E_2, PGE_2; prostaglandin $F_{2\alpha}$, $PGF_{2\alpha}$; 6-keto-prostaglandin $F_{1\alpha}$, 6-keto-$PGF_{1\alpha}$]) are detailed to demonstrate the differentiation of the toxic nephropathies (Table 34.1).[1–5]

The excretion patterns represent occupational exposure levels indicated by the specified mean blood or urine concentrations. Mercury and cadmium exposure[3–5] is associated with the isoenzyme HIAP, a sensitive and specific indicator of injury to the S3 segment of the proximal tubule. Total nonspecific alkaline phosphatase is increased after perchloroethylene exposure[6,7] and NAG and RBP are elevated after cadmium exposure.[3,8] The urinary eicosanoids PGE_2, $PGF_{2\alpha}$, and 6-keto-$PGF_{1\alpha}$ seem to be associated to the development of hypertension and injury to the glomeruli or renal medulla. Also, low levels of urinary albumin can also express proximal tubular dysfunction and the failure to reabsorb or metabolize albumin that passes through the glomerular filter.

The ability of these urinary markers to discriminate among the diverse nephrotoxins enhances with increasing exposure levels. Urinary markers should be collected in fasting fresh voided specimens (spot urines) at 8 AM, and expressed relative to the creatinine concentration. The specificity of tubular injury decreases in the presence of renal damage.

LEAD NEPHROPATHY

The first description of lead nephrotoxicity was made by Lancereaux in 1862, who reported a patient with saturnine (lead-induced) gout with kidneys showing interstitial nephritis at postmortem examination. Nevertheless, the demonstration of lead nephrotoxicity has presented some issues. There are difficulties proving the connection between late sequelae of chronic absorption to relatively low levels of lead, and distinguishing between glomerular and extraglomerular renal disease.[9] Another difficult aspect is how to separate the transient Fanconi syndrome of acute childhood lead poisoning from the chronic interstitial nephritis characteristic of lead nephropathy in adults. Finally, one confounding aspect is the differentiation of late complications of excessive lead

34.1 Urinary Markers in Toxic Nephropathies—European Cooperative Study

	HIAP	TNAP	NAG	RBP	THG	β_2-M	mAlb	TXB_2	PG
Pb	−	−	+	−	−	−	−	++	6F−

PCE	−	+++	−	−	±	−	+		F−
									E–

HIAP, human intestinal alkaline phosphatase; TNAP, total nonspecific alkaline phosphatase; NAG, N-acetyl-β-D-glucosaminidase; RBP, retinol binding protein; THG, Tamm-Horsfall glycoprotein; β_2-M, β_2-microglobulin; mAlb, microalbumin; TXB_2, thromboxane B_2; PG, prostaglandin; Pb, lead; Cd, cadmium; Hg, mercury; PCE, perchloroethylene; 6F, 6-keto-$PGF_{1\alpha}$; F, $PGF2_{1\alpha}$; E, PGE_2.

absorption and gout and hypertension renal lesions, which are other important causes of renal disease.

Diagnosis

The mainstay of laboratory diagnosis is the blood lead concentration, which is usually over 60 μg per dL, although recent evidence of lead-induced organ damage occurred with blood levels over 10 μg per dL.[10] Blood lead concentrations usually decrease significantly within 4 weeks of removal from exposure making the blood lead concentration relatively insensitive to cumulative body stores acquired over years. Around 95% of the body stores of lead are accumulated in the bone with a mean residence time of approximating 20 years[11] and cumulative past lead absorption is best assessed by the calcium disodium edetate ($CaNa_2EDTA$) lead-mobilization test.[12]

The ethylenediamine tetraacetic acid (EDTA) test is performed in adults by parenteral administration of 1 to 3 g (intravenous or intramuscular) of $CaNa_2EDTA$ over 4 to 12 hours with subsequent collection of 24-hour urine samples over 1 to 4 days. The intramuscular administration of 2 g of $CaNa_2EDTA$ (1 g of EDTA mixed with local anesthetic in each of two injections, 12 hours apart) seems to be a better option of performing the chelation test because it has been well standardized in both normal subjects and patients with renal failure.[13–18] In the presence of renal damage (serum creatinine > 1.5 mg per dL), urinary excretion of lead chelate should be extended to at least 3 consecutive days and the adequacy of collection checked by simultaneous measurement of urinary creatinine excretion (1.3 g of creatinine per day is an acceptable lower limit in normal adult males). Adults without undue prior lead absorption excrete up to 650 μg of lead-chelate in the urine.

Chelatable lead correlates well with bone lead[19,20] which reflects cumulative body lead stores. Bone lead concentrations can be accurately diagnosed by a new noninvasive technique, the in vivo tibial K X-ray fluorescence.[21,22]

Acute Lead Nephropathy

In acute lead nephropathy, a proximal tubule reabsorptive defect characterized by aminoaciduria, phosphaturia, and glycosuria (Fanconi syndrome) is observed,[23] usually in the presence of blood lead levels in excess of 150 μg per dL. An increase in urinary NAG is observed, which correlates positively with the blood lead concentration.[24] Tubular dysfunction is often reversed after chelation therapy is initiated to treat the more dangerous encephalopathy. Acute lead nephropathy is associated with acid-fast intranuclear inclusions in proximal tubule epithelial cells[25] which are a lead–protein complex, also observed in the urinary sediment.[25] These inclusions can occur in other organs such as in liver, neural tissue, and osteoclasts. Morphologic and functional defects in mitochondria are also observed in acute poisoning.

Chronic Lead Nephropathy

Chronic lead nephropathy is the slowly progressive interstitial nephritis observed in adults after prolonged lead exposure. The disease is more frequently recognized in lead workers after long periods (decades) of exposure but other groups have been described such as young adults who sustained acute childhood lead poisoning,[26] illicit whiskey ("moonshine") consumers, U.S. armed service veterans suffering from renal failure attributed to gout or essential hypertension,[13,14] and sporadic case reports such as geophagia,[27] Asian folk remedies, and cosmetics.

Chronic lead nephropathy causes chronic renal damage less responsive to chelating agents. There is evidence of associated functional impairment such as inhibition of both the renin-angiotensin system and Na^+-K^+-ATPase,[17,28] and these effects may be changed by chelation therapy. This explains why some exposed individuals can restore previous reductions in glomerular filtration rate (GFR) after long-term low-dose chelation therapy (1 g of $CaNa_2EDTA$ with local anesthetic three times weekly until the chelation test returns to normal). Proteinuria and glycosuria are initially absent and an increase in TXB_2, and a decrease in PGE_2 and 6-keto-$PGF_1\alpha$, in the urine is observed.[2,24]

Renal biopsies in chronic lead nephropathy show nonspecific tubular atrophy and interstitial fibrosis with minimal inflammatory response as well as mitochondrial swelling, loss of cristae, and increased lysosomal dense bodies within proximal tubule cells (Fig. 34.1).[15,19] Arteriolar changes indistinguishable from nephrosclerosis are found, often in the absence of clinical hypertension. Intranuclear inclusion bodies are often absent when the renal disease is long-standing or following the administration of chelating agents. Clumped chromatin and nuclear invaginations of cytoplasmic contents may be found even in the absence of intranuclear inclusions. Morphologic alterations are minimal in glomeruli until the reduction in GFR is advanced. This helps explain the association between lead toxicity and hypertension.

The association between lead and gout nephropathy has long been described.[29,30] Hyperuricemia and gout are common among individuals with excessive exposure to lead, apparently the result of decreased excretion and increased production of uric acid, and half of uremic patients with lead nephropathy have clinical gout.[26] There is substantial evidence that renal failure in gout is sometimes secondary to overt or unsuspected lead poisoning. In Queensland, Australia, as many as 80% of gout patients with renal failure have elevated EDTA lead-mobilization tests.[26] In New Jersey chelatable lead was found to be significantly greater among gout patients with renal failure than among gout patients with normal renal function.[13] Therefore, unrecognized lead poisoning can be an explanation for renal failure in some gout patients with no evidence of urinary calculi or intratubular uric acid deposition disease.

The initial renal injury from lead seems to be in the microvascular endothelium.[31] Although the mechanism of injury is not completely clear, it is well known that metabolism of lead is similar to that of calcium and other cations. Also, lead interacts with vasoactive substances that may modulate blood pressure and induce endothelial injury.[32,33] These aspects help to explain the association between lead toxicity and hypertension as suggested in several reports.[34,35] Some patients presenting as "essential hypertension with nephrosclerosis" may have evidence of lead nephropathy by the EDTA lead-mobilization test.[14] Mortality from hypertensive cardiovascular disease is more frequent among lead workers than the general population.[36] In these patients, lead seems to contribute to hypertension particularly in the presence of renal dysfunction.[17]

Treatment

Lead nephropathy is one of the few renal diseases that is preventable and potentially reversible by judicious use of chelation therapy.[16,37,38] However, there is no evidence that such therapy reverses established interstitial nephritis especially if serum creatinine concentration exceeds 3 mg per dL.[39] Reports of partial remissions may be the reversal of acute poisoning superimposed on chronic lead nephropathy.

Before chelation therapy is undertaken, it may be necessary to perform the EDTA lead-mobilization test and other possible causes of renal disease should be excluded. Long-term, low-dose EDTA therapy should be undertaken until an endpoint is achieved, such as reversion of the EDTA test to normal and restoration of renal function. The cumulative nephrotoxicity of prolonged EDTA therapy in patients with advanced renal failure is unknown. Reports of deterioration of renal function after $CaNa_2EDTA$ therapy have been described and treated patients warrant careful follow-up.[40,41]

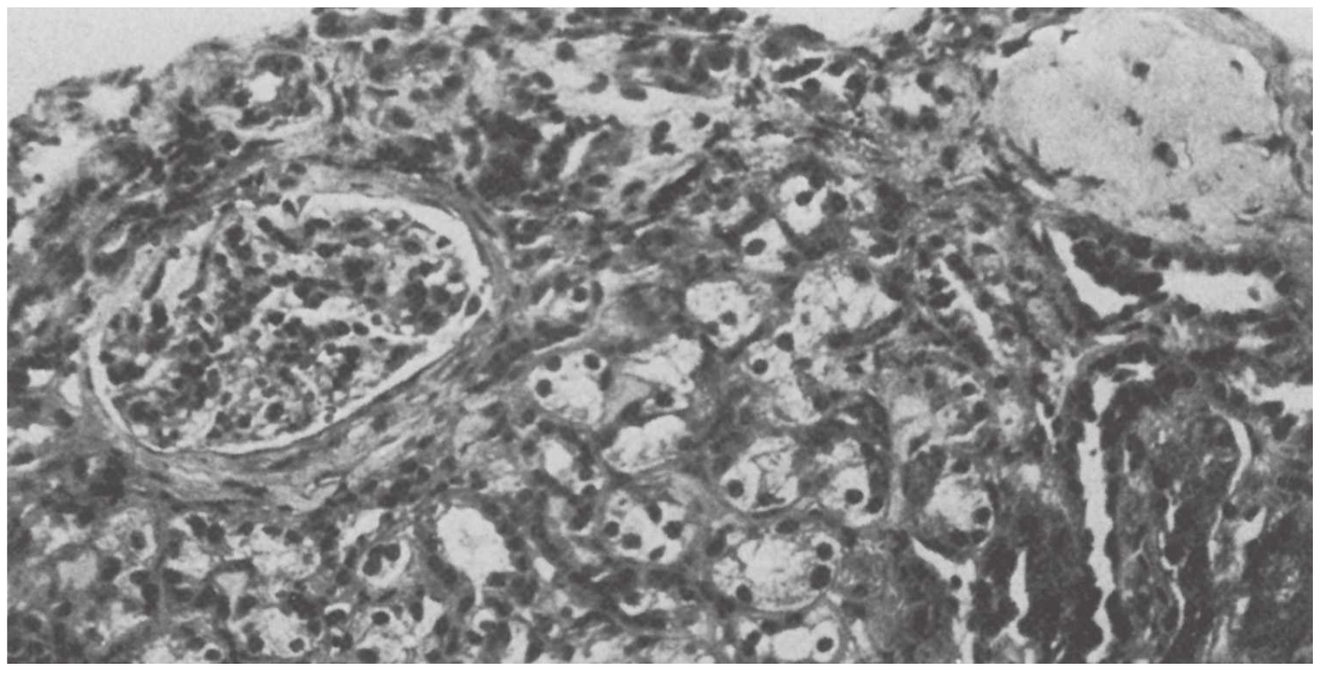

FIGURE 34.1 Renal biopsy obtained from a 28-year-old man who had prepared lead solder for 5 years. His ^{125}I-iothalamate clearance was 52 mL/min/1.73 m^2; hemoglobin, 9.6 g per dL; uric acid, 13.2 mg per dL; and blood lead, 48 μg per dL when he was initially seen. Lead-chelate excretion following 2 g of $CaNa_2EDTA$ intramuscularly was 5.2 mg for 24 hours. Light microscopy shows periglomerular fibrosis, a sclerotic glomerulus, and tubular atrophy. (Trichrome stain; magnification $\times$304.) (From Wedeen RP, Maesaka JK, Weiner B, et al. Occupational lead nephropathy. *Am J Med.* 1975;59:630, with permission.)

CADMIUM NEPHROPATHY

Several compounds containing cadmium are widely used in the manufacturing of pigments, plastics, glass, metal alloys, and electrical equipment. Acute absorption of small quantities as 10 mg of dust or fumes may cause severe gastrointestinal symptoms and fatal pulmonary edema, after a delay of 8 to 24 hours.[42] Chronic low dose exposure leads to slowly progressive emphysema, anosmia, and proximal tubular reabsorption defects characterized by low molecular weight proteinuria, enzymuria, aminoaciduria, and renal glycosuria.[43–46] Hypercalciuria (with normocalcemia), phosphaturia, and distal renal tubular acidosis result in clinically important osteomalacia, pseudofractures, and urinary tract stones.[47,48] Proximal tubular dysfunction can progress to chronic renal failure over years.[49,50]

Metabolism

Nonoccupationally exposed individuals can accumulate cadmium through food and cigarettes. The biologic half-life of cadmium in humans exceeds 15 years, and one third of the total body stores (10 to 20 mg) are accumulated in the kidneys.

Absorbed cadmium is initially sequestered in liver and kidney, where it is bound to metallothionein, a cysteine-rich apoprotein.[42,43] The cadmium–thionein complex is filtered at the glomerulus, taken up in the proximal tubule by endocytosis, and transferred to lysosomes, where it is rapidly degraded. Most of the cadmium accumulated in the proximal tubules is bound to protein and after a "critical concentration" of 200 μg per g of renal cortex is reached, renal effects become evident. Normal urinary cadmium excretion is usually under 2 μg per day and values over 10 μg per day are associated with cadmium accumulation. Urinary cadmium excretion in excess of 30 μg per day correlates with significant abnormalities of proximal tubular function.[51] Although blood cadmium concentration is less reliable as an indicator of health effects and cumulative absorption, blood levels greater than 1 μg per dL are considered evidence of excessive exposure.

β-2 microglobulin has been the most extensively examined urinary protein in cadmium nephropathy. Its excretion is an early renal effect of cadmium[42] but, considering its instability in acid urine, measurement of urinary RBP or NAG is probably more reliable.[3,8,24,51] Low level of albumin and transferrin are observed in the urine of cadmium workers with low molecular weight proteinuria and enzymuria,[3,52] but it is not clear whether this means glomerular injury or impaired tubular reabsorption. Proteinuria in cadmium workers rarely exceeds a few hundred milligrams per day and does not approach nephrotic levels.

Calcium Wasting

The leading feature of cadmium tubular dysfunction is increased calcium excretion.[53] Although osteomalacia is uncommon in cadmium workers, it can be observed, associated with diminished renal tubular reabsorption of calcium and phosphate, elevated circulating parathormone levels, and reduced hydroxylation of vitamin D metabolites.[54,55] Urinary calculi have been reported in up to 40% of those subjected to industrial exposure and ureteral colic is more likely to be the cadmium worker's chief complaint.[43,47,56]

Itai-Itai Disease

Itai-Itai disease is a painful bone condition associated with pseudofractures caused by cadmium-induced renal calcium wasting, first described in Japan. The origin is attributed to local contamination of food staples by river water polluted with industrial effluents, particularly cadmium. The syndrome afflicts postmenopausal, multiparous women presenting with reduced GFR, anemia, lymphopenia, and hypotension as well as osteomalacia. They also exhibit a waddling gait, short stature, anemia, glucosuria, and elevated serum alkaline phosphatase levels. β_2-microglobulin urinary excretion exceeds the normal maximum (1 mg per g of creatinine) by almost 100-fold, predicting the later development of renal failure. The renal damage progresses even after exposure has ceased.

Chronic Interstitial Nephritis

Although the role of cadmium in the induction of chronic interstitial nephritis has been controversial, analysis of postmortem tissue or renal biopsy specimens of exposed individuals was able to find tubulointerstitial nephritis.[57] These findings associated with recent epidemiologic studies in the United States[56] and Belgium,[58,59] and the long-term follow-up of Itai-Itai disease in Japan,[54] have consolidated cadmium as a cause of chronic interstitial nephritis. These studies presented some important evidence: there was an association between cumulative cadmium exposure and the later increase in serum creatinine after a latent period of several decades; and among exposed workers, there was an increase in serum creatinine concentrations over 5 years accompanied by an important increase in mean urinary β_2-microglobulin and loss of glomerular filtration (around 30 mL per minute, 30 times the predicted loss of kidney function for the group).

Diagnosis

Cadmium nephropathy is usually diagnosed based in a history of exposure associated with laboratory tests indicative of proximal tubule injury (e.g., increased excretion of urinary biomarkers, hypercalciuria, or renal glycosuria). Cadmium concentration over 10 μg per g of creatinine confirms the diagnosis. Assessment of renal and hepatic accumulation of cadmium by neutron-activation analysis has been explored and organ cadmium content correlates well with tissue and urinary cadmium levels and β_2-microglobulin excretion. When the hepatic cadmium level exceeds about 60 ppm, and renal cortical content exceeds 200 ppm (20 mg per kidney), tubular proteinuria is likely to occur. The diagnostic value of neutron-activation analysis of kidney is decreased in uremic patients because renal cadmium concentration tends to fall with the development of renal failure.[59]

Treatment

The chelating agent $CaNa_2EDTA$ has little effect after cadmium has been complexed with metallothionein[60] and it is not usually recommended. Progression of renal disease may occur despite removal from exposure.[54] Osteomalacia may be controlled by calcium and vitamin D replacement[51] and urinary tract stones are not a contraindication to such therapy.

MERCURY

The toxicity of mercury depends on both its chemical form and the route of absorption. Elemental mercury produces neurologic disease and even death but it does not cause nephrologic damage. However, the mercuric salt corrosive sublimate ($HgCl_2$) is the most nephrotoxic form which is accumulated in the cells of proximal tubules inducing acute tubular necrosis (ATN).[61] This mercurial compound binds avidly to sulfhydryl groups in circulating proteins and amino acids as well as intracellular glutathione, cysteine, and metallothionein. Mercury accumulates in the pars recta of proximal tubules which is accomplished by transport primarily from the luminal side of mercury bound to amino acids or proteins. Mercury-ligand complexes reach lysosomes by endocytosis[62] with subsequent release into the cytosol by intralysosomal enzymatic degradation.

Diagnosis

The diagnosis of mercury-induced renal disease is usually dependent on known exposure in the presence of renal dysfunction. Although blood mercury levels over 3 μg per dL or urine levels above 50 μg per g of creatinine are considered abnormal, the correlation of blood and urine concentrations with renal disease is poor.[63] Mercury exposure is associated with increased HIAP urinary excretion but little increase in TNAP, NAG, RBP, THG, β_2 microglobulin, or microalbuminuria (Table 34.1).[1,5] There is no evidence that enzymuria from mercury exposure predicts the development of renal failure.

Ingestion of as little as 0.5 g of $HgCl_2$ produces ATN in humans. Initially, the clinical picture is dominated by gastrointestinal symptoms including erosive gastritis with hematemesis and melena. Diuresis should be induced by hydration, mannitol, and furosemide to prevent the development of oliguric acute renal failure. Persisting oliguria in the face of adequate therapy indicates renal parenchymal damage. An elevated urinary sodium concentration (>40 mEq per L) and diminished concentrating capacity (UOsm <450 mOsm per L) in an acutely oliguric patient with adequate therapy confirms the diagnosis of ATN. Acute oliguric renal failure may rapidly lead to death unless dialysis is provided.

Histologic examination of the kidneys reveals necrosis of the proximal tubules, particularly the pars recta. Tubular necrosis extends to more proximal segments after larger doses although the extent of damage to individual nephrons is highly variable.[64]

Oliguria is replaced by polyuria, during the recovery phase, whereas the GFR is still low. Urine flow rates may double daily, achieving a maximum of 5 L per day whereas the serum creatinine continues to rise. Spontaneous regeneration of tubular epithelium occurs with subsequent recovery although dystrophic calcification of necrotic tubules may limit restoration of function, and the kidneys may show residual interstitial nephritis.[62] The process from acute oliguria through polyuria and recovery may last from a few days to many months.

Nephrotic Syndrome

Although there are some sporadic case reports of nephrotic syndrome following exposure to elemental or organic mercury since the 20th century,[65] the causal relationship of mercury exposure to proteinuria and the nephrotic syndrome has been controversial.[66] The dose-response is unpredictable and also the etiology of nephrotic syndrome unrelated to mercury is rarely known.

Renal biopsies have most often shown deposits within glomerular capillaries consistent with membranous nephropathy (Fig. 34.2),[67] but normal glomeruli and antiglomerular basement membrane (anti-GBM) antibody deposition also have been described. In most patients, proteinuria is self-limited and disappears spontaneously when the source of exposure is removed.

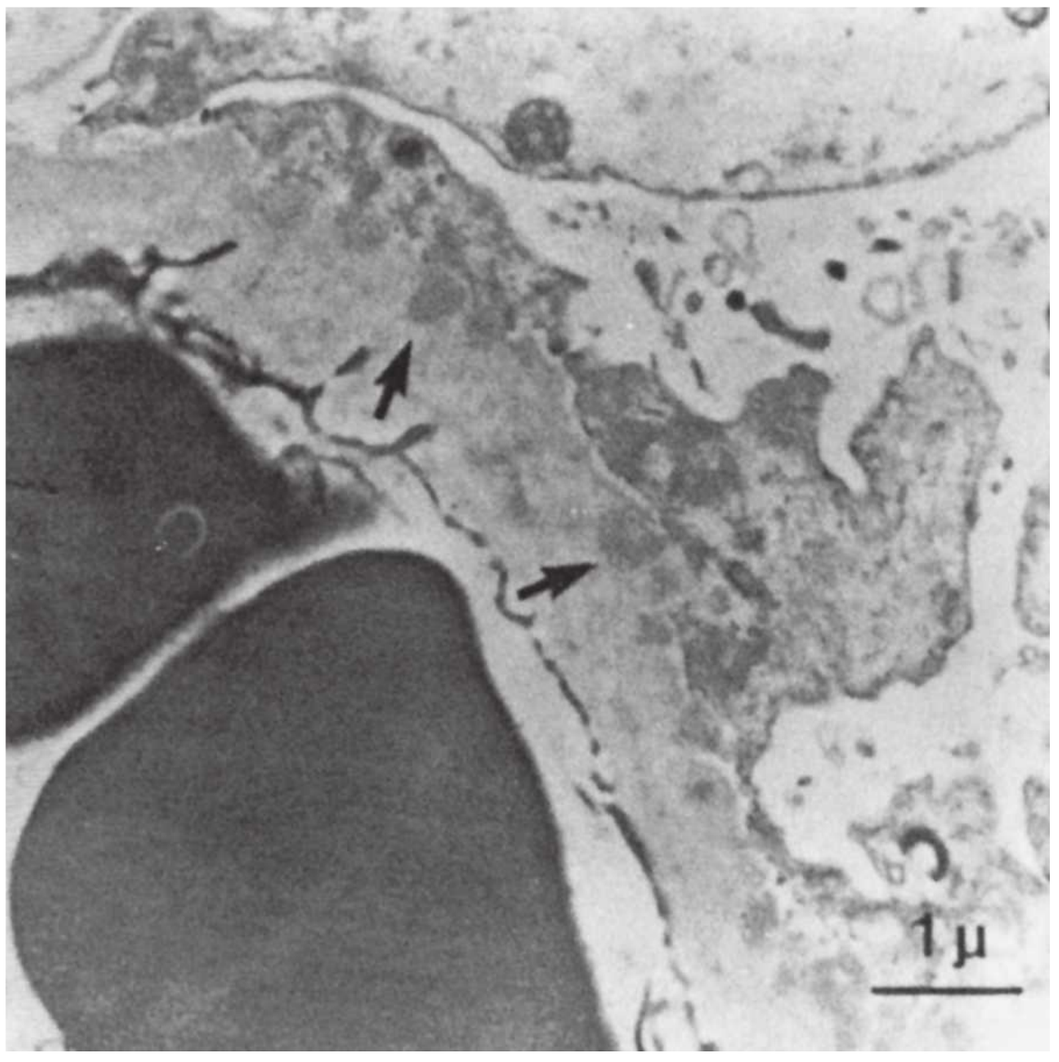

FIGURE 34.2 Electron micrograph of kidney from a 24-year-old man exposed to mercury vapor in an industrial electrolysis unit. The urinary mercury was 174 μg per 24 hours; urinary protein, 3.11 μg per 24 hours. Creatinine clearance was 116 mL/min/1.73 m^2. Subepithelial electron-dense deposits (*arrows*), presumably immune complexes, overlie the glomerular basement membrane. (Lead citrate and uranyl acetate; magnification ×11,000.) (From Tubbs RR, Gephardt GN, McMahon JT, et al. Membranous glomerulonephritis associated with industrial mercury exposure. *Am J Clin Pathol.* 1982;77:409, with permission.)

MINAMATA DISEASE

Endemic methyl mercury poisoning was recognized in Japan in the area of Minamata Bay in 1956, arising from the contamination of food by industrial effluents.[68] The mercury pollution had been going on for a decade and fish from Minamata Bay contained up to 36 mg of mercury per kg. Affected people presented neurologic defects including visual, speech, and gait disturbances. Cerebral palsy was common among the children of affected mothers. Similar clusters of cases were subsequently identified in Niigata, Japan, and in Iraq, where the disease was the result of bread prepared from grain that had been treated with methyl mercury fungicide.

Although the kidney manifestations of Minamata disease are minor, tubular proteinuria occurs[69] but clinically important albuminuria and azotemia are not common.

Treatment

Acute inorganic mercury poisoning is treated with the effective chelator British antilewisite (BAL). Recommended regimen is 5 mg per kg given by the intramuscular route, followed by 2.5 mg per kg twice daily for 10 days. In the presence of acute renal failure the mercury chelate can be removed by hemodialysis. BAL is not used in chronic poisoning, in which treatment is removal from the source of exposure. Succimer (DMSA), an oral chelating agent used for the treatment of lead poisoning in children, is not an effective chelator of mercury and its use is not recommended.[70]

OTHER HEAVY METALS

Uranium is selectively accumulated in the proximal tubule with a biologic half-life approximating 1 week for 95% of the renal stores.[71] After inhalation, the uranyl ion binds to circulating transferrin and to proteins and phospholipids in the second and third segments of the proximal tubule. ATN and increased β_2-microglobulin urinary excretion has been reported after uranium exposure, especially when urinary uranium levels were over the upper acceptable limit of 30 μg per L.[72] There is no evidence of association between uranium exposure and the development of chronic kidney disease (CKD).

Copper sulfate has been associated with ATN in young female science students attempting suicide in Delhi, India.[73]

Like other heavy metals, chromium is selectively accumulated in the proximal tubule and the hexavalent form is able to induce ATN, but there is no convincing evidence of tubular injury from usual occupational exposure.[74–78] Minimal tubular proteinuria has also been reported in chrome platers, but CKD was not documented.

Bismuth compounds prepared as therapeutic agents have produced unequivocal ATN. Lower dosages induce Fanconi syndrome with reduced glomerular filtration and bismuth-containing intranuclear inclusions in proximal tubule cells that are similar to, but distinguishable from, lead inclusions.[79–81]

Arsenic poisoning is associated with renal failure.[82,83] Usually associated with an industrial accident, arsine inhalation produces hemolysis, hematuria, and abdominal pain within a few hours, followed by acute oliguric renal failure and jaundice within 2 days.[84] Reticulocytosis, basophilic stippling, bilirubinemia, and free hemoglobin in the plasma may assist diagnosis, which is established by detecting arsenic in the urine. Patchy cortical necrosis with persistent residual renal failure has been reported.[82,85] BAL is ineffective once renal failure is present. Besides hemodialysis, exchange transfusions may be useful to eliminate hemoglobin-bound arsenic from the body.

SILICON

Silicon is a semimetal found as dioxide silica (SiO_2) in 28% of the earth's crust. Silicon is not a heavy metal because it has a specific gravity of only 2.3. It is present in the serum at concentrations of 20 to 50 μg per dL in an unbound form as silicic acid and is cleared in the urine at the rate of glomerular filtration. Silica is believed to induce renal disease by direct deposition of crystalline material in the renal parenchyma and by immunologic mechanisms acting as an adjuvant to stimulate the immune response.[86,87] Tubular proteinuria is found in workers exposed to silica dust,[88,89] and an increased risk to develop end-stage renal disease (ESRD) has been described.[90] In the accelerated form of silicosis known as silicoproteinosis, rapidly progressive, immune complex-mediated focal glomerulosclerosis, which simulates lupus erythematosus (Caplan syndrome), may appear.[89] Antineutrophil cytoplasmic antibody (c-ANCA)-positive Wegener granulomatosis has been associated with exposure to silica dust as well as to silicon containing compounds such as grain dust.[91]

GERMANIUM

Germanium has been used in the treatment of cancer, a variety of medical ailments, and in unproved remedies for conditions such as arthritis, acquired immunodeficiency syndrome (AIDS), and the chronic fatigue syndrome. Germanium-containing elixirs and health foods have been described to cause chronic tubulointerstitial nephritis first in Japan in the 1980s and more recently in Europe and the United States.[92–97] The kidney disease is different from that induced by other heavy metals in that widening of the interstitium and distal tubular atrophy has been evident after prolonged (6 to 36 months), high-dose (16 g to hundreds of grams) consumption. Electron-dense, periodic acid-Schiff (PAS) reagent-positive granules (containing germanium in the experimental rat) are found in distal tubular mitochondria.[95] The tubulointerstitial disease is slowly progressive even after exposure elimination. Fatal outcomes have been reported. The pathophysiologic mechanism of tubular damage is not defined because selective accumulation in the kidney was not found and immunologic mechanisms have not been implicated. There is no evidence of primary proximal tubular injury and proteinuria is absent.[92,94]

BALKAN NEPHROPATHY

Balkan endemic nephropathy is a slowly progressive tubulointerstitial nephritis of unknown etiology described about 40 years ago among middle-aged men and women living in farming villages along the Danube River in Croatia, Serbia (the former Yugoslavia), Romania, and Bulgaria.[98] Early clinical manifestations included clinically silent tubular dysfunction such as glucosuria and/or aminoaciduria. More advanced disease leads to decreased concentrating ability and progression to ESRD.[99] A variety of environmental factors have been suspected including lead, cadmium, and mycotoxins, but no single etiologic agent has been found. The prevalence of generally recognized kidney diseases has not been established in the Danube region, making differentiation of Balkan nephropathy from known renal diseases identified in other regions of the world problematic.

DRUG ABUSE

Substance abuse is common, involving lifetime exposure of 46% of the general population.[100] Substances with the potential to be abused include alcohol, opiates, sedatives and hypnotics, cocaine, cannabis, hallucinogens and psychedelic drugs, psychotropic, stimulant and anxiolytic medications, analgesics, and amphetamines. Such drugs have been associated with several kidney syndromes by varied mechanisms. Although some substances are directly nephrotoxic, other mechanisms are also involved, including glomerular, interstitial, and vascular diseases (Table 34.2).[101]

34.2 Renal Disease Associated with Drug Abuse

1.	Focal glomerulosclerosis in intravenous heroin users
2.	Amyloidosis in subcutaneous heroin abusers
3.	Endocarditis-associated glomerulonephritis in intravenous drug users
4.	Acute renal failure due to nontraumatic rhabdomyolysis
5	Cocaine-associated nephropathy
6.	Systemic necrotizing vasculitis
7.	Nephropathy in glue and solvent "sniffers"
8.	Hepatitis-related glomerulonephritis in drug abusers
9.	Focal glomerulosclerosis in drug abusers infected with HIV

Since the first reports in the late 1960s and early 1970s there have been numerous studies describing the clinical and pathologic features of renal diseases associated with chronic parenteral abuse of heroin, cocaine, morphine, amphetamine, and other narcotic and hallucinogenic drugs, including several adulterants. Renal disease in cocaine and heroin users is associated with the nephrotic syndrome, acute glomerulonephritis, amyloidosis, interstitial nephritis, and rhabdomyolysis.

In the past few decades an explosive growth in illicit drug use has occurred in many parts of the world. Reports indicate that in some areas of the United States the percentage of cocaine addicts among young people is as high as 20%. In a university population in the United States, 6% were found to be cocaine users as documented by hair analysis.[102] Other than the more common acute renal effects of the abuse of multiple drugs, chronic abuse may also be associated with CKD and progression to ESRD.

HEROIN

Heroin is processed from a naturally occurring substance, morphine, extracted from various poppy plants. It can be sniffed ("snorting"), eaten, smoked ("chasing the dragon"), injected subcutaneously ("skin popping"), or injected intravenously ("mainlining").[103] The purity of heroin depends on the presence of adulterants. Commonly used adulterants include sucrose, dextrose, mannitol, lactose, starches, powdered milk, quinine, caffeine, inositol, lidocaine, procaine, acetylprocaine, methapyrilene, and strychnine.[104]

Heroin is the most commonly abused opiate in the United States and has become a growing health-related problem in large metropolitan areas.[100] The term "heroin-associated nephropathy" includes different morphologic findings following chronic drug abuse.[105] Although the prevalence of heroin use in the United States has increased, the incidence of "heroin nephropathy" has declined. Socioeconomic conditions, cultural and behavioral practices, or differences in genetic susceptibilities may be more associated with the development of nephropathy in heroin users than the drug's pharmacologic properties.[103]

There are several renal complications from heroin abuse varying from hypotension to coma complicated by pressure-induced muscle damage and rhabdomyolysis. This latter event in the absence of coma, or evidence of muscle compression, could also occur as a direct toxic effect or an allergic response to heroin or the components in adulterated heroin.[106] The high rate of viral, bacterial, and fungal contamination associated with intravenous drug use increases the risk for glomerulonephritis (GN) associated with chronic infections. Local abscesses, due to Staphylococcus aureus, have been associated with GN. Bacterial and fungal endocarditis are also associated with immune-complex mediated GN. Other causes of GN in these patients are associated with hepatitis B and hepatitis C.

Secondary (AA) amyloidosis is also a cause of kidney disease in chronic drug users, particularly among those who inject drugs subcutaneously ("skin poppers").[107] In the majority of these patients, continued abuse leads to progression to end-stage renal failure and resolution of the lesions following abstinence from subcutaneous drug abuse has been reported.[108]

In the 1970s and 1980s, heroin-associated nephropathy (HAN) was described, presenting as nephrotic syndrome and progressing rapidly to end-stage renal failure. Kidney biopsy usually showed a focal segmental glomerulosclerosis.[109] Earlier studies suggested that heroin, or one of its adulterants, acted as an antigen leading to renal deposition of immune complexes in the kidney, but animal studies have shown that morphine has a direct effect on the glomerulus, causing proliferation of fibroblasts and a decrease in degradation of type IV collagen.[105,110] As heroin sold in streets became more pure a decrease in the incidence of HAN among intravenous heroin addicts was described.[111] At the same time, HIV-associated nephropathy (HIVAN) started to be diagnosed more frequently among heroin addicts with HIV infection.[112]

Recent studies suggest that morphine has direct effects on mesangial and glomerular epithelial cells (GEC), kidney fibroblasts, and the interaction of mesangial cells with circulating and resident macrophages. The classic lesion of focal segmental glomerulosclerosis (FSGS) starts with mesangial cell hyperplasia and GEC hypertrophy.[113] In the course of the FSGS, there is eventual loss of mesangial epithelial cells and GEC. The loss of GEC, or apoptosis, has been suggested as an underlying mechanism in the development of FSGS.[114] The glomerulosclerosis results from mesangial cell expansion, increased matrix deposition, and secretory factors that are modulated by macrophages. Morphine induces both inhibitory and proliferative effects on fibroblasts, mesangial cells, and macrophage activity.[115] At lower concentrations morphine predominantly stimulates mesangial cells and fibroblast proliferation, mesangial matrix deposition, and macrophage activity. At higher concentrations, morphine inhibits mesangial cells and fibroblast proliferation, mesangial matrix deposition, and macrophage activity.[115]

COCAINE-ASSOCIATED NEPHROPATHY

Cocaine (benzoyl methylecgonine) is extracted from the leaves of the South American plant Erythroxylum coca.[116] It exists in two major forms: Cocaine hydrochloride and alkaloidal freebase (crack) cocaine.[116] Cocaine abuse is epidemic in the United States, with an estimate that 34.3 million Americans have used cocaine at some time.[100]

Although the most frequent renal manifestation of cocaine abuse is acute kidney injury due to nontraumatic rhabdomyolysis, cocaine may induce nephropathy by other mechanisms.[101] The pathophysiologic basis of cocaine-related renal injury involves renal hemodynamic changes, glomerular matrix synthesis and degradation, oxidative stress, and induction of kidney atherogenesis.

Cocaine has potent vasoconstrictive effects on vascular smooth muscle.[117] It directly affects smooth muscle vascular cell calcium influx.[118–120] Endothelins (ET) have also been implicated in the vascular dysfunction that is induced by cocaine intoxication.[116] There is a high density of ET-1 receptors in the vascular smooth muscle of all renal resistance vessels.[121]

Cocaine inhibits catecholamine reuptake at the presynaptic nerve terminal, blocks norepinephrine reuptake in sympathetically innervated tissues, and releases norepinephrine and epinephrine from the adrenal medulla resulting in development of hypertension and tachycardia.[122,123]

The involvement of the renin-angiotensin-aldosterone system (RAAS) has been suggested because cocaine-induced ET release is inhibited by captopril and lisinopril in cultured human and bovine endothelial cells.[124] Activation of the RAAS and angiotensin II by cocaine may lead to renal fibrosis from stimulation of TGF-β.[116]

The resultant effect of cocaine on the kidney, through ET-1, the RAAS, and the l-arginine–NO pathway, leads to vasoconstriction of the glomerular microcirculation. Cocaine has been associated with accelerated and malignant hypertension as well as implicated in hastening the progression of hypertensive nephrosclerosis to ESRD.[125,126]

In an autopsy study 40 kidneys from patients with cocaine-related deaths were compared with kidneys from 40 accident victims.[127] The ratio of the number of sclerotic glomeruli to the total number of glomeruli was 18-fold greater in cocaine users than in controls. In that study, they also found significant differences in the degree of periglomerular fibrosis, the degree of interstitial cellular infiltrate, and hyperplastic arteriolosclerosis in cocaine users compared to controls. Medial thickening, luminal narrowing, and vessel obstruction were absent in the control group. The patients with cocaine-related deaths were found to have advanced coronary atherosclerosis, more extensive than expected in normal populations older than 60 years of age.

In a case-control study performed to examine recreational drug use as a risk factor for ESRD, cocaine use was associated with a threefold increased risk for developing ESRD.[128] In a prospective cohort including 647 patients, followed for a 15-year period, there was a threefold increased risk of kidney functional decline associated with use of cocaine or crack as compared to nonusers.[129]

Although these studies demonstrate an association of cocaine use and progression to CKD and ESRD, prospective, epidemiologic studies are needed to clarify the relationship between cocaine use and the development of CKD.

ECSTASY AND OTHER AMPHETAMINES

Ecstasy (MDMA: 3,4-methylenedioxymethamphetamine), originally used as an appetite suppressant, became a commonly used recreational drug. MDMA is rapidly absorbed, reaching plasma peak levels in approximately 2 hours.[130] It is metabolized by the liver and excreted by the kidney.

The increased physical activity, overheated environments, and dehydration associated with its use can result in hyperthermia. It has been shown that MDMA can cause fever even in the absence of strenuous exercise. Associated side effects can be mild—nausea, vomiting, headaches, cramps—or serious—convulsions, hyperpyrexia, hepatic dysfunction, rhabdomyolysis, disseminated intravascular coagulation, and acute kidney injury.[131]

There is an increased risk of hyponatremia associated with ingestion of large quantities of water to prevent dehydration and inappropriate antidiuretic hormone secretion.[132] As a consequence, cases of cerebral edema have occurred after ecstasy abuse. Ecstasy has marked sympathomimetic effects and has been associated with cases of accelerated hypertension and acute kidney injury.

SOLVENTS

Fumes of toluene or toluene-containing compounds (spray paint, household and model glue, lacquer, and paint thinners) contain a number of volatile substances including n-hexane, methyl ketones, chlorohydrocarbons, and benzene. The deliberate inhalation of volatile solvents ("glue sniffing") first emerged as a form of substance abuse in the early 1960s. Solvents can rapidly cause hallucinations of short duration (15 to 30 minutes), and are associated with a variety of electrolyte and acid–base disturbances. In addition, serious cardiac, pulmonary, hepatic, neurologic, and renal complications may develop, as well as sudden death.

The nephrotoxic insult of volatile glues appears to be due principally to toluene. Various renal lesions have been associated with its abuse: microhematuria, pyuria and proteinuria, distal renal tubular acidosis and Fanconi syndrome, urinary calculi, glomerulonephritis, Goodpasture syndrome, ATN, hepatorenal syndrome, and acute and chronic interstitial nephritis.[101] Taher and coworkers first recognized non-anion gap hyperchloremic metabolic acidosis in association with toluene "sniffing" in two patients.[133] The tubular defect was documented by the presence of metabolic acidosis (pH, 7.2 to 7.3) with a normal anion gap, hyperchloremia (level of 118 to 120 mEq per L), and an inappropriately high urinary pH (>6.0). Numerous other cases of hyperchloremic metabolic acidosis, due to toluene inhalation, have subsequently been reported. In addition, transient congenital renal tubular dysfunction with hyperchloremic metabolic acidosis due to maternal toluene abuse have been described.[134]

Toluene, a hydrophobic compound, accumulates in lipoidal structures. After sniffing stops, this volatile chemical is excreted via the lungs. The conversion of toluene to organic acids occurs in the liver where toluene is metabolized by the cytochrome P-450 system. There is a spectrum of disorders that are responsible for the metabolic acidosis associated with toluene abuse, caused primarily by the conversion of toluene to hippuric acid, with the subsequent rapid excretion of hippurate in the urine.[135] Patients with a fast metabolism of toluene by the cytochrome P-450 system have a high rate of production of organic, hippuric, and benzoic acids. With a normal kidney function these patients will usually present a hyperchloremic acidosis and a wide anion gap, if the production exceeds the excretion of the anions. In the presence of impairment in the rate of excretion of ammonium, demonstrated in 20% of the patients, the net acid excretion is reduced and, hence, distal renal tubular acidosis is present.[135] In chronic toluene abuse increased concentrations of NH_3 in the interstitium can lead to complement activation. Thus, toluene abuse can cause chronic interstitial diseases, and ultimately impair the ammonium excretion causing distal renal tubular acidosis.[136]

In addition to the acid-base disorders, fluid and electrolyte abnormalities are also common in the clinical presentation of toluene abuse. In fact, nausea and generalized weakness, which may result from volume contraction and hypokalemia, are the symptoms that frequently lead the patient to seek medical attention. The excretion of hippurate increases the excretion of ammonium, sodium, and potassium. About one quarter of the patients present with severe hypokalemia (potassium <2mEq per L). The degree of hypokalemia may be underestimated by the metabolic acidosis, a factor that should be anticipated during the treatment. The presence of concomitant hypophosphatemia increases the risk of rhabdomyolysis.[137]

LITHIUM

Introduction

Lithium is currently a drug of choice for treating bipolar illness and is widely used in this population. Approximately 0.1% of the U.S. population is undergoing lithium treatment for psychiatric problems and 20% to 54% of these patients have urinary symptoms during and after lithium use.[138] Approximately 30% of patients taking lithium experience at least one episode of lithium toxicity.

Chronic lithium ingestion in patients with bipolar illness has been associated with several different forms of kidney injury. The narrow therapeutic window (1 to 1.5 mEq per L during acute therapy and 0.6–1.2 mEq per L during maintenance therapy) contributes substantially to the frequency of acute and chronic toxicity. Close monitoring of serum levels is important to prevent acute and chronic kidney failure. Prevention is important and patients should be instructed to drink 10 to 12 glasses of liquid every day during lithium therapy, and keep a regular (non-low) salt diet. Patients should be oriented to contact a health care provider if fever, diarrhea, or vomiting develops. Certain drugs, especially diuretics, should be avoided with lithium use if possible. Cyclosporine and nonsteroidal anti-inflammatory drugs (NSAIDs; except low dose aspirin) potentially increase serum lithium levels and should be avoided. There is no gender or ethnic predisposition to the development of lithium toxicity, although some studies suggest that women may require fewer drugs to achieve therapeutic serum levels than men.

The most common renal side effect of lithium therapy is nephrogenic diabetes insipidus (NDI). Chronic tubulointerstitial nephropathy is the most common form of CKD associated with lithium therapy.[139] Although the majority of studies show infrequent and relatively mild renal insufficiency attributable to lithium therapy, ESRD secondary to lithium-associated chronic tubulointerstitial nephropathy does occur in a small percentage of patients, although the incidence of long-term lithium nephropathy is still a matter of debate.[139]

Renal Effects of Lithium

Lithium is a univalent cation, completely absorbed by the gastrointestinal (GI) tract. The drug is not protein bound and is completely filtered at the glomerulus. Although the majority, up to 60%, of the filtered load is reabsorbed by the proximal tubule, a significant amount is also absorbed in the loop of Henle and the early distal nephron. Lithium can act as a substitute for sodium in several sodium channels, particularly the sodium-hydrogen exchanger in the proximal tubule (NHE_3), the sodium/potassium/2chloride exchanger in the thick ascending limb of the loop of Henle ($NKCC_2$), and the epithelial channel of the cortical collecting tubule (ENaC).

Lithium nephrotoxicity can occur as soon as a month after the onset of use of the drug. The most common symptoms, polyuria and polydipsia, are reversible but can become permanent with chronically maintained high serum levels of lithium. Lithium-associated natriuresis is caused by the impaired regulation of the expression of the epithelial sodium channel in the cortical collecting tubule.[140] Lithium use partially inhibits the ability of aldosterone to increase apical membrane ENaC expression, resulting in inappropriate sodium losses.[141]

Nephrogenic diabetes insipidus is a common side effect of lithium; up to 12% of patients develop frank diabetes insipidus. Lithium impairs the ADH stimulatory effect on adenylate cyclase, and decreases cAMP levels.[142] Studies suggest that the ability of lithium to produce nephrogenic diabetes insipidus may also have an independent effect from cAMP generation and be associated with a decreased AQP2 mRNA levels.[143] Lithium most likely impairs water permeability in the principal cells by inhibiting water channel delivery and, over a prolonged period of time, by suppressing channel production.[144]

In patients with urine-concentrating defects, the improvement usually take weeks to months to occur, and can persist for years in some cases. One case report describes patients who still had diabetes insipidus 8 years after cessation of therapy. In another report, of a small subset of patients, up to 63% had persistent defects 1 year after stopping lithium.[138] The prolonged time to recover the concentrating ability may be linked to underlying renal histologic damage and may be worse with neuroleptic use and prolonged lithium therapy. Boton and colleagues, in a review, documented a 54% correlation between impaired urine-concentrating ability and the duration and total dosage of lithium treatment.[145] Chronic lithium use is also associated with a distal tubular acidification defect, exerted from the luminal side of the cell. Lithium is not known to cause significant hyperkalemia.

Acute Kidney Injury

Lithium toxicities appear to be dose and concentration dependent. Serum concentrations between 1 and 1.5 mEq per L will most likely cause impaired concentration, lethargy, irritability, muscle weakness, tremor, slurred speech, and nausea. Plasma concentrations greater than 2.5 mEq per L are associated with kidney failure. The mechanism associated with lithium acute kidney injury involve volume depletion due to natriuresis and water diuresis accompanied by elevated lithium levels, altered mental status, and subsequent poor oral intake. Cases of acute kidney injury, as a result of lithium-induced neuroleptic malignant syndrome, have also been described.[146] Adequate and timely fluid replacement can rapidly restore kidney function. Loop diuretics can decrease the lithium reabsorption in the loop of Henle and increase lithium excretion. This approach can be used in case of lithium toxicity, if adequate intravascular volume is maintained. Acetazolamide combined with sodium bicarbonate can be used because acetazolamide inhibits the reabsorption of lithium by the proximal tubules. Adequate electrolyte supplements, especially sodium and potassium, are fundamental. Lithium is entirely dialyzable and hemodialysis is the most efficient way to decrease lithium levels when patients cannot be managed medically or when kidney function is severely impaired. Dialysis is usually necessary when lithium concentrations are above 4 mmol per L. Hemodialysis increases lithium clearance to 3.0 L per hour; however, following hemodialysis, a rebound effect in the lithium concentrations can be observed. The rebound is expected to occur as lithium has a slow rate of redistribution from the peripheral tissues into the central compartment or from release of lithium from bone stores. Therefore, hemodialysis should be extended or repeated at frequent intervals.

Chronic Kidney Disease

The debate around lithium-induced CKD is the result of conflicting cross-sectional and longitudinal epidemiologic studies.[147] Some of these studies show a low incidence of kidney dysfunction in lithium-treated patients. Data from 14 studies, including 1,172 patients, estimated that the prevalence of reduced GFR, measured by different methods, was 15%.[145] The development of lithium-induced chronic tubulointerstitial nephritis was first demonstrated by Hestbech et al. in 14 patients treated with lithium for about 2 to 15 years.[148] Markowitz et al. recently reemphasized the risk of often irreversible biopsy-proven lithium toxicity being responsible for combined glomerular and tubulointerstitial damage.[139] Other studies have demonstrated interstitial fibrosis, tubular atrophy, and glomerulosclerosis among the chronic histologic changes associated with lithium. These

studies suggested that lesions correlated with the duration of lithium. However, most of the biopsy samples were obtained from patients that had a history of acute lithium toxicity, and many of the histologic changes were also identified in the control group. The histologic changes associated with acute lithium include ATN with nonspecific changes such as distal tubular flattening, proximal tubular necrosis, and cytoplasmic vacuolation and cellular and nuclear polymorphism of the distal tubular epithelial cells. Although chronic tubulointerstitial nephropathy represents a somewhat nonspecific pattern of disease, the presence of tubular cysts is highly characteristic of lithium toxicity, having been reported in up to 40% of cases.[149] Markowitz et al. revealed a chronic tubulointerstitial nephropathy in all 24 patients with biopsy-proven lithium toxicity, with associated cortical and medullary tubular cysts (62.5%) or dilatation (33.3%). The degree of tubular atrophy and interstitial fibrosis was graded as severe in 58.3%, moderate in 37.5%, and mild in 4.2% of cases. There was a surprisingly high prevalence of focal segmental glomerulosclerosis (50%) and global glomerulosclerosis (100%), sometimes of equivalent severity to the chronic tubulointerstitial disease. Despite discontinuation of lithium, seven of nine patients with initial serum creatinine values >2.5 mg per dL progressed to ESRD.[139] In 2003 a French group studied 74 patients with lithium-induced kidney failure.[150] They showed that the creatinine clearance at referral and at last follow-up was inversely related to the duration of lithium therapy in both univariate and multivariate analyses adjusting for age, gender, hypertension, and proteinuria. In 29 patients with a kidney biopsy, the degree of interstitial fibrosis was related to the lithium duration and cumulative dose. They estimated the prevalence of lithium-related ESRD as two per 1,000 dialysis patients, and the average time between onset of lithium therapy and ESRD was 20 years.[150] Although a minimal increase in the protein excretion rate has been reported in some patients who were taking lithium for at least 2 years, overt proteinuria is not a common complication. A rare association between minimal-change nephrotic syndrome and lithium administration has also been described. Renal dysfunction is often irreversible despite lithium withdrawal, and early detection is essential to prevent progression to ESRD. Although the debate around the rate of progression to CKD and ESRD associated with the chronic use of lithium continues, regular monitoring of estimated creatinine clearance is mandatory in long-term lithium-treated patients.

CHAPTER

35 Acute Tubulointerstitial Nephritis

Garabed Eknoyan • Rajeev Raghavan

For most of its medical history, the kidney has been considered a tubular organ. Even after Marcello Malpighi (1628–1694) described his eponymous "corpuscles" and William Bowman (1816–1892) that of his "capsule," the kidney continued to be viewed as a secretory tubular organ. In fact, after the milestone report of dropsical albuminuric medical cases by Richard Bright (1789–1858), which launched the study of kidney disease, the inflammatory diseases of the kidney that he described were classified in 1858 by Rudolph Virchow (1821–1902) as a nephritis principally affecting the tubules ("parenchymatous" nephritis) or the interstitium ("interstitial" nephritis). It is only after the improved resolution of microscopes and refinements in tissue processing that in 1869 "glomerular" nephritis was added to the list of nephritides by Edwin Klebs (1834–1913). Still, most diseases of the kidney continued to be considered as tubulopathies rather than glomerulopathies well into the first decades of the 20th century. It is within this context that the pathologic diagnosis of acute interstitial nephritis (AIN) was described in 1898 by William Councilman (1854–1933). In his now classic paper, based on a review of the literature and his postmortem examination of 42 cases, he reported on a nonsuppurative inflammatory interstitial lesion of the kidney occurring predominantly in patients with diphtheria (24 cases), scarlet fever (10 cases), and less frequently in those with other infectious diseases. He described the pathologic changes as

> an acute inflammation of the kidney characterized by cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent on, degeneration of the epithelium; the exudation is not purulent in character, and the lesions may be both diffuse and focal

and identified the infiltrating cells as "plasma cells that had migrated from the blood vessels and multiplied locally by mitotic division." He localized the foci of cellular infiltrates to three sites: the boundary zone of the pyramids, the subcapsular region of the cortex, and around the glomeruli. These meticulous observations and the lucid description are just as valid today as they were then, and they encapsulate the lesions of this disease of the kidneys more succinctly and thoroughly than much of what has been written since they were first reported.[1,2]

Subsequent reports confirmed Councilman's observation that nonsuppurative lesions of the renal interstitium appeared after short but variable periods from the onset of acute infections that were primarily streptococcal in origin.[3,4] This concept of acute tubular and interstitial injury following an acute infection was so well accepted that initial reports of acute tubular necrosis (ATN), which appeared before the proper characterization of acute renal failure due to tubular necrosis during World War II, termed the new lesion acute hematogenous interstitial nephritis and argued for the similarity of the lesions of ATN to those of AIN.[5] The difficulty in the differential diagnosis of these two variants of tubulointerstitial disease persists to this day if the kidney tissue is not examined carefully and is interpreted without benefit of the clinical history.[1,6,7] The introduction of antibacterials during World War II and the eradication of serious and fatal streptococcal infections resulted in a loss of interest in the entity described by Councilman, whereas attention focused on ischemic or nephrotoxic ATN as the predominant cause of acute kidney injury (AKI). Therefore, it is ironic that interest in AIN was revived in the 1960s when the very antibiotics used to treat streptococcal infections were identified as a cause of AIN.[1,8,9] In fact, the bulk of current reports in the literature are on drug-induced AIN, and the number of drugs implicated as causing AIN continues to increase, as does that of the variations in their clinical and laboratory manifestations.[8–10] AIN has since come to define the clinicopathologic syndrome that develops in diverse conditions, including infections, and is characterized by an acute deterioration of kidney function, the pathologic features of which remain those first described by Councilman as "cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent on, degeneration of the epithelium . . . and the lesions may be both diffuse and focal."[2]

Although this clinicopathologic syndrome initially was referred to as acute interstitial nephritis,[2] the more inclusive

and precise descriptive terms acute tubulointerstitial nephritis (ATIN) and acute tubulointerstitial nephropathy are used now.[1,11] The preferential use of tubulointerstitial stems from the fact that although the dominant morphologic features are those evident in the interstitium, the tubules also are affected, albeit to a degree that may be difficult to detect in some cases on light microscopy. Importantly, and independent of the severity of their structural injury, the disorders of tubular function constitute a characteristic component of the disordered kidney function and differentiate this entity from other forms of AKI due to glomerular or vascular disease. In fact, tubular dysfunction is an invariable accompanying feature of the reduction in glomerular filtration rate (GFR) in ATIN and, as a rule, precedes any clinically evident decrease in GFR.[1] In addition, although the interstitial cellular infiltrates contribute significantly to the pathogenesis of the disease, there is increasing evidence that the tubules play an important role in the processing and presentation of the antigenic stimulus and the immunopathogenesis of the disease process.[12–15] Although ATIN may be suspected clinically, its diagnosis depends on the presence of characteristic morphologic changes of the renal parenchyma. The adjective acute refers to the sudden onset and rapid progression of the clinical features of this syndrome and not to its pathologic features, which are notable for mononuclear cell infiltration rather than the polymorphonuclear leukocytes characteristic of an acute inflammatory reaction.

PATHOLOGIC FEATURES

Independent of the causative agent or the clinical condition responsible for ATIN, the principal morphologic features that characterize it are an increase in interstitial volume, mainly because of edema; mononuclear cell infiltrates of varying degrees and distribution; tubular injury and degeneration of differing severity, which in general are localized to the sites of the greatest cellular infiltrates; and the transformation of tubular epithelial cells into migratory fibroblasts that cross the basement membrane (Fig. 35.1). The glomeruli are generally spared, but may show some degree of periglomerular infiltrates and ischemic change except in ATIN associated with nephrotic syndrome, where an effacement of the podocyte foot processes is seen on electron microscopy. Although the extent and severity of each of the tubulointerstitial lesions show some correlation with the level of reduction in GFR, the closest correlation appears to be with the infiltrative process. The interstitial infiltrative lesions may be

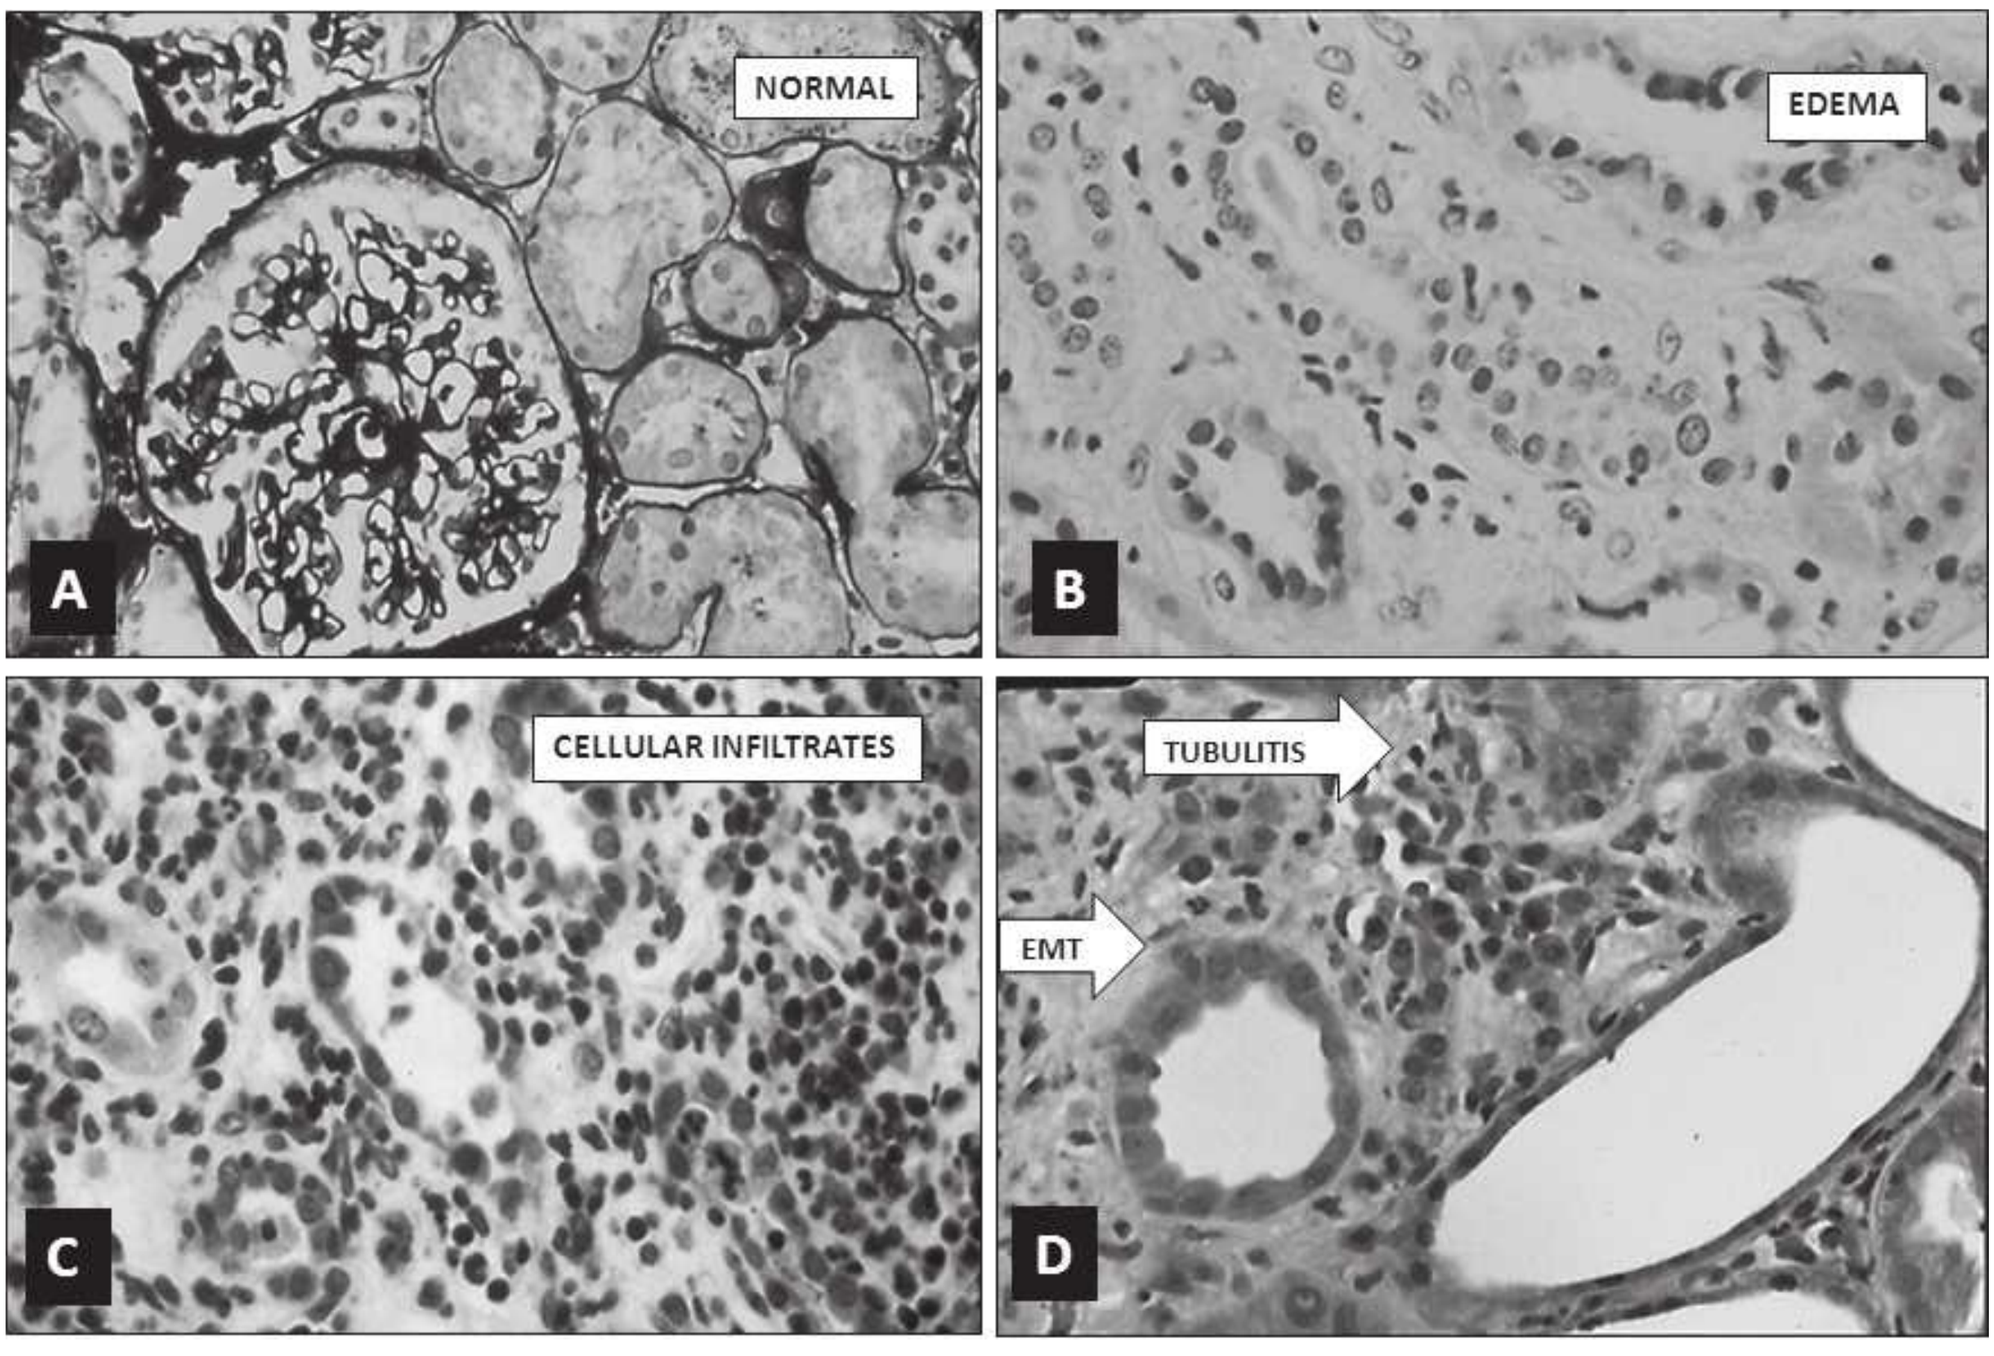

FIGURE 35.1 The pathologic features of a kidney biopsy in acute tubulointertitial nephritis. Compared to a normal kidney **(A),** there is increased interstitial space between the tubules showing edema **(B)**; interstitial infiltration by mononuclear inflammatory cells and bilobed eosinophils **(C)**; and variable manifestations of tubular injury **(D)** showing peritubular infiltrating cells disrupting the tubular basement membrane or "tubulitis" and epithelial-mesenchymal transition (EMT).

diffuse but usually are patchy in distribution and are most evident in the cortex and corticomedullary junction, and less commonly in the outer medulla of the kidney. When the infiltrating cells are meager, they show a focal peritubular distribution that is most evident in the corticomedullary region; when profuse, they are more prominent at certain foci but literally obscure the normal appearance of the tubules and extend to the periglomerular space (Fig. 35.1C). Diffuse infiltrative lesions are associated with higher levels of serum creatinine and a poorer prognosis for recovery than patchy infiltrative ones.[1,8,9]

The infiltrating cells are composed mostly of mononuclear cells, lymphocytes, and plasma cells, and rarely, polymorphonuclear cells and macrophages. The prognosis appears to be less favorable when 1% to 6% of the interstitial infiltrating cells are composed of neutrophilic granulocytes.[1,9] By the same token, an increase in the number of macrophages (usually <10%) and the presence of granulomatous reactions are associated with a prolonged course of AKI and varying degrees of residual impairment of kidney function.[1,9,16] When present, eosinophils are sparse and constitute only a small component of the infiltrating cells, except in occasional cases of antibiotic-induced ATIN, where they may be marked. The presence of infiltrating eosinophils shows no relation to the increased eosinophilia or the presence of urinary eosinophils that also occur in drug-induced ATIN. A role for a specific eosinophil chemoattractant cytokine, eotaxin, which is expressed in the kidney, has been proposed as a mechanism for the tissue eosinophilia of ATIN.[17,18]

An immunologic characterization and an analysis of the interstitial cellular infiltrates reveals that most (up to 80%) of the mononuclear cells are activated T lymphocytes. B lymphocytes also are present but constitute a much smaller portion of the cellular infiltrates, being highest in cases due to nonsteroidal anti-inflammatory drugs (NSAIDs).[1,8] The infiltrating T cells are predominantly CD4+ and CD8+ cells. In most cases, the CD4 variety predominates over the CD8 variety.[1,19] Natural killer lymphocytes are rare; when present, they constitute only a small proportion of the infiltrating cells.[18] A slight prevalence (just over 50%) of the CD8+ subset has been reported in cases of ATIN associated with massive proteinuria after exposure to NSAIDs.[8,9] The relevance of this observation to massive proteinuria as a feature of ATIN is unknown.[1,19] Convincing evidence has been advanced that the infiltrating cells are antigenically activated and immunologically engaged in the pathogenesis of the lesions. However, no diagnostic pattern of markers or cell types has come to be identified with the lesions associated with any specific form of ATIN.[1,20]

Variable degrees of tubular injury usually are present, but tubular atrophy is absent. The tubular lesions are most evident at the site of the greatest concentration of infiltrating cells. They usually are focal and are more severe in the proximity of infiltrating cells. A distinguishing lesion that results from these localized peritubular infiltrates is the disruption of the tubular basement membrane (TBM) and its epithelial cell lining, so-called "tubulitis," which is characteristic of ATIN (Fig. 35.1D). Granulomatous reactions, multinucleated epithelioid cells, and polymorphonuclear leukocytes are detected in cases with marked tubular injury that display tubulitis. Another feature of tubular injury is the phenotypic change of their lining epithelial cells into migrating fibroblasts, so-called epithelial-mesenchymal transition (EMT) (Fig. 35.1D), an event considered to herald the onset of fibrosis.[15] Even in the absence of evident epithelial cell injury on light microscopy, an electron microscopy reveals structural cell changes, the loss of the brush border, and the fragmentation or lamination of the TBM. As a rule, immunofluorescent studies are not revealing. Scant and nonspecific granular staining for immunoglobulins, usually without complement, may be detected along the TBM. In rare drug-induced cases, linear deposits of immunoglobulin G (IgG) and complement (C3) may be present, indicating antibodies directed against tubular membrane antigens.[1,8,9]

There is increasing evidence for a participatory role of the epithelial cells in the pathogenesis of ATIN.[8,9,13–15] The enhanced expression of the human leukocyte antigen (HLA) class II antigens (HLA-DR) of injured tubular epithelial cells has been demonstrated, but shows no correlation with the intensity or phenotype of the infiltrating interstitial cells.[20] The overall profile of immunocompetent cells identified in ATIN suggests an important pathogenetic role for cell-mediated immunity in which the epithelial, vascular, and infiltrating cells are active and participating components.[8,9,21–24]

PATHOGENESIS

The immune response implicated in the pathogenesis of ATIN can be categorized into three phases: an antigen expression and recognition phase, an integrative or regulatory phase, and an effector or mediator phase (Fig. 35.2). In the first phase, either the resident peritubular interstitial cells or the injured tubular epithelial cells, which express major histocompatibility complex (MHC) class II, may function as antigen presenters.[1,25]

The subsequent integrative or regulatory phase may suppress or intensify the reaction to the stimulus provided by the antigen-presenting cells. This is a rather complicated phase of the immune response, in which T cells and antibodies directed at the presented antigen play a central role. Locally produced cytokines implicate a participatory role for the resident interstitial, tubular epithelial, and vascular pericytes and endothelial cells in this regulatory phase.[13,14,24,25] The exposure of tubular epithelial cells (TECs) to selected insults or toxins results in the activation of the TECs and their expression of various growth factors and chemokines, such as interleukins (IL), monocyte chemoattractant proteins (MCP), MHC, vascular endothelial growth factor (VEGF), transforming growth factor (TGF), and regulated on activation, normal T expressed and secreted (RANTES).[26,27] In this phase, the subsequent bidirectional cross-talk between the

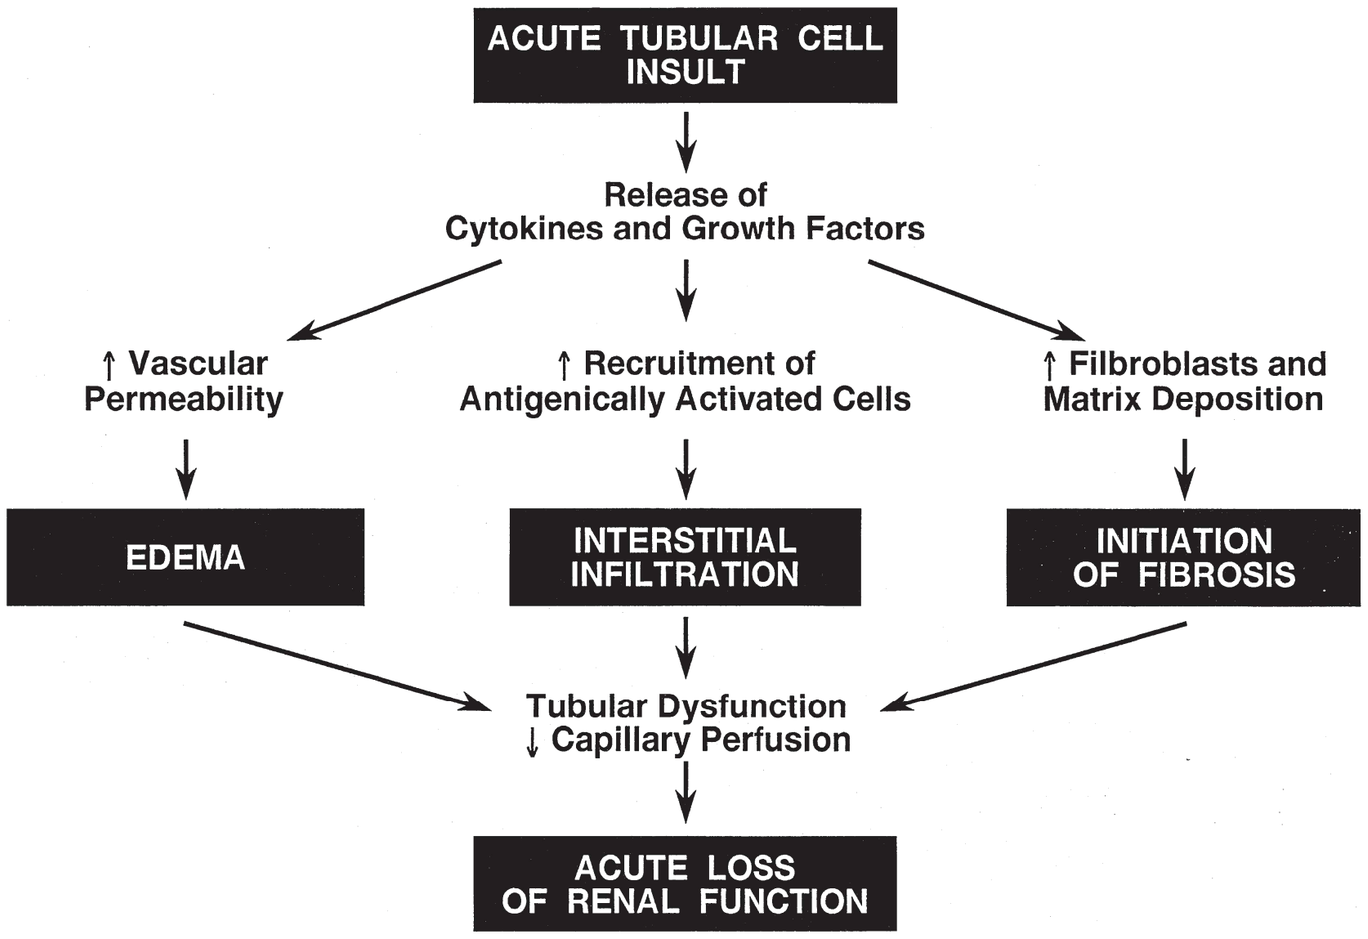

FIGURE 35.2 The pathogenic pathways implicated in acute tubulointerstitial nephritis.

TECs and the recruited infiltrating inflammatory cells, either by soluble factors or by direct contact, ultimately modulates the course of renal involvement and its potential for reversibility.

The final effector or mediator phase is mediated primarily by humoral factors released by the infiltrating cells, with the TECs and vascular pericytes playing a participatory role. The cytotoxic cells may induce injury by the release of proteases, and the inducer cells may do so by the release of lymphokines, which in addition to a direct detrimental action, augment the role of the macrophages. In turn, the release of collagenases, elastases, and reactive oxygen species by the macrophages magnifies the injury initiated by the lymphocytes. Lymphokines also promote fibroblast proliferation and alter the balance in favor of increased matrix synthesis rather than removal.[8,13,14,26]

In the final analysis, it is the presence of a rather wide range of activated mononuclear cells and their interaction with each other and with renal parenchymal cells during the integrative and regulatory phases that is potentially damaging to the kidney (Table 35.1). Several of the cellular (epithelial, endothelial, lymphocytes, macrophages) signals have varying, often overlapping, functions that interact to modulate or amplify the inflammatory reaction of ATIN. Some of those that have been identified include cell surface markers that have either antigenic (MHC, HLA class II, secreted protein acidic and rich in protein [SPARC]) or adhesive (intercellular [ICAM-1] and vascular [VCAM-1] adhesion molecules, integrins, selectins) properties. Others are chemoattractant MCP-1; osteopontin; macrophage inflammatory protein-1 (MIP-1); eotaxin; RANTES, proinflammatory (interleukin [IL]-6 and IL-8; TGF-β; platelet-derived growth factor-β [PDGF-β]; granulocyte–monocyte colony-stimulating factor [GM-CSF]; tumor necrosis factor-α [TNF-α]), vasoactive (adenosine; nitrous oxide [NO]; endothelin-1 [ET-1]), cytotoxic (metalloproteinases [MP]; tissue inhibitor metalloproteinases [TIMP-1]; reactive oxygen radicals; ferric ion), or fibrogenic [TGF-β, PDGF, IL-1, IL-6, TNF, plasminogen activator inhibitor (PAI)]. Evidence also exists for possible protective cytokines that can favorably modify the proinflammatory sequence of events.[27] The resultant integration, during the regulatory and effector phases, either suppresses the effector phase, as in mild forms of ATIN, or amplifies it, as in severe forms of ATIN. Ultimately, feedback mechanisms and the removal of the inciting agent restore the response to injury to its baseline dormant state with consequent recovery of normal kidney function or residual permanent damage.[1,18,24,28–31]

The bulk of the available information about the phases of the immune response and the interstitial inflammatory reaction in ATIN derives from studies in experimental animals, particularly in models of recombinant rats and mice.[9,26,29,32] Unfortunately, there are no animal models that correspond to the reaction that occurs in human ATIN. A principal limitation of human studies is that the data derived from kidney biopsies provide information only at fixed moments in the course of a lesion that is an evolving process. The same limitation applies to the serologic data provided in clinical studies that are obtained at a fixed period, usually when the lesion is well established and often at its worst, with limited or no data available on the onset or resolution phases of the lesion. These limitations notwithstanding, considerable evidence has accrued for a role of the principal immunologic mechanisms—cell-mediated injury, anti-TBM antibodies, immune complex deposition—in the pathogenesis of ATIN. Although there is evidence that all three mechanisms may be operative to varying degrees in different patients, the bulk of the available information favors a predominant role for cell-mediated injury.[8,9,25]

Contrary to the extensive experimental data in support of anti-TBM disease from animal models of interstitial disease, anti-TBM antibodies have been detected only rarely

in human ATIN.[1] The dearth of evidence for anti–TBM-mediated disease is far from convincing for an important role, if any, of this mechanism in human ATIN. The same limitations apply for a role of immune complex–mediated ATIN. The cases in which granular deposits of IgG have been detected have been in patients with Sjögren syndrome[32] and systemic lupus erythematosus,[29,30] the underlying disease mechanism of which accounts for the deposition of immune complexes in the kidneys as well as other body organs. Granular deposits in other, more common forms of ATIN are rare and never a dominant feature.

By contrast, the evidence in favor of cell-mediated disease is overwhelming. The infiltrating cells are antigenically activated. T-cell reactivity has been demonstrated from in vitro studies of lymphocyte stimulation.[19,22,32–34] Comparative studies of ATIN due to NSAIDs or antibiotics have failed to reveal significant differences in the overall percentage composition of T cells, B cells, and monocytes.[20] The reported differences in infiltrating cell subtypes can be due to individual genetic background, the nature of the insult, and the point in time during the course of the disease when biopsies were obtained. Nevertheless, it is clear that where sought, activated antigens have been demonstrated on the surface of the infiltrating cells, and plasma cells containing IgE, IgA, IgG, and IgM have been detected. However, no diagnostic pattern of markers or infiltrating cells has emerged.[1,20]

FUNCTIONAL MANIFESTATIONS

The principal manifestations of ATIN are those of tubular dysfunction, which is one reason that the term tubulointerstitial nephritis was introduced in preference to the initial appellation of interstitial nephritis. As a rule, tubular dysfunction precedes the onset of azotemia, which in turn precedes that of oliguria. As such, vigilance to clinically evident abnormalities of tubular function, including polyuria, is essential to the early detection of ATIN during its initial reversible stages.

Because of the focal nature of the lesions and the segmental nature of normal tubular function, the pattern of tubular dysfunction that results varies depending on the major site of injury, whereas the extent of damage determines the severity of tubular dysfunction (Fig. 35.3). The principal hallmarks of glomerular disease, such as salt retention, edema, and hypertension, characteristically are absent. However, massive proteinuria does occur in ATIN as a result of NSAIDs use and, occasionally, antibiotic use.[8–10,34] In addition to the direct injury to epithelial cells that may account for tubular dysfunction, changes in the interstitial volume and composition contribute to the functional abnormalities that develop. A major part of the reabsorbed or secreted tubular fluid has to traverse a true interstitial space.[35] The structure, composition, and permeability characteristics of the interstitial space must, out of necessity, exert an effect on such an exchange. A change in any of these parameters of the interstitium or those of the epithelial cell tight junctions, by delaying equilibration or exchange processes, could account for the functional alterations of the renal tubule that develop in ATIN (Fig. 35.3). It also is possible that changes in the pressure of the supporting interstitium, which are transmitted to the periarterial space, could affect the blood

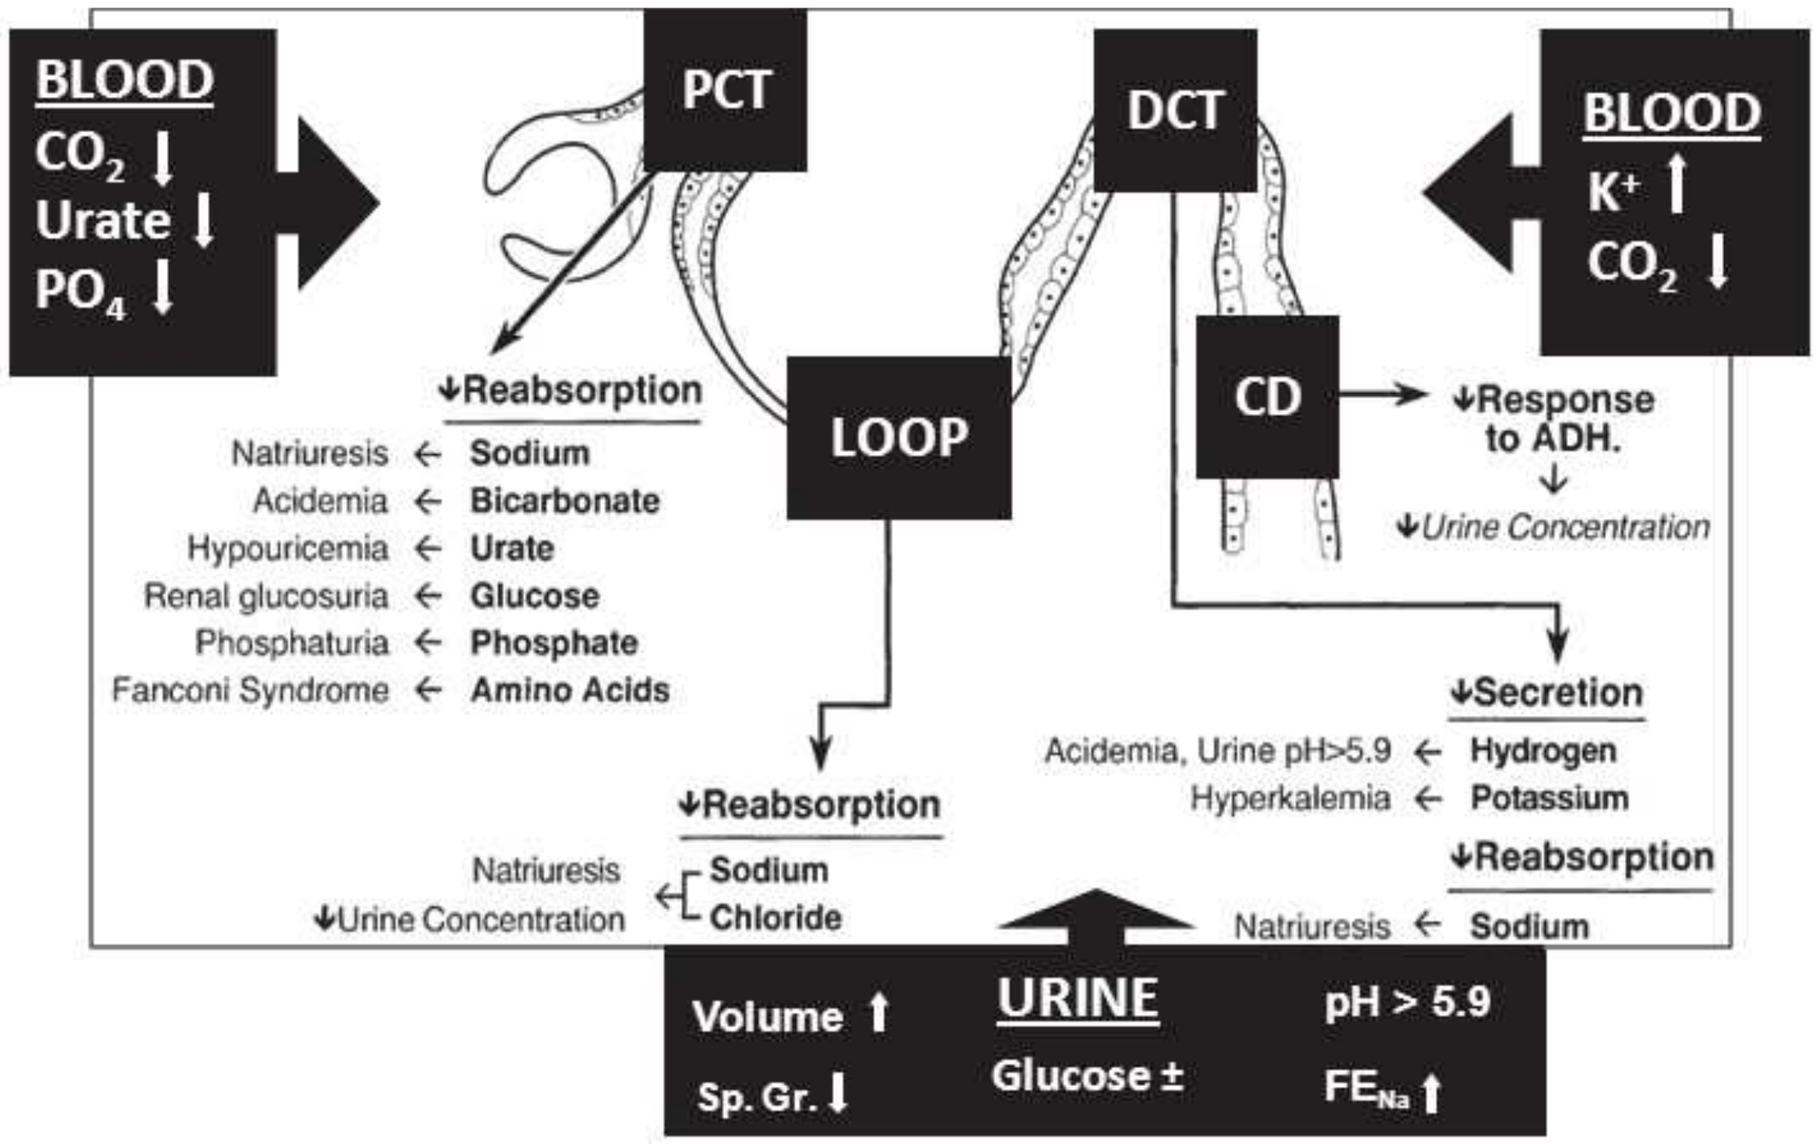

FIGURE 35.3 A schematic representation of the sites of tubular dysfunction in acute tubulointerstitial nephritis. The abnormalities are shown in bold lettering and their clinical manifestations are shown in regular lettering. The *boxed arrows* indicate the principal changes reflected in blood and urine tests. The *arrows* indicate the directional changes. *PCT*, proximal convoluted tubule; *DCT*, distal convoluted tubule; *Loop*, loop of Henle; *CD*, collecting duct; *Sp. flow to the adjacent tubule and thereby cause further tubular dysfunction. Tubular alterations also may be reflected in reductions of the GFR through tubuloglomerular feedback as the function of the affected proximal tubular segments becomes compromised and both the rate and the load of solute delivery to the macula densa are altered.[1] Furthermore, the increase in hydrostatic pressure of the edematous interstitium, as has been demonstrated in allograft rejections, may adversely affect the intra-arteriolar pressure and may cause a reduction of the hydrostatic pressure transmitted to the glomerular capillaries. In addition, a vasoactive effect of the cytokines, eicosanoids, and reactive oxygen species elaborated by the interstitial infiltrating cells and injured epithelial cells may affect renal hemodynamics through the increased production of vasoconstrictive substances, such as thromboxane A_2 and leukotrienes, and through the decreased production of vasodilators, such as nitric oxide, by the injured proximal tubule cells.[36–38] Evidence for a role for cytokines released by the infiltrating cells in the reduction of renal blood flow and GFR has been advanced from studies of an experimental model of acute obstructive nephropathy that is characterized by acute mononuclear cell infiltrates.[39]

The tubulointerstitial lesions usually are principally localized in the cortex and corticomedullary junction. Cortical lesions predominantly affect either the proximal tubule or the distal tubule. Corticomedullary lesions affect the loop of Henle and the medullary collecting duct. The change in the normal function of each of the affected segments then determines the manifestations of tubular dysfunction (Table 35.2 and Fig 35.3). Lesions principally affecting the proximal tubule result in bicarbonaturia (proximal renal tubular acidosis), glucosuria (renal glucosuria), aminoaciduria, β_2-microglobinuria, phosphaturia, and uricosuria.[1] The latter two events can be valuable in suggesting the possibility of tubulointerstitial disease when the serum phosphate and urate levels are lower than expected in any patient with reduced kidney function. The presence of glucosuria when blood sugar levels are normal should always lead to a consideration of ATIN. The distal nephron segment secretes hydrogen and potassium and regulates the final amount of sodium chloride excreted. Lesions primarily affecting the distal tubule will result in the distal form of renal tubular acidosis, hyperkalemia, and salt wasting. Lesions that primarily involve the corticomedullary junction disproportionately affect the loops of Henle, the collecting ducts, and other medullary structures essential to achieving and maintaining medullary hypertonicity, resulting in different degrees of nephrogenic diabetes insipidus, polyuria, and nocturia. Because of the reduced proximal tubular reabsorption and the disrupted medullary function, a polyuric phase almost always precedes the onset of oliguria in ATIN.[1]

Although this general framework is useful in localizing the site of injury, considerable overlap is encountered

35.2 Causes, Principal Sites of Injury, and Patterns of Tubular Dysfunction in Acute Tubulointerstitial Nephropathies

Site of Injury	Causes	Tubular Dysfunction	Clinical Manifestation
Cortex			
Proximal tubule	Antibiotics Multiple myeloma Immunologic diseases Neoplastic diseases Idiopathic	↓ Reabsorption: Na+, glucose, HCO_3^-, urate, PO_4, amino acids	Glucosuria, hypouricemia, hypophosphatemia, aminoaciduria, alkaline urine, acidemia
Distal tubule	Antibiotics Immunologic diseases NSAIDs Idiopathic	↓ Secretion: H+, K+ ↓ Reabsorption Na+	Alkaline urine, acidemia, hyperkalemia, inability to preserve sodium
Medulla and papilla	Infections Analgesics NSAIDs Disorders of uric acid, calcium, oxalate Immunologic diseases Idiopathic	↓ Reabsorption: Na+ ↓ Concentrating ability	Polyuria, nocturia, inability to preserve sodium

NSAIDs, nonsteroidal anti-inflammatory drugs.

clinically with different degrees of proximal, distal, and medullary dysfunction present in any one patient, all of which usually precede any clinically detectable changes in GFR. In most cases, however, the reduction in GFR and consequent azotemia are the presenting clinical abnormalities calling attention to the acute kidney injury. Preceding or coexistent evidence of tubular dysfunction, unless specifically sought, may go undetected and may either delay the diagnosis or result in the wrong clinical diagnosis. One can only speculate on the number of cases of ATIN that go undetected clinically because of the presence of tubular dysfunction alone in the absence of significant azotemia or oliguria—hence the importance of monitoring for tubular dysfunction in patients exposed to agents known to be associated with ATIN, and the necessity of documenting tubular dysfunction in those with mild azotemia to marshal evidence for the diagnosis of ATIN, before its progression to kidney failure (Table 35.2). Importantly, it is at this early stage of the disease that the lesions of ATIN are potentially reversible and responsive to therapy.[8,9,40]

CLINICAL FEATURES

The clinical presentation of individual cases of ATIN is diverse and varies to some degree depending on the causative factor (Table 35.3). The manifestations best characterized in methicillin-induced ATIN can be considered the prototypically classic clinical manifestations of a hypersensitivity reaction, around which general variation occurs depending on the causative agent and individual variation occurs depending on the particular case encountered clinically.[8,9,21,25]

In most cases, symptoms develop several days or even weeks after exposure to the inciting agent, which in the case of drugs, is not dose dependent. The classic triad of low-grade fever (35% to 70%), fleeting skin rash (25% to 40%), and mild eosinophilia (35% to 60%) described with methicillin-induced ATIN is not always present, and certainly it is less common for all three to occur together. Their documentation depends to some degree on the vigilance with which they are sought because they may be mild and transient. The full triad was noted to be present in approximately 20% of cases of methicillin-induced ATIN, but the triad was noted only in less than 10% of cases of ATIN induced by other drugs in which any one of them (fever, rash, or eosinophilia) is less likely to occur than with methicillin.[8,9,11,41] The skin rash consists of erythematous maculopapular lesions, which often are pruritic, and preferentially affect the trunk and the proximal portion of the extremities. Flank pain or a sense of fullness, reflecting edema-induced distention of the renal capsule, may be present in over one-third of the cases when queried and may be the presenting symptom in some cases.[42] Gross hematuria, another presenting feature, may be present in 5% to 15% of drug-induced ATIN cases. A transient

35.3 Prevalence of Clinical Manifestations of Acute Tubulointerstitial Nephropathies

Systemic		Urinary	
Fever	35%–70%	Gross hematuria	5%–15%
Rash	25%–40%	Micro hematuria	70%–90%
Eosinophilia	30%-60%	Proteinuria (<2 g/d)	70%–85%
Flank pain	25%–40%	Pyuria	70%–80%
Arthralgias	25%–40%	FE_{Na} >1%	~100%
Hypertension	10%–20%	Eosinophiluria	? %

FE_{Na}, fractional excretion of sodium.

eosinophilia, often in methillin-induced ATIN (~60%) and less commonly with other drugs (~30%), is present, but may go undetected unless specifically sought. A history of arthralgia may be elicited in more than one-fourth of cases.[8,9,21]

A urinalysis can be helpful in the diagnosis (Table 35.3). Proteinuria, hematuria, and pyuria are present in most cases. The proteinuria is mild, seldom exceeds 2 g per day, and only rarely is in the nephrotic range, except in those cases due to NSAIDs.[8,9,11] Microscopic hematuria is present in 70% to 90% of cases; rarely, red blood cell casts may be detected. The pyuria is nonspecific except when eosinophils are detected in appropriately prepared and carefully examined urinary sediment.[1,8,9] White blood cell casts occur and are fairly characteristic when they contain eosinophils.[43] Although eosinophils may be observed with a Wright stain of well spun urinary sediment, the use of a Hansel stain on the sediment of an alkalinized urine sample is superior in detecting eosinophils. The mere detection of eosinophiluria is not specific for ATIN.[1,44] The sensitivity of eosinophiluria for the diagnosis of ATIN has been estimated to be about 60% and its specificity has been estimated to be 85%, with a positive predictive value of 38%. These are figures derived from retrospective chart reviews of cases of clinically suspected ATIN but which were not established by a kidney biopsy or definite etiology.[44,45] Eosinophiluria is present in approximately 15% of hospitalized patients, in whom it usually is caused by a variety of other inflammatory diseases of the urinary tract, and in only 14% of those with eosinophiluria is it due to ATIN.[44,45] The presence of eosinophiluria is a better predictor of ATIN when more than 5% of the urinary leukocytes are eosinophils, in which case 40% of the eosinophiluric patients have been estimated to have ATIN, as opposed to an incidence of 3.5% in those in whom less than 1% are eosinophils.[44,45] Other conditions in which an eosinophiluria exceeding 5% may be present are urinary tract obstruction, cystitis, contrast-induced AKI, IgA nephropathy, and cholesterol emboli. Thus, the detection of eosinophiluria, although useful, is neither necessary nor sufficient for the diagnosis of ATIN. It is regrettable that compared to urine examinations for eosinophils in the diagnosis of ATIN, it is rare that attempts are made for the detection of specific tubular dysfunctions characteristic of ATIN such as renal glucosuria, increased fractional excretion of uric acid, an inability to concentrate the urine maximally, and to conserve sodium.[1]

The impairment in kidney function varies, ranging from discrete selective abnormalities of tubular function to frank kidney failure, with or without oliguria.[1,8,9,11] As a rule, increments in blood urea nitrogen and serum creatinine develop after tubular dysfunction is detectable and while the patient is still nonoliguric or even polyuric. Oliguria develops if early features of ATIN, modest azotemia, decrements in estimated GFR, and evidence of tubular dysfunction go undetected and exposure to the offending agent continues. Kidney injury is more likely to occur in older patients and is more severe in those who become oliguric. The duration of the oliguric period is variable, ranging from a few days to several weeks. Supportive renal replacement therapy may be required in approximately one-third of those patients. Reversal of kidney injury and a return to baseline kidney function is the rule in the majority of cases (about 60% to 65%). Irreversible kidney injury can occur but is rare (about 5% to 10%), whereas partial recovery with a persistent impairment of kidney function is relatively more common (10% to 20%), especially in cases where interstitial fibrosis and granulomas are present in biopsy specimens.[8,9,11,21]

Increased kidney size on ultrasonography, reflecting an interstitial edema, is common but nondiagnostic. Radioactive gallium uptake by the kidney, reflecting interstitial cellular infiltration, can be detected in one-third of cases, but lacks diagnostic specificity.[46] This modality may be particularly useful when a kidney biopsy is contraindicated or is difficult to perform in severely ill patients.[46] The lymphocyte stimulation

test can be valuable in the diagnosis of drug-induced ATIN, especially in determining the responsible agent in cases of multiple-drug therapy.[29,30] The serum level of IgE can be elevated and IgE-containing plasma cells have been demonstrated among the renal interstitial cellular infiltrates, providing further evidence for a hypersensitivity reaction.[25]

INCIDENCE AND DIAGNOSIS

The frequency with which ATIN accounts for cases of clinically encountered AKI is difficult to establish. The diagnosis of ATIN is based on the finding of characteristic morphologic features on a kidney biopsy and on the identification of the causative factor. Both of these requirements for a correct diagnosis are fraught with difficulties and limitations, leading to the overall underdiagnosis of ATIN.

Part of the difficulty associated with diagnosing ATIN stems from the relatively low index of suspicion with which its possibility is considered clinically and the general reluctance to perform a kidney biopsy in cases of AKI in general, and in cases of ATIN in particular when symptoms subside after the discontinuation of the causative medications.[7] Almost all cases of ATIN that have been biopsied have been in renal failure. Even if a biopsy is performed, there are difficulties in differentiating the lesions of ATIN from those of ATN, which is a distinct possibility in most cases of AKI in which the prevailing clinical condition could be conducive to either ATIN or ATN.[1,6] An essential differential feature between the two entities is the magnitude of interstitial edema and cellular infiltrates, which are more prominent in ATIN, and the magnitude of tubular cell injury, which is more prominent in ATN (Fig. 35.4). However, given the variable degree to which each of these features may be present in each entity, there is sufficient overlap between the extent of edema and the severity of tubular injury in ATIN and ATN to make it difficult to differentiate among them on morphologic features alone, at least in some cases.[6,45] There also are difficulties associated with identifying the causative factor. Clinically, the removal of a suspected agent followed by the reversal of the lesion strongly suggests the diagnosis of ATIN. This can be particularly convincing in the presence of systemic manifestations of a hypersensitivity reaction, such as fever, skin rash, and eosinophilia in addition to AKI, all of which subside on the removal of the inciting factor or agent. Difficulties arise when the only manifestation is AKI and when a number of corrective measures are instituted simultaneously. Moreover, most patients are on several drugs, and there is the expected tendency to incriminate the most common and better known agents that have been associated with ATIN.[8] The diagnostic limitations of removing agents wrongly surmised as a cause of ATIN have been shown by studies in which drug-induced lymphocyte stimulation testing (DLST) revealed causative agents that had not been suspected clinically.[34]

Most of the figures quoted in the literature on the incidence of ATIN stem from retrospective studies based on kidney biopsies. A review of unselected kidney biopsy specimens reveals a low incidence of ATIN. A review of biopsy specimens from patients with unexplained AKI reveals a frequency that ranges from 8% to 22%,[7,47–50] which generally is higher in the elderly population.[51] Thus, given the very small number of patients with AKI who are subjected to a kidney biopsy, the necessity of a kidney biopsy to diagnose ATIN, and the failure to suspect the diagnosis of ATIN clinically all render conclusions derived from biopsy reports of limited value in estimating the true incidence of ATIN.[7] Furthermore, because of the variable and often subjective reasons for which kidney biopsies are done in different centers, any attempt to compare or combine results from different reports would not be useful. In cases of clinically evident AKI, ATIN probably accounts for approximately 15% to 20% of them.[7–9]

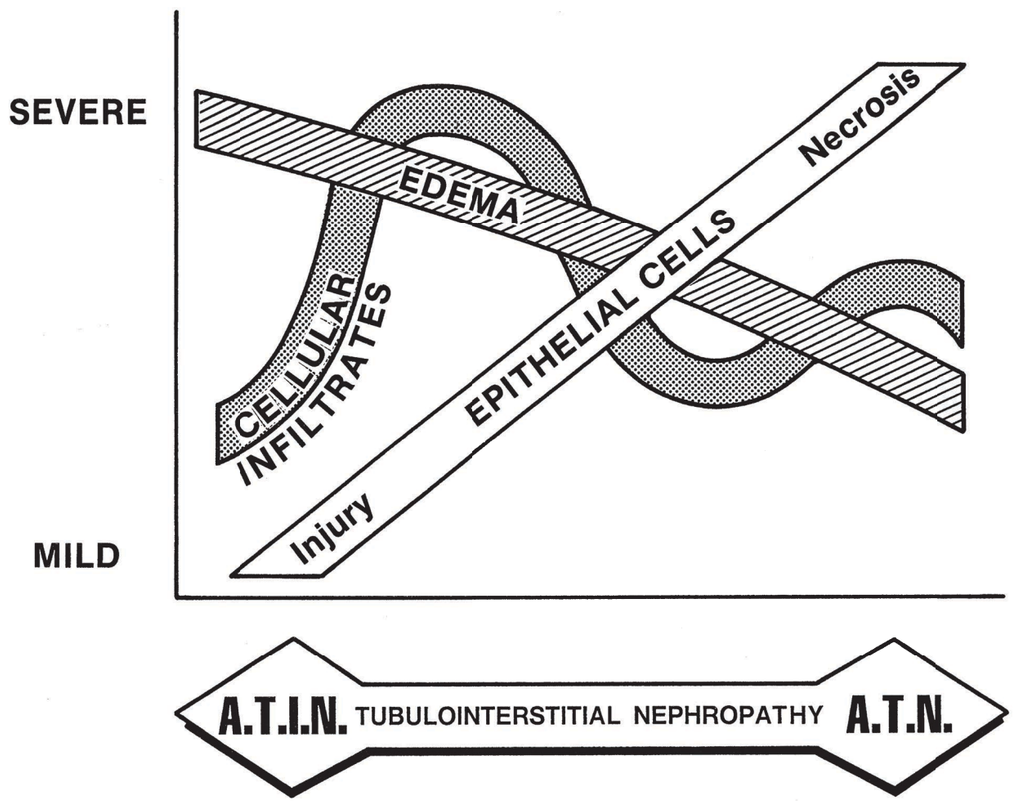

FIGURE 35.4 A schematic representation of the spectrum of structural changes associated with cases of acute renal failure due to acute tubulointerstitial nephritis (ATIN) and acute tubular necrosis (ATN). New York: Churchill Livingstone; 1988:491, with permission.)

TREATMENT

The primary treatment of ATIN is that of the underlying cause if an infection or a systemic disease and the discontinuation of the suspected offending agent if it is drug-induced. In addition to supportive measures, including dialysis where indicated, it is important to inform the patient in order to ensure the prevention of reexposure to the incriminated drug.

As a hypersensitivity reaction with systemic manifestations in which steroids are often used, patients with ATIN have been treated with corticosteroids.[25] From the outset of reported studies in the 1960s, there has been suggestive evidence that a short course of treatment with steroids improves the kidney lesions and expedites recovery from drug-induced ATIN; however, this is not a uniformly observed response and the use of steroids has been controversial.[46,50]

Unfortunately, no controlled clinical trials are available; all reported studies are retrospective in nature, contributing to the controversy over the use of steroids. In a retrospective evaluation of biopsy-proven cases of ATIN in 2004, the routine use of steroids was not associated with a statistical difference in kidney function or outcome.[47] Recent retrospective studies report a more rapid and complete recovery when steroids are administered early, within 7 to 14 days of developing ATIN, at a time that there is absence or only minimal interstitial fibrosis on a kidney biopsy.[16,21] Nevertheless, the use of steroids should be considered in all patients with persistent kidney injury after the inciting agent has been discontinued, and in those whose biopsy reveals granulomatous lesions that are associated with an increased risk of permanent kidney injury.[1,8,10,21] Reversals of apparently permanent kidney injury after long-term steroid therapy in patients on maintenance hemodialysis have been reported.[1,52–54]

If steroids are used, a response usually is evident relatively early after their initiation. The course of treatment should be brief, and the steroids should be discontinued if no response is observed after 3 to 4 weeks of therapy.[1,16,52] If kidney function improves, steroid therapy should be maintained for 4 to 6 weeks with a slow dosage taper. For patients who fail to respond to steroids or are intolerant of them, a beneficial effect has been suggested from treatment with mycophenolate mofetil.[53] In this report of eight cases of biopsy-proven ATIN, all of whom had failed to respond to 6 months or longer of steroid therapy, treatment with mycophenolate for up to 2 years resulted in an average decline of creatinine levels by 0.3 mg per deciliter. However, given the long duration of the disease in these patients, it is questionable that they can actually be considered as cases of true ATIN. Whether mycophenolate is equal or superior to steroids as an initial therapy for ATIN remains to be addressed.[54]

Among the causes of ATIN, infections and drugs are the most common (Table 35.4).

35.4 Principal Conditions Associated with Acute Tubulointerstitial Nephropathy

Infections
Invasive of renal parenchyma
Reactive to systemic infections
Drugs
Antibiotics
Sulfonamides
Nonsteroidal anti-inflammatory drugs
Other drugs
Systemic diseases
Metabolic disorders
Immune diseases
Neoplastic disease
Idiopathic with or without uveitis

INFECTIONS

Infectious causes of ATIN often are overlooked; as a consequence, their diagnosis is missed and their incidence as a cause of ATIN is underestimated. This occurs for several reasons. First, the introduction of antibiotics led to the eradication of serious streptococcal infections that were first associated with ATIN. Subsequently, the recognition that these antibiotics could also result in ATIN has led to the preferential consideration of anti-infective drugs as the principal cause of ATIN. Second, the hemodynamic changes associated with severe infections and the potentially nephrotoxic antibiotics used for their treatment are usually implicated as a cause of any deterioration of kidney function without an adequate investigation into ATIN. Third is the common but questionable notion that postinfectious acute glomerulonephritis is the most common kidney lesion associated with infections. Finally, modest reductions in kidney function and a return to baseline as the infection is treated limit the clinical consideration given to changes in kidney function. In conclusion, unless the possibility of infection-induced ATIN is considered seriously and the diagnosis is pursued actively, cases of infection-induced ATIN will go undetected, and its true incidence will remain underestimated. Nevertheless, several new causes of infection-induced ATIN have come to be identified since Councilman described their association.

Tubulointerstitial lesions may develop in the kidney either because of direct invasion of the kidney parenchyma by the infective microorganisms or because of reactive changes to a nonrenal systemic infection.

Invasive Infections

The classic and by far the most common example of ATIN is due to direct bacterial invasion of the kidney, although fungal, viral, and parasitic infections also may account for it. The usual forms of pyelonephritis are considered in Chapter 23 and are not detailed here, except to highlight their differential features from ATIN reactive to a systemic infection. Apart from the classic local and systemic manifestations of acute pyelonephritis that clinically differentiate it from reactive ATIN, there are distinct morphologic differences between the two entities that deserve emphasis. Acute bacterial pyelonephritis is a focal rather than a diffuse lesion, which usually is limited to individual pyramids and rarely affects all the pyramids of the kidney. The areas of infection are characteristically wedge-shaped, with the apex directed toward the medulla. The infected foci are focal and sharply demarcated from the adjoining uninfected parenchyma, and lack the tendency to spread laterally.[55] Contrast-enhanced computed tomography scans reveal the typical wedge-shaped, nodular, hypodense areas corresponding to the distribution of these

typical lesions and heavy cellular infiltrates in pyelonephritis, which are quite distinct from the generalized and diffuse changes of ATIN.[46] In the absence of an obstruction, the infection tends to be confined to the originally affected lobule and to resolve gradually over a period of weeks. An acute reduction in kidney function is rare except in severe cases and in those with an obstruction, or when the infection is superimposed on a preexisting chronic kidney disease.[56] As recovery occurs, the initial polymorphonuclear leukocytic infiltrate is replaced by mononuclear cells and the development of streaks of fibrous tissue, which account for the cortical scars encountered in such cases.[57]

Occasional cases of ATIN have been reported in association with otherwise invasive infections such as mycoplasmal pneumonia,[1] toxoplasmosis,[1] salmonellosis,[58] cytomegalovirus infection,[59] infectious mononucleosis,[60] polyomavirus infection,[1] hantavirus infection,[61] Rocky Mountain spotted fever,[1] leptospirosis,[62] Legionnaires' disease,[63] candidiasis,[1] cryptococcus,[64] Yersinia pseudotuberculosis,[65] Ascaris lumbricoides,[66] hepatitis A virus,[67] and adenoviral infection.[68] A greater number of such cases are now encountered clinically and recorded in the literature because of the increasing number of immunocompromised hosts such as patients with AIDS, transplant recipients, and the elderly. Although passage of the implicated organisms through the renal parenchyma and their isolation from the urine has been demonstrated, their localization in the kidney is less well substantiated. The interstitial cellular infiltrates are mononuclear cells rather than polymorphonuclear cells, and evidence has been advanced for an immunologic mechanism responsible for the renal reaction elicited by some of them.[69] Antigenic material has been demonstrated in the renal parenchyma of humans with ATIN associated with some of these infectious agents, such as Mycoplasma, polyomavirus, the rickettsiae responsible for Rocky Mountain spotted fever, and leptospira.[1,70] The complex nature of the lesions encountered in some of these infections can be better appreciated from a specific consideration of some of them.

Leptospirosis

Acute kidney injury occurs in almost half the cases of leptospirosis, and the degree of kidney involvement often determines the gravity of the disease. In fact, in endemic areas of the disease, leptospirosis is one of the most common causes of AKI.[1] Although there might be evidence of renal involvement in the preicteric phase of the disease, it is in its icteric phase that ATIN develops in conjunction with a rapid deterioration of kidney function. The renal lesions of leptospirosis are limited exclusively to the tubules and the interstitium. They are focal in distribution and are most pronounced at the corticomedullary junction, a structural feature characteristic of ATIN lesions that are reactive to infections. Initially, interstitial edema and cellular infiltration are minimal but ultimately become prominent, such that the whole kidney becomes enlarged, congested, and soft. The infiltrates consist of mononuclear cells, plasma cells, and eosinophils. The interstitial lesions may be present even in the absence of clinically detectable kidney injury. The tubular lesions occur during leptospiral migration through the renal parenchyma, and during this stage the spirochetes can be detected in the urine. Thus, whereas direct tubular injury by Leptospira may account for some of the renal lesions, evidence exists for a leptospiral antigen-mediated immunologic mechanisms of injury.[70–72] Leptospiral outer membrane proteins and lipoproteins have been implicated in causing tubular dysfunction and initiating immunologic injury by inhibiting Na^+-K^+-Cl^- cotransporter activity and messenger RNA (mRNA) synthesis in the thick ascending limb.[71,72] This could account for the polyuria and hypokalemia frequently seen in these cases. Furthermore, the experimental exposure of cultured proximal and thick ascending limb cells to the leptospiral outer membrane proteins results in the activation of a proinflammatory cascade, with increased induction gene expression of nuclear factor-kappaB (NF-κB), iNOS, MCP-1, and TNF-α.[70,71] The superimposition of shock and volume depletion in severe cases of the disease may further contribute to the tubular lesions, and the structural changes observed may represent the cumulative effect of both direct invasion and ischemia, possibly coupled with an immune injury.[1]

Although the interstitial changes may persist for several months in an occasional patient, usually with persistent spirochetes in the urine, in most cases the renal changes subside within a few weeks after the resolution of the disease with appropriate antibiotic therapy. In these usual cases, kidney function returns to normal, whereas in those who develop a chronic carrier state the leptospira localize in the kidney, fibrosis and tubular atrophy develop, and permanent impairment of kidney function ensues.[1,73]

Hantavirus Infection

The once mysterious entities of "hemorrhagic fever with renal syndrome" in Asia and "nephropathia epidemica" in Europe are now recognized as due to infection with one of the related RNA viruses of the Hantavirus genus, which belong to the family of Bunyviridae. The availability of serologic tests for the specific antibodies, which appear early in the course of the infection and may persist indefinitely, now allows for the easier diagnosis of this once enigmatic disease that mimics several of the features of leptospirosis.[74,75]

The renal lesions consist of the classic changes of ATIN. They are most prominent in the outer medulla and the corticomedullary junction, and together with the hallmarks of Hantavirus nephropathy include vascular congestion and interstitial hemorrhage.[74] This accounts for the microhematuria and, because of the enlarged kidneys, for the back pain present in most cases. The transient heavy proteinuria (>2 g per day) noted at the onset of the disease correlates with the urinary excretion of IL-6.[76] The severity of the lesions and the frequency of renal injury are higher and the prognosis is worse in the Asian than in the European and American varieties of the infection.[74,77]

Polyoma Virus

Polyoma is a double-stranded DNA virus family, one strain of which, the BK virus, commonly causes ATIN. Typically, the virus is acquired in childhood but remains latent—over 70% of adults are seropositive.[78] However, when the immune system is compromised, as in AIDS patients and transplant recipients, the virus reemerges and causes ATIN.[79,80] Its incidence in kidney transplant recipients is reported to be 3% to 5%, with an associated 10% to 50% graft loss among those affected.[81,82] It is considered to result from overimmunosuppression; thus its incidence has increased with the use of newer, more potent immunosuppresants. Decreasing immunosuppression has been effective in the management of some cases but is associated with increased episodes of acute rejection.[81,82]

The diagnosis of BK virus nephropathy (BKVN) is based on findings on a kidney biopsy that are distinct from those of acute rejection. This includes tubulitis with an abnormal chromatin pattern in the tubular epithelium and intranuclear viral particles on an electron microscopy.[82] The finding in the urine of cells that have viral inclusions, so-called decoy cells, are indicative of viral replication in the urinary tract. Quantifying viral DNA load is potentially useful for the detection of significant viral reactivation, and can serve as a quantifiable surrogate marker of the course of the infection.[81] Biopsy-proven BKVN is always associated with greater than 10^4 viral copies per milliliter.[82] There are reports of another polyoma virus (the JC virus) associated with ATIN in renal transplant recipients; however, this strain is considered less virulent than the BK virus.[82]

Candidiasis

Disseminated candidiasis almost always affects the kidney. Candida albicans causes two types of lesions in the kidneys. The first type, which is relevant to this chapter, occurs during the candidemic phase with the initial seeding of the kidney, which rapidly elicits an inflammatory reaction with polymorphonuclear infiltration limited to the renal cortex in 52% to 82% of cases.[83] Depending on the severity and the extent of the lesions, pyuria and candiduria may be the only findings, with varying degrees of renal insufficiency in approximately half the cases. When multiplication extends to the tubular lumen, they may invade the interstitial tissue and elicit a severe interstitial inflammatory reaction in the medulla.[1]

The second type of lesion develops in the more chronic form of the infection and results from the multiplication of the organisms in the urinary tract, where no limiting inflammatory reaction can be elicited. This can result in the proliferation of the organisms into mycelial filaments that form occluding bezoars of Candida in the renal pelvis and calyces resulting in obstructive nephropathy, hydronephrosis, and chronic tubulointerstitial nephritis.[84]

Hepatitis A Virus

Acute hepatitis A (AHA) is one of the most common infectious diseases worldwide; it is usually self-limiting and primarily affects the liver.[69,85] Extrahepatic manifestations, especially kidney involvement, is rare but has been reported with fulminant or nonfulminant AHA. In one series, 7.2% of patients with AHA presented with AKI, and 33% of this group underwent kidney biopsy. The common histopathologic lesions included acute tubular necrosis and ATIN.[85] This is far different from the well-described immunologically mediated glomerular lesions of hepatitis B and C. The mechanism of AHA-associated AKI is unknown, but has been attributed to bile salt nephrotoxicity. In most reports, the clinical course is benign, although renal recovery can be substantially delayed.[69,85]

HIV

Patients with AIDS constitute a special challenge in the diagnosis of ATIN, not only because of their propensity to contract unusual infections,[86] but also because of the number of drugs they consume, such as protease inhibitors and sulfamethoxazole, which can cause ATIN.[87,88] Acute tubulointerstitial nephritis without other features of HIV-associated nephropathy is reported in 11% of HIV-positive patients who undergo a kidney biopsy.[85] Sometimes, this lesion is encountered in the setting of immune reconstitution inflammatory syndrome (IRIS), a multiorgan system disorder occurring at the initiation of antiretroviral therapy.[89] Tubulointerstitial nephritis in HIV-positive patients commonly presents with normotension, pyuria, and minimal proteinuria.[87,88] The renal lesion consists of a diffuse lymphocytic interstitial inflammation and tubulitis, with sparing of the glomeruli.[90] Prior to the availability of antiretroviral therapy, HIV-positive patients with AKI were often treated with corticosteroids. In those with an improved renal function after steroids, repeat biopsies showed the resolution of concurrent interstitial nephritis.[91]

Noninvasive Infections

Acute tubulointerstitial nephritis may complicate infections in the absence of bacteremia and parenchymal invasion of the kidneys. Before the availability and widespread use of antibiotics, ATIN was a relatively common complication observed at the autopsies of cases of β-hemolytic streptococcal infections.[1,3,4] Although the lesions of ATIN were noted to be more common in cases of scarlet fever,[3] the more severe destructive lesions occurred in cases of diphtheria.[4] The availability of specific vaccines has eradicated diphtheria, whereas specific antibiotic therapy has ameliorated the severity of streptococcal infections such that, although renal lesions continue to occur, their clinical outcome is now more favorable. Unlike the relatively later renal changes of streptococcal infections, which occur in the 2nd or 3rd week after the onset of the infection and cause typical postinfectious acute proliferative glomerulonephritis, the lesions of ATIN usually occur early in the course of the infection, often between the 9th and 12th day of the disease, and in the absence of edema or hypertension.[1,3,4]

In contrast to the detailed morphologic changes reported in the early literature describing this entity, the clinical

information provided is sparse. Where noted, proteinuria and pyuria were said to be common.[4] In a careful study of the urinary sediment of 14 children with scarlet fever, abnormal sediment was reported to be present in all cases. In larger series, the urinary sediment is noted as being abnormal in only 50% to 60% of the cases.[1]

The lesions described by Councilman[2] are much less rarely noted in the current literature, and most of the available information on them dates back to the preantibiotic or early antibiotic periods, although they continue to be encountered, particularly in children,[92] and must be considered in streptococcal infections with AKI in the absence of hypertension and edema, and with normal complement levels.[93]

Drugs

Drugs have emerged as the most common cause of ATIN. Drug-induced ATIN has been observed in 6.5% to 27% of all renal biopsy samples when only cases of unexplained AKI are considered.[7,21] First described in conjunction with the sulfonamides used in the 1940s, the lesion was next reported to occur during penicillin therapy in the 1950s, and was ultimately best characterized in patients treated with methicillin in the 1960s.[8,9] Since then, the number of drugs implicated as a cause of ATIN continues to increase. The most common causes of drug-induced ATIN are antibiotics and NSAIDs.[8,94] Although the implicated mechanisms and the general morphologic feature on a kidney biopsy are the same as those described with methicillin, the clinical presentation of drug-induced ATIN is variable with other drugs. Symptoms range from asymptomatic to constitutional (fevers, chills), flank pain, or arthralgias. The presentation is usually nonoliguric, and rarely with the triad of eosinophilia, fever, or skin rash.[21] The blood may show elevated IgE or an increased sedimentation rate, and the urine may contain red blood cells or white blood cell casts.[12,13,21]

The association of ATIN with most of the incriminated drugs is quite rare and often based on individual case reports. The evidence for a causative role of the drug is merely circumstantial, particularly in the absence of a kidney biopsy. Even in cases where a kidney biopsy is available, the possibility of ATIN due to the underlying infection or of ATN due to the hemodynamic instability of infected patients could make an interpretation of the biopsy difficult and the attribution of ATIN to the implicated drug suspect, especially in instances where only a single case is reported in the literature. In cases where a kidney biopsy is not available for documentation, the acute deterioration of kidney function and abnormal urinary sediment, even in the presence of the eosinophiluria used to implicate ATIN, may be due to any of the other possible causes, such as preexisting kidney disease, acute tubular necrosis, postinfectious glomerulonephritis, or a direct nephrotoxic effect of the implicated agent or one of the coadministered drugs. The latter possibility is particularly confounding because any one of the multiple agents used in the treatment of most patients can be responsible for ATIN, even when least suspected.[1,34]

Drug-induced ATIN is an idiosyncratic hypersensitivity reaction, as evidenced by several facts: It occurs in only a small number of people exposed to the drugs; it is not dose-related; it often is associated with other systemic manifestations of hypersensitivity such as fever, skin rash, eosinophilia, and arthralgia; the reaction recurs on reexposure to the same drug or one of its congeners; circulating antibodies to the incriminated drugs have been demonstrated in some instances; and laboratory evidence for a hypersensitivity reaction has been documented in some cases. In addition, the structural features of individual drugs (propionic acid derivatives) or those common to some groups of drugs (β-lactams) do seem to predispose one to the development of ATIN. Histologically, drug-induced ATIN can be discriminated from other types of AKI due to the presence of a T lymphocyte rich interstitial infiltrate.[95] The immunogenicity of drugs is thought to depend on their ability to form covalent bonds with larger proteins to form a hapten-carrier complex, which is an immunogenic molecule that stimulates a T- and B-cell immune response.[25,95]

Antibiotics

Of the several antibiotics that have been incriminated as a cause of ATIN, most share the β-lactam structural ring—penicillin, its derivatives, and the cephalosporins.

Methicillin

Methicillin is the agent with the highest incidence of drug-induced ATIN and the one in which the clinical features of this side effect of antibiotics are best characterized.[1,8,11] The mean period of drug administration before the renal lesions occur is approximately 15 days, with a reported range of 10 to 45 days. The incidence of ATIN has been estimated to be approximately 2% of those exposed to the drug and increases to 15% in those who are exposed to it for over 2 weeks.[96] In those who experience a reaction, subsequent exposure to methicillin results in the recurrence after a much shorter period of exposure and at lower doses of the drug. With the reduced clinical use of methicillin, there has been a reduction in the number of cases encountered clinically and reported in the literature.

Systemic manifestations of a hypersensitivity reaction are a dominant feature of methicillin-induced ATIN, and are more evident than in most other drug-induced ATIN (Table 35.3). Characteristically, drug-induced fever appears after the initial fever caused by the infection has subsided following the initiation of methicillin therapy. The recurrent episode of fever usually is accompanied by a skin rash, eosinophilia, and arthralgias. The skin rash is fleeting and consists of erythematous, often pruritic, maculopapular lesions that are present in 30% to 50% of cases. Eosinophilia is common (60%) but transient, as is the eosinophiliuria. Arthralgias are nonspecific and less common (10% to 20%) than other systemic manifestations.[1,8,9,21]

As a rule, patients are polyuric as kidney function begins to deteriorate, and when the AKI is first detected, it is nonoliguric in two-thirds of patients. Independent of

the severity of the AKI, the outcome is favorable after the withdrawal of methicillin in the majority of cases. The initial improvement, which is rapid over the first few weeks of discontinuing methicillin, is followed by a slower return of kidney function to normal in most (greater than two-thirds of cases), but only to near normal in some 20% of cases.[11,21] Instances of persistent kidney injury are rare (<10%), and are more likely in those whose kidney biopsy reveals diffuse infiltrates, interstitial fibrosis, granulomatous reaction, and severe tubular injury.[97,98] Recovery is faster and more likely in those whose dominant kidney lesions consist of interstitial edema rather than cellular infiltrates, and when the cellular infiltrates are focal rather than diffuse.

A metabolic derivative of methicillin, dimethoxyphenylpenicilloyl, has been implicated as the inciting antigen on the basis of its demonstration by immunofluorescence techniques along the TBM and the detection of circulating antibodies to dimethoxyphenylpenicilloyl in cases of ATIN.[99] However, neither of these findings appears to be specific to the incidence of ATIN because both have been shown to be present in methicillin-treated cases with no evidence of acute kidney injury.[1]

Rifampin

Since the introduction of rifampin (rifampicin) as an antituberculous agent in 1976, over 150 cases of ATIN have been ascribed to it in the literature. As a rule, AKI occurs during intermittent administration of the drug (once or twice weekly), and usually appears several months after the institution of therapy. A more abrupt onset occurs with rifampin readministration after a hiatus in its previous daily, uneventful use. ATIN during continuous daily rifampin therapy also has been noted. However, most cases reported have occurred during intermittent therapy, and the number of cases noted has decreased since the intermittent use of the drug has been abandoned.[100,101]

Circulating antibodies to rifampin have been detected in most, but not all, affected patients, as well as in the serum of those without any adverse reaction to the drug. The suggestion has been made that the kidney lesions develop in response to a critical level of antigen–antibody complexes that accumulate during intermittent rifampin therapy.[102] However, immunofluorescence staining of kidney biopsy specimens for deposits of antibodies to rifampin has been negative in most cases, although it has been positive in an occasional case. A role for cell-mediated immune injury appears more likely based on in vitro studies of lymphocyte activation on exposure to rifampin.[103]

A direct nephrotoxic effect that is slower in onset has been reported with rifampin. A kidney biopsy in such cases reveals marked proximal tubular injury but very little interstitial infiltration.[100,101] Actually, the majority of lesions of rifampin-induced AKI are those of ATIN. Occasionally, glomerular lesions have also been reported. Certainly, the accompanying systemic manifestations—eosinophilia, recurrence on challenge, the reported humoral studies, as well as the morphologic features seen on kidney biopsy—are strongly supportive of ATIN due to an allergic hypersensitivity reaction to the drug as the most common lesion of rifampin-induced AKI. The severity of AKI due to ATIN is variable. Dialysis may be required in some patients in whom prolonged oliguria develops. The course of renal injury usually is favorable, with the return of kidney function to normal in most cases after the withdrawal of rifampin, although a residual impairment of renal function may occur in some. The role of steroids in accelerating recovery from rifampin-induced ATIN is undetermined. The lesion has occurred in a patient who was receiving steroids for other reasons.[1]

Penicillin and Congeners

Acute tubulointerstitial nephritis that is clinically and pathologically undifferentiable from that described with methicillin also occurs with penicillin and its congeners, but is much less common than with methicillin. The dose of penicillin used has been fairly large, 12 to 60 million U per day, although ATIN has been reported at lower doses and even after a single dose.[104]

Other penicillin derivatives that have been associated with the lesions of ATIN are, in descending order of frequency, ampicillin, oxacillin, carbenicillin, nafcillin, and oxacillin and amoxicillin.[102,105]

Cephalosporins

Acute tubulointerstitial nephritis also has been noted with the cephalosporins. It is more common with cephalothin, followed in descending order of frequency by cephalexin, cephradine, cefoxitin, cefazolin, cefaclor, cefotaxime, cefotetan, cefoperazone, cephaloridine, cefamandole, ceftriaxone, and cephapirin.[8,106–109]

Linezolid

Linezolid is the first member of the oxazolidinone class and is a generally well-tolerated oral agent active against most methicillin-resistant gram-positive bacteria. It has been linked with an increasing number of hypersensitivity reactions, including ATIN. In reported cases, ATIN developed within 2 weeks of initiating the drug, often with systemic manifestations (rash, fever, eosinophilia, arthralgias), and with renal function recovery with corticosteroids.[110] Most linezolid-associated systemic hypersensitivity adverse effects correlate with the duration of treatment.[111]

Sulfonamides

The introduction of sulfonamides in the 1930s heralded a new and welcome era in the specific treatment of infectious diseases. Despite their usefulness and general safety, severe adverse reactions were quite common with these agents and often necessitated cessation of their use. The introduction of antibiotics during the following decade led to a consistent decline in the use of sulfonamides until the introduction of trimethoprim–sulfamethoxazole (TMP/SMX),[112] when a resurgence of adverse reactions attributed to sulfonamides

was observed, necessitating modification of the warnings in the labeling of TMP/SMX. The advent of AIDS with the associated prophylactic use of TMP/SMX,[112] as well as its use in transplant recipients,[113] has led to the increased incidence of these side effects.[114,115]

The renal effects observed with the initially available, less soluble sulfonamides (sulfathiazole, sulfapyridine, sulfadiazine) were due to the precipitation of sulfa crystals in the renal tubules, with consequent hematuria, obstructive uropathy, and kidney injury. The renal lesions consisted of focal tubular necrosis, sometimes with sulfa crystals noted in the lumen, and with peritubular interstitial infiltration and edema in the affected segments.[116] The introduction of more soluble sulfonamides (sulfisoxazole, sulfamethoxazole, sulfamerazine, sulfasalazine) made this complication less common, but by no means eliminated it.[117,118] An idiosyncratic hypersensitivity reaction as a cause of the acute renal injury, which was recognized from the outset, now is the principal cause of the renal adverse effects of sulfonamides. The symptoms develop at a mean of 14 days after the initiating therapy. The onset of AKI is generally preceded by fever and skin rashes of varying severity. Eosinophilia is an accompanying finding in most cases. Unlike antibiotic-induced ATIN, there may be evidence of multiple organ involvement (heart, liver, lungs) in patients who have sulfonamide-induced ATIN. The kidney injury is reversible after the withdrawal of the drug and the institution of steroid therapy, although residual fibrosis and tubular atrophy with persistent impairment of renal function may occur.[117,118] The predisposition of patients to idiosyncratic reactions has been attributed to individual differences in the metabolism of sulfonamides. Those who develop idiosyncratic reactions are slow acetylators of sulfonamide, which leads to the accumulation of drug metabolites that can covalently bind to cell macromolecules and can cause cell injury, or can elicit a secondary immunologic phenomenon.[25] Acute kidney injury due to a hypersensitivity reaction also occurs with TMP/SMX. The increase in serum creatinine that occurs with this agent does not necessarily indicate renal injury because trimethoprim interferes with the tubular secretion of creatinine, with a consequent increase in the serum creatinine level, without necessarily affecting true glomerular filtration rate. The clinical and morphologic features of ATIN induced by TMP/SMX are identical to those induced by other sulfonamides and are due to the sulfamethoxazole content. Most of the reported cases of TMP/SMX-induced ATIN have been in patients with reduced kidney function or in transplant recipients. The propensity of patients with reduced kidney function to ATIN has been attributed to the accumulation of a toxic metabolite, which predisposes them to the adverse effects of the drug, much like that noted in the genetically predisposed slow acetylators. Crystalluria occurs with the use of high doses of TMP/SMX. In patients with severe renal insufficiency, this could cause further deterioration of kidney function without necessarily eliciting an allergic reaction.[1,114,115]

Other Antibiotics

The incidence of ATIN with other antibiotics is much less than that encountered with methicillin, penicillin congeners, and rifampin, except for ciprofloxacin, with which an increasing number of cases continue to be reported.[119–121] Isolated instances of ATIN have been reported with minocycline, doxycycline, gentamicin, polymyxin, vancomycin, lincomycin, mezlocillin, chloramphenicol, erythromycin, flurithromycin, netilmicin, norfloxacin, tetracycline, ethambutol, telithromycin, moxifloxacin, and levofloxacin.[1,8,9,121,122]

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs provide a relatively effective approach to the treatment of musculoskeletal pain and inflammation, which are among the most common complaints of an aging population. As a result, NSAIDs have become one of the most widely prescribed category of drugs. Recent reports of an increased relative risk for cardiac death associated with NSAIDs are bound to have a dampening effect on their widespread use.[123,124]

The most serious untoward effects of NSAID use have been noted in the gastrointestinal tract and the kidney. The renal effects include a reduction in GFR and renal blood flow, acute and chronic renal injury, and abnormalities of sodium and potassium homeostasis.[123,125] By far the most common of these side effects is the hemodynamically mediated, reversible AKI related to the prostaglandin-inhibitory action of these agents, which occurs principally in patients with congestive heart failure, cirrhosis of the liver, nephrotic syndrome, septicemia, and volume depletion from any cause. Less common has been the development of AKI due to tubulointerstitial nephritis, which, unlike other drug-induced ATINs, is frequently associated with massive proteinuria. A necrotizing vasculitis also has been reported in a few cases in association with fenoprofen, indomethacin, and diclofenac.[1,126]

The duration of exposure to NSAIDs before the onset of ATIN is variable, ranging from 2 weeks to 18 months; as a rule, ATIN develops after prolonged exposure (mean: 5.4 months) to the incriminated agent.[8,9,21] The propionic acid derivatives fenoprofen, ibuprofen, and naproxen account for approximately three-fourths of the cases reported.[124,126,127] Fenoprofen alone has been incriminated for over one-half of the reported cases. The lesions have been noted after the self-administration of over-the-counter ibuprofen, of mefenamate in drug mixtures, and to recur after exposure to different NSAIDs of the same group or on reexposure to the same agent.[128] Other NSAIDs that have been incriminated include, in decreasing order of frequency, tolmetin, zomepirac, indomethacin, diclofenac, and diflunisal.[1,8] Isolated cases have been reported with the use of phenylbutazone, mefenamate, phenazone, sulindac, noramidopyrine, flurbiprofen, and piroxicam.[8] Contrary to initial expectations, they also occur with the selective cyclooxygenase-2–inhibitory agents such as celecoxib, rofecoxib, and nimesulide.[9,21]

The proteinuria and clinical manifestations of the nephrotic syndrome usually are of insidious onset and precede the

onset of azotemia. Nephrotic syndrome, without renal insufficiency, may be the only manifestation in approximately 10% of cases. On the other hand, kidney injury without nephrotic syndrome occurs in approximately 15% of cases.[8,9,11,126] The variation in clinical presentation has been attributed to the severity of the allergic hypersensitivity reaction, with a more rapid course presenting with reduced kidney function and nephrotic syndrome in hyperreactors.[127] The clinical features of hypersensitivity reaction (fever, rash, eosinophilia) occur in less than 20% of cases, compared with an incidence of over 80% in patients with methicillin-induced ATIN. The serum complement and IgE levels usually are normal, and anti-TBM antibodies are absent. Most of the patients reported have been older than 60 years of age, which is more a reflection of the greater use of NSAIDs in this age group than of age as a predisposing factor.[124] In the diagnosis of proteinuria due to NSAIDs, it should be kept in mind that tolmetin can produce pseudoproteinuria, due to the effect of its dicarboxylic metabolite on the detection of proteinuria by the acid precipitation (sulfosalicylic acid and trichloroacetic acid) methods. In such cases, no proteinuria is detected with dye-impregnated reagent strips, electrophoresis, or nephelometry.[1]

A histologic examination of the kidney reveals the characteristic changes of ATIN. In some cases, the proportion of infiltrating B lymphocytes and CD8+ cells has been more than that noted in other forms of ATIN. Eosinophils have been observed in one-third of the cases reported and may constitute up to 20% of the infiltrating cells, even when eosinophiluria is absent. The glomeruli are minimally altered, if at all, except for the effacement of the podocyte foot processes consistent with minimal-change disease. Mesangial electron-dense deposits have been noted in rare instances in association with modest membranous and subendothelial deposits. Membranous glomerulonephritis, reversible after drug withdrawal, has been reported with sulindac and other NSAIDs. Immunofluorescent microscopy is negative, although a slight, nonspecific focal immunofluorescence of the glomeruli and TBM occasionally has been noted. Granulomatous reactions occur in severe cases.[8,9,21,127]

The kidney injury, although insidious in onset, can be severe enough on clinical presentation to require supportive dialytic therapy in approximately a third of the patients. The severity of the kidney injury may stem from the additive effects of ATIN, reduced renal blood flow due to the inhibition of prostaglandin, altered glomerular permeability, and an absence of systemic effects, the latter of which leads to delayed diagnosis early in the course of the disease process until patients finally present with nephrotic syndrome and AKI. The response to discontinuation of the offending NSAIDs has been favorable in most cases, with improvement of kidney failure occurring within a few days, but with a slower subsidence of proteinuria over weeks or months. Cases of persistent kidney injury have been reported. Progression of the kidney lesion to focal glomerular sclerosis has been noted on repeat kidney biopsies in some patients.[1,127] Steroids have been used in the treatment of severe cases. The response to steroid therapy, if any, appears to be slow, and the value of corticosteroids in this entity remains questionable.[1,8]

The pathogenesis of NSAID-associated ATIN remains undetermined. The rarity of the lesion despite the widespread use of these agents (estimated at 1 in 5,300 patient-years of treatment with fenoprofen) supports an idiosyncratic reaction.[124]

Protease Inhibitors

Since 1995, nine protease inhibitors have been approved for the treatment of HIV infection: saquinavir, ritonavir, tindinavir, nelfinavir, lopinavir, atazanavir, fosamprenavir, tipranavir, and darunavir. ATIN has been reported with two of these agents: indinavir and atazanavir. The former is primarily known for its association with crystal nephropathy. It is possible that the crystalluria (even if asymptomatic) triggers an inflammatory response significant enough to cause ATIN.[88]

Atazanivir is a newer protease inhibitor, which has been linked to some 10 cases of ATIN since its approval in 2004.[129] In one biopsy series of 22 HIV positive patients on antiretroviral therapy, 3 of the 4 cases of ATIN were associated with use of atazanavir. All 3 cases resolved after the discontinuation of this agent without the use of steroids.[130]

Phenindione

An increasing number of hypersensitivity reactions were noted with the anticoagulant phenindione after its introduction in 1947. The more common reactions were skin rash, fever, diarrhea, blood dyscrasias, stomatitis, and hepatitis, in descending order of frequency. The reactions appeared after 3 to 5 weeks of therapy and continued to progress even after discontinuation of the drug, proving fatal in one-half of the cases. AKI caused by ATIN, which was granulomatous in some cases, also was reported in approximately 30 cases, usually coincident with the development of jaundice and hepatotoxicity. ATIN was accompanied by the classic triad of skin rash, fever, and eosinophilia, usually with a prolonged period of oliguria and death in one-third of the cases reported, chronic kidney disease in some, and massive proteinuria in others.[8,9]

Because of the high incidence (10%) of these adverse side effects and their severity, this agent was prescribed much less over the years, leading to the cessation of its manufacture in 1983 for economic reasons. It is, however, still available in some countries and as an investigational drug in the United States. Phenindione is an inanedione derivative, or a vitamin K antagonist. Newer agents from this class (fluindione, anisoindione, diphenadione) remain in use and have been linked with ATIN.[131]

Allopurinol

Severe hypersensitivity reactions to allopurinol have been reported since its introduction in 1963. They have the features of a diffuse vasculitis involving multiple organs.[132] The symptoms appear approximately 4 weeks after the initiation

of therapy and consist of fever, rather severe generalized skin rashes that may be desquamative, eosinophilia, hepatic failure, and prolonged oliguric kidney injury.[1,132]

The structural changes in the kidney are characteristic of ATIN, including those of a granulomatous reaction in severe cases. Although renal lesions have been reported in patients with normal kidney function, most cases have occurred in either patients with preexisting kidney disease or in those receiving other drugs that might themselves cause ATIN. The decreased excretion of a toxic metabolite of the drug, possibly oxypurinol, has been implicated as the inciting agent in those with reduced kidney function. A predisposing role of thiazides, furosemide, and ampicillin has been implicated in those who have experienced a reaction while receiving other drugs.[1,21,132]

H_2-Antagonists and Proton Pump Inhibitors

H_2-Antagonists, including cimetidine and ranitidine, have been used to treat acid-related gastrointestinal disorders since 1976. Proton pump inhibitors (PPIs) are also used to treat acid reflux and have been in use since 1989; this class of drug is now more widely used because of its demonstrated superiority. Both classes are associated with drug-induced ATIN.[8,21]

The renal lesions reported with cimetidine are patchy, with focal areas of tubule cell injury and interstitial inflammatory infiltrates consisting of lymphocytes and a few eosinophils.[133] In one carefully studied case report, the presence of infiltrating IgE-producing plasma cells strongly implicates cimetidine in a cell-mediated immune reaction.[134] ATIN has also been reported with other H_2-antagonists such as ranitidine.[41,133,135,136]

Omeprazole was the first PPI to be introduced, and now six different PPIs are available. ATIN has been reported with five of them: lansoprazole,[137] omeprazole,[48,138–140] rabeprazole,[141] esmoprazole,[142] and pantoprazole.[143] The first case of PPI-induced AIN was described in 1992, and now over 100 cases have been ascribed to this class of drugs.[9,21] Fewer than 10% of PPI-induced ATIN present with the classic symptoms of the hypersensitivity syndrome (fever, rash, eosinophilia); most patients report nonspecific complaints such as weakness, fatigue, malaise, and anorexia.[122,141,142] Eosinophils are identified in up to 83% of the renal biopsy samples.[21,141] In one series of 18 biopsy-proven cases of PPI-induced ATIN, reduced kidney function remained present at 6 months.[144]

Phenytoin

One of the adverse side effects associated with the anticonvulsant phenytoin, formerly known as diphenylhydantoin, is a delayed hypersensitivity reaction characterized by a systemic reaction and ATIN. The systemic manifestations include fever, hepatitis, myositis, lymphadenopathy, skin rashes that may be exfoliative, eosinophilia, and anemia. Nephrotic syndrome has been observed in some patients. The lesions are reversible on withdrawal of the drug; steroid treatment has been successfully used in most reported cases.[145,146] Circulating antibodies to human TBM were detected, and linear deposits of anti-TBM antibodies demonstrated along the renal TBM in two cases.[147]

Diuretics

An acute reduction in kidney function often is associated with the use of diuretics. The renal insufficiency that results usually is prerenal in origin and is a result of the compensatory mechanisms mediated by extracellular fluid volume depletion induced by the diuretics. Less commonly, the deterioration of kidney function is the result of other mechanisms, including direct renal toxicity, such as with mercurial diuretics; obstruction, such as with triamterene nephrolithiasis; necrotizing vasculitis, such as with thiazides; and occasionally, ATIN that has been noted to occur with furosemide, thiazides, triamterene, chlorthalidone, ethacrynic acid, tienilic acid, and indapamide.[8,148] Most of the reported cases have been associated with the use of thiazides and furosemide, both of which are structurally related to sulfonamides, another group of drugs associated with ATIN. A potentiating role of triamterene used in conjunction with thiazides or furosemide has been suggested.[149]

Several of the patients with diuretic-induced ATIN had preexisting kidney disease, although the lesions also are noted in patients with normal kidney function. The deterioration of kidney function usually is insidious in onset but may be rapid and lead to oliguric AKI. Systemic symptoms of drug-related hypersensitivity reaction (fever, skin rash, and eosinophilia) were present in almost all the patients reported. The kidney biopsy findings were those of classic ATIN, with a granulomatous reaction in an occasional case. Abatement of symptoms and a return of kidney function to baseline have occurred in all patients reported after the removal of the incriminated diuretic and the administration of steroids to some patients.[1,8,148]

Given the frequency with which diuretics are prescribed, the fact that less than 20 cases of ATIN have been reported with their use reflects the relative rarity of diuretic-induced ATIN.

Alternative Medicines

Alternative or traditional medicines are used by a growing number of patients for preventive and palliative care. Due to a lack of professional surveillance, specific data on systemic and kidney toxicity are not easily available. Furthermore, the use of alternative medications is not always disclosed to the physician. The alternative medicines reported to cause ATIN include: cape aloes, uno degatta, taxus celebrica, Tung shueh, ephedra, glycyrrhiza, hypericum, and ledum. Most associations are via case reports or case series with fewer than 10 patients. It is possible that the cause of AKI is adulteration of these drugs with known nephrotoxins, such as NSAIDs or aristolochic acid. Use of alternative medications is more common in East Asia or Africa where it is said to be a more common and underreported cause of end-stage renal disease (ESRD).[150]

Antineoplastic Agents

Antineoplastic agents represent one of the fastest growing pharmaceutical markets. Most agents are linked to isolated tubular injury or a reduction in the glomerular filtration rate. For example, interstitial nephritis is absent in most cases of the archetypal nephrotoxin in this class, cisplatin.[151] Yet, as novel agents receive approval, their association with AKI and ATIN will continue to grow.[152]

In gemcitabine-induced nephritis, crystal deposits within the tubular lumen and subsequent crystal-induced epithelial damage likely instigates ATIN.[153] In a patient receiving lenalidomide for multiple myeloma, the diagnosis was suspected when ATIN recurred on rechallenge, prompting a change in chemotherapy.[154] The tyrosine kinase inhibitors (sunitinib and sorafenib) are generally well tolerated, but hypersensitivity reactions, including ATIN, have been reported with them.[155]

Other Drugs

The list of other drugs associated with ATIN continues to expand. Most of these have been isolated, single case reports of patients who often were using more than one drug. By far the most common among these to be associated with ATIN are the analgesics glafenin, and its derivatives, antrafenin and floctafenin.[8,21] Although direct drug toxicity with lesions of ATN has been incriminated as the cause of AKI in some of these patients, clinical and laboratory evidence of an immunologically mediated hypersensitivity reaction causing ATIN has been sufficiently well documented to justify incriminating these agents as a cause of ATIN.[8,10]

Other drugs that have been implicated are sulfinpyrazone, aminopyrine, azathioprine, quinine, clofibrate, propylthiouracil, carbamazepine, amidopyrine, amphetamine, phenobarbital, p-aminosalicylic acid, captopril, diltiazem, methyldopa, acyclovir, interferon, indinavir, griseofulvin, ifosfamide, intravenous immunoglobulin, phentermine, phendimetrazine, foscarnet, interleukin, rosiglitazone, etanercept, and even aspirin.[1,8,155–157]

Snake and Insect Bites

The kidney is prone to injury due to snake venom toxicity; however, the spectrum of renal involvement varies widely.[158] Snakebite-associated toxicities are classified as hemotoxic or myotoxic, with the incidence of postbite AKI ranging from 5% to 29%. Degeneration of the tubular epithelial cells has been observed with both types of snake venom.[158] There are several case reports linking the Russell's viper bite to ATIN, which is attributed to the metalloproteases present in the venom that bind to renal integrins and disrupt the cell matrix and cellular adhesion.[158] Apart from specific antivenoms, treatment is generally supportive and may include plasmapheresis or blood exchange.

Insect bites, particularly of the Hymenoptera order (bees, wasps, etc.) are linked with anaphylactoid and hypersensitivity reactions, including ATIN.[159,160] Wasp envenomation has been associated with ATN, ATIN, and pigment nephropathy.[161] In the reports of wasp bite–associated ATIN, eosinophiluria and eosinophilic infiltration of the renal parenchyma are common.

SYSTEMIC DISEASES

Although most cases of ATIN are due to a hypersensitivity reaction to drugs or infections, an acute deterioration of kidney function with the structural changes of ATIN also occurs in a variety of systemic diseases. In these, the renal involvement is due either to the metabolic disturbances associated with the underlying disease, the immunologic basis of the primary disease process, or the infiltrative nature of the disease (Table 35.4).

Metabolic Disorders

The metabolic disorders in which ATIN develop are those due to abnormalities in the metabolism of urate, oxalate, calcium, potassium, and heavy metals.[1,162]

Uric Acid

The kidney, as the major organ responsible for uric acid excretion, becomes the principal target organ affected by disorders of urate metabolism. Renal involvement results from the precipitation of uric acid in the renal parenchyma and the urine outflow tract. Depending on the load of uric acid presented to the kidney and the duration of the exposure, the parenchymal lesions that develop are those of either an acute or a chronic urate nephropathy. In the acute form of urate nephropathy, the renal changes are those of an ATIN.[162] The most common condition in which this is encountered is in AKI associated with the tumor lysis syndrome and in massive soft tissue destruction such as rhabdomyolysis.[163]

Oxalate

The increased metabolic production or intestinal absorption of oxalate and its consequent excretion by the kidney almost invariably results in the precipitation of calcium oxalate in the urine outflow tract. Microcrystallization first occurs in the proximal tubule, where oxalate is secreted. However, the lesions that develop are more prominent in the medulla, where the urine is concentrated and acidified. This results in injury of the epithelial cells with interstitial edema and inflammatory cell infiltration around the injured tubular segments, which is characteristic of ATIN.[163,164]

When the hyperoxaluria is sudden and massive, such as after ethylene glycol ingestion, methoxyflurane anesthesia, or the ingestion of star fruit, the acute deterioration of kidney function occurs, the morphologic features of which are those of ATIN.[165,166] Otherwise, when the hyperoxaluria is modest and chronic, such as in inflammatory bowel disease, the onset of kidney injury is insidious and the lesions are those of chronic tubulointerstitial nephritis, although AKI associated with enteric hyperoxaluria can occur.[164,167,168]

Immune Diseases

Diseases due to an immune mechanism primarily affect the glomeruli, with secondary involvement of the tubules and the interstitium. Primary tubulointerstitial nephritis mediated by an underlying altered immune mechanism is extremely rare in humans. The two conditions in which an immune mechanism may result in AKI primarily due to tubulointerstitial lesions, with only limited glomerular involvement, are a transplanted kidney and systemic lupus erythematosus.[1,9]

The diagnosis of ATIN in kidney transplant recipients can be challenging.[169] Despite the numerous medications these patients receive, drug-induced ATIN is an uncommon cause of AKI in them. Drug-induced ATIN lesions can resemble acute cellular rejection morphologically, and both entities can show improvement after steroid therapy. Although infiltrating eosinophils can be seen in acute cellular rejection, their presence and localization at the corticomedullary junction and the presence of granulomatous lesions are suggestive of drug-induced ATIN, whereas that of tubulitis is a defining feature of an allograft rejection.[170,171] Clinically, the diagnosis is compounded by the fact that allograft recipients are prone to infection-induced ATIN, such as cytomegalic virus,[172] adenovirus,[173] and polyoma virus.[174]

In systemic lupus erythematosus, the glomerular lesions are the main renal complication. There are fewer than 20 cases reported demonstrating predominant tubulointerstitial lupus nephritis with only minimal glomerular abnormalities.[175]

AKI with prominent tubulointerstitial lesions may occur in other diseases due to altered immune mechanisms, but again, only rarely in the absence of glomerular lesions. These diseases are Sjögren syndrome, mixed cryoglobulinemia, anti-neutrophil cytoplasmic antibody–associated vasculitis, crescentic glomerulonephritis, sarcoidosis, IgA nephropathy, primary biliary cirrhosis, and autoimmune pancreatitis.[176–179] ATIN is also associated with inflammatory bowel disease that is unrelated to calcium oxalate deposition or 5-aminosalicylic acid use.[180,181]

Neoplastic Diseases

An acute deterioration of kidney function may occur in any neoplastic disease, either because of direct invasion of the kidney or the urinary tract by malignant cells or because of the metabolic disorders (hypercalcemia, hyperuricemia) that may be caused by the malignancy. The institution of antineoplastic therapy, which may itself be nephrotoxic or can magnify the existing tumor-related metabolic disorder (hyperuricemia), is another mechanism of the acute renal injury experienced by these patients.[182] Lymphoproliferative disorders and plasma cell dyscrasias are the two neoplastic diseases in which ATIN due to neoplastic cellular infiltrates is a principal cause of the AKI.[1,183]

Lymphoproliferative Disorders

The kidney is one of the most common extranodal sites of metastatic lymphomas, although a primary lymphoma in the kidneys without evidence of extrarenal lesions also can occur.[183,184] Infiltration of the kidney is more common in non-Hodgkin lymphomas and acute lymphoblastic leukemia than in Hodgkin disease.[183] Leukemic infiltration of the kidney has been noted in two-thirds of patients with leukemia, usually in those with the acute form of the disease.[1] In one large autopsy case series, lymphomatous infiltrates were present in 34% of cases but was diagnosed in only 14% before the time of death.[184,185] Renal infiltrates usually are bilateral and symmetrical and may go undetected unless extensive parenchymal infiltration occurs, in which case flank pain, palpable, tender kidneys, gross hematuria, and AKI are the presenting findings.[184,185] The infiltrates are localized to the interstitium and compress the tubules but sparing the glomeruli, thereby mimicking the classic morphologic features of an ATIN. Irradiation of the kidneys or systemic chemotherapy can result in a dramatic reversal of the structural and functional abnormalities.[185]

Plasma Cell Dyscrasias

The renal complications of plasma cell dyscrasias are a major cause of morbidity and mortality in patients with multiple myeloma. AKI occurs in approximately 10% of these patients, and chronic kidney disease is present in more than two-thirds of them.[1,186]

The pathogenesis of AKI is multifactorial.[186,187] The acute lesions directly related to multiple myeloma, the so-called myeloma cast nephropathy, are those that result from the excessive production of light chains and their precipitation as dimers in the distal tubules. As a result, varying degrees of injury, necrosis, and regeneration of the tubular epithelial cells occur, with interstitial edema and inflammatory cellular infiltration. Immunofluorescent study of the kidney tissue can provide the definitive diagnosis when fluorescence is positive for specific sera for either κ or λ light chains.[187]

IDIOPATHIC ACUTE TUBULOINTERSTITIAL NEPHRITIS

Since the entity of idiopathic ATIN was first recorded in the literature in 1972, an increasing number of cases of ATIN in the absence of exposure to drugs, infections, or any of the other conditions usually associated with ATIN have been reported.[8,9,21]

The only common feature of these cases has been the presence of reversible AKI and the finding of edema and a mononuclear inflammatory infiltration of the interstitium on a kidney biopsy. Although certain laboratory features of a hypersensitivity reaction (elevated IgE levels, eosinophilic infiltrate, and eosinophiluria) are present in some of the cases, the systemic manifestations of a hypersensitivity reaction (fever, arthralgia, rash) are characteristically absent. Linear deposits of IgG, C3, and anti-TBM antibodies have been detected on immunofluorescent studies of kidney biopsies in some cases and granular deposits of C3 and IgG were seen

in others, but no deposits were present in the majority.[188,189] A subtype of idiopathic ATIN with a prominent lymphoplasmacytic infiltration of IgG4-positive plasma cells has been reported; the presence of this infiltrate portends a better response to corticosteroids.[190]

The clinical presentation of most cases has been nonspecific, except for the acute deterioration of kidney function. The AKI has been severe enough in a third of reported cases to necessitate supportive dialytic therapy. The outcome has been favorable in most cases, with recovery occurring spontaneously or after the institution of steroid therapy. There also have been cases of irreversible kidney injury that have failed to respond to steroid therapy.[1,22] Clinically, the nonspecific presentation of idiopathic ATIN coupled with its favorable prognosis and response to steroids, at least in some cases, mandates that its possibility be considered in the differential diagnosis of every patient with AKI in whom the cause of the kidney dysfunction is uncertain.

Idiopathic ATIN constitutes more than 15% of cases of AKI that are sampled for a biopsy.[50] Systemic diseases, such as chronic active hepatitis or ulcerative colitis, have been present in the occasional case. Uveitis, on the other hand, has been a feature of several patients with idiopathic ATIN. This group constitutes a variant that deserves separate consideration.

Idiopathic Acute Tubulointerstitial Nephritis with Uveitis

An acute eosinophilic interstitial nephritis that occurred in association with an anterior uveitis of unknown cause was first described in 1975 in two patients who also had bone marrow and lymph node granulomas.[191] The syndrome of ATIN with uveitis has since been noted to occur rarely in other granulomatous conditions, but most reported cases have been in patients with no bone marrow granulomas.[192] In reported cases, tubulointerstitial nephritis and uveitis (TINU) is more common in adolescents with a 3:1 female to male predominance, although the lesion may also occur in adults and the elderly. Familial occurrence and an association with certain HLA serotypes have been suggested, with a strong association with the HLA-DQ and HLA-DR alleles.[193] Anorexia, asthenia, nocturnal fever, and weight loss may be present for several months before the onset of the ocular complaints. A moderate anemia is common, and hyperglobulinemia usually is present.[194] There also is evidence of tubular dysfunction, such as glucosuria, proteinuria, aminoaciduria, β_2-microglobulinuria, impaired urinary concentrating ability, and azotemia.[194] Uveitis may occur as a manifestation of a variety of systemic diseases but rarely in association with ATIN, except in sarcoidosis and Sjögren syndrome.[1] Hence, the occurrence of uveitis and ATIN is termed renal ocular syndrome or tubulointerstitial nephritis and uveitis (TINU) syndrome.[1,195]

More than 200 cases of TINU syndrome have been described worldwide, primarily in the ophthalmology and pediatric medical literature.[195] The cause remains undefined but has been presumed to be the result of an autoimmune process in genetically predisposed individuals or a reaction to an as yet undetermined viral infection. It has been described in individual cases of toxoplasmosis, tuberculosis, giardiasis, chlamydiosis, and Epstein-Barr virus infection.[195–197] The demonstration of circulating immune complexes in some cases has led to the suggestion of a role for an immune-mediated process. Urinary β_2-microglobulin and serum Krebs von den Lunge–6 (KL-6) protein have been reported as potential diagnostic markers.[195] The occurrence of hyperthyroidism with TINU syndrome suggests that thyroid function should be measured in all TINU patients.[198,199] Both the ocular and renal changes respond to a brief course of steroid treatment, but can relapse. Spontaneous remission without steroid treatment has been reported, primarily in children; hence, the reluctance to use steroids in this age group.[194–197] Uveitis may be asymptomatic, indicating the need for ophthalmologic examination in all cases of idiopathic ATIN.[200] Uveitis can precede the onset of ATIN or a relapse without any renal manifestations, in which instances it responds to topical steroid or cycloplegic treatment.[195] In children and adolescents, the long-term prognosis is good, with the recovery of kidney function and no documented visual loss. In adults, the prognosis is less favorable and kidney injury requiring dialysis may develop, particularly if steroid therapy is withheld.

CHAPTER

36 Acute Kidney Injury Associated with Pigmenturia or Crystal Deposits

Abolfazl Zarjou • Anupam Agarwal

ACUTE KIDNEY INJURY RESULTING FROM HEME PIGMENTS

Myoglobinuric Acute Kidney Injury

Rhabdomyolysis is a potentially life-threatening syndrome involving damage and the breakdown of skeletal muscle causing myoglobin and other intracellular proteins and electrolytes to be released into the circulation. This syndrome is a relatively common cause of acute kidney injury (AKI)* and accounts for 7% to 10% of AKI in the United States.[1] Perhaps the first historical suggestion of rhabdomyolysis goes back to biblical times where it is related that the Israelites became ill and died after eating large quantities of quail, which had probably fed on hemlock seeds. In modern times, the initial description of the consequences of traumatic muscle injury on kidney function is attributed to Bywaters and Beall,[2] who vividly documented the brown-black granular casts, a reduction in urinary output, hyperkalemia, and ultimately, death in the victims of crush injuries at the time of the London bombing during World War II. In addition, Bywaters et al.[3,4] were the first to establish a definite pathophysiologic relationship between crush injury, myoglobinuria, and acute tubular necrosis.

Causes of Rhabdomyolysis and Myoglobinuria

A variety of conditions and diseases can lead to rhabdomyolysis and AKI, and the list of causes is constantly being expanded with new case reports (Table 36.1). Although the list is long, it can be divided into eight basic categories: (1) direct muscle injury, (2) drugs and toxins, (3) genetic disorders, (4) infections, (5) excessive muscular activity, (6) ischemia, (7) electrolyte and endocrine/metabolic disturbances, and (8) immunologic diseases. The common denominator for all the causes is a disruption of normal skeletal muscle cell structure or metabolism leading to derangements in Ca^{2+} homeostasis. Adenosine triphosphate (ATP) depletion further interferes with Ca^{2+} sequestration, leading to lethal intracellular Ca^{2+} overload that activates a number of autolytic enzymes, causing myofibril and membrane damage.[5] The subsequent death and lysis of skeletal muscle cells results in the release of intracellular contents into the circulation. In the United States, the three most common causes of rhabdomyolysis are drug abuse (with a substantial percentage related to ethanol use), muscle compression, and seizures.[1]

Crush injuries[1,6,7] and prolonged compression of the limbs can lead to massive rhabdomyolysis and its sequelae, including AKI. Significant volume and electrolyte imbalance may ensue due to a massive influx of extracellular fluid and solutes into and efflux of major intracellular ions such as potassium and phosphate out of the damaged cells.[1,7]

Drugs and toxins have also been implicated in causing rhabdomyolysis.[8,9] Several mechanisms underlie drug- and toxin-induced rhabdomyolysis, including (1) drug-induced coma leading to compression of a limb; (2) excessive muscular activity (e.g., phencyclidine, LSD, hemlock); (3) drug-induced hyperthermia; (4) drug-induced vasoconstriction with muscle ischemia (e.g., cocaine); (5) impaired ATP formation (e.g., cyanide, salicylates); (6) the induction of potassium or phosphorus depletion (e.g., diuretics); (7) a hypersensitivity reaction resulting in myositis; (8) a direct toxic effect on skeletal muscle cells (e.g., ethanol); and (9) drugs whose mechanism of toxicity is still controversial (e.g., statins).[10,11] Although certain drugs, such as heroin[12] or ethanol,[13] may have a direct toxic effect on skeletal muscle cells, a more important factor in causing rhabdomyolysis is the occurrence of a coma after their use leading to muscle compression and ischemia. In addition, drug use may be associated with other conditions that predispose one to rhabdomyolysis. For example, in the alcoholic patient, concomitant hypokalemia,[14] hypophosphatemia,[15] and starvation[16] may contribute to rhabdomyolysis. The presence of multiple etiologic factors may be a common scenario, as noted in a large clinical series by Gabow et al.,[17] in which more than

*In recent years, the term acute kidney injury (AKI) has replaced acute renal failure (ARF), because AKI denotes the entire clinical spectrum from mild increases in serum creatinine to overt renal failure (Molitoris et al. J Am Soc Nephrol. 2007;18:1992–1994).

36.1 Causes of Rhabdomyolysis

- Traumatic muscle injury
  - Crush injuries
  - Compression/pressure necrosis
  - Severe burns
  - Contact sports
  - Direct muscle trauma
- Drugs and toxins (partial list)
  - Ethanol
  - Heroin
  - Barbiturates
  - Cocaine
  - Amphetamines
  - Benzodiazepines
  - Phencyclidine
  - HMG-CoA reductase inhibitors (statins)
  - Fibric acid derivatives (clofibrate, gemfibrozil)
  - Hemlock
  - Salicylates
  - Carbon monoxide
  - Ethylene glycol
  - Isopropyl alcohol
  - Snake and insect venoms
  - Succinylcholine
  - Colchicine
  - Propofol
  - Paraphenylenediamine
  - Colchicum autumnale (autumn crocus)
  - Monensin
- Genetic disorders
  - Phosphorylase deficiency (McArdle disease)
  - Phosphofructokinase deficiency
  - α-Glucosidase deficiency
  - Carnitine palmityltransferase deficiency
  - Amylo-1,6-glucosidase deficiency
  - Phosphohexoseisomerase deficiency
- Infections (partial list)
  - Influenza
  - Tetanus
  - Gas gangrene
  - Legionnaires' disease
  - Shigellosis and salmonellosis
  - Coxsackievirus
  - Leptospirosis
  - Streptococcus
  - HIV
- Excessive muscular activity
  - Vigorous exercise
  - Seizures/status epilepticus
  - Delirium tremens
  - Status asthmaticus
  - Psychotic muscle contractions
  - Tetany
- Ischemia
  - Arterial occlusion
  - Compression
- Electrolyte and endocrine/metabolic disorders
  - Hypokalemia
  - Hypophosphatemia
  - Hypothyroidism
  - Diabetic ketoacidosis
  - Diabetic hyperosmolar nonketotic coma
  - Hypothermia and hyperthermia
- Immunologic disease
  - Polymyositis
  - Dermatomyositis

HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A.

one factor capable of injuring muscles was present in 51 of 87 episodes of rhabdomyolysis. One such etiologic factor demonstrating the variable causes of rhabdomyolysis is fire ant bites. In a recent case report, a patient was described who developed AKI because of rhabdomyolysis after extensive red fire ant bites.[18] It was suggested that formic acid, an important constituent of fire ant venom, was the underlying mechanism for rhabdomyolysis. In small doses, formic acid is an antibiotic, but in larger doses it acts as an inhibitor of the mitochondrial cytochrome oxidase complex causing tissue suffocation and, consequently, cell death.[18]

Various hereditary enzyme deficiencies and defects have been associated with rhabdomyolysis and myoglobinuria. These are divided into groups of patients with hereditary deficiency of enzyme(s) in (1) glycolytic/glycogenolytic pathways; (2) the fatty acid oxidation pathway; (3) the Krebs cycle; (4) the pentose phosphate pathway; (5) the purine nucleotide cycle; (6) the mitochondrial respiratory chain; (7) patients prone to malignant hyperthermia; and (8) other miscellaneous causes such as sarcoplasmic Ca^{2+}-ATPase deficiency.[19]

The myositis occasionally associated with infectious diseases such as influenza, HIV, and leptospirosis can lead to a

disruption of skeletal muscle cells and thus rhabdomyolysis and myoglobinuria.[19,20] In addition, infections like gas gangrene produce a clostridial toxin that is directly myotoxic.[20]

Excessive muscular activity has been increasingly recognized as a common and preventable cause of rhabdomyolysis.[21,22] Strenuous and exhaustive exercise, especially in deconditioned men (so-called "white collar" rhabdomyolysis), can result in serious rhabdomyolysis.[23] Contributing factors to this syndrome include exercising in a hot or humid environment, volume depletion, fasting, eccentric muscle contractions (e.g., running downhill), preexistent muscle injury (e.g., alcoholic myopathy), and male sex.[23] Intense muscle contractions deplete energy reserves, thus disrupting normal cellular transport processes and permitting calcium to accumulate in the cell, resulting in the activation of proteolytic enzymes and cell death. Based on a number of studies,[23] physical training raises the threshold and induces a degree of resistance to the development of exertional rhabdomyolysis. Training may induce this adaptation by increasing the number of collateral blood vessels, hence improving oxygen delivery, fuel storage, and use. Other conditions associated with excessive muscle contractions and significant rhabdomyolysis include seizures, tetanus, delirium tremens, electrical shock injury, and extensive burns.

Severe potassium deficiency can lead to rhabdomyolysis, myoglobinuria, and AKI. Hypophosphatemia, especially in the setting of severe alcoholism, has been associated with muscle cell injury and rhabdomyolysis.[15] Other metabolic conditions that have been reported to cause rhabdomyolysis include hyperaldosteronism, ketoacidosis, hypothyroidism, and deranged core body temperature.[19]

Myoglobin Metabolism

Myoglobin is composed of a folded polypeptide portion (globin) and a prosthetic group, heme, which contains an atom of iron.[24,25] Based on tracer studies, the half-life of myoglobin in the circulation varies from 1 to 3 hours; after 6 hours, it disappears completely.[24,25] Small quantities of myoglobin (milligram amounts) released during normal conditions are probably cleared by the reticuloendothelial system. Because of its relatively small molecular weight and size, larger quantities of myoglobin released from the muscle in states of injury or disease are readily filtered at the glomerulus and thus can be cleared by renal mechanisms.

In human circulation, myoglobin appears to be bound to an α_2-globulin that has a binding capacity of 23 mg per deciliter. Because myoglobin is loosely bound to α_2-globulin at concentrations below 23 mg per deciliter, approximately 15% to 50% of the myoglobin is in an unbound state and is filtered (fractional clearance relative to inulin, 0.75) and excreted in the urine. This interesting kinetic relationship between myoglobin and its binding protein probably explains why myoglobin is detected in the urine when plasma levels are less than 23 mg per deciliter.[24,25] According to Kagen,[26] the effective renal threshold for myoglobin occurs when the plasma concentration exceeds 0.5 to 1.5 mg per deciliter. Based on a distribution volume of myoglobin of 28.5 L and a muscle myoglobin content of 4 mg per gram, Knochel[27] has calculated that injury of approximately 102 g of muscle would be required to exceed a renal threshold of 1.5 mg per deciliter. Beyond this threshold, the factors that determine the urinary concentration and the excretion rate of myoglobin include (1) the plasma concentration of myoglobin, (2) the extent of myoglobin binding in plasma, (3) glomerular filtration rate (GFR), and (4) urine flow rate.

Myoglobin is visible in plasma or urine to the unaided eye when the concentration exceeds 100 mg per deciliter. Because of the relatively rapid renal clearance of myoglobin, visible plasma levels of myoglobin have never been reported. Knochel[27] has estimated that a visible plasma level of myoglobin would require the destruction of 7.1 kg of muscle in an anephric patient. In contrast, because myoglobin is cleared rapidly in patients with a normal renal function, visible myoglobinuria is achieved with far less muscle necrosis. For example, necrosis of only 178 g of muscle, achieving a plasma myoglobin level of only 2.5 mg per deciliter, is sufficient to produce visible myoglobinuria in a patient with normal renal function excreting concentrated urine.[27] However, reduced renal function or a high urine flow rate decreases the concentration of myoglobin in urine, thus diminishing the use of a visual inspection of the urine to detect myoglobinuria for a given amount of muscle necrosis. In these situations, benzidine, guaiac, or orthotoluidine (dipstick) tests detect levels as low as 0.5 mg per 100 mL. These tests, however, do not distinguish between myoglobin and hemoglobin. This can be accomplished by immunodiffusion.[28] Multiple alternative methods of detection are now available, including hemagglutination inhibition, radioimmunoassay, and complement fixation.[19]

Given the rapid renal clearance of myoglobin (1 to 6 hours), its presence in the blood or urine may not be the most sensitive method to detect rhabdomyolysis. In contrast, creatine kinase, an intracellular muscle enzyme, appears to be a more sensitive plasma marker for rhabdomyolysis because of its slower clearance (serum half-life, 1.5 days), and therefore is the preferred diagnostic modality.[29]

Pathophysiology of Myoglobinuric and Hemoglobinuric Acute Kidney Injury

Given the biochemical similarity between myoglobin and hemoglobin, the general consensus that they share a common pathogenetic pathway, and the fact that the classical animal models used to study pigment-induced oliguric AKI share intravascular hemolysis (hemoglobinuria) and rhabdomyolysis (myoglobinuria), the pathogenesis of these two pigments are presented together in this discussion.

The proposed mechanisms by which myoglobinuria or hemoglobinuria cause AKI include (1) hypovolemia and renal ischemia, (2) direct tubular toxicity of myoglobin/hemoglobin, (3) tubular obstruction from heme pigment casts, and (4) glomerular fibrin deposition. As in many clinical syndromes, it is probably the interplay of these proposed

FIGURE 36.1 The pathophysiologic processes involved in myoglobinuric and hemoglobinuric acute kidney injury. (Modified from Zager RA. Rhabdomyolysis and myohemoglobinuric acute renal failure. *Kidney Int*. 1996;49:317, with permission.)

mechanisms that results in AKI rather than any one single factor. These interactions are schematized in Figure 36.1.

Hypovolemia and Renal Ischemia

During the initial phase of glycerol-induced AKI (an animal model for rhabdomyolysis), there is a marked reduction in cardiac output (36%), renal blood flow (RBF) (20%), and an increase in renal vascular resistance.[30] Subcutaneous or intramuscular (but not intravenous) glycerol not only produces muscle injury but also causes sequestration of fluid into the injection site.[31] Thus, the hemodynamic changes are due, in part, to the migration of plasma water into the site of injury with consequent severe intravascular volume contraction occurring in this model of myohemoglobinuric AKI. Comparable hemodynamic changes occur in clinical settings that damage and cause necrosis of the skeletal muscle such as crush syndrome.[7] Moreover, the conditions that predispose one to rhabdomyolysis, such as drug-induced coma with accompanying poor oral intake, or excessive insensible fluid losses from exhaustive exercise or burns, contribute to intravascular volume depletion and compromise of renal function.

In the initial phases of glycerol-induced AKI, the reduction in RBF is associated with a redistribution of regional blood flow from the outer to the inner cortex[32] and vasoconstriction of the afferent and efferent arteriole. The proposed mediators of this initial renal vasoconstriction include (1) increased sympathetic nerve activity, (2) augmented activity of the renin–angiotensin system, (3) reduced nitric oxide production and availability, (4) suppressed renal prostaglandin production, (5) increased plasma vasopressin concentration, and (6) glomerular microthrombi.[33] The reduction in nitric oxide may be due to the fact that heme proteins can scavenge this important endogenous vasodilator. Nitric oxide synthase inhibition worsens and nitric oxide supplementation protects against glycerol-induced AKI. This lends support to the protective effects of nitric oxide in the pathogenesis of myoglobin-induced AKI.[34]

The critical role that intravascular volume depletion plays in the pathogenesis of myohemoglobinuric AKI is demonstrated by studies in which volume status is manipulated in the glycerol-treated rat. In initial studies, Oken et al.[35,36] noted that renal damage was ameliorated if the rats ingested adequate quantities of water before the administration of glycerol. Similarly, Hsu et al.[30] found that the reduction in RBF and function in response to the administration of glycerol was attenuated in rats chronically drinking saline compared with rats drinking water. Reineck et al.[37] provided a better understanding of the important temporal relationship

between volume expansion and improvement of renal function in the glycerol-treated rat. Like other investigators, they noted a significant reduction in RBF and GFR after the administration of glycerol. These variables could be restored to normal levels by volume expansion with Ringer's solution at 3 and 6 hours, but not at 18 hours after the administration of glycerol. They concluded that the initial decrease in GFR and the low fractional excretion of sodium was due to a decrease in RBF (renal hypoperfusion), whereas other events (e.g., tubular necrosis) accounted for decreased GFR at later time points. These preclinical studies support the clinical observation that, initially, patients with myoglobinuric AKI have features of prerenal azotemia, including a low urinary fractional excretion of sodium.[38] In addition, they provide the rationale for early use of volume expansion in patients with rhabdomyolysis and hemoglobinuria.

Myoglobin and Hemoglobin Nephrotoxicity. Bywaters and coworkers[2,3] expanded on their original description of the clinical syndrome of rhabdomyolysis-induced AKI to examine the role of myoglobin as a direct nephrotoxin. They noted that rabbits ingesting an acid diet with a urine pH below 6.0 had AKI after the infusion of human myoglobin, whereas rabbits ingesting a normal diet were spared from renal injury.[3] Other investigators[39,40] have confirmed this observation that intravenous infusions of myoglobin are relatively benign but can become highly nephrotoxic in the setting of acidemia/aciduria and volume depletion. Vetterlein et al.[41] demonstrated that infusions of myoglobin had no effect on RBF in normal rats, but worsened RBF in hypotensive animals. Thus, it appears that heme proteins can intensify the degree of vasoconstriction in the setting of hypovolemia. This may explain the clinical observation that the mere presence of myoglobinuria or a markedly elevated creatine kinase at the time of hospital admission had little predictive value in determining who experiences AKI.[17] These observations suggest that other conditions (i.e., volume depletion, acidemia) are required for renal injury to occur.

To address the question of why heme pigments are nephrotoxic only in certain metabolic conditions, Braun et al.[31] investigated the effect of breakdown products of heme pigments on renal tubular transport. First, they noted that 4 hours after a subcutaneous glycerol administration to rats there was both swelling and pallor of the proximal tubule and depression of normal tubular uptake of hippurate and tetraethylammonium. The investigators measured the uptake of hippurate in renal cortical slices incubated with various specific heme proteins or their derivatives and found that incubation with hemoglobin did not depress uptake if the pH of the medium was kept at 7.4. However, uptake was depressed when the pH was lowered to 5.4 or during hypoxic conditions. In an acidic medium (pH $<$5.6), both myoglobin and hemoglobin dissociate into ferrihemate (hematin; molecular weight, 670 Da) and their respective globin moieties.[42] Incubation with ferrihemate, regardless of the pH of the medium, depressed the uptake of hippurate in the renal cortical slices, whereas incubation with either globin or albumin alone had no significant effect on transport. The inhibitory action of ferrihemate on hippurate transport could be mitigated if the incubation medium also contained albumin, which presumably bound the ferrihemate. Intravenous injection of ferrihemate has been shown to cause glomerular and tubular damage in the dog.[43] Therefore, it has been proposed that after filtration by the glomerulus, myoglobin or hemoglobin is converted to ferrihemate in the presence of an acid tubular fluid, or after exposure to the acid pH of cellular lysosomes, and it is this metabolite that is directly nephrotoxic.

These and other studies implicate the heme moiety as a potent pro-oxidant molecule.[44,45] It is well established that free heme can facilitate the production of reactive oxygen species via Fenton/Haber-Weiss reactions. Under physiologic conditions, free heme is sequestered by heme binding proteins, and oxidative stress can cause the release of heme, thereby increasing free heme levels. In addition, evidence suggests that the iron component of heme is the culprit of heme-induced oxidative damage.[44,45] The central role of iron has been substantiated by a number of studies demonstrating amelioration of both myoglobinuric and hemoglobinuric AKI and lipid peroxidation by the iron chelator, deferoxamine.[46] On the other hand, Zager[47] has also shown that deferoxamine attenuates renal damage in the glycerol-induced model of AKI, but concluded that iron toxicity is mediated by factors other than free radical generation. For example, it has been suggested that heme protein endocytosis in the proximal tubule sensitizes the tubular cell membranes to the damaging effects of phospholipase A_2.[48] In addition, heme proteins appear to deplete cellular ATP stores and, thus, have an adverse effect on cellular energetics.[5] Iron toxicity may be due to redox cycling of the heme moiety from ferrous to ferric and to ferryl oxidation states.[49]

In order to contend with the pro-oxidant heme moiety, the kidney induces antioxidant defensive machinery, including heme oxygenase-1 (HO-1).[44,45] HO-1 catalyzes the rate-limiting step in the oxidative degradation of heme liberating equimolar amounts of iron, carbon monoxide, and biliverdin. Iron in turn induces the expression of ferritin. HO-1 is known to have important antioxidant, anti-inflammatory, and antiapoptotic functions that have been attributed to one or more of its byproducts.[44,45] Nath et al.[50] have demonstrated that the renal induction of both HO-1 and ferritin is increased in the glycerol-induced model of myohemoglobinuric AKI. Prior induction of HO-1 coupled with increased ferritin synthesis attenuated renal damage, whereas pharmacologic inhibition of the enzyme or its gene deletion worsened renal function.[50,51] This increased activity of HO-1, or possibly a broad-based proximal tubular cytoresistance in the kidney, may explain the experimental observation that after induction of myohemoglobinuric AKI rechallenging the animals with a second dose of glycerol does not result in AKI.[52] One speculation is that in the setting of clinical myoglobin-induced AKI, there may be factors contributing to the inhibition of HO-1 and ferritin synthesis, or a

diminution in proximal tubular resistance, resulting in both an accumulation of nephrotoxic iron and in tubular necrosis.

Tubular Obstruction. Filling of the tubular lumen by pigmented casts that become inspissated and obstruct urinary flow with subsequent injury to tubular epithelium is one of the earliest mechanisms proposed to explain the nephrotoxicity of the heme pigments.[53] In their original clinical description of rhabdomyolysis-induced AKI, Bywaters and Beall[2] described the prominent histologic features, including the appearance of tubular obstruction by cellular debris and pigmented casts. It has been suggested that hypovolemia and academia, and the concomitant acidic concentrated urine, facilitate the precipitation of filtered myoglobin or hemoglobin leading to obstructive cast formation.[54] The presence of the Tamm-Horsfall protein in the tubular lumen is critical for heme protein cast formation in the distal nephron. Moreover, an obstructing cast induces urinary stasis, providing for an extended time for proximal tubular heme reabsorption and its attendant tubular toxicity, as noted previously.[55]

Tubular obstruction can decrease GFR either by increasing the tubular pressure and thus decreasing the glomerular transcapillary hydraulic pressure, or by inducing the release of factors (e.g., thromboxane) that cause renal vasoconstriction, thereby reducing glomerular blood flow. The importance of tubular obstruction as a possible mechanism of heme pigment–induced AKI is suggested by the studies of Zager[47] that explored the reasons why mannitol exerts a protective effect against this syndrome. The major beneficial effect of mannitol was attributed to its diuretic effect, which presumably decreased cast formation and proximal tubular uptake of heme proteins. Similarly, alkalinization of the urine may mitigate against myoglobinuric AKI by increasing the solubility of myoglobin (reduced cast formation) and inducing a solute diuresis.[54]

Although there is evidence that tubular obstruction may be a factor in the pathogenesis of the AKI, it probably is not the primary cause of the initial decrease in GFR in myoglobinuric AKI. Rather than high intratubular pressures from obstructing casts, intratubular pressures were found to be low in the glycerol-induced model of AKI.[35] This observation was interpreted to indicate that the presence of casts is the result, rather than the cause, of the decrease in GFR and urine flow. Instead of causing the initial decrease in renal function, cast formation may play a role in the maintenance of the renal failure once it develops.[56]

Glomerular Fibrin Deposition. Because of the liberation of tissue factors, both rhabdomyolysis and intravascular hemolysis can initiate disseminated intravascular coagulation (DIC).[19] Fibrin strands have been demonstrated in glomeruli from patients[57] and experimental animals[58] with rhabdomyolysis-induced AKI. Intravenous infusion of a muscle extract in rabbits resulted in DIC, renal dysfunction, and glomerular microthrombi, whereas an intravenous infusion of pure myoglobin had no untoward effect.[59] This led to the conclusion that myoglobin, per se, is not the primary cause of the coagulation cascade activation in the crush syndrome, but rather it is the release of other muscle constituents that induces DIC and the subsequent deposition of glomerular microthrombi that are responsible for rhabdomyolysis-induced AKI.

Clinical and Laboratory Features of Rhabdomyolysis and AKI

The diagnosis of myoglobinuria can be suspected from a history and physical examination. However, the clinical features of rhabdomyolysis are nonspecific and the course of the syndrome is quite variable depending on the underlying cause and the general condition of the patient. The syndrome has local as well as systemic features and early or late complications may occur. Because the prompt recognition of rhabdomyolysis is critical to preventing late complications, all suspected cases must undergo a complete clinical inquiry, observation, and laboratory follow-up.

Risk Factors for Acute Kidney Injury. The frequency of AKI in the setting of rhabdomyolysis is unknown, and reports of frequency have ranged from 13% to 50%.[1] Gabow and colleagues[17] emphasized that no single laboratory value could predict which patients are at high risk for the development of AKI. However, using discriminant analysis, patients could be separated into high- and low-risk groups, with the high-risk group (elevated serum potassium and creatinine and reduced serum albumin concentrations) having a 41% prevalence of AKI.

Based on a large historical cohort (157 patients), Ward[60] identified clinical and laboratory differences between those patients in whom renal failure did or did not develop, and factors predictive of progression to renal failure. As shown in Table 36.2, patients with rhabdomyolysis and renal failure were older, had a higher incidence of hypertension, and were more hypotensive and volume depleted. A significantly greater proportion of them had a creatine kinase level greater than 16,000 IU per liter, although elevations to this degree were seen in 10.7% of patients in whom renal failure did not develop (Table 36.3). The renal failure group also had significantly higher serum potassium and phosphorus levels and lower serum calcium and albumin concentrations, and was more acidemic with a concomitant lower urinary pH. Sepsis, burns, and drug ingestion were the causes of rhabdomyolysis more closely associated with the development of renal failure. Using multiple logistic regression analysis, a scoring system was developed predicting the risk of renal failure in patients with rhabdomyolysis based on the variables of serum phosphorus, potassium, albumin, and creatine kinase concentrations, and the presence of volume depletion and sepsis. A point score of 7 or higher predicted a greater than 50% likelihood for the development of renal failure. In a multivariate analysis of 72 consecutive patients with rhabdomyolysis due to illicit

drug use, patients with a creatine kinase level greater than 25,000 IU per liter, hypotension, and leukocytosis were at a greater risk of developing AKI, whereas hyperthermia (temperature >38.5°C) was associated with a reduced risk.[61] This association does not indicate that hyperthermia is protective against rhabdomyolysis, rather it is most likely due to earlier presentation to, or evaluation or fluid resuscitation in the emergency department.

Urinalysis. Examination of the urine provides the first laboratory clue to the presence of myoglobinuria. Classically, the initial urine is dark (Table 36.4) and usually with an acid pH; the benzidine or orthotoluidine reagent gives a positive reaction for blood (3+ to 4+), but microscopic examination of the urinary sediment fails to reveal any red blood cells (RBCs). Specific tests for urine myoglobin determination are available in some clinical laboratories but, as noted earlier, urine myoglobin levels are not the most sensitive clinical markers for rhabdomyolysis. Although the strongest clinical clue for myoglobinuria is the presence of strongly heme-positive urine and the absence of RBCs, in one major series[17] hematuria was present in 32% and the dipstick was heme negative in 18% of the patients with rhabdomyolysis. In addition, proteinuria was detected by dipstick in 45% of patients,[17] which may be attributed to altered glomerular permeability or tubular transport of small proteins.[62] The urinary sediment demonstrates brown "debris" and, with the evolution of renal injury, pigmented brown granular casts and renal tubular epithelial cells are seen.

Serum Potassium Concentration. The most life-threatening consequence of rhabdomyolysis is the release of large amounts of intracellular potassium into the circulation. Given the crucial role that potassium plays in maintaining the homeostasis of resting membrane potential, it is evident that vital organs such as the heart are at greatest risk to sustain arrhythmogenic activity. This implies that an electrocardiographic follow-up is mandatory to monitor for potentially grave arrhythmias. Because more than 98% of total body potassium resides in cells, and skeletal muscle represents 60% to 70% of the total cellular mass, breakdown of even a small area of skeletal muscle releases a considerable potassium load. The presence of

acidosis may shift more potassium extracellularly and worsen the hyperkalemia. As noted in the previous section on Risk Factors for AKI, admission serum potassium levels tend to be higher in patients who go on to experience AKI.[60] Approximately half of an acute potassium load is handled by renal excretion[63]; therefore, in AKI, serious hyperkalemia can result and is usually the major indication for dialysis.

Creatine Kinase. The classic laboratory finding of rhabdomyolysis is an elevated serum creatine kinase of at least five

36.4 Differential Diagnosis of Pigmenturia

Factors	Myoglobinuria	Hemoglobinuria	Porphyria
Urine color	Brown	Reddish brown	Dark red

times the normal value, where the striated muscle isoenzyme (CK-MM) is predominately found. The serum half-life of creatine kinase (~36 hours) is much longer than myoglobin, which makes it a more reliable tool for diagnosis. Normal creatine kinase levels are 45 to 260 IU per liter. Following muscle injury, the level rises within 12 hours, peaks in 1 to 3 days, and declines 3 to 5 days after the cessation of muscle injury.[29] Although no correlation has been established between the absolute level of the creatine kinase and the risk for development of AKI, creatine kinase levels are significantly higher in patients in whom renal failure develops.[19,29] Following admission, changes in creatine kinase concentrations provide some insight into whether the rhabdomyolysis is worsening or resolving, and following levels is essential to observe for the "second wave" phenomenon (described later in this chapter).

Acid–Base Balance. The conditions that cause rhabdomyolysis involve tissue trauma or ischemia and predispose one to an augmented acid load. In a study by Ward,[60] patients with rhabdomyolysis who progressed to renal failure tended to be more acidemic. An elevated serum anion gap is usual in patients with rhabdomyolysis and due to the impaired renal excretion of intracellular organic acids released from damaged muscles, as well as a retention of inorganic anions such as phosphate.[64]

Uric Acid. Due to the release of intracellular purines from damaged myocytes, hyperuricemia is expected in patients with rhabdomyolysis, especially when the muscle injury is due to strenuous exercise or exertion.

Blood Urea Nitrogen: Creatinine Ratio. Both AKI and the increased release of creatine from damaged myocytes increase the serum concentrations of blood urea nitrogen (BUN) and creatinine. However, the rise in creatinine is more pronounced and, in turn, alters the normal 10:1 ratio of BUN to creatinine to a ratio of 6:1 or less. Based on creatine:creatinine kinetics and their respective concentrations in skeletal muscle, Oh[65] challenged this conventional view. He pointed out that the patient population in which rhabdomyolysis develops tends to have a larger percentage of younger men with a greater muscle mass, whereas other forms of AKI are more often associated with older and more cachectic patients who have less muscle mass and thus reduced creatinine production rates.

Calcium–Phosphorus Metabolism. The perturbations of calcium and phosphorus metabolism usually seen in most types of AKI appear to be exaggerated in rhabdomyolysis-induced AKI.[19,66] Following the destruction of muscle cells, the release of inorganic phosphorus into the plasma causes hyperphosphatemia[19,64] and subsequent hypocalcemia through the deposition of calcium phosphate in the destroyed muscle cells (dystrophic calcification) and other tissues. Hypocalcemia may be accentuated by the inhibition of renal vitamin D 1α-hydroxylase, which results in the downregulation of the production of the active form of vitamin D ($1,25[OH]_2D_3$). This observation may be explained by hyperphosphatemia, which is known to decrease synthesis of $1,25(OH)_2D_3$ and to stimulate the production of the parathyroid hormone.[64,67] A recent case report described elevated FGF23 levels in rhabdomyolysis-induced AKI and may provide a mechanism for the inhibition of renal 1α-hydroxylase.[68] Regardless of the mechanism, in the absence of frank tetany, hypocalcemia usually does not require treatment. In fact, correction of the hypocalcemia with vigorous intravenous calcium replacement may increase both dystrophic (calcium deposition in damaged muscle) and metastatic calcification due to the high serum PO_4 and the $Ca \times PO_4$ product.

Approximately 20% to 30% of patients with myoglobinuric AKI experience transient hypercalcemia during the recovery (diuretic) phase.[19,64] Early studies[69,70] suggested that hypercalcemia was due to the normal remobilization of calcium deposits in the injured muscle that occurs during the recovery phase of AKI. Alternatively, it has been proposed that as renal function improves, the combination of a decreasing serum phosphorus concentration and the ambient secondary hyperparathyroidism, secondary to hypocalcemia, stimulates the synthesis of $1,25(OH)_2D_3$ resulting in an "overshoot" hypercalcemia.[64] This augmented $1,25(OH)_2D_3$ production may be due, in part, to the release of vitamin D from damaged muscle tissue.[64,71]

Urinary Sodium Excretion. Impaired renal tubular reabsorption of sodium is typically seen in most types of oliguric AKI as manifested by a high fractional excretion of sodium. However, in both myoglobinuric and hemoglobinuric AKI, a low fractional excretion of sodium (<1%) has been observed[38] that resembles a prerenal azotemia during the early course. As noted earlier in this chapter, this phenomenon is most likely due to hypovolemia and vasoconstriction, which lead to renal hypoperfusion.

Disseminated Intravascular Coagulation. DIC is commonly present in patients with rhabdomyolysis and may be due to the release of intracellular thromboplastins that activate the clotting cascade.[63,64] Moreover, DIC may be an important factor in the pathogenesis of the AKI (see section on Glomerular Fibrin Deposition, previously).

Differential Diagnosis

Myoglobin-induced AKI should be suspected in patients with trauma presenting with the classic triad of heme-positive urine, an elevated serum creatine kinase level, and dark (pigmented) urine containing dirty-brown granular casts without RBCs. More subtle cases, usually associated with diffuse nontraumatic rhabdomyolysis, may be more difficult to detect. The differential diagnosis of pigmenturia is limited (Table 36.4). Although certain drugs may impart an orange, red, or brown hue to the urine such as rifampin and nitrofurantoin, they do not react with the benzidine or orthotoluidine reagent on the urine dipstick. Porphyrins also color the urine brown

but do not react to give a positive test for occult blood. The most difficult challenge is to discriminate myoglobin from hemoglobin in the urine. Because these are heme proteins, they both react with the benzidine or orthotoluidine reagent and both are associated with the absence of RBCs in the urine sediment. One helpful clue may be the color of the serum in these two conditions. Because myoglobin is relatively rapidly cleared by the kidney, serum levels of myoglobin are not sufficiently elevated to alter the color of the serum in patients with rhabdomyolysis. In contrast, because of its much larger size and its avid binding to haptoglobin, hemoglobin is not as rapidly cleared by the kidney and serum levels may be high enough to result in a pink discoloration of the serum in patients with hemoglobinuria.

Clinical Course and Complications of Myoglobinuric Acute Kidney Injury

Myoglobinuric AKI can run a course ranging from mild renal dysfunction with only transient oliguria and rapid recovery to a much more catastrophic disease requiring frequent dialysis for periods of 2 or 3 weeks. Typically, the duration of oliguria is 7 to 10 days; during this interval a period of anuria may exist for up to 3 days. Resumption of more normal urine formation heralds the recovery of renal function as patients enter the diuretic phase with a subsequent clearing of azotemia and the cessation of the requirement for hemodialysis.

In addition to muscle injury and AKI, patients with rhabdomyolysis may have peripheral neuropathies. These can result from compartment syndromes in which involved muscles become edematous in confined tissue spaces with compromise of blood supply to both muscle and nerves in the area.[69] Measurement of tissue pressure has been advocated as a tool in identifying those areas of damaged muscle at risk, and a surgical fasciotomy may be required to avoid this complication.[64] Swelling of the muscles can lead to impairment in the blood supply of the muscles, resulting in a recurrence or "second wave" of muscle necrosis, as reflected by a second rise in the serum creatine kinase concentration. Neuropathy also can result from traction if rhabdomyolysis is caused by prolonged coma, as from drug overdose.[64]

Prevention and Treatment of Myoglobinuric Acute Kidney Injury

Understanding the possible mechanisms by which rhabdomyolysis causes AKI can provide the basis for the various therapies advocated for this disorder. If possible, treatment of the underlying condition is a priority. Given the pathogenic nature of hypovolemia, renal hypoperfusion and, based on experimental and clinical data, early intravascular volume expansion by intravenous administration of NaCl 0.9% is essential to restore RBF, maintain GFR, and ultimately prevent AKI.[64,72] Because myoglobin is more nephrotoxic at an acid pH, most groups advocate alkalinization of the urine with sodium bicarbonate.[64,72,73] By correcting cellular acidosis, bicarbonate therapy may reduce renal tubular epithelial swelling and attenuate renal tubular and vascular collapse.[74] There is a theoretical concern that inducing a metabolic alkalosis with such treatment may enhance metastatic calcification, but the salutary benefit of bicarbonate therapy probably outweighs any untoward effect.

Following the repletion of volume and the production of urine within an acceptable range, the patient could undergo forced diuresis. Mannitol has long been recognized to be an effective agent in the prophylaxis against the development of experimental and clinical AKI, in particular when there is suspicion of compartment syndrome. However, recent studies have shown that the administration of NaCl 0.9% in combination with mannitol is not more effective in the prevention of AKI than the administration of NaCl 0.9% alone. Furthermore, mannitol can cause AKI and should be used with caution.[75]

Furosemide, a loop diuretic, has the theoretic advantage of inhibiting sodium transport in the thick ascending limb of the Henle loop. Oxygen consumption is dictated primarily by the rate of sodium transport, and a precarious balance exists in this segment between the rate of oxygen delivery and its consumption.[76] By inhibiting sodium transport, furosemide may reduce oxygen consumption in the face of limited delivery and thereby preserve cell viability. In addition, the augmented urinary flow induced by the diuretic may reduce the risk of tubular obstruction. However, loop diuretics can cause increasing acidification of the urine, worsening intravascular volume depletion, and can induce ototoxicity, and thus the use of these agents has not been generally recommended.[77]

Although there are no controlled trials to show a direct benefit of a "mannitol-bicarbonate cocktail" in the prevention of AKI in rhabdomyolysis, there are case reports suggesting such therapy was instrumental in averting renal injury.[78,79] Adequate fluid hydration and bicarbonate therapy, however, did not ameliorate the development of renal failure in a large retrospective study.[60] Moreover, in a retrospective evaluation of 382 intensive care unit trauma admissions with a creatine kinase of >5,000 IU per liter, the use of bicarbonate and mannitol in 40% of this group had no effect on rates of renal failure, the need for dialysis, and mortality, although there was a trend to a lower mortality rate in patients with creatine kinase greater than 30,000 IU per liter who were treated with bicarbonate and mannitol.[80] This may provide a window of therapeutic potential for patients with extremely high levels of creatine kinase. Initially, the optimization of intravascular fluid volume deficits should be carried out with dispatch using isotonic crystalloid solutions, usually normal saline. Variables useful in following this course of therapy include a physical examination of the state of the circulation and hematocrit, and the recording of external fluid balance. If the clinical assessment suggests that a euvolemic state has been achieved but no improvement in oliguria has occurred, a decision must be made about further intervention. Usually by this time, laboratory results offer further support for the diagnosis of myoglobinuria and acute renal insufficiency, and we recommend the prompt infusion of a mannitol–bicarbonate solution. This is made by adding two ampules, each containing 12.5 g mannitol in 50 mL, and two ampules of 50 mEq $NaHCO_3$ in 50 mL to 800 mL of 5% dextrose

in water (D5W) for intravenous infusion. This reconstituted liter is roughly isosmotic with plasma once the glucose is metabolized and contains both mannitol and 100 mEq $NaHCO_3$. It should be infused at 250 mL per hour; urine flow rate should increase by the end of the 4-hour infusion if the treatment is successful. If this is the case, the solution should continue to be administered at a rate equal to urine output and sufficient to achieve a urine pH greater than 6.5 until such time as azotemia has started to clear and all evidence of myoglobinuria has disappeared. If urine flow does not increase after the 4-hour infusion, the patient has entered the established phase of oliguric renal failure and should be treated conservatively until dialysis can be arranged based on conventional indications. This approach corrected oliguria, hastened the clearing of azotemia, and avoided the need for dialysis in roughly half of patients with myoglobinuric AKI.[79] As a group, these patients had somewhat lower indices of muscle damage and somewhat better preservation of renal function than the half that did not respond. Whether this reflects the earlier intervention or a less severe degree of muscle injury, or both, is not known, and it is also possible that vigorous volume expansion with normal saline alone might have caused the same result in some patients. Given that complications from the mannitol–bicarbonate infusion are few, even in those patients who do not respond, its use should be seriously entertained in patients with myoglobin-induced AKI.

When AKI has become established, dialysis must be used. Early and intensive hemodialysis may be associated with significantly lower morbidity and mortality rates.[64,81] Experience with peritoneal dialysis indicated that solute clearance using this modality was inadequate to keep pace with the rapid rate of solute appearance in these highly catabolic patients,[82] and thus, hemodialysis should be the modality of treatment. Even so, daily hemodialysis often is required for the first several days until the consequences of extensive muscle injury have abated and rates of urea and potassium accumulation have fallen. Thereafter, a schedule of thrice-weekly dialysis usually is adequate unless other factors, such as continued catabolism from infection or surgical wound débridement, or volume overload from parenteral nutritional therapy demand more frequent treatments. Although the overall prognosis for the renal failure is favorable, the ultimate prognosis for the patient probably depends more on other coexisting conditions such as sepsis, bleeding, and respiratory failure.

Hemoglobinuric Acute Kidney Injury

During most types of extravascular hemolysis, the released hemoglobin is quickly taken up by the reticuloendothelial system and metabolized to bilirubin. Thus, extravascular hemolysis rarely results in AKI. On the other hand, due to the binding capacity of haptoglobin, which effectively sequesters free hemoglobin, and advances in blood bank technology that prevent massive intravascular hemolysis from mismatched blood transfusions, the frequency of hemoglobinuric AKI is an uncommon event compared to myoglobinuric AKI.

Causes of Hemoglobinuria

Hemoglobinuria results from the filtration of free hemoglobin in plasma, due almost exclusively to intravascular hemolysis, which occurs in a variety of conditions (Table 36.5). Although each of the listed causes may be associated with acute renal dysfunction, hemoglobinuria is more likely

36.5 Causes of Hemoglobinuria and Acute Kidney Injury

to occur in only a few settings. These include hemolytic transfusion reactions, DIC, march hemoglobinuria, glucose-6-phosphate dehydrogenase deficiency, and infections with clostridia and Plasmodium falciparum malaria, the latter causing blackwater fever.[83]

Hemoglobin Physiology and Metabolism

Hemoglobin has a molecular weight of 68,000 Da and is a tetramer of two α and two β globin chains surrounding a ferrihemate core. As noted earlier, free hemoglobin in plasma is tightly bound to haptoglobin, and the hemoglobin–haptoglobin complex is too large to be filtered by the glomerulus. Thus, free hemoglobin appears in the urine only after the plasma concentration of hemoglobin exceeds the maximum binding capacity of haptoglobin, which is approximately 100 mg per deciliter (in contrast to 1.5 mg per deciliter for myoglobin). In the setting of intravascular hemolysis, the relatively low renal clearance of hemoglobin (fractional clearance relative to inulin, 0.03) results in an increase in plasma hemoglobin levels sufficient to be visible to the naked eye as pink-colored plasma, whereas with rhabdomyolysis, the rapid renal clearance of myoglobin (fractional clearance, 0.75) prevents myoglobin retention in the plasma, and the plasma color is not visibly altered. The color of the plasma is an important "bedside" clue that helps to distinguish between these two forms of pigmenturia.

Clinical and Laboratory Features of Hemoglobinuric Acute Kidney Injury

Because both myoglobin and hemoglobin are heme-containing proteins, and the heme moiety has been implicated as a major factor in inducing renal injury, it is generally accepted that the mechanisms by which they both cause nephrotoxicity are similar. Moreover, in the clinical settings, most commonly associated with it other pathogenetic mechanisms have been proposed to account for the AKI. For example, with hemolytic transfusion reactions, the interaction of antigens on the red cell stroma with preformed antibodies may be responsible for adverse effects on kidney function.[84] In DIC, afferent arteriole and glomerular capillary fibrin deposition are the events most directly related to AKI.[85] March hemoglobinuria occurs from the traumatic hemolysis of RBCs, most likely in people with a genetic susceptibility[83]; AKI in this setting results from a volume depletion as well as hemoglobinuria. In blackwater fever, hemolysis is caused by the abrupt release of P. falciparum trophozoites and perhaps also from the quinine used to treat it.[86] These patients are dehydrated, volume depleted from sweating, and have high fevers. Clostridial sepsis also has multiple effects on renal function including hypotension, acidosis, and DIC, as well as hemolysis.[87]

Laboratory features of intravascular hemolysis and hemoglobinuria include (1) increased serum lactate dehydrogenase (LDH) levels, (2) low serum haptoglobin levels, (3) increased unconjugated (indirect) serum bilirubin, (4) increased reticulocyte count, and (5) hyperkalemia.[83] As with myoglobinuria, hemoglobinuria and hemoglobinuric AKI are associated with pigmented urine casts. The differential diagnosis and clinical course of hemoglobin-induced AKI are similar to those described for myoglobinuria.

Prevention and Treatment of Hemoglobinuric Acute Kidney Injury

The prevention of hemoglobinuric AKI involves many of the same preventive measures for myoglobinuric AKI, such as correcting the volume depletion and the administration of bicarbonate. In fact, Bywaters' therapy to treat crush injuries using saline and bicarbonate in the 1940s was based on earlier reports demonstrating such therapy was beneficial in preventing renal failure in mismatched blood transfusion reactions.[88] Interestingly, in an experimental animal model of hemoglobinuric AKI, the simultaneous administration of the amino acid, lysine, prevented the development of AKI. This was attributed to the ability of lysine to inhibit proximal tubular reabsorption of hemoglobin or its heme moiety.[89] The clinical use of such therapy remains to be determined.

The management of sustained AKI usually requires hemodialysis. These patients, in general, are less catabolic than patients with rhabdomyolysis. The AKI usually lasts 1 to 2 weeks, but full recovery of renal function is often the case.

CRYSTAL-INDUCED ACUTE KIDNEY INJURY

Uric Acid Nephropathy

Acute uric acid nephropathy is the term given to the development of AKI caused by renal tubular obstruction by urate and uric acid crystals. The main clinical setting in which uric acid nephropathy occurs is the treatment of malignancy, especially of leukemia and lymphoma. Treatment of these malignancies results in cell death and the release of large amounts of uric acid precursors. Some patients with these malignancies also have renal insufficiency and high serum uric acid levels before chemotherapy, possibly because of early uric acid nephropathy and the rapidly dividing cell population.[90]

Properties of Uric Acid

The final breakdown product of purine degradation in humans is uric acid (Fig. 36.2). Most other mammals degrade purines to the soluble end product allantoin, but humans lack the enzyme uricase. Uric acid (2,6,8-trioxypurine) is a weak acid with a pK_a of 5.75. Urates are the ionized form of uric acid, and at a physiologic pH of 7.4, over 95% of uric acid dissociates into urates, with 98% existing as monosodium urate. However, uric acid predominates in acidic urine. Although initial in vitro and in vivo studies had shown urate binding to plasma proteins, urate binding to human serum proteins probably is not significant.[90]

At a temperature of 37°C and a plasma pH of 7.40, the saturation point of urate is at a concentration of 8.8 mg per deciliter, which is only slightly above the normal physiologic range

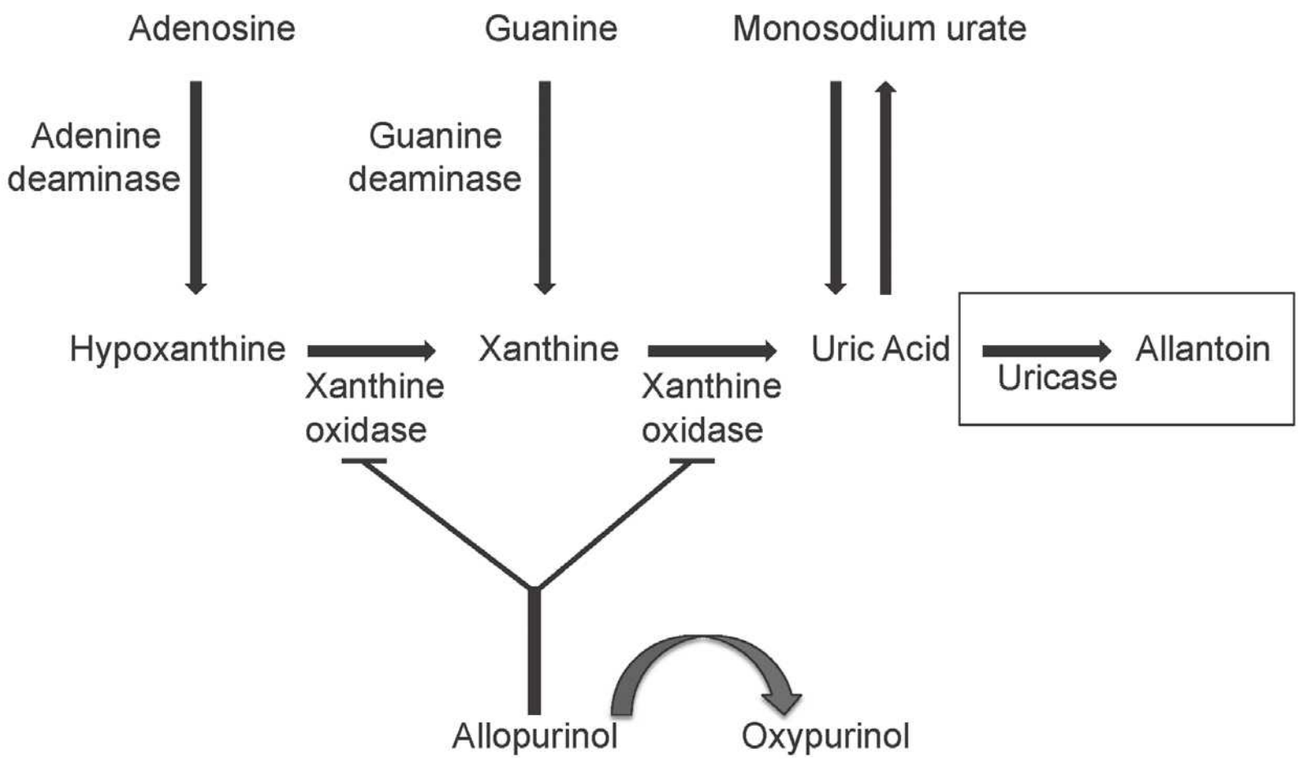

FIGURE 36.2 The pathway of purine degradation showing the competitive inhibition of urate formation by allopurinol and the site of action of rasburicase. The conversion of uric acid to allantoin by uricase (urate oxidase) does not occur in humans.

in humans.[91] However, urate crystal precipitation in the bloodstream does not occur even with concentrations much higher than the saturation point. On the other hand, the precipitation of urate occurs in extracellular fluid when the solubility concentration is exceeded. The most important factor affecting the solubility of uric acid is pH. For example, in a buffer medium at a pH of 5.0, saturation with uric acid occurs at a concentration below 10 mg per deciliter, whereas at a pH above 7.0, saturation occurs at a concentration above 150 mg per deciliter.[91]

There are four components to the renal handling of urate (Fig. 36.3). First, urate is filtered freely at the glomerulus. Virtually all of this filtered urate is then reabsorbed in the proximal tubule. An amount equal to 50% is then secreted, and after further absorption, 10% is finally excreted.[92] In humans, there is net reabsorption of urate with the fractional excretion of urate being approximately 10%.[93] Animal micropuncture studies have localized the primary nephron site of urate absorption and secretion to the proximal tubule. An anion exchanger and a voltage-dependent pathway seem to be the mechanisms involved in urate transport.[93]

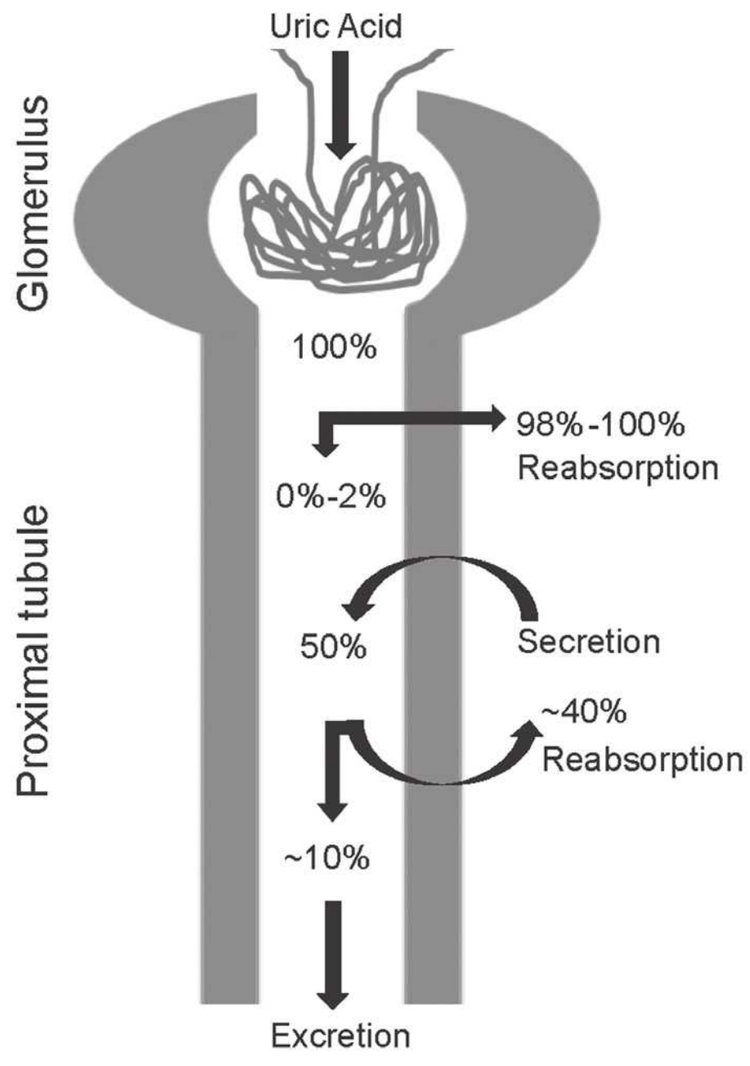

FIGURE 36.3 The renal elimination of uric acid. A four-component model of renal uric acid handling.

Pathogenesis of Uric Acid Nephropathy

Experimental animal models of uric acid nephropathy are characterized by hyperuricemia, hyperuricosuria, and uric acid deposits in and dilation of the kidney tubules, as observed in the clinical entity.[93] Along with the presence of extensive distal tubule deposits of uric acid and urate, micropuncture studies in the rat have shown increased proximal and distal tubular pressures. The vasa recti also show deposits, and efferent arteriolar and peritubular capillary pressures also are increased.[94]

Humans with malignancies and hyperuricemia have an increased urinary excretion rate and urinary concentration of uric acid both in the presence and absence of renal insufficiency.[90] Autopsy studies have documented the presence of uric acid crystals in patients with leukemia. The uric acid crystals were found only within the lumens of renal tubules, in contrast to patients with gout, in whom no uric acid crystals were found in tubular lumens.[95,96] In addition, internal hydronephrosis has been described in association with the intraluminal uric acid crystals, but the glomeruli and tubules usually are intact.[97] Supporting the concept that mechanical intraluminal obstruction causes uric acid nephropathy are the observations that the renal failure reverses after a short time and that there is earlier and greater depression of inulin clearance compared with p-aminohippurate clearance.[97] This evidence is consistent with the concept that uric acid nephropathy occurs because of uric acid crystals obstructing the renal tubular segments with maximum acidifying and concentrating abilities, namely, the distal tubule and the collecting duct. The obstruction then leads to increased intraluminal pressure, decreased filtration pressure, and a reduction in GFR.

Clinical and Laboratory Manifestations

The initial reports of uric acid nephropathy focused on patients treated for acute lymphoblastic leukemia, 10% of whom had uric acid nephropathy.[90,97] In these early patient series, risk factors for uric acid nephropathy included urine pH less than 5.0, dehydration, rapid response to chemotherapy, elevated serum uric acid, increased urinary excretion of uric acid, and preexisting renal insufficiency.[97] Tumor lysis syndrome and acute uric acid nephropathy develop primarily during the treatment of leukemia and lymphoma, but can also occur in association with the treatment of other types of malignancies or in other situations associated with elevated plasma levels and the urinary excretion of uric acid. Multiple other nonhematopoietic neoplasms have been reported to cause acute uric acid nephropathy and tumor lysis syndrome.[90] Hyperuricemic AKI also has been reported after epileptic seizures, during pregnancy, following heat stress, and in the setting of cyclosporine use and renal transplantation.[98–100]

Uric acid nephropathy during tumor lysis syndrome is characterized by elevations in serum urea nitrogen, creatinine, potassium, uric acid, and phosphate concentrations, and by a decrease in the serum calcium concentration. Hyperuricemia before chemotherapy occurs in 30% to 50% of patients with leukemia and lymphoma, and renal insufficiency seems to be more common in patients with hyperuricemia before chemotherapy.[90] The uric acid levels are now routinely normalized with allopurinol, alkalinization, and diuresis prior to the initiation of chemotherapy.[90] Patients receiving chemotherapy are at risk for other forms of renal failure in addition to acute uric acid nephropathy, and the urinary uric acid-to-creatinine ratio is a useful test to differentiate these various forms of renal failure. A ratio greater than 1 is consistent with acute uric acid nephropathy.[90] This is supported by the observation that both the serum uric acid concentration and the urinary excretion of uric acid are elevated in acute uric acid nephropathy as opposed to other forms of renal failure, where serum uric acid concentrations may be high but urinary excretion is not elevated.[101] The urinary uric acid-to-creatinine ratio is more helpful in the diagnosis of uric acid nephropathy than urinalysis, which usually is nondiagnostic. The urine sediment may be normal or may occasionally reveal amorphous material containing uric acid crystals.[90] Uric acid crystals appear as needle-shaped, negative birefringent crystals or as microcrystallites (Fig. 36.4A,B).

Elevations in BUN and serum creatinine typically develop 2 days after the initiation of chemotherapy, with a return to baseline after 7 to 10 days. Prior renal insufficiency seems to predispose one to the development of uric acid nephropathy.[102] The AKI is usually of the oliguric variety, even when treated with diuretics.[102] When indicated, one to four dialysis treatments are usually sufficient before the spontaneous return of renal function.[102]

As noted previously, the electrolyte abnormalities associated with the tumor lysis syndrome and uric acid nephropathy are hyperkalemia, hyperphosphatemia, and hypocalcemia. These abnormalities result from the release of intracellular contents after tumor necrosis, and patients with large tumor burdens are at higher risk for tumor lysis syndrome.[90] Hyperkalemia actually occurs in less than 5% of patients after chemotherapy, but if it develops, it can occur within 24 hours of the initiation of chemotherapy and can be severe enough to necessitate emergent dialysis. In fact, sudden death has been reported as a consequence of tumor lysis–induced hyperkalemia, occurring within 48 hours of chemotherapy.[103] Hyperkalemia also is more likely to occur in patients with preexisting renal insufficiency.[102]

Hyperphosphatemia, on the other hand, is very common in the tumor lysis syndrome and occurs in virtually all patients in whom AKI develops and in 30% of patients with normal renal function.[90] The development of hyperphosphatemia also is correlated with the tumor burden. In patients with renal failure, the phosphorus concentrations average 12 mg per deciliter with a range of 7 to 22 mg per deciliter.[90,102] Hypocalcemia also is common, and the development of hypocalcemia correlates with hyperphosphatemia.[90] In the presence of hyperphosphatemia, the etiology of hypocalcemia may be the precipitation of calcium phosphate salts, as discussed in the section on Myoglobinuric Acute Kidney Injury, discussed previously. When this occurs in the kidney, it may contribute to the AKI seen in tumor lysis syndrome.[104] Hyperphosphatemia also may contribute to the development of hypocalcemia by depressing the production of $1,25(OH)_2D_3$. Hyperphosphatemia has been shown to worsen experimental AKI but the mechanism is not clear because calcium phosphate deposition could not be demonstrated in animal models.[105] Calcium deposits have been found at an autopsy in the calyces and tubules of a patient who had AKI in association with tumor lysis syndrome, hyperphosphatemia (20 mg per deciliter), and hypocalcemia.[106]

Despite these characteristic manifestations of tumor lysis syndrome, it is difficult to predict in which patients acute uric acid nephropathy will develop. Even when appropriate prophylactic measures are taken with hydration, alkalinization, and allopurinol, the following still may develop: hyperuricemia in 9%, hyperphosphatemia in 25% to 50%, hypocalcemia in 10% to 60%, and hyperkalemia in 8%. However, the incidence of clinically significant tumor lysis syndrome after chemotherapy is only 5%.[90] The likelihood for the development of acute uric acid nephropathy is increased in the presence of renal insufficiency, in patients with oliguria before therapy, and in patients with lymphoma with high serum LDH levels.[102,107]

Differential Diagnosis

The diagnosis of acute uric acid nephropathy should be suspected when AKI, in concert with tumor lysis syndrome, develops within the first 1 to 3 days after the initiation of chemotherapy for lymphoma or leukemia. The diagnosis sometimes is made difficult by the variety of drugs, radiographic studies requiring contrast exposure, and the associated clinical problems common during the early presentation of malignancies. Renal complications associated with

Haber, Department of Pathology, Rush Medical College, Chicago, IL.)

malignancies include direct lymphomatous or leukemic renal infiltration, obstruction due to stones, and obstruction due to malignancy (summarized in Table 36.6). However, despite the common occurrence of direct lymphomatous or leukemic renal infiltration, it rarely causes AKI.[102]

Spontaneous hyperuricemia occurs more commonly with lymphomas, and some patients present with renal insufficiency before treatment, possibly because of uric acid nephropathy.[90] Ultimately, the diagnosis of acute uric acid nephropathy is made in the presence of tumor lysis syndrome with the urinary uric acid-to-creatinine concentration ratio greater than 1 and with the exclusion of other causes of AKI.

Prophylactic Measures and Treatment

Before the dialysis era, the mortality rate from AKI associated with uric acid nephropathy was 50%, but with modern treatment, including proper prophylaxis and dialysis, uric acid nephropathy is rare, but when it does occur the prognosis for the AKI is excellent.[90] The treatment approach to uric acid nephropathy is divided into two stages. The first is to prevent or minimize the metabolic consequences of the tumor lysis syndrome, and the second is to treat these consequences when they do occur (Table 36.7). The approach to both prophylaxis and the treatment of tumor lysis syndrome includes the inhibition of xanthine oxidase, forced diuresis, and urinary alkalinization. When these measures fail to prevent the consequences of tumor lysis, and AKI from uric acid nephropathy develops, dialysis must be initiated to treat uremia and severe electrolyte problems, and to control hyperuricemia. However, rasburicase, a recombinant form of urate oxidase, is an additional option for patients with AKI from uric acid nephropathy and in patients with a high risk to develop tumor lysis syndrome (see the following).[108]

36.6 Acute Renal Complications Associated with Malignancies

Prerenal
Extracellular fluid depletion (poor intake, vomiting, diarrhea, hypercalcemia)
Hepatorenal syndrome (veno-occlusive disease, hepatic resection)
Drugs (calcineurin inhibitors, nonsteroidals)
Intrinsic
Glomerular Membranous nephropathy Amyloidosis (multiple myeloma) Pamidronate-associated collapsing Glomerulopathy (incidence unknown) Light-chain deposition disease
Tubulointerstitial Acute tubular necrosis (toxic/ischemic) Lymphomatous infiltration of the kidney Light-chain deposition disease Drugs (cisplatin, ifosfamide) Intravenous contrast Cast nephropathy (multiple myeloma)
Vascular Thrombotic-thrombocytopenic purpura/ hemolytic uremic syndrome (post-HCT, gemcitabine, mitomycin C) Tumor infiltration (renal cell carcinoma with renal vein thrombosis)
Postrenal
Intratubular obstruction
Uric acid nephropathy
Methotrexate
Cast nephropathy (multiple myeloma)
Extrarenal obstruction
Bladder outlet, ureteral (primary disease, retroperitoneal lymphadenopathy, retroperitoneal fibrosis)

HCT, hematopoietic cell transplant.

36.7 The Approach to Uric Acid Nephropathy and Tumor Lysis Syndrome

Approach to prophylaxis for tumor lysis syndrome and uric acid nephropathy
Patients presenting prior to chemotherapy with hyperuricemia and evidence of a large tumor burden: allopurinol, 300–600 mg 4–5 L/24 hr of normal saline. Add diuretics if the patient is well hydrated and not maintaining an adequate urine output. If there is no response to diuretics, match fluid input with urine output. Urinary pH should be maintained above 7.0 by titrating intravenous bicarbonate therapy. Start with 100 mEq/L of sodium bicarbonate in D5W per hour. Bicarbonate therapy should be discontinued after serum uric acid is normalized. If clinically feasible, postpone chemotherapy until uric acid is normalized along with any other electrolyte abnormalities.
Patients presenting prior to chemotherapy and with a normal uric acid level but still at risk for tumor lysis syndrome: Allopurinol, 300–600 mg 4–5 L/24 hr of normal saline as described If clinically feasible, postpone chemotherapy until 2 days after start of allopurinol
Treatment of uric acid nephropathy and tumor lysis syndrome
Hemodialysis initiated per the routine indications including hyperkalemia, acidosis, hyperphosphatemia, volume overload, or uremia. Hemodialysis for control of hyperuricemia unresponsive to the previous measures. Adjust allopurinol doses for renal failure:

Creatinine clearance	Allopurinol dose
0	100 mg q3d
10	100 mg q2d
50	200 mg qd

After hemodialysis, supplement with 50% of allopurinol dose.
D5W, 5% dextrose with water; q3d, every 3 days; q2d, every 2 days; qd, every day.

Inhibition of Xanthine Oxidase. Allopurinol is a substrate for and a competitive inhibitor of the enzyme xanthine oxidase (Fig. 36.2). It blocks the conversion of hypoxanthine and xanthine to uric acid resulting in a reduction in both serum uric acid concentration and a urinary excretion of urates. In the presence of allopurinol, hypoxanthine and xanthine accumulate instead of uric acid, and the urinary excretion of these precursors also increases.[109] Hypoxanthine is highly soluble and even with increased renal excretion does not cause clinical problems. Xanthine, on the other hand, is less soluble than uric acid. Precipitated xanthine can be found in the urine of patients receiving allopurinol, but these precipitates do not correlate with the development of renal failure.[109] However, well-documented cases of xanthine nephropathy and xanthine calculi associated with allopurinol use have been reported.[109,110]

The half-life of allopurinol is less than 2 hours owing to prompt renal elimination and rapid conversion to its chief metabolite, oxypurinol. Oxypurinol is an active metabolite and reduces serum uric acid concentration and urinary uric acid excretion half as much as allopurinol.[111] Unlike allopurinol, oxypurinol is eliminated solely by the kidney, with a half-life of approximately 24 hours.[111] Renal clearance of oxypurinol is decreased with reduced renal function and with creatinine clearance such that with a creatinine clearance of less than 10 mL per minute, the half-life of oxypurinol is approximately 1 week.

In patients with normal renal function and hyperuricemia associated with malignancy, allopurinol decreases serum uric acid within 48 hours with a peak effect at 5 days.[112] The clinical effects of allopurinol probably are mediated by oxypurinol because the half-life of allopurinol is short. Despite the use of allopurinol, hyperuricemia and acute uric acid nephropathy sometimes cannot be avoided, and reasons for this failure include a large tumor burden, aggressive chemotherapy, and the inability to delay chemotherapy until allopurinol has decreased the serum uric acid concentration.

For optimal prophylaxis, allopurinol should be administered at least 3 days before chemotherapy. The level of existing renal function also must be considered when dosing the drug. Allopurinol can lead to a life-threatening toxicity syndrome that is characterized by a diffuse, desquamative skin rash; fever; hepatic dysfunction; eosinophilia; and worsening renal function of unknown etiology, which, however, is consistent with a diffuse vasculitis. Eighty percent of patients reported with this toxicity had renal insufficiency.[113] Improper dosing of allopurinol also can lead to xanthine nephropathy.[113]

Optimal allopurinol dosing is reflected by a therapeutic serum oxypurinol concentration that ranges from 30 to 100 μmol per liter.[114] Patients with end-stage renal disease achieve therapeutic levels of oxypurinol after one dose of allopurinol (300 to 600 mg) and maintain this level until the next dialysis, at which time the serum level is reduced by 40%.[113] Therefore, the maintenance dose must be reduced in patients with renal insufficiency to avoid an accumulation of oxypurinol. The oral route is equivalent to intravenous dosing of allopurinol; therefore, intravenous dosing should be considered only in patients unable to take anything by mouth. A rectal administration of allopurinol is not effective and should not be used.[114] Allopurinol started at 300 to 600 mg is safe and achieves therapeutic levels of oxypurinol, but the peak clinical effect on uric acid production is not seen for 3 days.

Rasburicase. As previously mentioned, most mammals degrade purines to the soluble end product allantoin, using the enzyme uricase (Fig. 36.2), which humans lack. Rasburicase, the recombinant form of urate oxidase, has several advantages over allopurinol. Rasburicase has a rapid onset of action and has been shown to return uric acid to normal levels with hours.[115,116] Unlike allopurinol, which inhibits the production of uric acid, rasburicase quickly reduces the existing uric acid levels and does not rely on the renal clearance of existing uric acid or alkalization of the urine. In one compassionate use trial, rasburicase (0.20 mg per kilogram) was administered intravenously once a day for 1 to 7 days. The mean uric acid level in 29 hyperuricemic children decreased from 15.1 to 0.4 mg per deciliter, and in 27 hyperuricemic adults, the mean level decreased from 14.2 to 0.5 mg per deciliter.[117] Rasburicase is an expensive drug and although clinical trials have compared rasburicase to allopurinol, the outcomes have been a decrement in uric acid levels rather than important metabolic outcomes or AKI.[115,116] Furthermore, there are recent reports of methemoglobinemia and hemolytic anemia that may be related to the use of rasburicase.

Forced Diuresis. Animal data have suggested that high renal tubular fluid flow induced by a solute or water diuresis is important in the prevention of acute urate nephropathy. In fact, rats treated with high-dose furosemide and Brattleboro rats with central diabetes insipidus and water diuresis both had complete protection from uric acid nephropathy, whereas rats treated solely with urine alkalinization had only partial protection.[118] Diuresis probably imparts protection by lowering the urate concentration in the collecting duct where uric acid precipitation occurs, or by effects on tubular urate handling. Whether these results can be applied to humans is not known because species differences in urate handling exist.

Despite efforts to maintain high urine flow with hydration and diuretics, a lower urine flow rate preceding chemotherapy is more common in patients who have renal failure than in those who do not.[102] Although this observation probably reflects the existence of mild spontaneous uric acid nephropathy before chemotherapy, it is reasonable to assume that increased urine flow would add protection from uric acid nephropathy. Patients should be hydrated with 4 to 5 L of normal saline every 24 hours. If the patient is well hydrated and not maintaining the expected urine output, diuretics should then be initiated. If urine output remains

low, fluid intake should be adjusted to match output in the effort to avoid fluid overload.

Urinary Alkalinization. Although evidence is lacking to confirm its role in preventing uric acid nephropathy, urinary alkalization remains a prominent component in prophylactic regimens. The theoretical benefit of urinary alkalinization is to increase the solubility of uric acid. However, in animal studies, the most important intrarenal dynamic in the prevention of acute uric acid nephropathy was high urine tubular flow.[118] In this study, the use of acetazolamide achieved only partial protection, which was likely due to the drug's diuretic effect and not its effect on urine pH.[118] Along with the inherent risk of causing a severe metabolic alkalosis when attempting to alkalinize the urine with sodium bicarbonate administration, other potential disadvantages include increasing the risk of symptomatic hypocalcemia and calcium phosphate precipitation, which can cause AKI by itself in this setting.[119] Urinary alkalinization also does not have an effect on xanthine precipitation because the pK_a of xanthine is 7.4, as opposed to 5.6 for uric acid.

Bicarbonate therapy should be included in the prophylactic regimen only when attempting to correct hyperuricemia. If hyperuricemia is present before chemotherapy, bicarbonate should be added to intravenous fluids with the aim of keeping the urine pH above 7.0. Once hyperuricemia has been corrected, bicarbonate therapy should be discontinued.

Hemodialysis. Dialysis assists in the management of acute uric acid nephropathy in two ways. First, dialytic therapy is initiated for the typical indications common in AKI such as hyperkalemia, severe hyperphosphatemia, azotemia, and fluid overload, although these indications may be more severe and may occur more rapidly than in other forms of AKI. Cases of fatal hyperkalemia have occurred within hours after the initiation of chemotherapy.[119] Second, dialysis is an effective way to reduce the serum uric acid level. This is an important role for dialysis because patients usually do not recover from acute uric acid nephropathy until the serum uric acid level is reduced.[120] Once this occurs, usually after only one to four dialysis treatments, recovery of renal function is signaled by a brisk diuresis.

Depending on the dialyzer and blood flow used, hemodialysis has a uric acid clearance rate of 90 to 150 mL per minute, whereas peritoneal dialysis clearance is only 10 to 20 mL per minute.[120,121] When starting a patient on hemodialysis, caution should be taken not to use a high-calcium bath if severe hyperphosphatemia is present because of the risk of increasing the calcium–phosphorus product. Selected patients may benefit from continuous renal replacement therapy such as CVVHD.

Ethylene Glycol Toxicity

Acute ethylene glycol intoxication is a medical emergency that, if not treated aggressively, leads to serious neurologic, cardiopulmonary, and renal dysfunction, and may result in death. Ethylene glycol, an odorless and clear liquid, is the major ingredient in antifreeze, and is most commonly consumed either intentionally by alcoholics seeking an ethanol substitute or accidentally by children. An ingestion of 100 mL is considered the minimal lethal dose of ethylene glycol.[122,123] Diethylene glycol is a condensation product of ethylene glycol production, and ingestion causes the same toxicities as ethylene glycol.[124] Diethylene glycol was used as the diluent in the first sulfa antibiotic, sulfanilamide, and consequently led to mass poisonings in 1937. One hundred five patients died from the therapeutic use of Elixir Sulfanilamide, and one important consequence of this tragedy was the 1938 Federal Food Drug and Cosmetic Act requiring proof of product safety before release of a drug.[125] Unfortunately, this kind of governmental supervision of pharmaceutical companies does not exist in other countries such as Nigeria and Haiti, where 47 and 85 children, respectively, died when diethylene glycol was used as a solvent in a preparation of cough syrup.[126,127]

Metabolism of Ethylene Glycol

The metabolism of ethylene glycol is complex and incompletely understood. As is the case with other alcohols such as ethyl and methyl alcohol, nicotinamide adenine dinucleotide (NAD)-dependent alcohol dehydrogenase is responsible for the first oxidative step converting ethylene glycol to glycolaldehyde (Fig. 36.5). After this first step the pathways have not been well elucidated in humans, but are thought to include the following: glycolaldehyde oxidized to glycolic acid by aldehyde oxidase, glycolic acid to glyoxylate by glycolic acid oxidase or LDH, and then numerous subsequent pathways for glyoxylate metabolism, including one to oxalate by LDH and glycolic acid oxidase (Fig. 36.5).[122] Glycolate is converted to glyoxylate very slowly and is probably the rate-limiting step in the metabolism of ethylene glycol, whereas glycolaldehyde and glyoxylate have very short half-lives.[128]

Ethylene glycol metabolites are thought to mediate the toxicity seen with ethylene glycol ingestion, and ethylene glycol itself is not toxic. In fact, the inhibition of ethylene glycol metabolism with ethyl alcohol or pyrazole prevents toxicity.[129,130] The observation that the mortality rate in rats is reduced by performing a partial hepatectomy before the administration of ethylene glycol and glycolate illustrates the importance of ethylene glycol metabolites on toxicity. The partially hepatectomized rats metabolized ethylene glycol more slowly to its toxic byproducts, which allowed more time for renal excretion of the nontoxic and unchanged ethylene glycol.[131] Glycolate and oxalate are thought to be important mediators of ethylene glycol toxicity.

The pathophysiologic process of ethylene glycol toxicity is multifactorial and is thought to include the accumulation of toxic ethylene glycol metabolites, calcium oxalate crystal deposition in tissues, and the effects of severe acidosis. After the administration of a lethal dose of ethylene glycol in rats, profound renal oxalosis is produced, and the same occurs with administration of glycolic acid and glyoxylic acid. Renal

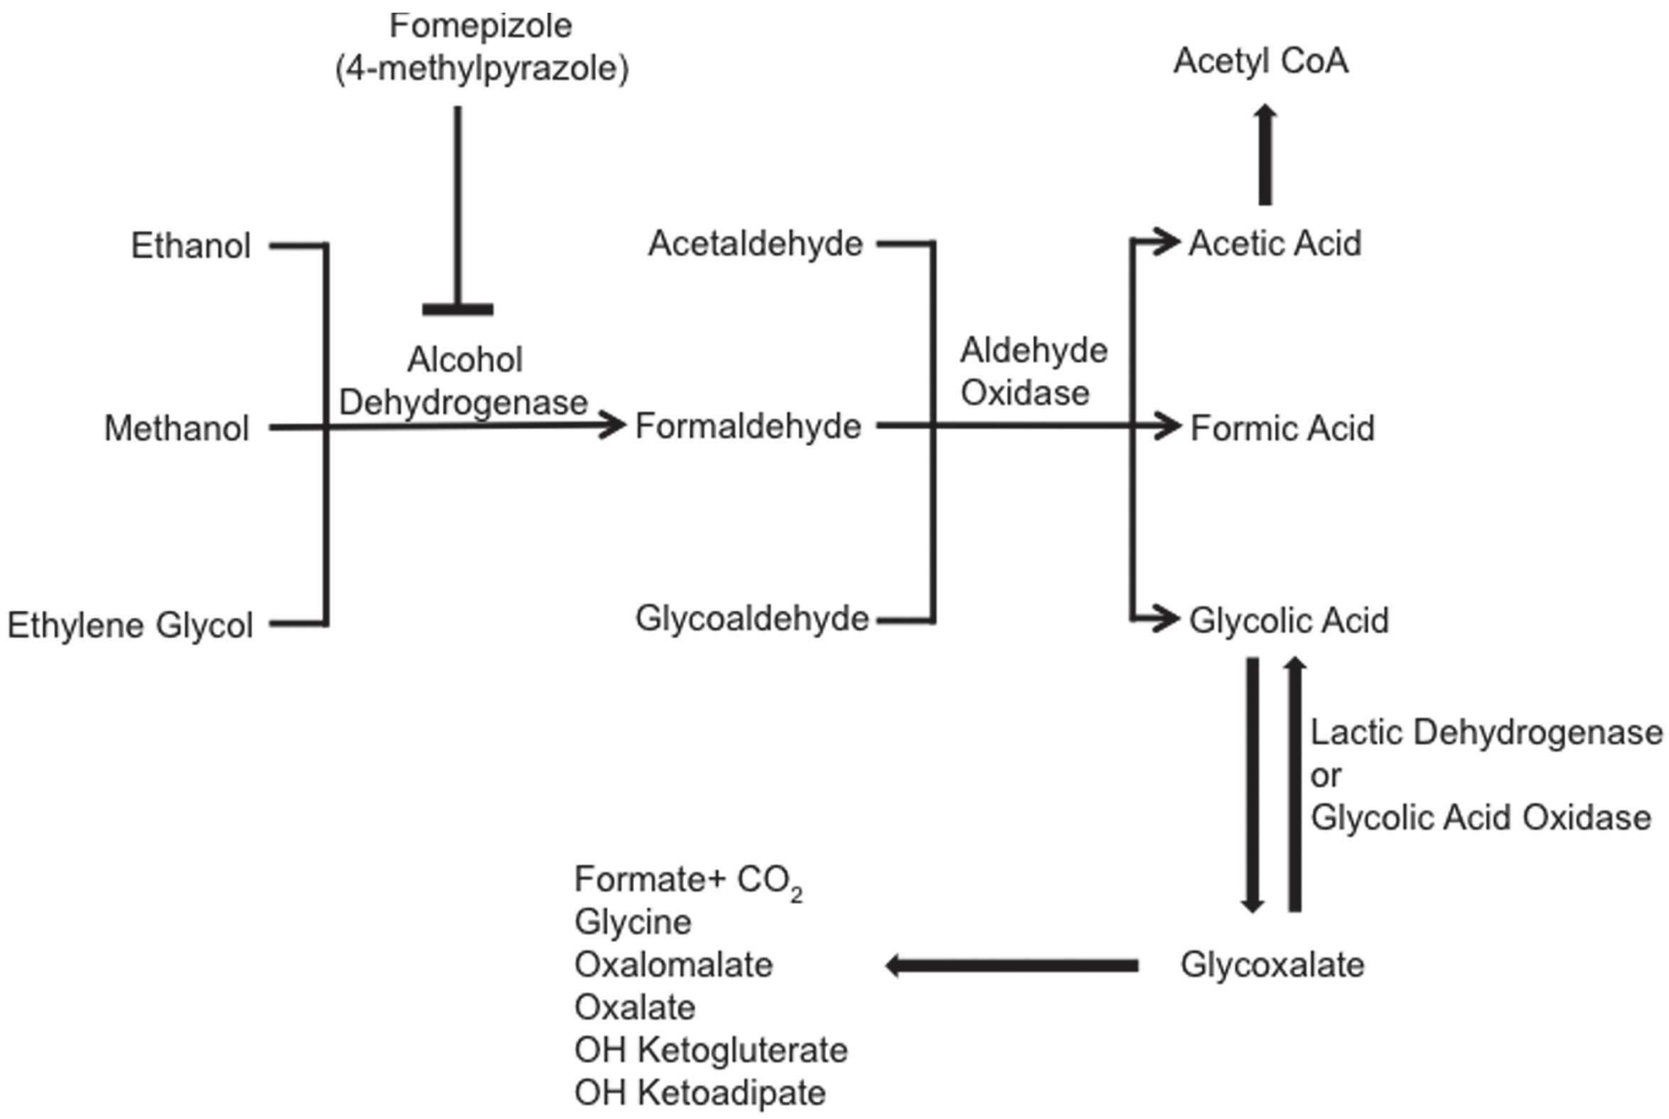

FIGURE 36.5 The pathway of ethylene glycol degradation.

pathology in these rats demonstrated calcium oxalate crystals in the proximal and distal convoluted tubules, with smaller amounts in the collecting tubule and none in the glomeruli or renal interstitium.[132] The degree of crystal formation correlated with diffuse convoluted tubular dilatation, but occasional epithelial necrosis seemed to bear a relation to the degree of crystal formation. The administration of glycolaldehyde did not produce significant crystal formation or the same degree of microscopic changes, but did lead to pronounced tubular epithelial swelling. In addition to the renal findings, oxalate crystals were found in brain tissue.[132] In dogs given nonlethal doses of ethylene glycol, renal biopsy specimens revealed interstitial edema, tubular dilatation, hydropic degeneration, and tubular cell necrosis even in areas free of crystals. Electron microscopic findings were most prominent in proximal tubule cells and included vacuolization, cellular rupture, cytoplasmic buds, and increased density of mitochondria.[133] This pattern of proximal tubule damage is similar to other models of ischemic and nephrotoxic forms of AKI.[133]

These findings are similar to human autopsy series that also have found calcium oxalate crystals in renal tubules. In these studies, renal epithelial cells appear either normal or extensively necrotic depending on the interval between ingestion and death and appear minimal if any damage of the glomeruli has been reported.[122,123] Despite severe clinical neurologic disturbances, the brain characteristically has only mild perivascular and meningeal deposition of calcium oxalate crystals, but edema, capillary engorgement, hemorrhage, and infarctions also have been described.[122,123,134] Although crystal deposition usually is not reported, myocardial tissue findings are consistent with myocarditis.[134] Autopsy and renal biopsy studies do not support the hypothesis that calcium oxalate crystallization is the primary cause of ethylene glycol toxicity; despite widespread renal tubule damage, calcium oxalate crystal deposition is patchy; and despite the presence of crystals there is no tubule obstruction or dilatation.

High–anion-gap metabolic acidosis is a major feature of ethylene glycol intoxication, and is also thought to contribute directly to the clinical toxicity. In rats poisoned with ethylene glycol, survival rates are five times greater after treatment with sodium bicarbonate alone or with ethanol alone compared with no treatment. Giving ethanol and sodium bicarbonate together improved the survival rate to six times that seen in rats with no treatment.[135] The major determinant of the metabolic acidosis is glycolic acid; in dogs and monkeys, the administration of ethylene glycol produces severe metabolic acidosis and the depressed bicarbonate is matched by the increase in glycolic acid production.[122] Oxalic acid is very toxic to kidneys and is lethal in doses much lower than toxic doses of ethylene glycol, but in rats and monkeys, only 0% to 2.5% of the original dose of ethylene glycol is excreted as oxalic acid.[136,137] In humans with ethylene glycol poisoning, the plasma glycolate concentration correlated with the increased anion gap, and the serum concentrations of oxalate and glyoxylate were negligible in these patients.[122,128] Although studies have suggested that organic acids such as lactic acid contribute to the severe metabolic acidosis of ethylene glycol intoxication, glycolic acid seems to be the main cause of the acidosis with lactic and β-hydroxybutyric acids being elevated in special circumstances such as that associated with hypotension or alcoholic ketoacidosis.[138,139]

It has been postulated that the production of glycolaldehyde, glyoxal, glycolate, and glyoxylate from ethylene glycol metabolism is important in the pathophysiologic process of toxicity. Aldehyde production is greatest 6 to 12 hours after ethylene glycol ingestion, and this is when cerebral symptoms are most severe.[122,123] However, as mentioned, glycolate is the only metabolite that accumulates; its direct toxicity has not been well studied, but it is known to be toxic in animals.[137] For example, glycolic acid given to rats is lethal and also causes renal tubular oxalosis.[132] The role that glycolic acid plays in human renal, cerebral, and cardiac toxicity remains to be proven, but it probably is one of the multifactorial causes along with acidosis and calcium oxalate crystals.

Clinical and Laboratory Manifestations

The initial reports of ethylene glycol poisoning in the 1940s and 1950s noted that the clinical manifestations of acute ethylene glycol poisoning could be divided into three stages.[140] During the first stage, occurring 30 minutes to 12 hours after ethylene glycol ingestion, the central nervous system manifestations predominate. During the second stage, occurring over the next 12 hours, cardiopulmonary dysfunction develops and includes tachypnea, pulmonary edema, and cardiac failure. In patients who survive past the first 24 hours, the third stage is characterized by prolonged renal failure. Before the advent of aggressive treatment with hemodialysis and intravenous ethanol, these stages were very typical of the clinical course of most patients, but with modern treatment and depending on the amount of ethylene glycol ingested, the sequence and occurrence of these clinical features and stages vary considerably.[122,123]

In addition to apparent inebriation without an alcoholic odor, central nervous system manifestations include nystagmus, depressed reflexes, seizures, and coma.[122,123] The delayed appearance of multiple cranial nerve deficits also has been reported, and the deficits have not always been reversible.[141] Ocular effects are a main feature of methanol ingestion but ophthalmoplegia, papilledema, loss of visual acuity, and eventual optic atrophy also have been reported with ethylene glycol ingestion.[142] Abdominal signs and symptoms including nausea, vomiting, and pain are very common.[122,123] For unexplained reasons, mild hypertension, tachycardia, and a low-grade fever sometimes are present.[122,123]

High–anion-gap metabolic acidosis with a high osmolar gap is the most striking initial laboratory finding and, when combined with clues in the history of the patient, is the main diagnostic feature. The severity of the clinical presentation depends on the quantity of ingested ethylene glycol and the elapsed time since its ingestion, but typically, patients present with a pH of less than 7.2, bicarbonate less than 10 mEq per liter, anion gap greater than 20, mean osmolal gap of 35, measured osmolality greater than 300 mOsm, and hyperkalemia.[122,123] Hypocalcemia is a frequent finding and can be severe and symptomatic leading to tetany or cardiac arrhythmia.[122,123] The onset of hypocalcemia is usually within the first 12 hours, and serum calcium usually remains low despite treatment. Hypocalcemia probably is caused by a combination of chelation of calcium by oxalate and an abnormal parathyroid hormone response.[122,123]

Lumbar puncture frequently is performed because of mental status changes, and the cerebrospinal fluid sometimes reveals pleocytosis with a sterile culture.[122,123,134] A normal hematocrit and platelet count, but a moderate leukocytosis of 10,000 to 40,000/mm^3 with a predominance of polymorphonuclear cells is seen commonly in the initial complete blood count.[122,123,134]

The urinalysis typically includes a low specific gravity, mild proteinuria, microscopic hematuria, and pyuria.[122,123] Crystalluria is not invariably present but usually is seen on presentation. The envelope-shaped calcium oxalate dihydrate form of crystal (octahedral dihydrate) (Fig. 36.4C) traditionally has been thought of as the most commonly seen crystal in ethylene glycol intoxication, but in fact needle-shaped monohydrate calcium oxalate crystals predominate in ethylene glycol intoxication.[122,123] Monohydrate calcium oxalate crystals are thermodynamically stable, and with time, the dihydrate form transforms to the monohydrate form.[143] In vitro, the dihydrate form is seen only at high concentrations of both calcium and oxalate.[143] The pattern of oxalate crystals in individual patients transforms from the envelope-shaped crystals to the needle-shaped crystals in a matter of hours.[138]

The cardiopulmonary consequences of ethylene glycol intoxication now are rarely seen with prompt, aggressive treatment. After the ingestion of ethylene glycol sufficient to cause metabolic acidosis, oliguric renal failure develops in most patients.[144,145] If aggressive treatment, including dialysis and fomepizole or ethanol, is provided soon after the ethylene glycol is ingested, renal failure can be avoided. However, most patients do not seek medical attention until symptoms develop, which usually is many hours after ingestion. Thus, renal failure is common and may develop as soon as 24 hours after ingestion.[122,146] The course of the renal failure is typical of oliguric acute tubular necrosis. The oliguria lasts 4 to 5 days and is followed by a diuretic phase. BUN and serum creatinine usually peak at 7 to 10 days, and most patients require only 1 to 2 weeks of dialytic support.[147,148] However, some patients require dialysis for many months, and despite the return of sufficient kidney function to stop dialysis, kidney function does not always return to baseline values.[138]

Diagnosis

In the absence of ketoacidosis, and in the presence of the characteristic signs and symptoms, it should be assumed that all patients presenting with metabolic acidosis combined with increased anion and osmolal gaps have either methanol or ethylene glycol poisoning.[148] The prognosis of both these poisonings is improved with early diagnosis and treatment, and therefore, if the diagnosis cannot be confirmed with serum levels of methanol or ethylene glycol treatment with

bicarbonate and ethanol infusion and hemodialysis should be initiated.[148] Determining specific levels of each alcohol is the most specific test. Because these tests are not available in all hospitals,[149] adding fluorescein to the urine and then observing for urine fluorescence with an ultraviolet Wood lamp is helpful in making the diagnosis.

Once the diagnosis of ethylene glycol poisoning has been confirmed and the blood concentration of any concomitantly ingested ethanol has been determined, the serum ethylene glycol level can be estimated using the osmolal gap.[150,151] Ethylene glycol levels above 20 mg per deciliter can be lethal if not treated aggressively.[144]

Clinical Course and Treatment

Initial Emergency Department Treatment. Gastric lavage should be initiated to reduce further drug absorption if the patient is seen in the first few hours after ethylene glycol ingestion.[148,152] Both methanol and ethylene glycol intoxication were previously treated with an ethanol infusion (to prevent the production of toxic metabolites) followed by hemodialysis to remove the actual substance from the body.[148,152] However, fomepizole (4-methylpyrazole; Antizol) is now the drug of choice.[153,154] Hemodialysis to provide a source of bicarbonate and to clear ethylene glycol and its metabolites is the therapy of choice for the treatment of the acidosis. However, hemodialysis usually is delayed and during this waiting period, patients require large doses (300 to 500 mEq) of sodium bicarbonate, and the metabolic acidosis is not corrected until hemodialysis is initiated.[155]

Correction of the acidosis may increase the likelihood of symptomatic hypocalcemia such as seizures, tetany, and cardiac dysfunction. Intravenous calcium supplementation should be given cautiously because of the potential risk of further calcium oxalate precipitation. Calcium should be given if clinical signs or symptoms of hypocalcemia develop, but not prophylactically.[148,152] Thiamine and pyridoxine are cofactors required in the nontoxic metabolic pathways of ethylene glycol (away from oxalate), and early replacement of these cofactors is advocated to prevent potential depletion.[148,152]

The administration of ethanol and hemodialysis has traditionally made up the definitive treatments for ethylene glycol intoxication. Compared with ethylene glycol, ethanol has a higher affinity for alcohol dehydrogenase and therefore inhibits the metabolism of ethylene glycol to the toxic metabolites, permitting the ethylene glycol to be renally excreted or dialyzed. With a blood ethanol level of 100 mg per deciliter liver alcohol dehydrogenase is saturated, and the half-life of ethylene glycol increases from 3 to 17 hours.[122,148,152] Since the first report of ethanol treatment in humans, ethanol has been used in conjunction with dialysis in the treatment of ethylene glycol poisoning, and ethanol is not recommended as a sole treatment.[129] Although there have been reports of successful treatment with ethanol without dialysis, these were isolated cases in which ingestion only of small amounts of ethylene glycol occurred.[156]

For the maximal inhibition of ethylene glycol metabolism, the plasma ethanol concentration should be maintained between 100 and 200 mg per deciliter. This is achieved with a loading dose of 0.6 g per kilogram, followed by a maintenance dose of 66 mg per kilogram in nondrinkers, and 154 mg per kilogram in regular alcohol consumers. During dialysis, 7.2 g per hour should be added to the maintenance dose.[157] Oral ethanol also can be used, but the dose should be increased by 50% if given soon after the administration of charcoal.[157] Intravenous ethanol comes in 5% and 10% solutions diluted in dextrose and water, whereas a 20% or 50% solution usually is used for oral or nasogastric administration. The specific gravity of ethanol is used in calculating the correct dose.[157] Until the correct dose to achieve a level between 100 and 200 mg per deciliter has been ascertained, hourly ethanol concentrations should be checked. The dosing guidelines for ethanol in ethylene glycol toxicity is summarized in Table 36.8.

36.8 Dosing Guidelines for Ethanol Treatment

Ethanol Solution and Route of Administration	Specific Gravity of Ethanol (g/dL)	Loading Dose (100 mg/dL of ethanol × 0.6 L/kg) (mL/kg)	Maintenance Dose in Nondrinkers 66 mg/kg/hr (mL/kg/hr)	Maintenance Dose in Drinkers 154 mg/kg/hr (mL/kg/hr)	During Dialysis Add the Following to the Maintenance Dose (mL/hr)
5% IV	3.9	15.4	1.7	3.9	185
10% IV	7.8	7.7	0.84	2.0	90
20% PO	15.8	3.8	0.42	1.0	45
50% PO	39.5	1.5	0.17	0.4	18

Oral ethanol dose should be increased by 50% after charcoal therapy. IV, intravenous; PO, orally.

4-Methylpyrazole (Fomepizole). Fomepizole is a potent inhibitor of alcohol dehydrogenase, and animal studies have shown that fomepizole prevents ethylene glycol–related mortality and toxicities, and increases the urinary excretion of ethylene glycol by preventing its metabolism.[130] In humans, fomepizole has been shown to normalize acidosis within hours, to prevent decreases in renal function if used early, and to decrease serum levels of ethylene glycol toxic metabolites.[153,154,158] In humans without AKI, treatment results in an increase in the ethylene glycol half-life from 3 to 14 hours, an increase in urinary excretion of ethylene glycol, and the prevention of clinical toxicity.[153,154]

Fomepizole offers advantages over ethanol treatment including predictable pharmacokinetics, avoiding the need to achieve and maintain the desired blood ethanol level, and avoiding an ethanol-induced central nervous system depression. Fomepizole is available as a parenteral solution. The loading dose is 15 mg per kilogram intravenously, followed by 4 more doses of 10 mg per kilogram every 12 hours, after which it is continued at a rate of 15 mg per kilogram every 12 hours until the ethylene glycol concentration is undetectable or the patient is asymptomatic with a resolution of the high–anion-gap metabolic acidosis. Like ethanol, the dose of fomepizole is adjusted during dialysis therapy. At the start of dialysis, the next scheduled dose is given if it has been longer than 6 hours since the last dose, but if it has been less than 6 hours, the next scheduled dose is held. Fomepizole is then given every 4 hours during dialysis. At the completion of dialysis, no additional dose is given if it has been less than 1 hour since the last dose, one-half of the next scheduled dose is given if it has been 1 to 3 hours since the last dose, and the next scheduled dose is given if it has been longer than 3 hours since the last dose. The maintenance dose off dialysis is continued 12 hours after the last dose.[153,154]

Fomepizole has been used to treat ethylene glycol poisoning successfully without hemodialysis or ethanol, but these patients had normal renal function, and fomepizole treatment was initiated soon after ethylene glycol ingestion.[159,160] In mild cases of ethylene glycol poisoning, as evidenced by normal renal function and no high–anion-gap acidosis, ethanol or fomepizole is used by some as sole therapy without dialysis. However, in these cases, forced diuresis with intravenous fluids or furosemide should be used to avoid dehydration, minimize renal calcium oxalate crystal formation, and maintain the renal clearance of ethylene glycol.[159] More recent data suggest that an abnormal presenting serum creatinine concentration ($\geq$1.5 mg per deciliter) predicts significantly prolonged ethylene glycol elimination during fomepizole therapy, and in the presence of metabolic acidosis, patients should undergo hemodialysis.[161]

Hemodialysis. Hemodialysis is indicated in all cases of confirmed or strongly suspected ethylene glycol poisoning presenting with renal failure, metabolic acidosis, and/or deteriorating clinical status. Ethylene glycol and glycolate have low molecular weights, no protein binding, and a volume of distribution of 0.8 and 0.55 L per kilogram, respectively, making them easily dialyzable.[147,148,152] Large surface-area dialyzers ($>$2 m^2) can achieve a clearance of ethylene glycol of greater than 200 mL per minute, and with smaller surface-area dialyzers (1.1 to 1.6 m^2) clearance of ethylene glycol and glycolate typically ranges from 150 to 190 mL per minute and 140 to 170 mL per minute, respectively.[147,148,152] The renal clearance of ethylene glycol can be as high as 30 mL per minute in patients with preserved renal function, but the importance of hemodialysis is illustrated by the fact that most patients present with renal insufficiency, and in these patients the renal clearance of ethylene glycol and glycolate is negligible.[162] The length of the hemodialysis session should be determined by the quantity of ethylene glycol ingested, but this rarely is known. Although blood ethylene glycol levels are helpful, they do not necessarily reflect the total quantity ingested because the blood ethylene glycol level is influenced by time since ingestion and amount metabolized. Dialysis should be continued for 8 hours if ethylene glycol levels are not available, and when levels are available, the dialysis prescription should be calculated using the total body water, the blood ethylene glycol level, and the manufacturer-specified dialyzer urea clearance (in milliliters per minute) at the initial observed blood flow rate.[163] Bicarbonate-based dialysate is probably optimal compared with acetate dialysate, which is associated with greater hemodynamic instability, more central nervous system symptoms, and more oscillations in plasma bicarbonate.[164] Although peritoneal dialysis clears ethylene glycol and oxalate, it should not be used over hemodialysis because of the high efficacy of hemodialysis.[165]

Sulfonamide Antibiotics, Indinavir, and Acyclovir

Crystal-induced AKI also can be caused by drugs used for therapeutic purposes. If the solubility limit of a given drug is exceeded in the renal tubules, the drug can then crystallize and possibly cause obstructive nephropathy. Certain sulfonamide antibiotics and acyclovir are the most common drugs that can cause crystalline AKI, but other drugs such as methotrexate, triamterene, acetazolamide, several herbal medicines, and high-dose vitamin C potentially can crystallize and cause stones or obstructive nephropathy.[166–169] Before the AIDS era, crystalline AKI had become fairly rare, but with the frequent use of high-dose sulfadiazine, sulfamethoxazole, indinavir, tenofovir, and acyclovir in this population, it is again an important cause of AKI.[170,171]

Sulfonamides. The sulfonamides were introduced into medical practice in 1936, and early animal experiments recognized that sulfonamides of low solubility were able to crystallize in the urinary tract and the renal parenchyma, causing obstructive nephropathy.[172,173] Reports of patients with hematuria, crystalluria, renal colic, and renal failure were common until the 1950s, when sulfonamides with greater solubility became available.[172] In patients with AIDS, high-dose sulfadiazine is again commonly being used in

conjunction with pyrimethamine for the treatment of toxoplasmosis. After an oral dose, sulfadiazine is rapidly absorbed and then partially acetylated in the liver. The half-life of sulfadiazine is 8 to 17 hours in patients with normal renal function and is 22 to 34 hours in patients with severe renal insufficiency.[171] Renal crystal formation in the nephron is promoted as the filtrate is concentrated and acidified. The solubility of sulfadiazine is almost 10-fold higher at a pH of 7.5 than at a pH of 6.5.

Patients with sulfonamide-induced AKI classically present with renal colic, hematuria, and oliguria or anuria.[174] Although renal failure develops in most patients in the first week after the start of the sulfadiazine patients also can present months after the start of the medication. Delayed presentation of AKI usually occurs with the concurrent development of volume depletion, often due to diarrhea, and these patients can be managed with hydration without stopping the sulfadiazine.[175] The urinalysis usually shows hematuria, mild pyuria, and "shock of wheat" crystals (Fig. 36.4D). Renal ultrasonography may reveal multiple echogenic foci in the renal parenchyma, but occasionally may show frank hydronephrosis with ureteral stones.[175,176]

AKI should be managed with intravenous fluids containing sodium bicarbonate with the aim of maintaining urine pH over 7.15 and urine output over 1 L per day. Urologic intervention sometimes is required in patients who remain anuric. Bilateral retrograde ureteral catheterization with warm 5% sodium bicarbonate solution, ureteral stents, and stone extraction with a stone basket all have been used in cases of ureteral obstruction with stones.[177] Although temporary hemodialysis sometimes is necessary, the recovery of renal function to baseline is the rule within 7 days.[176]

Patients starting sulfadiazine therapy should receive prophylaxis against renal toxicity. To minimize crystal formation, patients should be encouraged to maintain fluid intake over 2 to 3 L per day and should be started on sodium bicarbonate (6 to 12 g per day) to maintain a urine pH higher than 7.15.[174] Patients with renal insufficiency, diarrhea, or volume depletion should be monitored closely with urinalyses looking for hematuria and crystalluria, and sulfadiazine levels should be considered in patients with renal insufficiency.[174]

Indinavir. Indinavir is one of the most common protease inhibitors used in patients with AIDS as part of a highly active antiretroviral therapy. Indinavir causes nephrolithiasis in 3% to 4% of patients, and symptomatic urinary tract disease, including nephrolithiasis with renal colic, flank pain without evidence of stones, and dysuria or urgency in 8% of patients taking the drug.[178,179] Most patients presenting with symptomatic urinary tract disease have crystalluria, and many have radiographic evidence of either stones or renal parenchyma filling defects. However, only a minority of patients have mild-to-moderate renal insufficiency. Hydration can prevent symptomatic urinary tract disease, but a permanent discontinuation of indinavir is necessary in some because of recurrence of symptoms. Asymptomatic indinavir crystalluria is found in 20% of patients receiving the drug in the normal dosage of 800 mg orally three times a day, and the drug should not be discontinued for asymptomatic crystalluria. The presence of crystalluria and pyuria may signal the presence of interstitial nephritis, which may not reverse with conservative treatment with hydration alone.[180]

Acyclovir. High-dose acyclovir also is associated with AKI and crystalluria. Early preclinical toxicology studies in animals clearly demonstrated that high-dose acyclovir given to rats resulted in the precipitation of drug crystals in the distal nephron and also caused reversible obstructive nephropathy.[181,182] Although it has been assumed that intratubular acyclovir crystallization is also responsible for the renal failure observed in humans, the pathophysiologic process is not entirely clear. Most reported kidney biopsy or autopsy specimens have not demonstrated intrarenal crystals, but typically show normal glomeruli, no obstruction, occasional ruptured tubules, and minimal focal areas of interstitial hemorrhage, congestion, and inflammatory infiltrates.[183,184] In one case report of acyclovir nephrotoxicity, the renal biopsy was consistent with acute tubular necrosis without any evidence of intratubular crystals.[185] Crystal dissolution during tissue fixation or the time interval between discontinuation of acyclovir and obtaining the renal biopsy could account for the inconsistent demonstration of crystals in renal tissue.[185]

Renal impairment after intravenous acyclovir was commonly observed when bolus injections were used instead of slow infusions; one series reported that increased BUN or serum creatinine levels developed in 58 of 354 (16%) of patients 24 to 48 hours after the administration of acyclovir.[182,186] Unlike all other subsequent reports, one infant in this series with renal failure did show birefringent crystals in the renal tubules at the postmortem examination.[182] In contrast to bolus injections, renal failure after slow intravenous infusions or oral acyclovir is less common but does occur, especially in patients with renal insufficiency or volume depletion.[184]

AKI caused by acyclovir typically develops 24 to 72 hours after the first dose of intravenous acyclovir. Unlike with the sulfonamide antibiotics, most patients do not have renal colic, stones, or ultrasonographic findings of obstruction. Many patients also have neurotoxicity, including headache, irritability, tremulousness, ataxia, nystagmus, lethargy, dysarthria, confusion, and coma.[184] The urinalysis usually reveals both mild hematuria and pyuria, and an examination of the urine with a polarizing microscope may show birefringent, needle-shaped crystals within leukocytes.[184,187]

Risk factors for the development of acyclovir-induced AKI include volume depletion, bolus dosing, chronic renal failure, and an acyclovir serum level of greater than 25 μg per milliliter.[182,188] The renal function in patients with AKI usually normalizes within 4 to 9 days after drug discontinuation.[184,188] Conservative management, with hydration and the discontinuation of acyclovir, is sufficient in most

patients, but in patients with combined severe neurotoxicity and nephrotoxicity, hemodialysis can be used to reduce serum acyclovir levels. This results in the prompt reversal of acyclovir-associated neurologic symptoms.[187] In cases of mild renal failure, acyclovir nephrotoxicity can be managed by hydration and dose reduction of acyclovir.[189]

The half-life of acyclovir is 3 hours, and renal excretion is the major route of elimination. For example, over 90% of a given dose of acyclovir can be recovered unchanged in the urine of subjects with normal renal function 12 hours after dosing.[190] There is a linear relationship between creatinine clearance and the renal clearance of acyclovir. The renal clearance of acyclovir is three times that of a given creatinine clearance, indicating significant tubular secretion.[190] In subjects with preexisting renal insufficiency, the half-life of acyclovir can be as high as 20 hours, and dosing in renal insufficiency should be adjusted according to the level of renal function.[190,191] Hemodialysis effectively removes acyclovir, reducing the half-life to 5 hours, and can effectively remove 40% of acyclovir in body stores.[190,192]

CHAPTER

37 Acute Kidney Injury Secondary to Tropical Hemorrhagic Viral Infections and Snakebites

Emmanuel A. Burdmann

TROPICAL HEMORRHAGIC VIRUS INFECTIONS

Viral hemorrhagic fevers (VHF) are a group of highly infectious diseases with similar clinical presentations, characterized by an intense inflammatory status, endothelial injury, increased vascular permeability, and bleeding. They are caused by RNA viruses from the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae, and can be transmitted directly or by tick or mosquito bites. Among the VHF, dengue and yellow fever are the most medically relevant for the tropical areas and can cause acute kidney injury.

Dengue

Dengue is a mosquito-borne infectious disease caused by small (50 nm) single-stranded RNA arboviral viruses, from the Flaviviridae family. There are four closely related, yet antigenically distinct, serotypes of dengue virus: DVN1, DNV2, DNV3, and DNV4. Infection by one serotype does not confer lasting immunity to the others.[1–5]

The main vector for dengue infection is the female of the Aedes aegypti mosquito. They stay in or around houses where they emerge as adults and usually acquire the virus while feeding on the blood of infected individuals. The male mosquito does not transmit the disease because they feed on plant juices. Other species of mosquitoes may also transmit dengue, such as Aedes albopictus, Aedes polynesiensis, and Aedes scutellaris.[1–5]

In the last 50 years, the world has seen an explosive outbreak of dengue, which is now considered the most important human viral mosquito-borne infection and an extremely significant global health problem. The average number of cases annually reported to the World Health Organization (WHO) jumped from 908 during 1955 to 1959 to 925,896 during 2000 to 2007. In the same time frame, the number of countries reporting dengue has been augmented from less than 10 to more than 60, and in the last 10 years the disease has spread from the rural to the urban setting.[1–5]

Currently, more than 50 million dengue cases are estimated to occur annually. Dengue is considered endemic in more than 100 countries in all WHO regions except Europe and 2.5 billion individuals, representing two-fifths of the entire world population, are at risk of dengue. Dengue affects mainly tropical developing countries, but warmer areas of developed countries, such as the southern parts of the United States, are also affected.[1–7]

Multiple factors have led to this increasing incidence. Growth in international business and tourism travelling; immigration flow from countries where dengue is endemic; the occurrence of climate changes, such as global warming, and increases in the intensity and duration of the rainy season, which facilitates the Aedes aegypti dispersion; the growth of uncontrolled and unplanned urbanization; and the difficulty in effectively eradicating the disease vector will likely maintain and even worsen the dengue global health problem in the future.[5]

Dengue is a flulike illness with a multifaceted clinical picture. It can be asymptomatic, or it can manifest as an undifferentiated fever without symptoms, similar to several other acute febrile diseases. It can also appear as classic dengue fever (DF), a painful but self-limited disease course, or as a life-threatening form, namely dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS).[1–5]

DF is characterized by the high and abrupt onset of fever lasting 2 to 7 days, prostration, severe headaches, retro-ocular pain, diffuse body aches, myalgia, arthralgia, mild hemorrhagic manifestations, a positive tourniquet test, facial flushing, and a diffuse cutaneous erythematous maculopapular rash. Anorexia, nausea, vomiting, biphasic fever, and liver enlargement may occur. A laboratory examination typically reveals leukopenia, and varying degrees of low platelet count. Increased liver enzymes, especially serum aspartate transaminase (AST), are frequently seen.[1–5,8,9]

DHF and DSS are the most severe varieties of dengue disease presentations. The early manifestations of DHF and DSS are similar to DF. In fact, there is controversy if DHF and DSS are single nosologic entities or the ends of a continuum of the same illness. Children, infants, and adult patients with secondary heterotypic infections are at a higher risk of developing DHF/DSS.[1–5]

DHF is defined as a clinical picture with a simultaneous occurrence of high fever, thrombocytopenia ($\leq$100,000/mm^3), severe hemorrhagic phenomena, and evidence of increased vascular permeability. This includes hemoconcentration (increased hematocrit), hypoalbuminemia, pleural effusion, and ascites. Depending on the amount and the rate of fluid leaving the intravascular space, the patient may develop hemodynamic instability, tachycardia, signs of poor capillary perfusion, and finally, hypotension and shock, thus characterizing DSS. If this picture is not quickly and efficiently reverted, the patient frequently experiences multiple organ failure and massive bleeding.[1–5] Whereas mortality rate in DF is less than 1%, it rises to approximately 12% in DHF and to up to 40% in DSS.[10]

The rapidly changing pattern of dengue epidemiology exposed the idea that the classification of dengue in DF, DHF, and DSS was frequently inadequate for use in the clinical setting.[11] Furthermore, an increased number of life-threatening cases of dengue that did not strictly adhere to DHF criteria have been observed.[11] Therefore, although the classification of DF, DHF, and DSS continues to be widely used, the WHO has suggested a new one, dividing the dengue spectrum into nonsevere dengue (without or with warning signs), corresponding to DF and severe dengue, that will include and expand the concept of DHF and DSS.[5] Severe dengue was defined by the WHO as the presence of one or more of the following:

1. Plasma leakage that may lead to shock (dengue shock) and/or fluid accumulation, with or without respiratory distress.
2. Severe bleeding.
3. Severe organ impairment, even in the absence of plasma leakage or shock (liver, kidneys, central nervous system, heart).

This new classification is strongly based on patient behavior during the three pathophysiologic phases of the disease. The first one is the febrile phase, when viremia occurs, and it is similar between nonsevere and severe dengue forms. It comprises the clinical and laboratory picture already described for DF. The second is the critical phase, when after 3 to 7 days of high fever, the temperature decreases or normalizes. At this point variable degrees of endothelial dysfunction causing increased capillary permeability and plasma leakage will occur. This phase lasts for 1 to 2 days and it is critical in differentiating nonsevere and severe dengue. Some patients have mild and limited increases in capillary permeability and will start to improve and recover. Others have significant and maintained plasma leakage and will progress to severe dengue. These patients usually have warning signals, such as abdominal pain or tenderness, persistent vomiting, body fluid accumulation, mucosal bleeding, lethargy, restlessness, liver enlargement, and their hematocrit increases simultaneously with a rapid platelet count decrease. The third phase, or the recovery phase, begins when the critical phase ends and it is characterized by the halting of plasma leakage and the reabsorption of fluids from the extravascular compartment. The patient's clinical recovery is manifest and laboratory parameters go back to normal. The presence of a petechial rash, with multiple small round islands of unaffected skin ("isles of white"), and generalized pruritus are distinctive findings of this phase.[5]

The diagnosis of dengue should be suspected in individuals with a suggestive clinical picture who live or have visited an endemic area for this illness. Considering the alarming increase in the number of patients infected with dengue viruses, the occurrence of several outbreaks of the disease, the spread of the vector, and the high number of international traveling days, even medical staff working in dengue-free areas must be aware of this diagnostic possibility in febrile patients.[12,13]

Laboratory diagnostic methods for confirming a dengue virus infection include immunoglobulin M (IgM) and IgG antibodies, dengue antigen, virus or viral nucleic acid detection, or a combination of these procedures. After the start of the disease, the virus can be found in corporal fluids and tissues for 4 to 5 days. During the early stages of the disease, it can be isolated and its nucleic acid or antigen can be detected. At the end of the acute phase of dengue infection, when there is no more fever, serology is the method of choice for diagnosis.[14]

The differential diagnosis for dengue, principally in the acute febrile phase, includes other febrile viral diseases (yellow fever, Hantavirus, influenza, Chikungunya virus, O'nyong-nyong virus, acute viral hepatitis, measles, rubella, and enteroviruses), bacterial infections (leptospirosis, typhoid fever, meningococcemia, and bacterial sepsis), rickettsial diseases, malaria, autoimmune diseases, and severe acute hematologic diseases.[1–5,14]

There is no specific treatment for dengue. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided. Early and adequate support, maintaining adequate blood pressure, and intravascular volume repletion are absolutely essential in severe dengue.[1–5,14]

Dengue-Induced Renal Disease

There are no prospective studies specifically designed to assess the effects of dengue infection on renal function and structure, and most of the available information is derived from retrospective data, small case series, and case reports.

Serum creatinine (SCr) elevations, acute kidney injury (AKI), acute tubular necrosis (ATN), hemolytic uremic syndrome (HUS), proteinuria, nephrotic syndrome, and glomerulonephritis have been described in dengue patients.[15–45]

The frequency of AKI reported in dengue range widely, from approximately 1% to 3% to 27% to 35% (Table 37.1).[23,26,32,34,35,37,40,42,44] Most of the series studied DHF/DSS, but AKI has also been reported among DF patients. The use of different definitions of AKI, the diverse ethnic background of infected individuals, and the clinical heterogeneity of the assessed population make it hard to compare the diverse studies. DHF/DSS, obesity (in children), older age, and simultaneous bacterial infection have been pointed to as possible risk factors for AKI development, which consistently carried higher mortality for dengue patients.[35,37]

37.1 Series of Dengue Patients and Frequency of Acute Kidney Injury

Author, year (ref)	Country	Number of Patients	Type of Dengue	AKI (%)
Mendez/Gonzales, 2003 (23)	Colombia	617 children	DHF	1.6
Lee et al., 2005 (26)	Taiwan	88 adults	DHF/DSS	10.2
Wang, 2007 (32)	Taiwan	606 adults	N/A	1.2
Khan, 2008 (34)	Saudi Arabia	91 adults/children	93% DF; 7% DHF	2.2
Kuo, 2008 (35)	Taiwan	273 adults	79.4% DF; 20.6% DHF	27.1
Lee, 2009 (37)	Taiwan	304 adults	DHF	3.3
Laoprasopwattana, 2010 (40)	Thailand	2,893 children	DHF/DSS	0.9
Parkash, 2010 (42)	Pakistan	699 (>14 y)	87% DF; 13% DHF/DSS	2.7
Basu, 2011 (44)	India	28 adults	N/A	35.7

AKI, acute kidney injury; DHF/DSS, dengue hemorrhagic fever/dengue shock syndrome; DF, dengue fever; N/A, not available.

Renal histology data are scarce in AKI patients. One case report found acute tubular necrosis in the renal biopsy of a patient who had DF-associated AKI requiring dialysis.[38] An autopsy of a fatal dengue case disclosed renal cortical hemorrhage of glomerular capillaries and proximal tubules, and a medullar mononuclear infiltrate around the collecting ducts, with hemorrhagic foci, interstitial edema, and vascular congestion.[46] Renal biopsies were performed 11 to 44 days after AKI development in three children who survived an episode of DSS. Two had interstitial nephritis and one only had slight mesangial matrix expansion. Immunofluorescence studies have found traces of C3 with a granular pattern at some vessels in one patient.[40]

Renal replacement therapy has been performed in about 7% to 44% of the patients with dengue-associated AKI, and both peritoneal and extracorporeal blood purification techniques have been used.[40,44,45]

The pathogenesis of renal injury in dengue is not clearly established. Different mechanisms have been proposed, such as systemic hemodynamic instability, shock, rhabdomyolysis, and hemolysis. However, dengue-induced severe rhabdomyolysis and myositis with dark urine and high creatine phosphokinase (CK) levels have been reported without the development of AKI.[25,47–51] Cases of DF-associated AKI without rhabdomyolysis or hemodynamic instability have also been described,[33,38] suggesting a possible direct or cytokine-mediated effect of the dengue virus on kidney function. Supporting this hypothesis, viral particles have been found in the renal tissue from humans and from animals infected with dengue.[46,52–54]

Other renal complications that have been associated with dengue include proteinuria and glomerulonephritis. The prevalence of proteinuria was described to be over 70% in children with DHF[15] and in hospitalized patients during a dengue outbreak in Australia.[19] Moreover, proteinuria in the nephrotic range was described in dengue patients.[19,43,55] Renal histology results confirmed the association between dengue and glomerular injury. Renal biopsies performed in children with DHF and proteinuria, hematuria, or both demonstrated hypertrophy and hyperplasia of mesangial and endothelial cells, monocytelike cells in some glomerular capillary lumens, and focal thickening of the glomerular basement membrane. Glomerular and arteriolar IgG, IgM, or both, and C3 immune complexes were found in biopsies obtained 2 weeks after the onset of symptoms.[16] More recently, transient IgA nephropathy was reported in a biopsy from a 15-year-old patient with DF-associated severe AKI.[39] Experimental studies carried out in mice showed that dengue virus inoculation causes early glomerular structural changes (diffuse glomerular proliferation, glomerular volume enlargement, increased endocapillary and mesangial cellularity), and glomerular IgM deposition.[52,56]

In conclusion, dengue is associated with several different forms of renal injury. The development of AKI in dengue patients is related to unfavorable outcomes. Probably, the renal involvement in dengue is underestimated. Prospective studies assessing kidney function in dengue are deeply necessary.

Yellow Fever

Yellow fever (YF) is a mosquito-borne infectious disease caused by the yellow fever virus, a 40-nm diameter arbovirus, which is considered the prototype for the Flavivirus genus and Flaviviridae family. The name yellow fever originated from the striking jaundice observed in the severe cases of this disease.[10,57–61]

YF originated in Africa and was spread to the American continent and to Europe through commercial routes and the slave trade. Devastating and deadly epidemics occurred throughout the 17th, 18th, and 19th century in North, South, and Central America, and European cities. The development of large-scale public health campaigns aiming at control of the mosquito vector and the development of efficacious vaccines virtually eradicated the disease in North America and Europe, and drastically decreased its incidence in Central and South America and Africa. However, because the natural epidemiology of YF in Africa and the Americas encompass a cycling of the virus between forest mosquitoes and wild nonhuman primate hosts, it is not possible to completely eradicate the disease.[59,60]

The current vectors for YF are blood-eating mosquitoes from the Culicidae family, belonging to the Haemagogus genus in the Americas and to the Aedes genus in Africa. There exist three possible cycles of YF transmission: jungle (sylvatic), intermediate, and urban transmission. In the jungle cycle, the virus is transmitted between nonhuman primates and mosquito species inhabiting the forest canopy. Occasionally, infected sylvatic mosquitos contaminate individuals working or visiting the forest. This cycle occurs in Africa and South and Central America rainforests.[10,57–61] One important difference between the American and African cycles is that although in the American continent the infected monkeys frequently die, in Africa they usually survive without signs of infection.[58] An intermediate cycle is characterized by the YF virus (YFV) transmission to both nonhuman primates and human individuals. It occurs in the humid African savanna bordering the equatorial forests, when Aedes sp. mosquitoes indiscriminately feed on nonhuman primates and humans. The intermediate YF cycle produces small-scale outbreaks in rural villages, which are currently the most usual form of YF epidemics in Africa.[10,57–61] The urban cycle involves the transmission of YFV from human to human by Aedes aegypti domestic mosquitoes in urban areas. It is a major cause of concern because explosive, large-scale outbreaks can occur. It is at this time present in Africa, particularly in Nigeria.[10,57–61] It has not been described in tropical South America since 1942, in Brazil.[58]

YF is nowadays endemic in tropical regions of Africa and South America and in Panama. The existing data on the YF burden are probably inexact due to the underreporting of the disease and the limitation of diagnostic capabilities in many regions where YF is endemic.[59] In South America, the rate of transmission of YF is lower than in Africa, most likely due to the launching of mass vaccination campaigns as a reaction to outbreaks of the disease.[59]

YF currently affects over 200,000 individuals annually in Africa and South and Central America, with approximately 30,000 fatalities. Forty-four countries, 32 in Africa and 12 in South and Central America, are within the YF endemic zone, with almost 900 million people at risk for infection. The recent resurgence of virus circulation, urban reinfestation by the A. aegypti, and the expansion of the YF endemic zones in Africa and South America make for a dramatic potential scenario for the reemergence of explosive epidemics of urban YF.[10,58–62]

YF is a multisystem viral sepsis, which might be asymptomatic or have a clinical spectrum ranging from a nonspecific febrile disease to a severe and fatal hemorrhagic illness associated with shock, liver, kidney, heart, and nervous system injury. YF characteristically evolves through three phases. The first, known as the infection phase, when viremia takes place, starts 2 to 6 days after the virus inoculation and lasts for several days. The symptoms comprise an abrupt onset of high fever, chills, anorexia, nausea, vomiting, irritability, dizziness, mild hemorrhagic phenomena, malaise, tiredness, headache, generalized myalgia, lower back pain, and Faget sign, which is increasing fever with a paradoxical bradycardia. Laboratory abnormalities include low white blood cell count and increased serum transaminases. The second phase, remission, is characterized by a rapid (24 to 48 hours) reduction of fever, the abatement of other symptoms, and the viral clearance from the blood. Approximately 80% of the patients will have a benign course of the disease, recovering at this phase without the development of jaundice. The third and last phase, the intoxication phase, is distinctive as the most severe, hemorrhagic form of the disease and occurs in about 20% of the patients. The high fever returns and the patient presents with epigastralgia, vomiting, and jaundice. Multiorgan failure affecting the liver, the kidneys, and the central nervous system develops. The disease evolves with exuberant hemorrhagic diathesis, characterized by petechiae, ecchymoses, epistaxis, and hematemesis (the characteristic YF "black vomit") due to liver failure, platelet dysfunction, and disseminated intravascular coagulation. Laboratory examination will show intense leukopenia, very high transaminases and bilirubin levels, blood coagulation disorders, increased serum creatinine, and albuminuria. At this phase, the viruses are usually missing in the blood and antibodies will appear. Later shock, confusion, seizure, and coma will develop, presaging death. The lethality rate of YF ranges from 20% to 50%. Infancy, older age, and the development of jaundice and the intoxication phase are associated with an increased severity and lethality of YFV infection.[10,14,57,58,60,61]

YF can be distinguished from the other viral hemorrhagic viruses by the characteristic severity of liver damage and the development of jaundice. The disease can be diagnosed by serology (detection of IgM), virus isolation, immunohistochemistry, and reverse transcription polymerase chain reaction (RT-PCR).[10,14,57,59–61]

Kidney Injury in Yellow Fever

The kidneys are frequently cited as target organs in severe cases of YF,[59,60] but there is very little consistent information about the types, evolution, prevalence, and mechanisms of YF-associated kidney injury in the literature.

Oliguria has been described to occur after 5 to 7 days in severe YF, and even earlier in African patients without jaundice or liver abnormalities.[57,63] Gross pathology of fatal

human YF usually revealed grossly enlarged, congested, and edematous kidneys. Renal histology disclosed acute tubular necrosis.[60]

The mechanisms causing the kidney injury in YF have been poorly studied. Studies performed in rhesus monkeys suggested that prerenal mechanisms predominate until the late phase of the disease, when frank acute tubular necrosis develops.[64–66] In severe YF cases, the presence of microcirculatory failure and tissue ischemia, due to shock and disseminated intravascular coagulation associated with extremely high bilirubin levels, are possible mechanisms for AKI development. The finding of viral antigens in the renal epithelium of three fatal cases of YF and the virus isolation from renal tissue from patients with YF vaccine-induced viscerotropic disease[67,68] suggest a possible direct effect of the YF virus on the kidneys. Consistent with this hypothesis, YF viral antigens were detected in glomeruli 2 to 3 days after experimental inoculation in monkeys,[66] and renal structural changes culminating in renal cell necrosis were observed 24 hours after infection in a murine YF model.[69]

SNAKEBITES AND ACUTE KIDNEY INJURY

The estimated number of existing snake species is 3,000, of which around 19% are considered venomous, belonging to the families Elapidae, Viperidae, Colubridae, Hydrophiidae, and Atractaspididae.[70–72]

Snake venom is highly modified saliva that is injected by specialized fangs to immobilize and digest prey, and for self-defense against predators. Snake venoms contain a multitude of components; 90% to 95% of its net weight is composed of proteins, which are responsible for the venom's toxic and lethal effects. The nonproteic fraction, which is responsible for nonlethal biological effects, contains carbohydrates, lipids, metals, biogenic amines, free amino acids, and nucleotides. The venom composition can differ among the same species of snakes, depending on the geographic area and food accessibility, and even in the same animal, depending on its age.[70,73]

The vast majority of venomous snakebites affect previously healthy, young male farmers and agricultural workers in the rural areas of poor health resourced tropical countries. Accordingly, venomous snakebite is in fact considered an occupational hazard in the tropical areas of the developing world, leading to significant mortality and disability in the young rural active labor force of these countries. Children are also frequent victims of snakebite accidents.[70,71,73–77] The most often affected anatomic sites are feet, legs, ankles, and hands.[78] Consequently, many survivors will be afflicted by permanent disability caused by the necrotic effects of the venom on the tissue.

The exact global burden of venomous snakebite incidences and its related morbidity and mortality is elusive. The limited information available comes mainly from data obtained from the hospital records or from published epidemiologic studies.[79,80] This methodology clearly underestimates the real problem because most victims do not have access to medical facilities and, consequently, the accidents and the complications are not recorded.[70,71,76,81,82] The more recent publication, which combined the literature and was analyzed with the WHO mortality data, reported an approximate annual global burden of 1,200,000 to 5,500,000 snakebites with 421,000 to 2,650,000 envenomations and 20,000 to 94,000 deaths (Table 37.2).[81] The highest burden exists in South and Southeast Asia, in sub-Saharan Africa, and in Central and Latin America.[70,71,80–82] South Asia, and particularly India, have the highest incidence and mortality rates from snakebites worldwide.[70,83,84] Recently, a clear negative association between snakebite mortality and government spending on health was demonstrated, confirming the existence of a strong association between snakebite-induced mortality and poverty. The same authors pointed out that venomous snakebites have higher mortality rates in the tropics than do some of the world's recognized neglected tropical diseases (NTDs), such as schistosomiasis and leishmaniasis.[76]

37.2 Global Estimates of Annual Snakebite Morbidity and Mortality

	Swaroop & Grab, 1954[79]	Chippaux, 1998[80]	Kasturiratne, 2008[81]
Assessed population	$1{,}122 \times 10^6$	$5{,}840 \times 10^6$	169 countries
Snakebites	500,000	5,400,000	1,200,000–5,500,000
Envenomation	NR	2,682,500	421,000–2,650,000
Deaths	30,000–40,000	123,345	20,000–94,000

NR, not reported.

At this time, the only treatment with confirmed efficacy against snakebite envenoming is the early administration of the specific antivenom in a correct dosage and by an adequate route, which is preferentially intravenous.[82]

Snake venom may cause several clinically relevant kidney disorders, such as AKI,[73,74,85–111] proteinuria and/or hematuria,[112–114] nephrotic syndrome,[115] and hemolytic-uremic syndrome (Table 37.3).[116–119] Histopathologic descriptions of the effects of snake venom on renal structures are relatively limited, but the occurrence of acute tubular necrosis,[120–125] acute cortical necrosis,[85,124,125,126–133] acute interstitial nephritis,[134–136] papillary necrosis,[137] necrotizing vasculitis,[138] and glomerular injury[123,124,139–148] have been described (Table 37.3).

AKI is considered one of the main toxic effects induced by snake venom in humans, and has been pointed out as the main cause of mortality in individuals who survived the first impact of the venom.[73,74,87,96,102]

The reported frequency of AKI after a venomous snakebite varies widely from approximately 1% to 40%. The majority of cases have been reported in Asia, Latin America, and Africa. Many factors can affect this percentage, such as the snake species, the size and age of the snake, the amount of venom inoculated, the geographic area, the severity of the accident, the time for antivenom treatment, among others. Moreover, many different definitions of AKI and methods for evaluating renal function were used in the published studies, making it difficult to compare results.[72–74,89–92,95,98–103,107,108,111,149–153] Finally, very few studies were prospective and were specifically designed to evaluate the snake venom-induced kidney injury.[102,107]

37.3 Clinical and Histopathologic Presentations of Snakebite-Induced Kidney Injury

Clinical	Histopathologic
Acute kidney injury	Acute tubular necrosis
Proteinuria	Cortical necrosis
Hematuria	Acute interstitial nephritis
Hemolytic-uremic syndrome	Papillary necrosis
Nephrotic syndrome	Necrotizing vasculitis
	Glomerular injury ■ Mesangial proliferation ■ Diffuse proliferative glomerulonephritis ■ Membranoproliferative glomerulonephritis

A delay in receiving the appropriate antivenom treatment, residing in a rural area, the creatine phosphokinase (CK) levels at admission, myalgia, neurotoxic facies, younger age (children), and advanced age have been associated with an increased risk of developing AKI after a snakebite.[74,90,94,100,102,105,108,154]

The etiology of the kidney injury after a venomous snakebite has been attributed to a venom-induced development of hemodynamic instability or shock, renal vasoconstriction, deposition of fibrin thrombi in microcirculation due to coagulation system activation, systemic rhabdomyolysis, hemolysis, cytotoxicity, oxidative stress, platelet activating factor, renal infiltration by venom-activated macrophages, direct venom nephrotoxicity, and hypersensitivity to the venomous or antivenomous proteins.[72,73,86,88,90,93,102,111,120,140,141,143,149,153,155–174]

Snake-bite induced AKIs have been described after accidents with practically all snakes with medical relevance, especially from the snakes of the Elapidae, Viperidae, and Colubridae families.[72,73,103,107,108,110,111,124,133,148–154] However, a careful review of the medical literature reveals that three snakes are responsible for the large majority of venomous snakebite-induced AKI. They are Russell's vipers (Daboia russelii) in Asia, the South American rattlesnake (Crotalus durissus) in South America, and members of the genera Bothrops in Central and in South America (Table 37.4).[72–74,85–105,107–112,121,123–127,129–132,148–155,161,175]

Russell's Viper (Daboia Russelii)

The Russell's viper (Daboia russelii) is a nocturnally active venomous snake with an average length of 1.2 m from the Viperidae family and the Viperinae subfamily. It is usually found in grassy and bushy areas, forested plantations, and farmland, such as paddy fields used for growing rice. Because this snake feeds mainly on rodents, which are frequently found around humans, it is attracted to the rural settlements and to highly populated areas. When threatened, Russell's vipers become very aggressive and can attack in a very fast and unpredictable way. Humans are bitten on the footpaths and roads at dusk and in the early night hours, or during the day in the paddy fields.[101] There are two peaks of accidents during the year, which correspond to the times of agricultural harvesting and cultivation.[101]

Russell's vipers are widely and equally distributed throughout South Asia, where they account for most of the snakebite incidents and deaths. In fact, it is the principal cause of lethal snakebites in India, Pakistan, Sri Lanka, Bangladesh, Burma, Thailand, and in parts of Indonesia.[72,83,176]

The principal toxic components of the Russell's viper's venom are the phospholipase A_2 (70% of the protein content), the coagulation factor V and X activators, a protease inhibitor, and the hemorrhagins.[176,177] The clinical and laboratory picture of the envenoming includes swelling at the bite site (and more rarely, local necrosis), coagulopathy (which may manifest as abnormal laboratory parameters, bleeding diathesis, systemic thrombosis), thrombocytopenia, hemolysis,

37.4 A Summary of Some Characteristics of the Principal Snakes Causing Acute Kidney Injury Worldwide

Name	**Russell's Viper** (Daboia russelii)	Bothrops **Genus**	**South American Rattlesnake** (Crotalus durissus)
Scientific classification	Family Viperidae Subfamily Viperinae	Family Viperidae Subfamily Crotalinae	Family Viperidae Subfamily Crotalinae
Geographic distribution	South Asia	Southern Mexico, some Caribbean islands, Central and South America	South America, few Caribbean islands
Average size	1.2 m	50 cm to 2 m (depending on species)	1 m
Habitat	Grassy, bush areas Forested plantations Farmland (paddy fields)	Humid environments Tropical forests Grassland Plantations	Semi-arid grassy areas, such as savannas and the Caatinga
Behavior	Aggressive; fast and unpredictable attack	Very aggressive	Less aggressive
Clinical picture	Bite site swelling Nephrotoxicity Coagulopathy (bleeding) Hypotension, shock Hemolysis Neurotoxicity Rhabdomyolysis Thrombocytopenia[a]	Bite site edema, blisters, ecchymoses, tissue necrosis Nephrotoxicity Coagulopathy (bleeding) Hypotension, shock[b]	Mild or absent bite site injury Nephrotoxicity Neurotoxicity Rhabdomyolysis Coagulopathy (rarely bleeding)
AKI etiopathogenesis	Direct nephrotoxicity Glomeruli microthrombi Hemoglobinuria Hypotension Renal vasoconstriction Myoglobinuria	Direct nephrotoxicity Glomeruli microthrombi Hemoglobinuria Hypotension Renal vasoconstriction Platelet activating factor Oxidative stress Cytotoxicity	Direct nephrotoxicity Renal vasoconstriction Myoglobinuria Oxidative stress Activated macrophage
Histopathologic pattern	ATN, CN, AIN, PN, glomerular injury, vasculitis	ATN, CN, glomerular injury	ATN
AKI prevalence	8%–86.3%	1.6%–38.5%	10%–29%

[a]It may differ among different geographic areas.
[b]It may differ between young and older snakes.
AKI, acute kidney injury; ATN, acute tubular necrosis; CN, cortical necrosis; AIN, acute interstitial nephritis; PN, papillary necrosis.

neurotoxicity, nephrotoxicity, rhabdomyolysis, and hemodynamic instability.[72,93,101,105,110,112,155,161,176–180] These clinical manifestations differ among the different geographical areas. For instance, in Sri Lanka, the venom is very neurotoxic, which is not true for the venom in India and Burma. Likewise, it causes rhabdomyolysis in Sri Lanka and South India, but not in Burma and Thailand.[101,176,177,179]

AKI is a universal, usual, and severe complication after a Russell's viper snakebite.[173] The reported frequency of nephrotoxicity and AKI ranges respectively from 18% to 41.7%,[101,112] and from 8% to 86.3% in a small series of 22 patients from Sri Lanka.[101,110,112,177–180] It occurs early after the bite (within hours), the AKI is frequently oliguric and may require renal replacement therapy, and the most frequently used modality in the reported series is peritoneal dialysis.[93,101,105,112,178,179] Increased urinary N-acetyl-β-D-glucosaminidase (NAG), seen 2 hours after the bite, was highly predictive of AKI development.[158] The described histopathologic patterns in Russell's viper–induced AKI comprise ATN,[123,124] cortical necrosis,[124,129,130] glomerular injury,[123,124,145] acute interstitial nephritis,[134,135] and vasculitis.[138] The early administration of the antivenom was associated with a decreased frequency of AKI.[105,108] The mechanisms possibly related to the development of AKI are venom direct nephrotoxicity, venom-induced renal vasoconstriction, hypotension, hemoglobinuria, myoglobinuria, and microthrombi deposition in the glomeruli.[72,93,101,111,112,137,150,153,155–159,161,162,173,176–182]

Bothrops **Genus Snakes (Lanceheads)**

Bothrops snakes belong to the Viperidae family and the Crotalinae subfamily. The Bothrops genus encompasses more than 30 species, with the most medically relevant being B. asper, B. atrox, B. erythromelas, B. neuwiedi, B. moojeni, B. jararaca, B. jararacussu, and B. alternates.[73,149,183]

Bothrops snakes mainly have crepuscular and nocturnal habits, when they prey on small mammals. Its size varies widely, from 50 cm to 2 m, depending on the observed species. They favor humid environments, such as the tropical forests, but can also live in the grassland regions or on plantations. They can be found in the rural areas and in the rural/urban fringes of large cities, in places with high rodent concentrations, such as in silos and wood deposits. Bothrops snakes have an extremely aggressive defensive behavior when they feel threatened. A higher frequency of accidents occurs in the rainy season and at times of the year when soil preparation, planting, or harvesting occurs.[73,149,183,184]

The Bothrops species are widely distributed in the American continent, from Southern Mexico, Central America (all countries), some Caribbean islands, through South America (all countries except Chile). Members of this genus account for the greater part of venomous snakebites in Central and South America (approximately 90% of bites), particularly the B. asper, B. atrox, and B. jararaca species.[73,149,183]

The venom composition, effects, and the envenoming clinical picture are similar among the different Bothrops species. The venom is proteolytic, anticoagulant, hemorrhagic, and nephrotoxic.[73,149,183,184] The clinical picture after a Bothrops snakebite is characterized by the rapid onset of pain and edema at the bite site. Ecchymoses, blisters, and local bleeding may occur. The local injury can evolve to severe tissue necrosis, resulting in relevant disability. The most important systemic manifestations are the development of hemorrhagic phenomena due to blood incoagulability, hypotension, shock, and AKI.[73,92,95,97–99,125,149,183,184,185] The venom composition and the clinical picture might differ in the same species, according to the snake's age and the geographic area. For instance, young B. jararaca venom is more procoagulant and less necrotic than the venom from the adults of the same species.[73,149,183,184]

AKI is the most severe complication of bothropic envenomation and it is the principal cause of death in patients who survived the initial effects of the venom.[96] The reported frequency (all the studies are retrospective) of Bothrops venom–induced AKI ranges from 1.6% to 38.5%.[149] The risk factors possibly related to the development of AKI include older patient age,[92,185] the snake species and size, the quantity of venom injected, and the time to receive specific antivenom in an adequate way.[65,149,170] In fact, a study of B. asper snakebites in Colombia found that a time interval of 2 hours between the bite and the administration of antivenom was associated with AKI development.[65] Confirming this clinical observation, the Bothrops venom–induced renal proximal tubule injury was blocked only when the antivenom and the venom were administered simultaneously.[170]

AKI may develop within hours to a few days after a Bothrops snakebite. It is frequently oliguric and severe, with 33% to 75% of the cases requiring the use of renal replacement theraphy (RRT). The mortality rate of Bothrops venom–induced AKI has been reported to range from 13% to 19%.[85,87,99,149] This mortality is very significant when we realize that most of the patients are previously healthy, young, working individuals.

The renal structural injuries caused by Bothrops venom are acute tubular necrosis,[120,125,143,186,187] cortical necrosis,[85,127,131] and glomerular changes.[140,141,143] The mechanisms possibly related to the Bothrops venom–induced AKI are renal ischemia due to microcirculation and/or glomeruli fibrin deposition, hypotension, renal vasoconstriction, platelet activating factor release, oxidative stress, cytotoxicity, venom direct tubular toxicity, and hemoglobinuria.[73,120,149,163,166–168,170,172,188,189]

South American Rattlesnake (Crotalus durissus)

The South American rattlesnake belongs to the Viperidae family, the Crotalinae subfamily, and the Crotalus genus. C. durissus terrificus and C. durissus collilineatus are the C. durissus subspecies with the higher medical relevance.[71,149] The South American rattlesnake average size is around 1 m, but it may reach 1.8 m in length. Its most remarkable characteristic is the existence of a rattle at the tail end, used to avert and to turn away predators. C. durissus snakes are not as aggressive

as Russell's viper and Bothrops snakes; they try to avoid humans and only attack if threatened. In Brazil they are responsible for approximately 10% of venomous snakebites.[92,149,190] Like the other venomous snakes studied in this chapter, accidents are more frequent in times of the year corresponding to agricultural harvesting and cultivation.[91] They habitually live in semiarid grassy areas, such as savannas and the Caatinga region in Brazil; have vespertine and crepuscular habits; and feed on small animals, such as rodents and birds. C. durissus can be found in all South America countries (except Ecuador and Chile) and in a few Caribbean islands.[92,149,190]

The venom of C. durissus contains several toxic peptides, such as crotoxin, crotamine, giroxin, convulxin, and a thrombinlike enzyme.[71,149] Crotoxin, which constitutes more than 50% of the venom protein content, is the major determinant for the neurotoxic, myotoxic, and nephrotoxic actions of the venom.[71,149,165,169,191]

The clinical picture seen after a C. durissus accident is typically characterized by mild or absent injury at the bite site and severe systemic manifestations.[71,89–91,100,102,149] Neurotoxicity is usually manifested by palpebral ptosis, visual disturbances, and facial muscle paralysis, but respiratory muscle impairment and acute respiratory failure have also been described.[71,89–91,96,100,102,149] The venom myotoxicity causes diffuse rhabdomyolysis that results in generalized muscle tenderness, myoglobinemia and myoglobinuria, dark urine, and elevated CK levels.[71,85–91,96,100,102,149] The thrombinlike enzyme disturbs the coagulation system, causing blood incoagulability and afibrinogenemia in approximately half of patients, but bleeding diathesis is a rare event.[71,85,89–91,96,100,102,149,192]

AKI is the most important complication in individuals who survived the first impact of the venom and is considered the main cause of death among these patients.[87,96] It is noteworthy that even considering that Crotalus durissus snakebites are 10 times less prevalent than Bothrops snakebites, the absolute number of AKI cases reported is similar for both snakes.[120,175] The frequency of AKI after Crotalus durissus snakebites ranges from 10% in retrospective studies[90,91,100,149] to 29% in the only prospective study available.[102] In this prospective study, the authors also noted that even patients that did not meet the criteria for AKI (defined as a creatinine clearance $<$60 mL/min/1.73m^2 in the first 72 hours after a snakebite) had a discharge glomerular filtration rate (GFR) significantly higher than the nadir values during hospitalization, indicating that some degree of renal dysfunction occurred in all of the patients. Finally, the same study identified that a time interval longer than 2 hours between the Crotalus durissus bite and the adequate antivenom administration, CK admissions levels over 2,000 UI per liter, and an age $<$12 years were independent risk factors for AKI development.[102]

AKI develops within the first 24 to 48 hours after the accident and may be severe enough to require RRT.[91,102,149] A high fractional excretion of sodium and mild proteinuria were documented in patients developing C. durissus–induced AKI.[102] The histologic lesion found in these patients was acute tubular necrosis.[86,149] The mortality rates reported for AKI after C. durissus envenomation range from 8% to 17%.[26,90,102,149]

Experimental studies and clinical reports indicate that the etiology of C. durissus venom–induced AKI is probably related to rhabdomyolysis, renal vasoconstriction, direct venom nephrotoxicity, activated macrophages, and oxidative stress.[71,86,88,149,165,169,171,174,191–193]

CHAPTER

38 Acute Kidney Injury following Hematopoietic Cell Transplantation and Severe Burns

Justin M. Belcher • Chirag R. Parikh

Acute kidney injury (AKI) occurs, with varying prevalence, across virtually all hospital settings. The most common etiologies of hospital-based AKI—acute tubular necrosis (ATN), contrast induced nephropathy, and prerenal azotemia—are familiar to every practicing nephrologist. However, AKI can also be uniquely associated with specific conditions. Two such situations are following hematopoietic cell transplantation (HCT) and in the setting of severe burns. Care for HCT and burn patients is highly specialized, typically restricted to tertiary care centers, and involves a limited number of patients. Thus, many nephrologists may have limited experience evaluating and managing AKI in these settings. However, although not commonly encountered, HCT and burns are associated with a remarkable incidence of AKI that portends subsequent worse outcomes. Therefore, this chapter explores the epidemiology, pathogenesis, and outcomes of AKI in these unique settings.

BACKGROUND
