PREFACE

The recent advances in many aspects of kidney diseases have mandated a new edition of Schrier's Diseases of the Kidney. As in previous editions, a group of international experts was assembled to present this information in a comprehensive, authoritative, concise, and readily accessible fashion. The chapters have been extensively revised and updated.

Nephrology is a discipline that combines the basic and clinical sciences. Successful integration of this knowledge is the goal of this Ninth Edition. The 11 sections of the two-volume book are actually individual texts that can stand on their own.

The first section presents an overall view of the structural, physiologic, and biochemical aspects of the kidney. This section incorporates the latest developments in cellular and molecular biology, emphasizing the most current information and concepts on cell signaling, receptors, and ion channels. The subsequent 10 sections are disease oriented, with each section beginning with a pathophysiology chapter. The goal of Schrier's Diseases of the Kidney is to publish the most comprehensive material for practicing and academic physicians caring for patients with kidney disease and hypertension. The 11 sections of the book cover 86 chapters and are summarized as follows:

I **Structural and Functional Correlations in the Kidney** includes structural, hemodynamic, hormonal, ion transport, and metabolic functions in eight chapters.

II **Clinical Evaluation** is covered in five chapters on urinalysis, laboratory evaluation, urography, tomography, angiography, with indications and interpretations for renal biopsy.

III **Cystic and Tubular Disorders** in seven chapters covers genetic mechanisms, medullary cystic and sponge disorders, polycystic kidney disease, Alport syndrome, Fabry disease, and nail-patella syndrome, as well as isolated renal tubular disorders.

IV **Infections of the Urinary Tract and the Kidney** are contained in seven chapters, including host-defense mechanisms; urinary bacterial infections, including tuberculosis as well as fungal infections; renal abscesses; and cystitis.

V **Acute Kidney Injury** is described in 11 chapters, including the pathophysiology of renal cell ischemia and nephrotoxic injury, acute tubular necrosis, acute interstitial nephritis, and acute nephrotoxic renal disease.

VI **Hypertension** and its renal manifestations are covered in six chapters, which include pathophysiology, renal vascular, and endocrine-related hypertension as well as hypertension in pregnancy and in diabetes.

VII **Glomerular, Interstitial, and Vascular Renal Diseases** are discussed in 13 chapters, including collagen vascular diseases, chronic interstitial nephritis, primary glomerulonephritides, and vasculitides.

VIII **Systemic Diseases of the Kidney** are covered in eight chapters, including diabetes, hepatorenal syndrome, sickle cell disease, gout, myeloma/amyloidosis, and tropical diseases.

IX **Disorders of Electrolyte, Water, and Acid Base** are covered in nine chapters, including syndrome of inappropriate antidiuretic hormone secretion, central and nephrogenic diabetes insipidus, cardiac failure, cirrhosis, and the nephrotic syndrome.

X **Chronic Kidney Disease,** a section of six chapters, covers pathophysiology, anemia, osteodystrophy, the nervous system, cardiovascular complications, and metabolic and endocrine dysfunctions.

XI **Management of End-Stage Renal Disease** by transplantation, peritoneal dialysis and hemodialysis, including complications, outcomes, and ethical considerations, is discussed in six chapters.

As editors, we have substantial expertise in most of these areas of nephrology and are very pleased with the content of the Ninth Edition. Out of 86 chapters, 44 have new authors. We would like to thank our authoritative and remarkably talented contributing authors, whose dedication to nephrology is unmatched.

CHAPTER 1

Structural–Functional Relationships in the Kidney

Wilhelm Kriz • Astrid Weins • Ruth Ellen Bulger

STRUCTURE–FUNCTION CORRELATIONS ALONG THE RENAL STRUCTURE

The kidney functions as it does, in large part, because of its architecture. In no instance is this more evident than in the urinary concentrating mechanism, where the complex nephron and vascular interrelationships permit the coordinated function of different nephron and vascular elements into countercurrent multiplication and exchange processes. A recent proliferation of detailed structural, biochemical, and functional information has led to an appreciation of other structural–functional relationships that are relevant to solute and water handling by the kidney. Moreover, it has become evident that an understanding of the pathologic developments in kidney diseases is only possible on the basis of a thorough knowledge of kidney structure.

The purpose of this chapter is to review some of the recent findings, with special emphasis on structural–functional relationships, to enhance our understanding of overall renal function; therefore, this chapter is divided into two parts. The first part considers the structural and functional interrelationships of each morphologic segment of the urinary tubule, stressing the unique characteristics of each segment. The second part discusses structure and function in terms of more general mechanisms used by several segments of the renal tubule to accomplish specific functions, such as ion or water transport.

FORM OF THE HUMAN KIDNEY

Human kidneys are paired, bean-shaped organs situated in a retroperitoneal position on the posterior aspect of the abdominal cavity, on either side of the vertebral column against the psoas major muscle. A fibrous capsule located within the perirenal adipose tissue and surrounded by perirenal fascia surrounds each kidney. The lateral border of each kidney is convex. The kidneys of an adult man weigh approximately 120 to 170 g each and measure roughly 11 × 6 × 2.5 cm; those of an adult woman weigh slightly less and are somewhat smaller. In both men and women, total kidney mass best correlates with body surface area.

The concave medial margin has a slitlike aperture, called the renal hilum. Branches of the renal artery, vein, nerves, lymphatics, and the expanded pelvis of the ureter pass through the hilum. The hilum communicates with a flattened space within the kidney called the renal sinus. Within this space, the renal pelvis branches into major and minor calyces.

Sections through the kidney reveal the cortex and medulla (Fig. 1.1). The human kidney is a multilobar organ containing 4 to 18 (average, 8) pyramids of medullary substance[1] and is situated so that their bases are adjacent to the cortex. The darker red cortical substance covers the base of each medullary pyramid like the cap of an acorn. During fetal life, the kidney surface is demarcated by clefts that gradually disappear in the normal adult kidney. The apex of each medullary pyramid (called the papilla) extends into the renal sinus and is capped by a funnel-shaped, minor calyx. The minor calyces receive the urine that is released from the kidney into the extrarenal collecting system. A lobe of the kidney is composed of the conical medullary pyramid and the surrounding cortical substance. During fetal development, some lobes may fuse and calyces are remodeled so that the mature kidney has fewer calyces and papillae than the original number of papilla anlagen[1]; one calyx may drain a fused papilla developed from up to four anlagen, predominantly at the kidney poles. Striated elements called medullary rays extend peripherally at intervals from the bases of the medullary pyramids and penetrate into the cortex. These rays resemble the medulla in structure and although they extend deeply into the cortex, they are part of the cortex. The rest of the cortex is called the cortical labyrinth.

The medulla can be subdivided further either grossly or microscopically (Fig. 1.2). The medulla has an outer zone that is adjacent to the cortex and an inner zone that includes the papilla. The outer zone is subdivided into an inner and outer stripe. This zonation is important because it represents the location and orientation of the various segments of the renal tubules within the kidney.

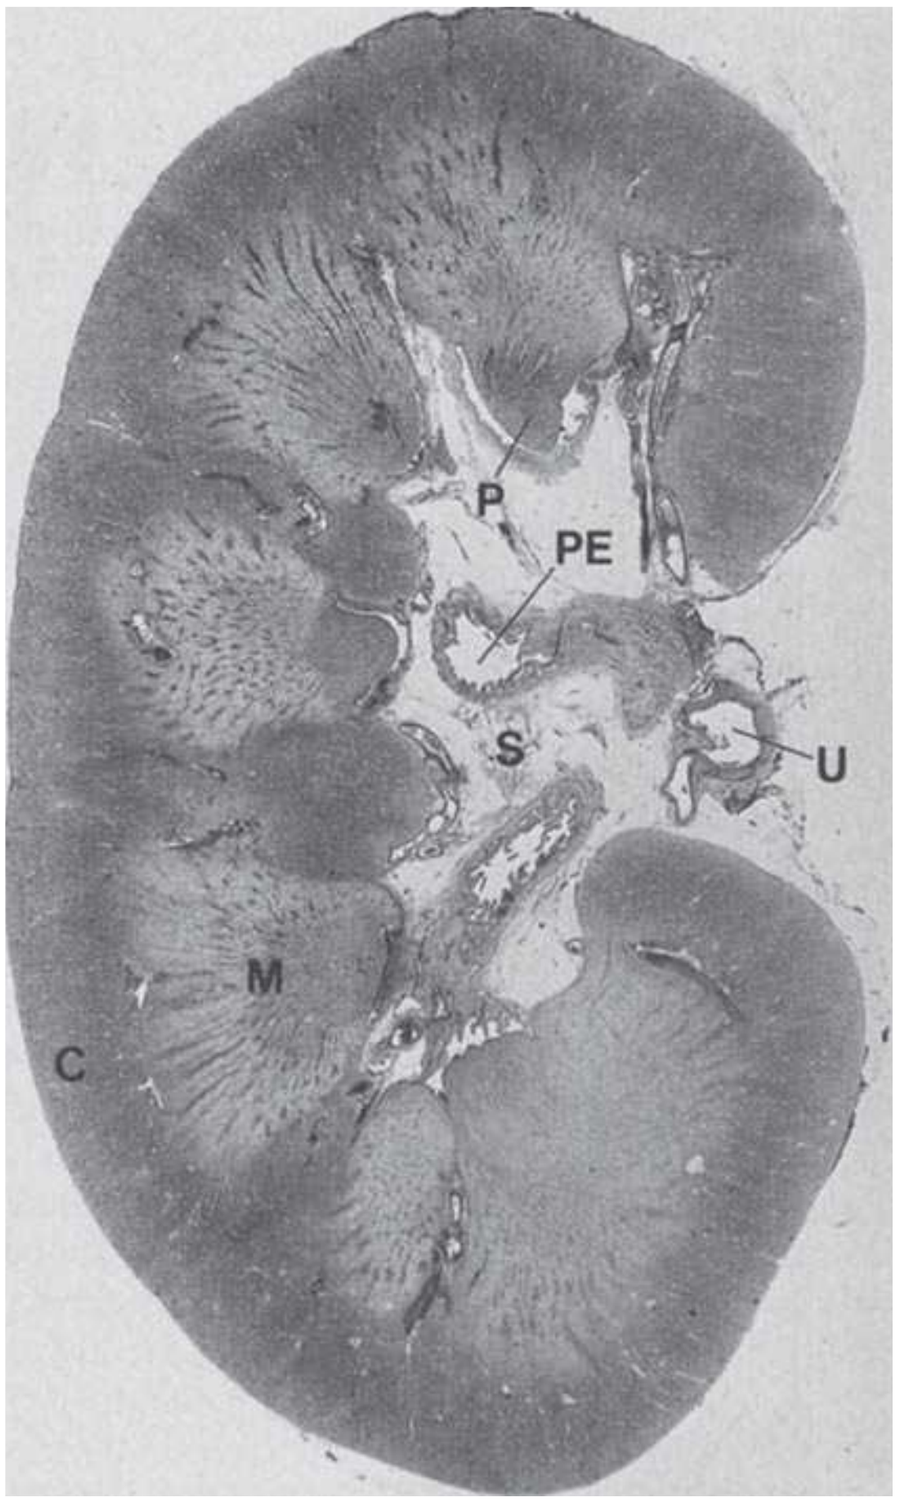

FIGURE 1.1 Gross anatomic appearance of a human kidney. A paraffin section through the whole kidney shows elements of the internal structure: *C*, cortex; *M*, medulla; *P*, papilla projecting into a minor renal calyx; *PE*, pelvis; *S*, sinus; *U*, ureter.

The relative volumes occupied by the cortex, outer medulla, and inner medulla are 70%, 27%, and 3%, respectively,[2] in humans. The relative thicknesses vary considerably among mammalian species.

RENAL (URINIFEROUS) TUBULES

Human renal morphology resulted from a long evolutionary process in which animals adapted to many changing environmental conditions. The three sequential types of kidneys that evolved were the pronephros, mesonephros, and metanephros. The urogenital system of each human embryo repeats this evolutionary process. The pronephros develops first, but degenerates before attaining any functional capacity.

The mesonephric kidney functions for a short period in utero, but it also degenerates, with the notable exception of the part of the mesonephric tubules that form a portion of the excurrent duct system of the male reproductive tract. The metanephric kidney forms last and eventually becomes the functional kidney of the human. The metanephric kidney is well suited to the human condition because of its efficient filtering device and its complex tubule, which allows for the production of not only dilute urine but also concentrated urine. This process occurs only in mammals and birds. Although it is well suited for maintaining homeostasis, the mammalian kidney is an inefficient organ for the elimination of salt and water. In humans, 180 L of fluid are filtered into the tubular lumen every 24 hours, of which approximately 178 L must be returned to the blood.

Each human kidney contains approximately 1 million functional units, called nephrons (with considerable interindividual variation).[3] Each nephron is made up of a renal corpuscle (glomerulus) and a complex tubular portion, which drain into a unifying tubular system called the collecting duct system. Both kinds of tubules represent the renal (or uriniferous) tubules.

The nephrons are derived from the metanephric blastema, the collecting ducts from the urethral bud. A connecting tubule lies between the nephron and collecting ducts. At present, there is controversy as to whether the connecting tubule is derived from the metanephric blastema[4–6] or the ureteric bud.[7] As is discussed in the next section, the connecting tubule has marked morphologic similarities to the cortical collecting duct (CCD).

The segmentation of the renal tubule then includes the following regions.[8]

The Nephron

I. Renal corpuscle (most of which is called glomerulus)
- A. Bowman's capsule
- B. Glomerular tuft

II. Proximal tubule
- A. Convoluted part (pars convoluta) consists of P_1 and the first part of P_2 (PCT)
- B. Straight part (pars recta) consists of the last part of P_2 and all of P_3 (PST)

III. Thin limbs of the loop of Henle (intermediate tubule)
- A. Thin descending part of short-looped nephrons (SDTL)
- B. Upper thin descending part of long-looped nephrons (LDTL up)
- C. Lower thin descending part of long-looped nephrons (LDTL lp)
- D. Ascending thin part of long-looped nephrons (ATL)

IV. Distal tubule
- A. Straight part (pars recta)
  1. Medullary thick ascending limb (MTAL), which includes regions located within the inner stripe and outer stripe of the medulla
  2. Cortical thick ascending limb (CTAL), which includes the part ascending through the cortex, the macula densa (MD), and the post macula densa segment
- B. Convoluted part (pars convoluta) (DCT)

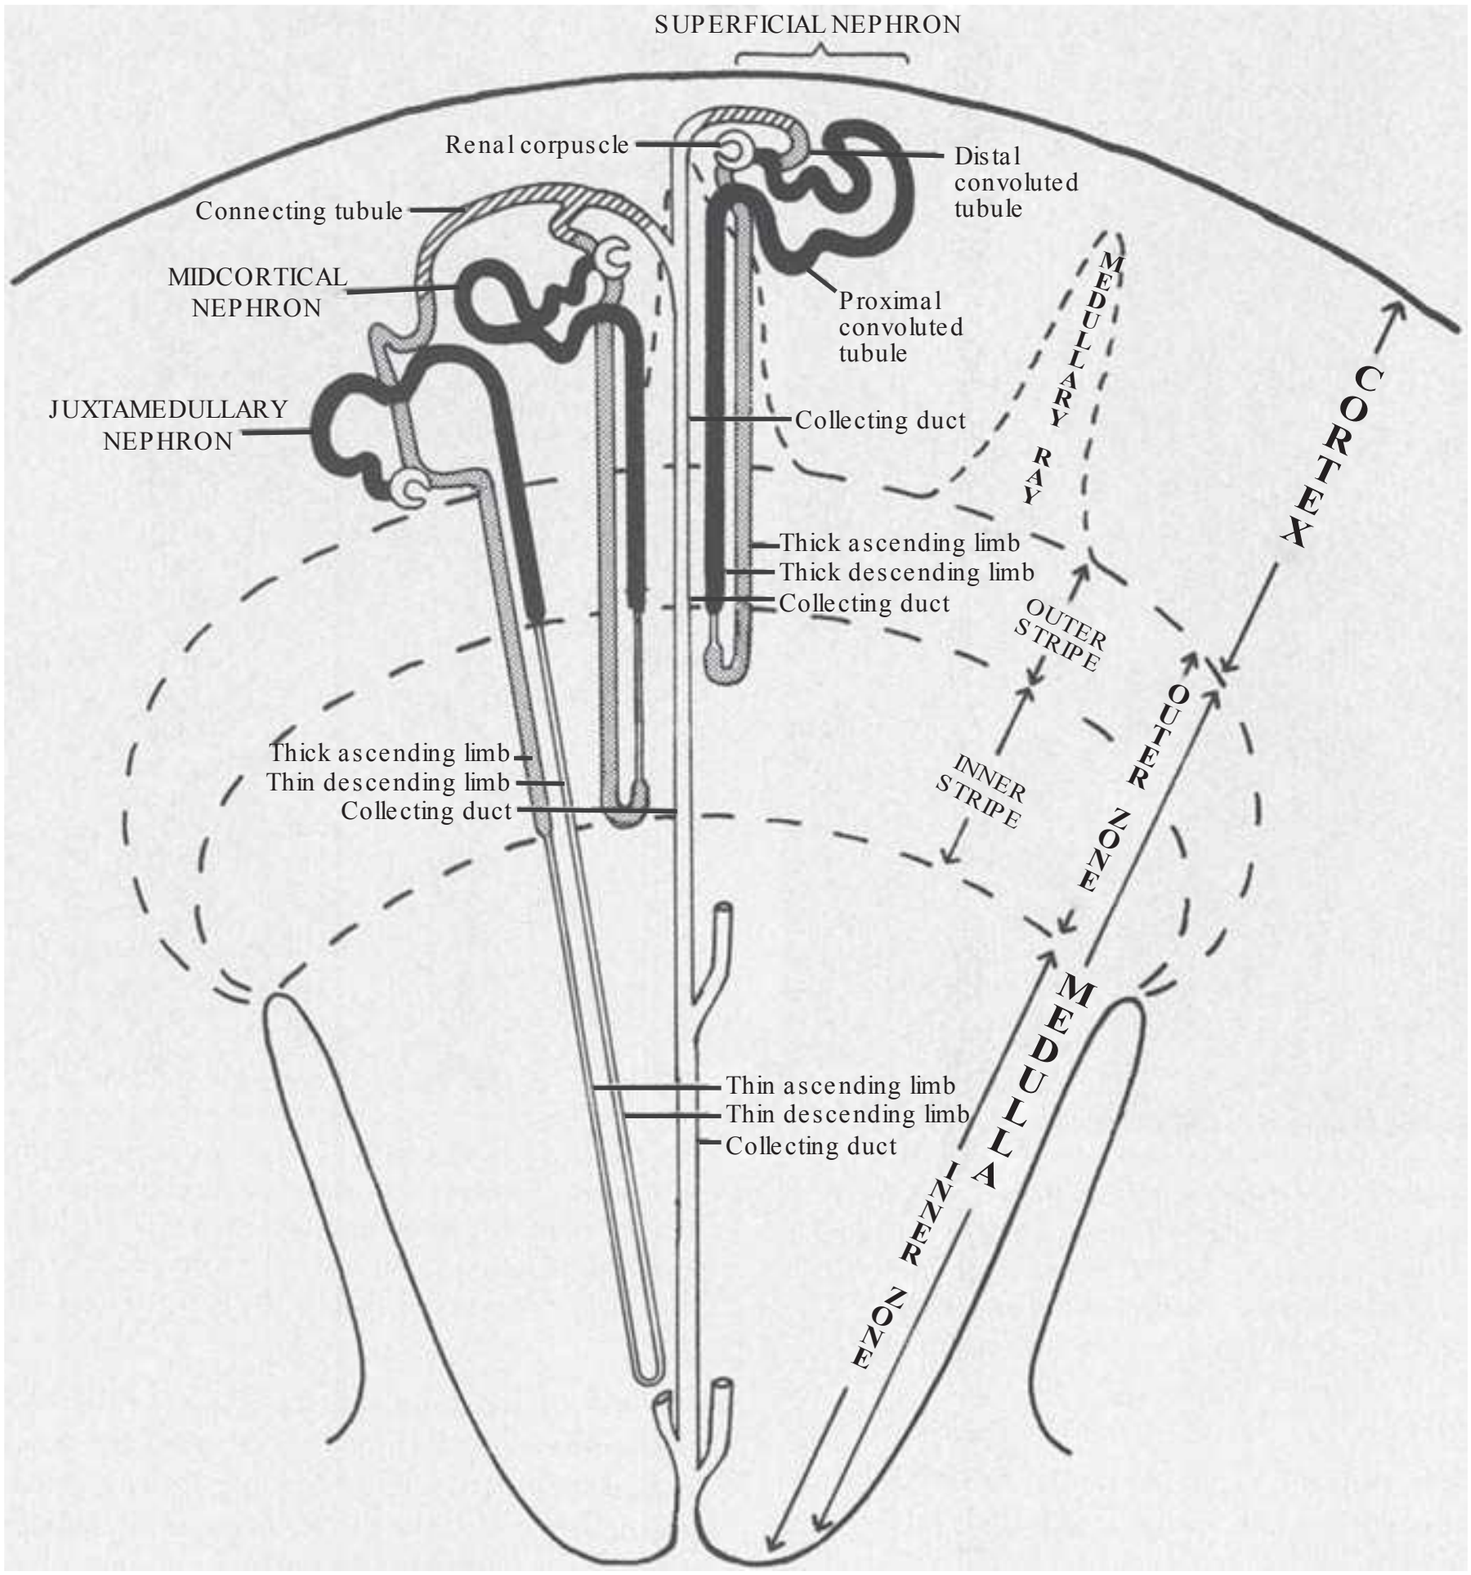

FIGURE 1.2 The relationship of nephron segments to zones of the kidney.

The Collecting Duct System

I. Connecting tubule (CNT)
II. Cortical collecting duct (or tubule) (CCD)
III. Outer medullary-collecting duct (or tubule) (OMCD)
IV. Inner medullary-collecting duct (or tubule) including the papillary collecting ducts (also called the ducts of Bellini; IMCD)

Nephrons lie in characteristic positions (Fig. 1.2), with the renal corpuscles and proximal convoluted segments in the cortex (Figs. 1.3 and 1.4). The straight part of the proximal tubule, the thin limb segments, and the straight part of the distal tubule form the loop of Henle, which enters a medullary ray of the cortex and extends into the medulla, where it bends, returning to the cortex by means of the same medullary ray. The loops of juxtamedullary nephrons directly connect the outer stripe of the medulla without ever being contained in a medullary ray. As the straight part of the distal tubule returns to the cortex, it passes by the renal corpuscle from which the nephron originated, forming the macula densa; then, after a short postmacula densa segment, it continues as the distal convoluted tubule within the cortex.

The morphology of the nephron varies with the position of the renal corpuscle in the cortex. Each nephron is classified as superficial, midcortical, or juxtamedullary, according to the position of its renal corpuscle within the respective regions of the cortex (Fig. 1.2) and the pattern of efferent vessel formation.[9–11] A given segment tends to occupy a specific region of the kidney, which gives rise to the gross zonation referred to in the preceding text. In the human kidney, superficial nephrons empty singly into a terminal collecting duct, whereas several juxtamedullary nephrons empty into an arched tubular portion (arcade) that courses peripherally in the cortex before it turns to enter a medullary ray. Most midcortical nephrons from humans empty individually as well.[5,12] As known from the study of several species (rats and rabbits), an arcade is established by the connecting tubule epithelium (data from studies in humans are not available).

Nephrons also are classified as short or long looped according to the location of the position where their loops of Henle turn within the kidney. Short-looped nephrons arise from renal corpuscles located in superficial and midcortical regions and have loops of Henle that turn within the outer medulla. In humans, some superficial nephrons may have loops within the cortex itself. Short-looped nephrons have

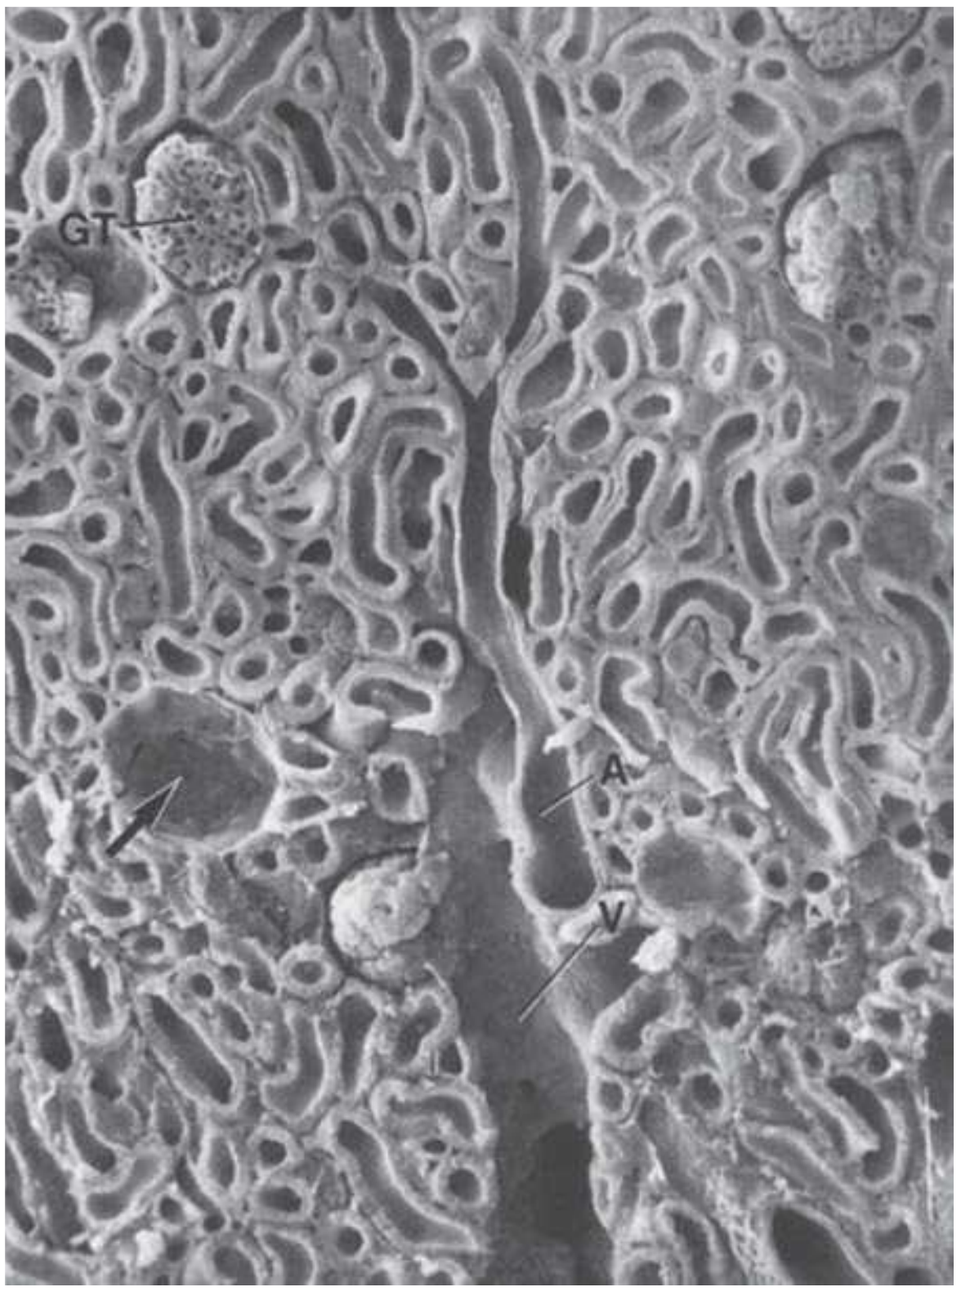

FIGURE 1.3 Scanning electron micrograph of the cortex. Convoluted tubules are shown, along with renal corpuscles, some of which contain a glomerular tuft (*GT*) and some from which the tuft is removed (*arrow*). A cortical radial artery (*A*) and vein (*V*) are also apparent. Note the thin wall of the vein. (Magnification ×140.)

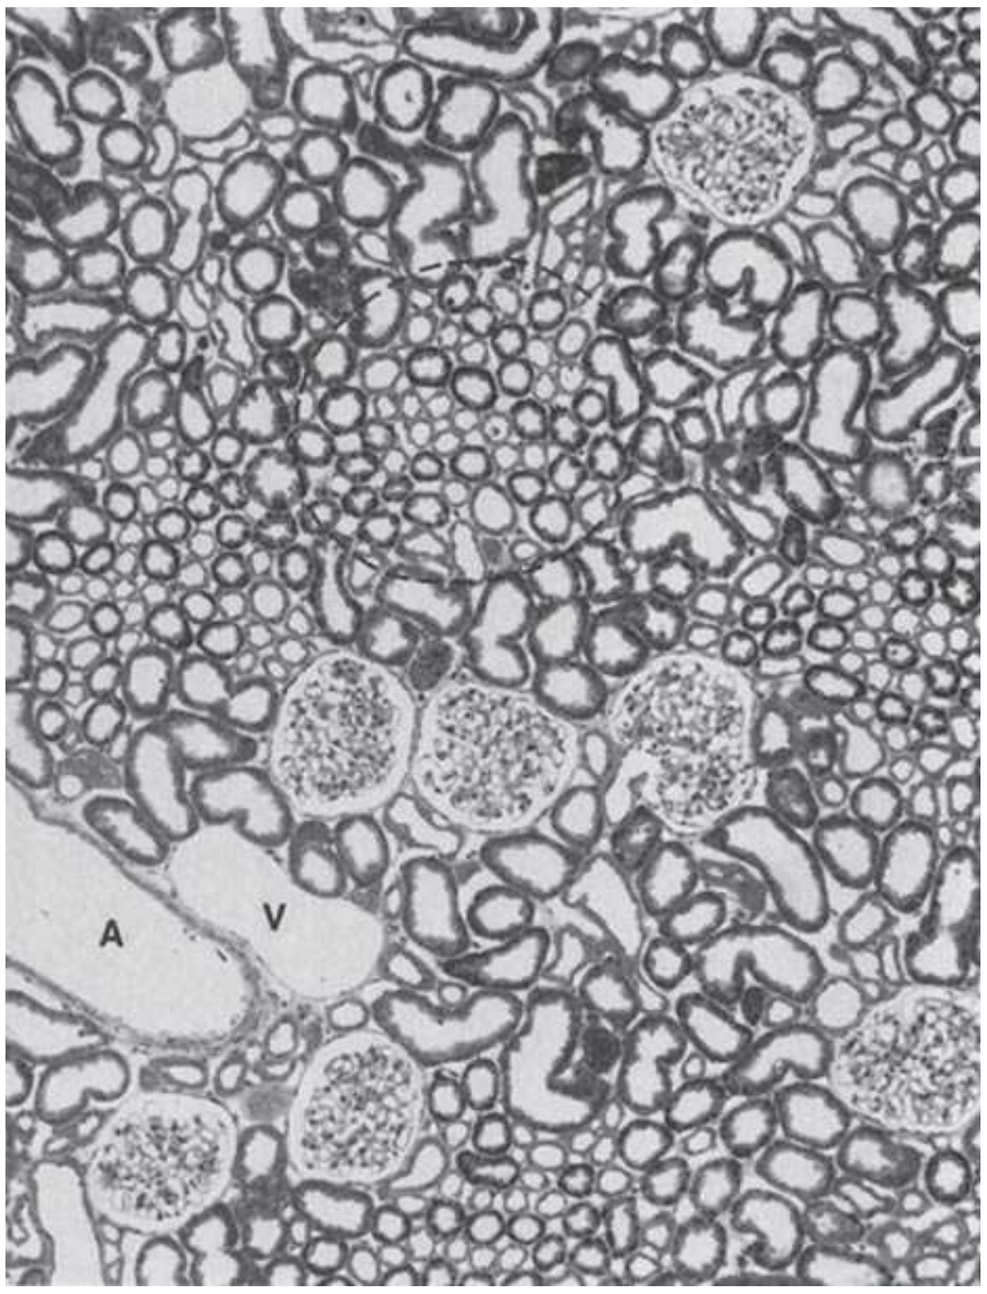

FIGURE 1.4 Light micrograph of renal cortex (rat). Cortical radial vessels (*A*, artery; *V*, vein), glomeruli, and convoluted tubules make up the cortical labyrinth. The straight tubular portions are found in the medullary rays of the cortex (one medullary ray is delineated by the *hatched line*). (Magnification ×80.)

short, thin limb segments that occur only along the descending limb. Long-looped nephrons have loops of Henle that turn within the inner medulla and have thin limb segments in both descending and ascending limbs. Although most species have both long- and short-looped nephrons, some species, such as dogs and cats, have only long ones,[13] whereas other species, such as beavers, have only short ones.[14,15] In human kidneys, the ratio of short- to long-looped nephrons is 6:1 to 7:1.

THE RENAL CORPUSCLE

The renal corpuscle (first segment of the nephron) is the site at which an ultrafiltrate of the blood is produced (Fig. 1.5). The filtrate moves from the capillary lumen into Bowman's space. This flow is influenced by the following factors: renal blood flow; the oncotic and hydrostatic pressures in the capillaries and in Bowman's space; the size, shape, and charge of plasma molecules; and the various morphologic components of the wall separating the capillary lumen from Bowman's space. The filtrate contains only barely detectable quantities of plasma proteins.[16] The filtration barrier increasingly restricts the passage of larger molecules, with very little filtration of molecules larger than albumin (70 kDa).[17]

The renal corpuscle consists of Bowman's capsule and the glomerular tuft. The latter is made up of capillaries, derived from the afferent arteriole, their supporting cells, and an envelope consisting of the glomerular basement membrane (GBM) and the visceral (podocyte) layer of Bowman's capsule (Fig. 1.5). At the vascular pole, the visceral epithelium becomes the parietal epithelium, which then transforms into the proximal tubule epithelium at the urinary pole (Fig. 1.5). The space between both layers is the urinary space (Bowman's space).

The human renal corpuscle is roughly ovoid and approximately 150 to 240 μm in diameter. The term glomerulus is widely used to refer to the entire renal corpuscle. The renal corpuscle without the parietal epithelial cells is referred to as the glomerular tuft. The afferent arteriole enters the renal corpuscle at the vascular pole, where it divides into several primary branches that each ramify to form a network of anastomosing capillaries, called a lobule. The lobule has a supporting region called the mesangium (Figs. 1.6 and 1.7). All lobules together establish the tuft; the converging mesangial regions are called the glomerular stalk, by which the tuft is connected to the extraglomerular mesangium (see Juxtaglomerular Apparatus). The capillaries coalesce toward the center of the capillary tuft to form

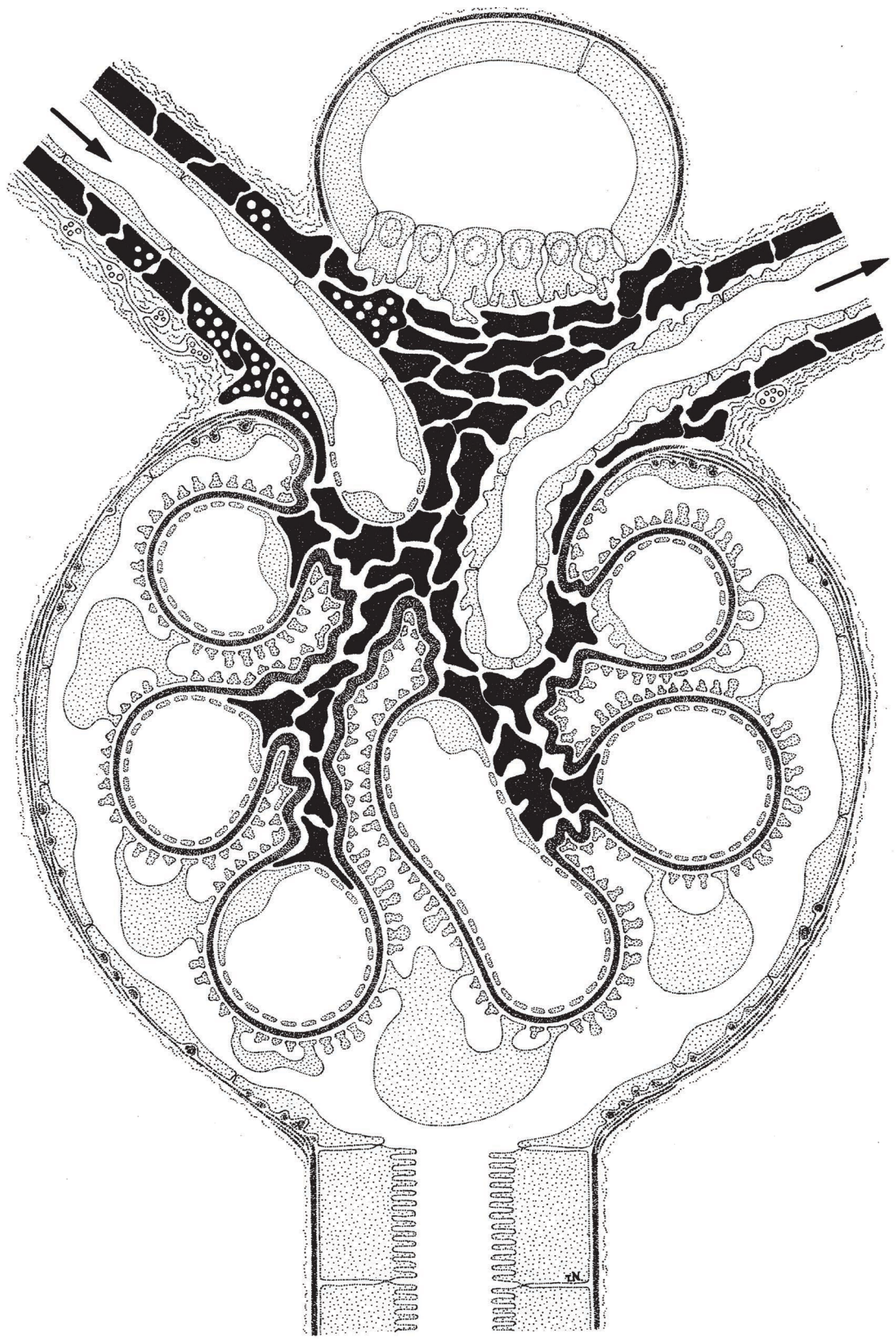

FIGURE 1.5 Schematic of a longitudinal section through a glomerulus and juxtaglomerular apparatus (*JGA*). The direction of blood flow in the glomerular arterioles is indicated by arrows. The capillary network, together with the mesangium, is enclosed in a common compartment bounded by the glomerular basement membrane (*GBM*) (shown in *dark gray*). The outer aspect of the GBM is covered by the glomerular visceral epithelium (podocytes). Note that there is no basement membrane at the interface between the capillary endothelium and the mesangium. At the vascular pole, the visceral epithelium, together with the GBM, is reflected into the parietal epithelium of Bowman's capsule, which, at the urinary pole, passes over into the epithelium of the proximal tubule. The JGA consists of the macula densa of the distal tubule, the extraglomerular mesangium (which is continuous between both arterioles and continues via the glomerular stalk into the intraglomerular mesangium), and the granular cells within the afferent arterioles. All cells that have been suggested to be of smooth muscle origin are shown in black. Note the sympathetic nerve terminals at the afferent arteriole. (From Kriz W, Sakai T, Hosser H. Morphological aspects of glomerular function. In: Davison AM, ed. *Nephrology*, Vol. 1. Proceedings of X International Congress of Nephrology, London, 1987. London: Bailliere Tindall; 1988:3, with permission.)

FIGURE 1.6 Schematic of a cross-section of a glomerular capillary and its relationships to the mesangium. The capillary is made up of a fenestrated epithelium. The peripheral part of the endothelium tubule is surrounded by the glomerular basement membrane (GBM; shown in *dark gray*), which, at mesangial angles (*arrows*), deviates from a pericapillary course and covers the mesangium. The outer aspect of the GBM is covered by the interdigitating pattern of podocyte foot processes. In the center, a mesangial cell is shown; its many processes contain microfilament bundles and extend toward the GBM, to which they are connected. The mesangial matrix contains an interwoven network of microfibrils. (From Venkatachalam MA, Kriz W. Anatomy of the kidney. In: Heptinstall R, ed. *Pathology of the Kidney*, 4th ed. Boston: Little, Brown; 1991, with permission.)

the efferent arteriole, which runs through the stalk and exits from the vascular pole. The efferent arteriole again breaks up to form a second capillary network, which surrounds the tubules and is called the peritubular capillary network.

The renal corpuscle, therefore, consists of the following parts: (a) the parietal epithelium, (b) the visceral epithelium (podocytes), (c) the endothelial cells lining the capillaries, (d) the glomerular basement membrane (GBM), and (e) the intraglomerular mesangial cells and matrix. In the rat, the ratio of the number of endothelial cells to mesangial cells to visceral epithelial cells is 3:2:1.[18]

The Visceral Epithelium of Bowman's Capsule

The visceral epithelial cells (nowadays generally called podocytes) are octopus-shaped cells that reside in Bowman's space and attach to the GBM only by way of their processes (see below). This shape was well described by Zimmermann[19] and is seen to advantage in scanning electron micrographs (SEM) (see later, Fig. 1.10). The exact details of cell shape differ depending

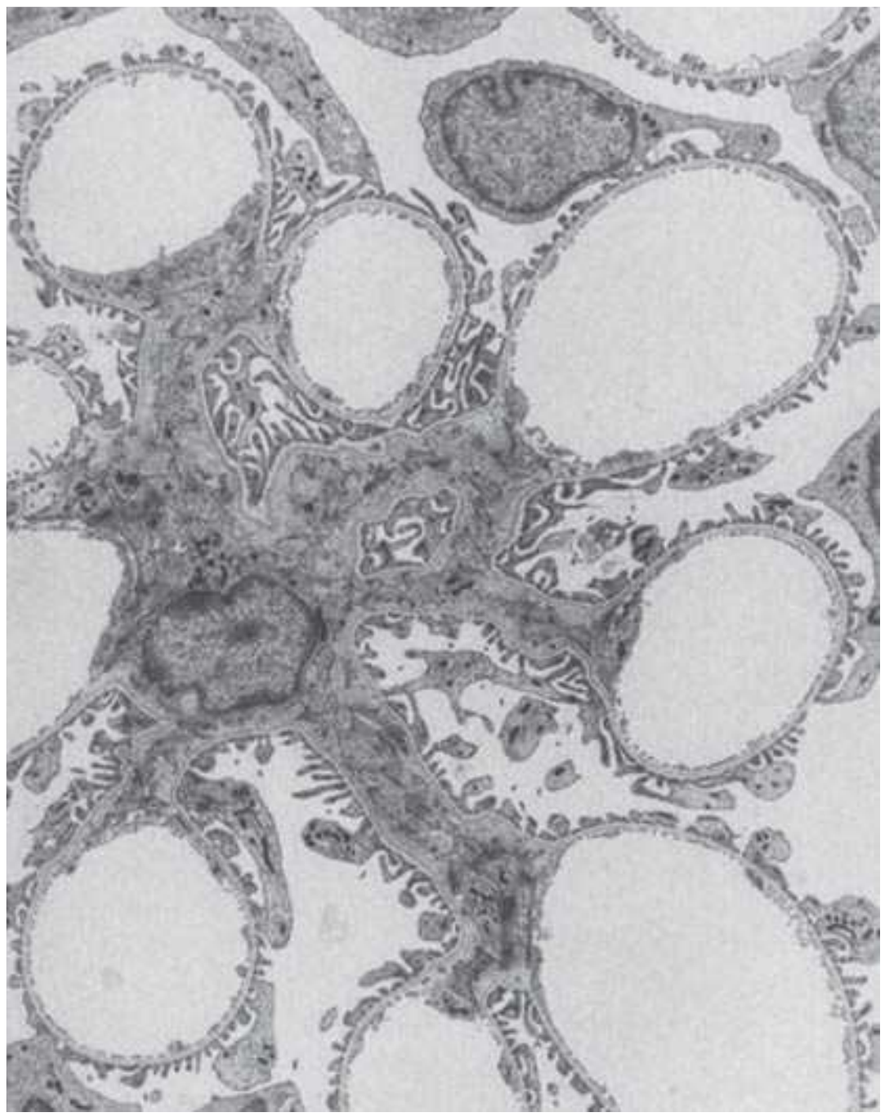

FIGURE 1.7 Transmission electron micrograph of a rat glomerular lobule. Glomerular capillaries and the glomerular mesangium occupy a common compartment enclosed by the glomerular basement membrane (GBM). The mesangial cell body (*in the center*) gives rise to many processes that fill (together with the mesangial matrix) radial arms that extend to the peripherally located capillaries. The outer aspect of the GBM is covered by podocytes. (Magnification ×3,500.)

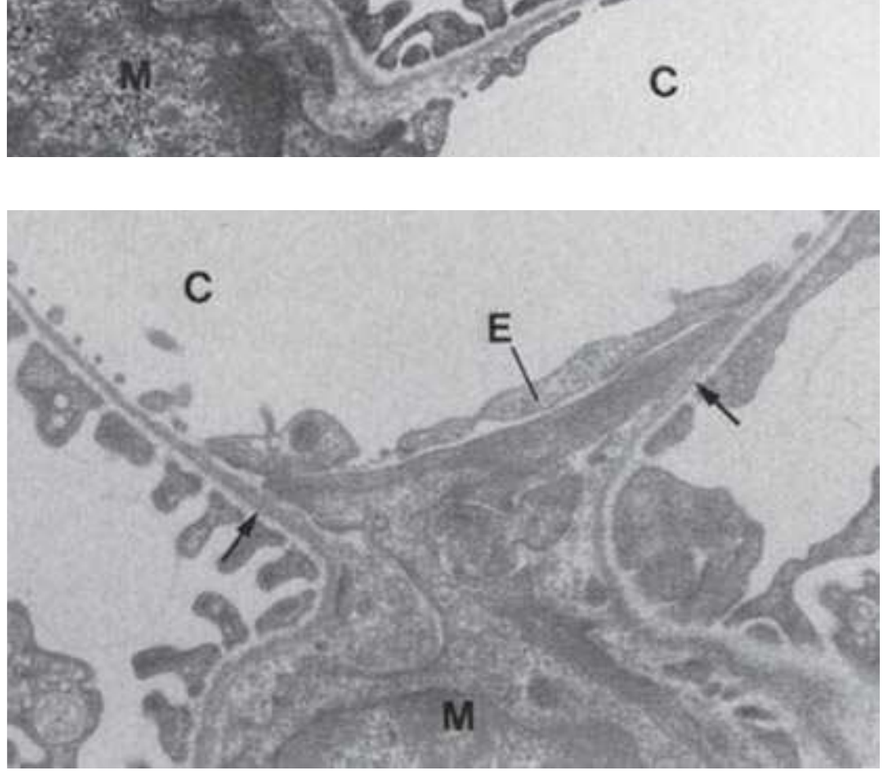
on the species being studied.[20,21] As a consequence of the high degree of differentiation, podocytes, like neurons, are incapable of regenerative cell replication in the adult. Thus, podocytes that were lost, for any reason, cannot be replaced by new ones.[22–24] On the other hand, in glomerular diseases based on dedifferentiation of podocytes (collapsing glomerulopathy), a vivid proliferation of the dedifferentiated cells accompanies the disease.[25]

Recent observations in parietal epithelial cells question this view. First, it has been proposed that a niche of glomerular epithelial stem cells resides within the parietal epithelium at the transition to the proximal tubule.[26,27] It is an intriguing hypothesis that proliferating stem cells from this locus may transform into podocytes and may reach the tuft via the transitions of the epithelia at the glomerular vascular pole. Migration of parietal cells onto the the vascular pole and subsequent transition into podocytes have been shown to occur in the newborn mouse.[28] However, evidence that such a process may be of any relevance in the adult has so far not been presented.[28] Moreover in the adult mouse, it has been shown that proliferating parietal epithelial cells may reach the glomerular tuft via tuft–capsule bridges; there they replace podocytes causing the collapse of the concerned tuft area obviously by bringing the local cross talk between podocytes and the endocapillary compartment to an end.[29]

The cell bodies give rise to large primary processes that may branch another time, finally splitting apart into terminal processes, called foot processes (as seen from SEM pictures, "finger processes" would be a better word) or pedicels (Figs. 1.6, 1.8 to 1.11, and see Fig. 1.13). The foot processes are anchored within the GBM to a depth of about



A

40 to 60 nm. The foot processes interdigitate in a complicated manner with those from adjacent cells to form an elaborate layer of small processes along the glomerular basement membrane. This interdigitation results in the formation of an extensive series of narrow slits between the foot processes, which provide a long extracellular path for filtration of water and solutes (Fig. 1.10). In transmission electron micrographs, these slits are bridged by a layer of extracellular material (4 to 6 nm thick) called the *filtration-slit membrane* (see Figs. 1.9 and 1.13). If tannic acid is added to the fixative solution, a highly ordered isoporous substructure is revealed in en face views of the filtration-slit membrane.[30] Staggered rodlike units project from the podocyte plasmalemma and connect to a central linear bar. These rodlike units delineate rectangular pores 4 × 14 nm within the slit membrane (i.e., which approximate the size of an albumin molecule).

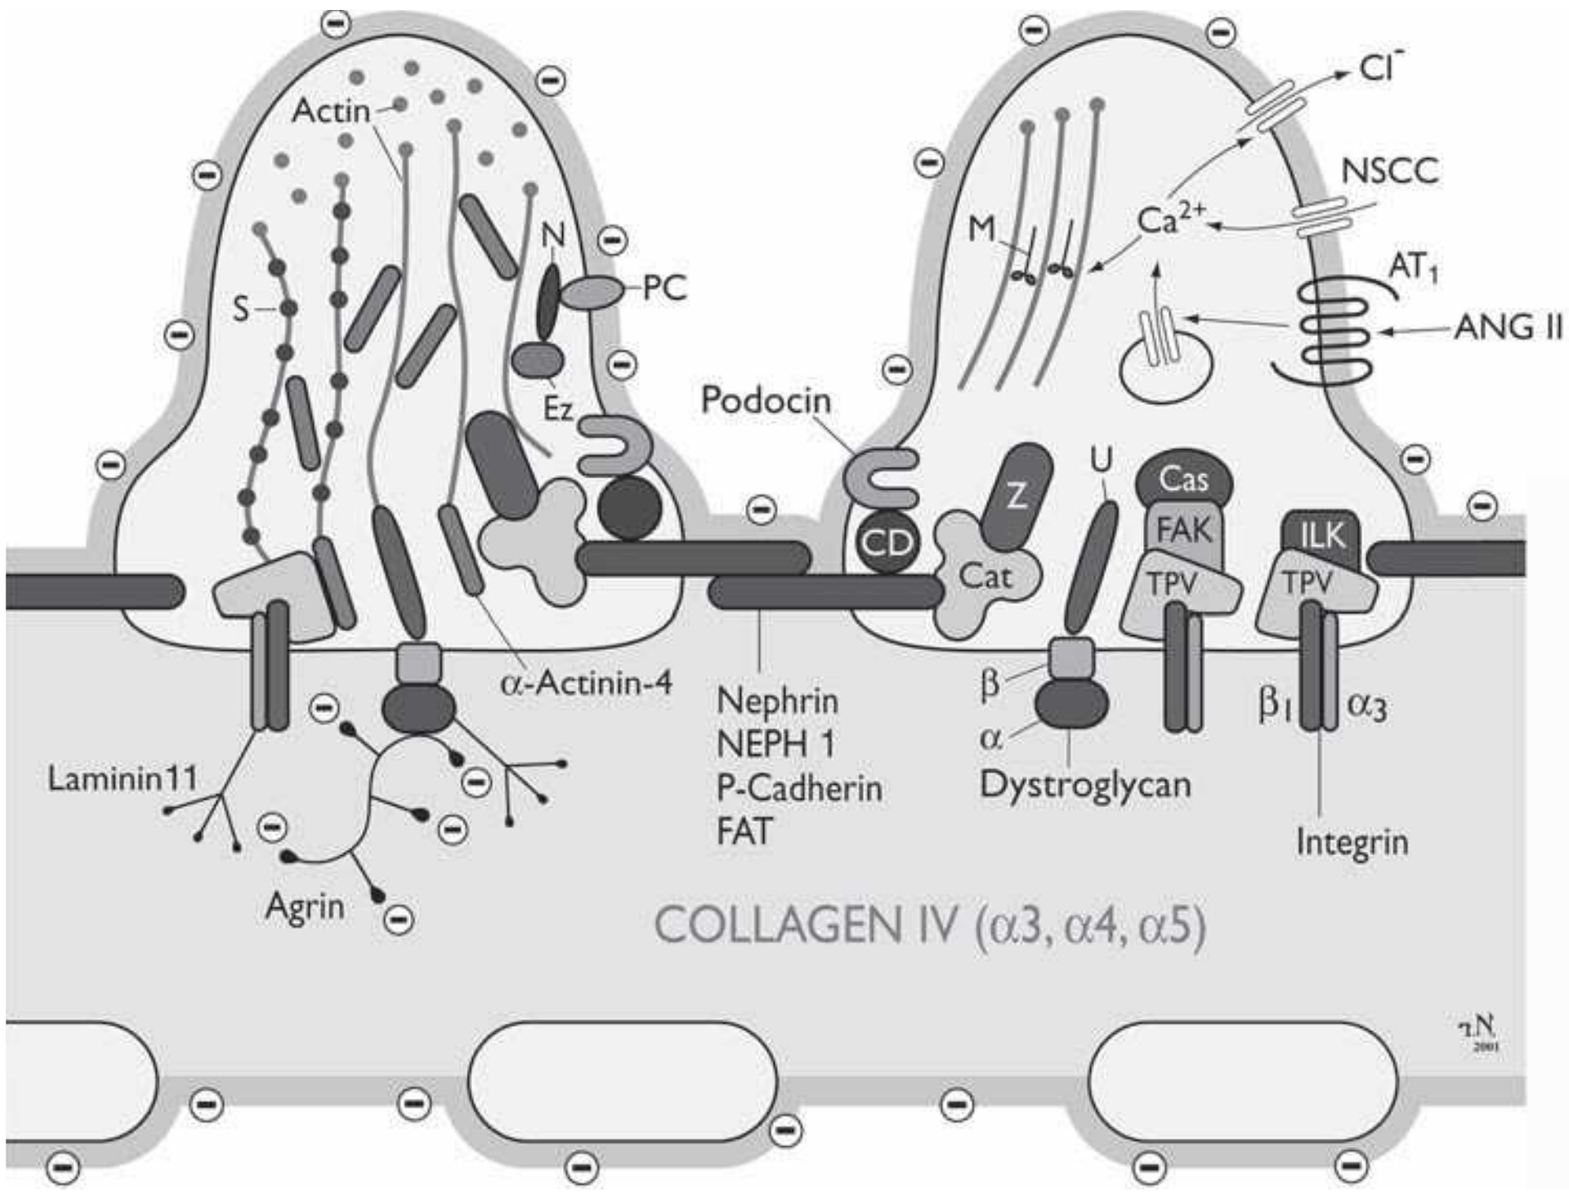

FIGURE 1.11 Schematic drawing of the molecular equipment of podocyte foot processes. *Cas*, p130Cas; *Cat*, catenins; *CD*, CD2-associated protein; *Ez*, ezrin; *FAK*, focal adhesion kinase; *ILK*, integrin-linked kinase; *M*, myosin; *N*, NHERF2; *NSCC*, nonselective cation channel; *PC*, podocalyxin; *S*, synaptopodin; *TPV*, talin-paxilinvinculin; *U*, utrophin; *Z*, ZO-1. See text for further explanations. (From Endlich K, Kriz W, Witzgall R. Update in podocyte biology. *Curr Opin Nephrol Hypertens*. 2001;10:331, with permission.)

Generally, the slit diaphragm is considered as an adherenslike intercellular junction.[31] Intensive research in recent years has uncovered several transmembrane proteins that participate in the formation of the slit membrane (Fig. 1.11)—including P-cadherin,[31] nephrin,[32] Neph1,[33] and FAT.[34] Other molecules, such as ZO1,[35] Podocin,[36] CD2AP,[37] and catenins mediate the connection to the actin cytoskeleton (see below). Nephrin is a member of the immunoglobin superfamily (IgCAM); its gene, NPHS1, has been identified as the gene whose mutations cause congenital nephrotic syndrome of the Finnish type.[32] In addition to its role as a structural component, nephrin acts as a signaling molecule that can activate MAP kinase cascades.[38] Neph1 is considered as a ligand for nephrin. Podocin belongs to the raft-associated stomatin family, whose gene, NPHS2, is mutated in a subgroup of patients with autosomal recessive steroid-resistent nephrotic syndrome.[36] These patients show disease onset in early childhood and rapid progression to end-stage renal failure. Podocin interacts with nephrin and CD2AP.[39] FAT is a novel member of the cadherin superfamily with 34 tandem cadherinlike extracellular repeats and a molecular weight of 516 KDa.[40] Because FAT has a huge extracellular domain, it is speculated that it dominates the molecular structure of the slit membrane[34]; the FAT mutant mouse fails to develop a slit membrane.[41] P-cadherin[31] is thought to mediate with its intracellular domain the linkage to β- and γ-catenin, a complex which then connects to the actin cytoskeleton via α-catenin and α-actinin. Taken together, many components of the slit membrane are known, but an integrative model of its substructure including all components is thus far lacking.

The cell body of podocytes contains a large nucleus that tends to be indented in the region of the large Golgi apparatus. Furthermore, it houses abundant rough-surface endoplasmic reticulum; individual cisternae, generally arranged in one complex per cell, are widened and filled with fine granular material of varying electrondensity—their relevance is unknown. In addition to the synthesis of membrane proteins necessary to supply the huge surface of their processes, podocytes in the adult synthesize and secrete all components of the GBM[42] (see below). On the other hand, abundant multivesicular bodies (predominantly found in the large cell processes) demonstrate strong catabolic activity in podocytes.

Podocytes contain a well-developed cytoskeleton that accounts for the unique shape of the cells and the maintenance of the processes. In the cell body and the primary processes, microtubules and intermediate filaments, such as vimentin and desmin, dominate, whereas microfilaments are densely accumulated in the foot processes. Here, they are part of a complex contractile apparatus.[43] The microfilaments form loop-shaped bundles, with their limbs running along the longitudinal axis of the foot processes. The bends of these loops are located centrally at the transition to the primary processes and are probably connected to the microtubules by the microtubule-associated protein τ.[44] Peripherally, the actin bundles appear to be anchored in the dense cytoplasm associated with the cell membrane of the soles of foot processes, and are dynamically linked to the slit diaphragm complex (discussed earlier). The importance of the podocyte actin cytoskeleton is emphasized by the discovery of inherited forms of focal segmental glomerulosclerosis (FSGS) caused by

mutations in actin-binding proteins: α-actinin-4 is a widely expressed homodimeric protein that bundles and crosslinks actin, and is highly expressed within podocyte foot processes. It interacts with a variety of other adhesion and signalling molecules. Several mutations in the ACTN4 gene encoding this protein cause a late-onset, autosomal dominant form of kidney failure.[45,46] More recently, nine independent missense mutations in INF2, which encodes a member of the formin family of actin-regulating proteins, were shown to segregate with FSGS in 11 unrelated families.[47]

Specific transmembrane matrix receptors anchor the podocyte foot processes to the GBM. Two systems are so far known. The first is a specific integrin heterodimer consisting of $\alpha_3\beta_1$ integrins. Within the GBM, these integrins bind to collagen type IV, fibronectin, and laminin 11.[48,49] Second, a dystroglycan complex connects the intracellular molecule utrophin to laminin 11, agrin, and perlecan in the GBM.[50,51] Both integrins and dystroglycans are coupled via adapter molecules (paxillin, vinculin, α-actinin, etc.) to the podocyte cytoskeleton, allowing outside-in and inside-out signaling as well as transmission of mechanical force in both directions.

In addition to the actin cytoskeleton within the foot processes, a subplasmalemmal actin system is found in podocytes.[43] This actin network is connected to the transmembrane sialoprotein podocalyxin, which represents the major protein of the negatively charged surface coat of podocytes.[52,53] The cell coat has the characteristics of a glycocalyx that contains sialic acid. A decrease in the content of sialic acid is associated with a podocyte foot process effacement and results in protein leakage through the filter, which has been shown under a great variety of circumstances.[54–58]

A huge body of data has been accumulated in recent years concerning the inventory of receptors and signaling processes starting from them in podocytes. cGMP signaling (stimulated by atrial natriuretic peptide [ANP], brain natriuretic peptide [BNP], and C-type natriuretic peptide [CNP], as well as by nitric oxide [NO]), cAMP signaling (stimulated by prostaglandin E_2, dopamine, isoproterenol, parathyroid hormone [PTH]/PTH-related peptide [PTHrP]), and Ca^{2+} signaling (stimulated by a huge number of ligands, including angiotensin II, acetylcholine, prostaglandin F_2 (PGF_2), arginine vasopressin [AVP], adenosine triophosphate [ATP], endothelin, histamine, etc.) have been identified.[59] An example of an ion channel of particular importance in podocytes is transient receptor potential canonical 6 (TRPC6), a nonselective cation channel, which is activated by diacylglycerol in a protein kinase C-dependent manner.[60] Mutations in TRPC6 were found to cause autosomal dominant, late adult-onset proteinuria, with a similar clinical phenotype as seen in ACTN4-mediated FSGS.[37] The major target of this signaling orchestra is the cytoskeleton, the concrete effects of which, however, are poorly understood. Other receptors, such as for C3b,[61] Heymann's antigen,[62] transforming growth factor β (TGFβ),[63,64] fibroblast growth factor 2 (FGF2),[65] and various other cytokines and chemokines have been shown to be involved in the development of podocyte diseases.[59]

Endothelium

The endothelium consists of a simple squamous layer of fenestrated (porous) cells with the cell nuclei generally located near the axial region of the capillary loop (Fig. 1.6). The fenestrated regions (Fig. 1.12), which compose roughly 55% of the surface area,[66] have a thin layer of cytoplasm (about 50 nm thick) penetrated by numerous fenestrae of round, oval, or irregular shape and varying sizes. The total area occupied by fenestrae accounts for 13% of the capillary surface. The fenestrated regions outline the pericapillary portions of the glomerular basement membrane, but also may be found adjacent to the mesangium (Fig. 1.8). The fenestrae have a diameter of 50 to 100 nm (thus they are larger than endothelial fenestrae elsewhere in the body) and are not bridged by diaphragms. Thus, this kind of a porous endothelium is unique for glomerular capillaries. Fenestrae with diaphragms are found only in the outflow segment of the efferent arteriole.[67] Nonfenestrated regions are generally seen over nuclei and mesangial cell regions. Human glomerular endothelial cells also are fenestrated.[68,69] A cell coat that is rich with polyanionic glycoproteins, including podocalyxin, covers the endothelial surface[70–72] and appears to fill the fenstraelike "sieve plugs."[73] In addition, above this "classic" glycocalix a 200-nm thick endothelial surface layer has been revealed consisting of loosely attached plasma compounds.[74]

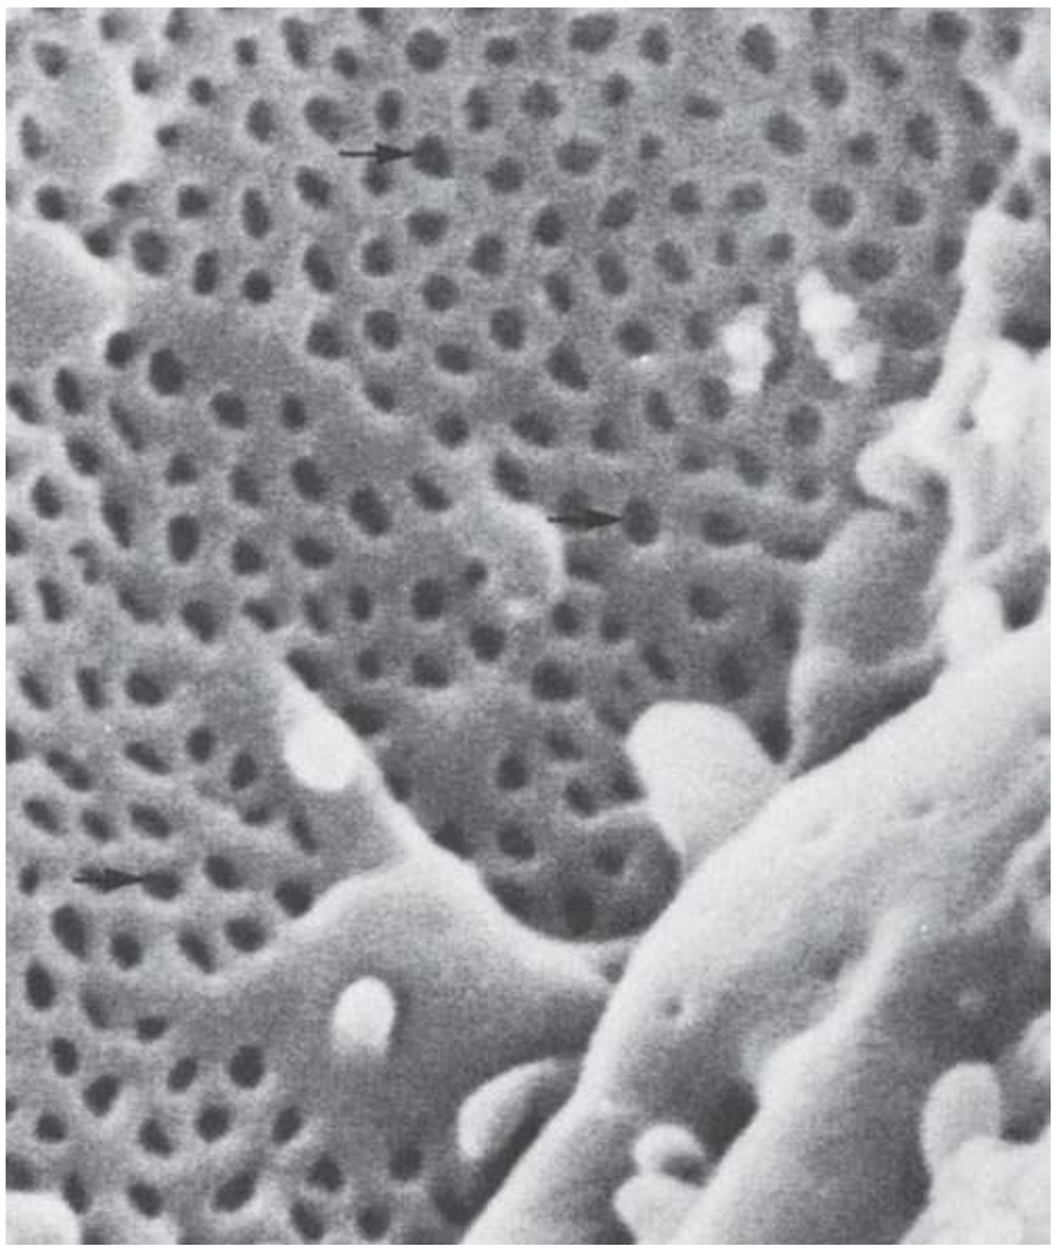

FIGURE 1.12 Scanning electron micrograph of a sectioned capillary loop showing the pores (*arrows*) of the endothelium. (Magnification ×50,400.)

As elsewhere in the body, glomerular endothelial cells are active participants in processes controlling coagulation, inflammation, and immune processes. Renal endothelial cells express surface antigens of the class 2 histocompatibility complex. Like platelets, glomerular endothelial cells contain components of the coagulation pathway and are capable of binding factors IXa and Xa and synthesize, release, and bind von Willebrand factor (factor VIII).[69] Glomerular endothelial cells synthesize and release endothelin-1 and endothelium-derived relaxing factor (EDRF).[75] Glomerular endothelial cells have receptors for vascular endothelial growth factor (VEGF) and angiopoetin I that are produced by podocytes.[76,77] The signaling axis via VEGF appears to have a major relevance for the maintenance of the glomerular tuft. Glomerular endothelial cells, in turn, synthesize and secrete platelet-derived growth factor β (PDGFβ) that acts on adjacent mesangial cells.[78]

Glomerular Basement Membrane

The GBM covers the capillary loops except in the axial region, where it is reflected over the mesangium to the next capillary loop, accompanied by the layer of foot processes (Figs. 1.6 to 1.8). The endothelial cells do not have a separate basement membrane; thus, the endothelial cells directly abut the mesangium toward axial regions. In adult humans, the basement membrane has a mean diameter of 320 to 340 μm.[79] It is thinner in young children and most laboratory animals.[80]

The basement membrane is composed of three layers: an outer, less dense subepithelial layer, the lamina rara externa; a central, electron-dense layer, the lamina densa; and an inner subendothelial layer, the lamina rara interna, which is continuous with the mesangial matrix (see Figs. 1.9 and 1.13).

During glomerulogenesis, the GBM is generated as two separate layers produced by glomerular endothelial and epithelial cells. The two sheets are fused together to form the mature GBM.[81–84] In the adult, the GBM is subject to a continuous turnover,[85–88] but few details are known so far about these processes. Podocytes appear to be the dominant cell type to synthesize and probably to degrade the GBM. Podocytes are alone capable to synthesize all the components of the GBM[42,89,90]; glomerular endothelial cells and also mesangial cells may contribute to the formation of the GBM.[91] It is less clear how the GBM degrades. In recent years, several extracellular matrix degrading enzymes have been described being produced by podocytes and mesangial cells.[92–94] The relevance of these enzymes for the turnover of the GBM remains to be established.

The GBM is generally considered as a hydrated meshwork consisting of collagen type IV, laminin, entactin/nidogen, and sulfated proteoglycans including agrin and perlecan.[42,95–99] Models of the ultramicroscopic structure of the basement membrane picture the GBM as a mat of collagen type IV. Monomers of type IV collagen consist of a 400-μm triple helix that, at its carboxy-terminal end, has a large noncollagenous globular domain called NC 1. At the amino-terminus the helix possesses a 60-μm triple helical rod, the 7S domain. Interactions between the 7S domain and the NC1 domain allow collagen type IV monomers to form tetramers that, by lateral association of triple helical strands, assemble into a three-dimensional network.[100,101] Laminin forms a second network that is superimposed to the collagenous network. Laminin is a noncollagenous glycoprotein consisting of three polypeptide chains, two of which are glycosylated and cross-linked by disulfide bridges.[95,102,103] Laminin binds to specific sites on the polymerized network of type IV collagen as well as the basal endothelial and epithelial integrins (see the preceding). The α-5-, β-2-, γ-1-laminin chains are assembled to form the GBM-specific heterotrimeric laminin 11.[48] This combined network of collagen type IV and laminin provides mechanical stability to the basement membrane and serves as a basic structure on which other matrix components attach.

The proteoglycans of the basement membrane consist of core proteins and covalently bound glycosaminoglycans, which are concentrated in the laminae rarae internae and externae, where they have been referred to as anionic sites and can be localized with cationic probes.[104] The major proteoglycans of the GBM are of the heparan sulfate type—the most prominent is agrin,[96] but perlecan also has been shown to occur in the GBM.[42] Digestion of these molecules with heparinase leads to a dramatic increase in the permeability of the basement membrane to anionic native ferritin used as a probe.[70]

Mesangium

The mesangium consists of mesangial cells that are embedded in a mesangial matrix. The term mesangium was introduced by Zimmermann in 1929[19] to describe the cells that form the stalk of the glomerulus and the axes of its lobules. Glomerular capillaries pursue a tortuous, highly anastomosing course around the mesangial axes. Together with the capillaries, the mesangium occupies the space inside the GBM, frequently termed the "endocapillary region." Topographically, the mesangium can be subdivided into a juxtacapillary region, where it abuts the capillary endothelium, and more centrally located axial regions, which are bound by the perimesangial GBM (Figs. 1.5 to 1.7).[105] The glomerular mesangium is continuous with the extraglomerular mesangium (Polkissen or lacis cells) along the glomerular stalk (Fig. 1.5). Both intraglomerular and extraglomerular mesangial cells have many similarities.

Mesangial cells are quite irregular in shape, with many cytoplasmic processes extending from the cell body toward the GBM. They have structural characteristics similar to those of smooth muscle cells in that they contain many bundles of microfilaments (especially within the cell processes) and peripheral dense bodies. Actin, myosin, and α-actin have been shown by immunocytochemistry to be contained in mesangial cells.[106,107] The relevance of mesangial cell contractility is discussed in the following text.

The processes of mesangial cells extend toward the GBM, to which they are attached either directly or by the interposition of extracellular bundles of microfibrils (Figs. 1.6 and 1.9). The GBM has to be considered as the effector structure of mesangial contractility.[105,108] Connections between mesangial cells and the GBM are especially prominent in the juxtacapillary region. At this site, tonguelike mesangial cell processes (packed with microfilament bundles) run underneath the capillary endothelium toward the turning points (mesangial angles) of the GBM, where they are anchored. Generally, two of these processes interconnect the GBM from two opposing mesangial angles (Fig. 1.8). In the axial mesangial region, contractile filament bundles are predominantly found within the numerous fingerlike projections of mesangial cells. These microprojections also run toward the GBM and are anchored to it. As in the juxtacapillary region, these microfilament bundles interconnect opposing parts of the GBM.[105]

The mesangial matrix fills the highly irregular spaces between mesangial cells and the perimesangial part of the GBM. In immunocytochemical studies, collagen types IV and V, heparan sulfate proteoglycan, fibronectin, laminin, and entactin have been localized within the mesangial matrix.[99,109,110] Among these components, fibronectin is the most abundant and has been shown to be associated with microfibrils.[109,111] Fibrillin 1 and other specific elastic fiber proteins have been detected in the glomerular mesangium and have been shown to be produced by mesangial cells.[112,113]

In specimens prepared for transmission electron microscopy according to routine methods, the mesangial matrix appears as basement membranelike material, albeit more fibrillar in character than the basement membrane proper.[114] In specimens prepared by a technique that avoids osmium tetroxide and uses tannic acid for staining, the mesangial matrix is seen to contain a dense network of microfibrils.[105,115] Microfibrils are noncollagenous, nonbranching, hollow structures of indeterminate length that are about 15 μm thick.[116] Within the mesangium, microfibrils form a three-dimensional network that establishes a solid base of contact between mesangial cells and the GBM, fettering the GBM to mesangial cells. Distinct bundles of microfibrils may be regarded as "microtendons" that allow the transmission of contractile force of mesangial cells to specific sites of the GBM.[105,115] The functional relevance of this system is discussed later.

The relevance of mesangial cells in phagocytosis is well documented. Mesangial cells are able to ingest particular tracers as well as macromolecules, such as thorotrast,[117] ferritin,[114] and aggregated proteins, as well as immune complexes.[118] An increased uptake of such materials by mesangial cells has been noted in proteinuric states.[114,119] It appears, however, that mesangial cells proper (i.e., mesangial cells that have contractile properties) are not primarily phagocytotic. A small subpopulation (3% to 7%) of cells in this region has been recognized as bone marrow-derived—they represent macrophages that have taken up residence in the mesangium.[120]

Supportive Functions of the Mesangium and Podocytes

The glomerular tuft is constantly exposed to comparably high intraglomerular pressures within glomerular capillaries and mesangium. The high intraglomerular pressures challenge not only the glomerular capillaries themselves but also the folding pattern of the glomerular tuft. Increased pressures lead to the loss of the folding pattern and to dilation of the glomerular capillaries. Therefore, we have to ask: what are the specific structures and mechanisms that counteract the expansile forces in the glomerular tuft? To answer this question we have to distinguish between the structures and mechanisms maintaining (1) the folding pattern of the glomerular tuft and those maintaining (2) the width of glomerular capillaries.

The folding pattern of the glomerular tuft is primarily sustained by the mesangium.[105,108,121] Mesangial cells are connected to the GBM by their contractile processes—they maintain the infoldings of the GBM by centripetal contractions, thereby allowing for the capillaries to arrange in the peripheral expansion of the GBM. This supporting role of mesangial cells is best illustrated under circumstances with loss of mesangial cells, such as Thy-1 nephritis.[122] Under those circumstances the folding pattern of the GBM is progressively lost, finally resulting in mesangial aneurysms. Podocytes clearly contribute to maintenance of the folding pattern by specific cell processes that interconnect opposing parts of the GBM from outside within the niches of the infoldings. This function is also best illustrated under circumstances with loss of mesangial support: podocytes are capable of maintaining a high degree of the GBM folding pattern for 2 to 4 days after which they obviously fail, and mesangial aneurysms become prominent.[122]

The width of glomerular capillaries, in the long run, is probably controlled by growth processes accounting for differently sized capillaries. The width of a given capillary, in an acute situation being exposed to changes in blood pressure, appears to be stabilized by the GBM, which is a strong elastic structure[123] and, together with the mesangial cell bridges (see previous text), capable of developing wall tension.[121,124] In addition, the tensile strength of the GBM is reinforced by podocytes. Podocytes are a kind of pericyte; their foot processes represent a unique type of pericyte process which, like elsewhere in the body, counteract the dilation of the vessel. Podocyte processes are firmly attached to the underlying GBM (see previous text); their cytoskeletal tonus counteracts the elastic extension of the GBM. In this function, podocytes cannot be replaced by any other cell—failure in this function will lead to capillary dilation.

Glomerular Filtration Barrier

The essential components of the glomerular filtration barrier are the endothelium (Fig. 1.13), which is perforated by large open pores, the extracellular matrix feltwork of the GBM membrane, and the slit diaphragms between the podocyte

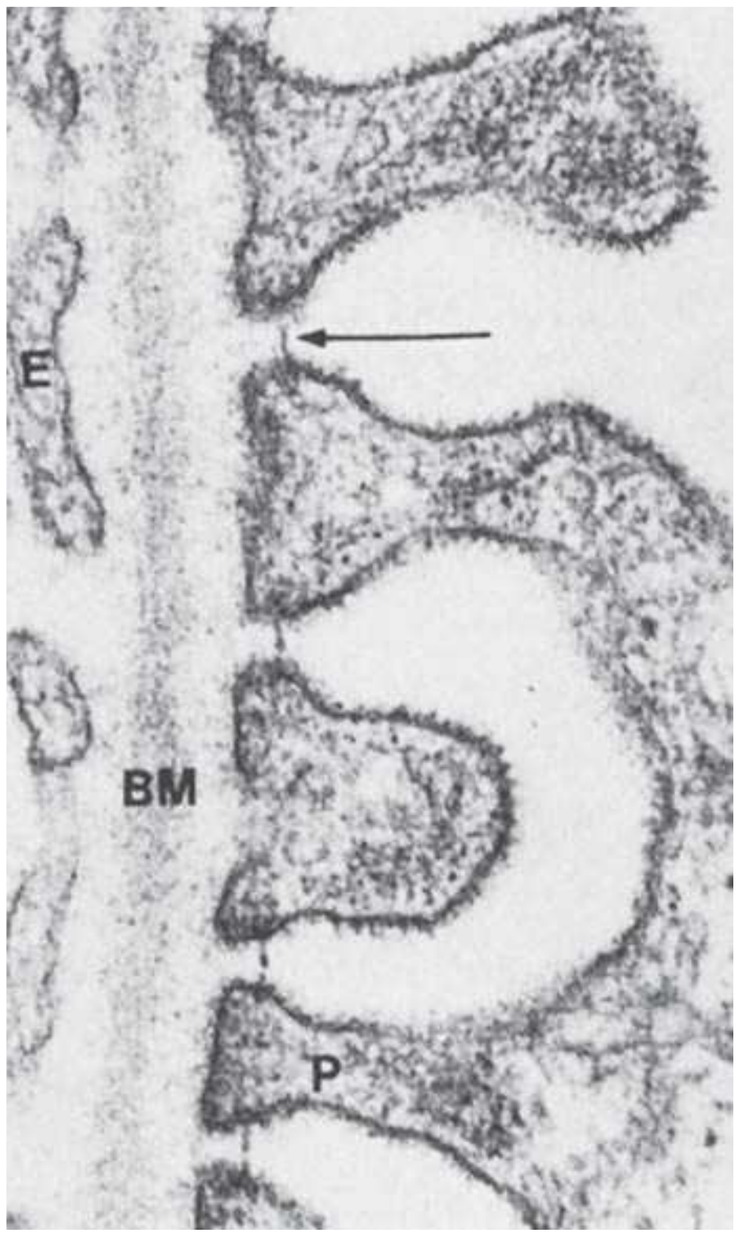

FIGURE 1.13 Transmission electron micrograph from a rat renal corpuscle showing the endothelial lining (*E*), the basement membrane (*BM*), and the pedicels (*P*). The filtration-slit membrane (*arrow*) bridges the pedicels. (Magnification ×23,600.)

foot processes. When compared with the barrier established in capillaries elsewhere in the body, a glomerular filtration barrier is quite different in two respects: its permeability to water, small solutes, and ions is extremely high, whereas its permeability to plasma proteins the size of albumin and larger is very low.

The high hydraulic permeability is rooted in the fact that filtration occurs along extracellular routes. All components of this route—the endothelial pores, the highly hydrated GBM, and the slit membrane—can be expected to be quite permeable to water and small solutes. Drummond and Deen[125] have calculated the hydraulic conductance of the individual layers. According to this calculation, the hydraulic resistance of the endothelium is negligible. The GBM and the filtration slits each make up roughly one-half of the total hydraulic resistance of the filtration barrier.

Any decrease in the length of the filtration slit, and thus in slit area, as in experimental and clinical glomerulopathies along with footprocess effacement, correlates with the decrease in the ultrafiltration coefficient K_f.[126,127] A model simulating those conditions showed, along with a decrease in slit area, its relevance in determining increases in flow resistance. The decrease in filtration slit area caused the average path length for the filtrate, through the basement membrane, to increase, thereby explaining the overall decreased hydraulic permeability.[128]

On the basis of evidence of contractility of mesangial cells exposed to vasoconstrictor stimuli in culture,[129,130] of dimensional changes observed in intact glomeruli ex vivo,[131,132] and of changes in ultrafiltration coefficient K_f found in vivo in response to vasoactive substances,[133,134] some researchers have concluded that mesangial cells contract in situ and that this contraction alters glomerular filtration dynamics by decreasing filtration surface area.

Other considerations speak against this possibility. The geometric arrangement of the mesangial contractile apparatus (Fig. 1.6), however, does not seem to be compatible with the previously mentioned sequence of actions. Shortening of the mesangial cell processes connecting opposing angles would only bring the angles closer together, compressing the mesangial capillary interface, but leaving peripheral capillary wall area (filtration area) unaltered. In addition, with regard to the contractility of mesangial cells ex vivo (in culture as well as preparations of whole glomeruli), it should be remembered that mesangial contraction in these cases is not opposed by intercapillary hydrostatic pressure as it is in situ. These considerations, together with the absence of measurable changes in glomerular tuft dimensions in morphometric studies,[135,136] as well as in response to vasoactive substances in vivo,[137] have led to the suggestion[121] that the mechanical action of the mesangial cell contraction is essentially static in nature, developing tension that serves to counteract expansile forces on the tuft without inducing significant changes in capillary dimension. If mesangial contractility acutely alters the glomerular ultrafiltration coefficient K_f, it is, therefore, probably not because of an acute change in filtration surface area.

The low permeability of the glomerular filtration barrier to plasma proteins is still poorly understood. Several points seem to be relevant. First, there is no vesicular transport of proteins through this barrier as in most other capillaries elsewhere in the body. The barrier function of the glomerular filter for macromolecules is quite specific and is selective for size, shape, and charge.[138–140]

In early extensive studies, Farquhar and associates,[138,141,142] as well as Rennke and associates,[143] used tracers, such as ferritin and dextrans of different sizes and charge, to elucidate the role of the various layers in determining the selectivity of this filtration barrier. When their results are summarized, it appears that the basement membrane may be the major barrier to anionic substances, whereas the most restrictive part for uncharged and cationic substances may be the slit diaphragm. Uncharged macromolecules up to an effective radius of 1.8 μm pass freely through the filter. Larger compounds are more and more restricted (indicated by their fractional clearances, which progressively decrease) and are totally restricted at effective radii of more than 4.0 μm. The effective radius is an empiric value, measured in artificial membranes, that takes into account the shape of micromolecules and also attributes a radius to nonspherical molecules. Plasma albumin has an effective radius of 3.6 μm; without the repulsion because

of the negative charge, plasma albumin would pass through the filter in considerable amounts.[144]

Thus, since these early studies, the glomerular barrier has been generally suggested to contain a size- and a charge-restrictive element. Despite more than 40 years of intensive research, the principles of the glomerular barrier function are still controversial and poorly understood—a situation that gives room even to hypotheses claiming that the glomerular barrier itself does not have any restrictive properties to macromolecules, such as albumin.[145–147] A more realistic and elegant recent barrier hypothesis is based on the observation that filtration—the flow of filtrate through the barrier—creates a potential difference of 0.02 to 0.05 mV negative in Bowman's space and that this potential difference is sufficient to hinder the negatively charged macromolecules like albumin from passing the filter.[148]

Summarizing the present status of knowledge, accumulating evidence suggest that the GBM has little relevance in size restriction, but the slit membrane is the decisive size-restrictive element within the glomerular barrier.[149] The current strong engagement in elucidating the molecular architecture of the slit membrane promises to enlighten the porous pattern of the slit membrane and, hopefully, explain its size-restrictive property. Regarding the charge selectivity, it appears that the proximal portion of the barrier, above all the endothelium, are most important.[73,150–152] Furthermore, prevention of albumin from entering the filter is also dependant on normal hemodynamic conditions in glomerular capillaries, as first shown by Ryan and Karnovsky.[153]

PROXIMAL TUBULE

At the urinary pole of the glomerulus, the flat parietal epithelium of Bowman's capsule transforms abruptly into the high epithelium of the proximal tubule. In some species (rabbits),[154] a neck segment is found interposed between the glomerulus and the proximal tubule—short neck segments also may be seen in humans.[80] In contrast, in mice, the proximal tubule epithelium generally begins deep within the Bowman's capsule.

The proximal tubule is composed of segments that have differing morphology, functional relevance, and vulnerability to toxins (Figs. 1.14 to 1.18). The two segments most frequently identified are the proximal convoluted portion (pars convoluta) occupying the cortical labyrinth (Figs. 1.14 to 1.17), and the straight portion (pars recta) in the medullary rays of the cortex and the outer stripe of the outer medulla (Fig. 1.18). Further subdivision on structural criteria results in the three segments of P_1, P_2, and P_3 according to Jacobsen and Jorgensen,[155] and S_1, S_2, and S_3 according to Maunsbach.[156,157] S_1, or P_1, corresponds to the first segment of the pars convoluta and lies exclusively in the cortical labyrinth; S_2, or P_2, corresponds to the remainder of the convoluted segment and the beginning of the pars recta, with the first part occupying the cortical labyrinth and the remainder

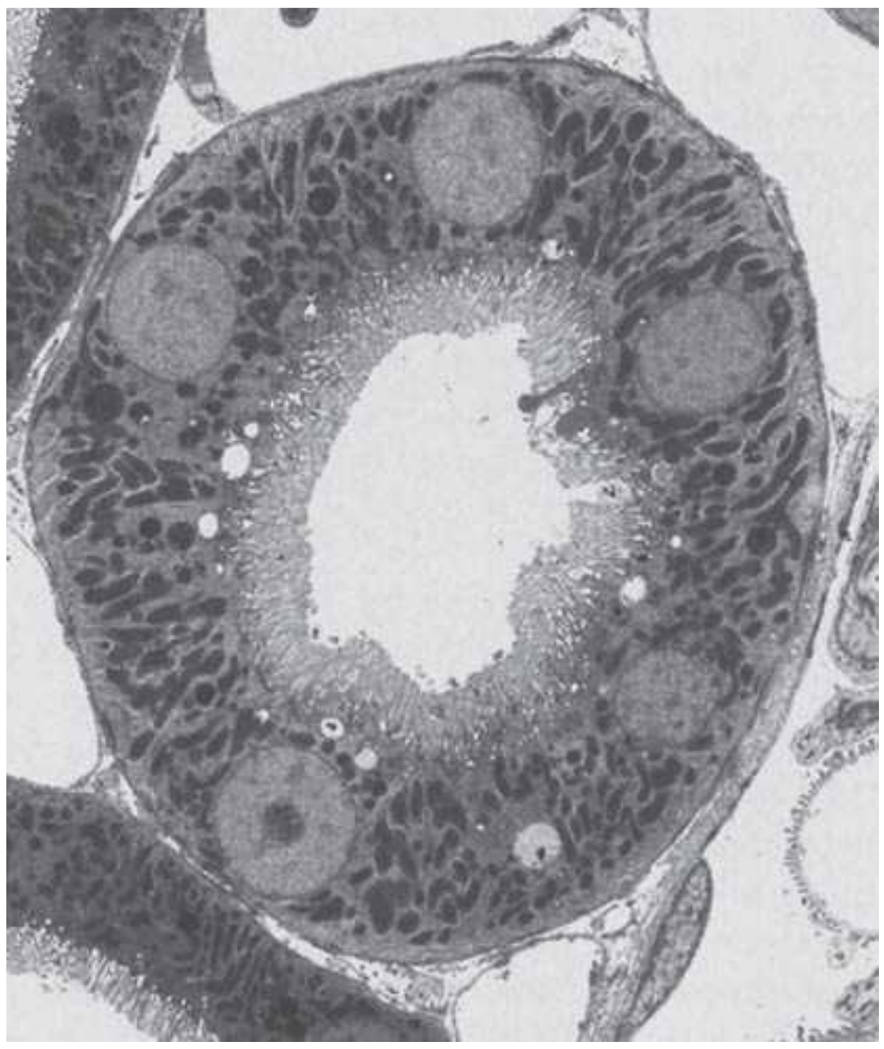

FIGURE 1.14 Transmission electron micrograph of a proximal tubule (P1 segment) of the rat. Note the apical brush border, the vesicular zone of the apical cytoplasm, and the basal zone of interdigitating cell processes filled with mitochondria. (Magnification ×2,300.)

occupying the medullary ray; and S_3, or P_3, corresponds to the remaining part of the pars recta located primarily in the outer stripe of the outer zone of the renal medulla. The transition from P_1 to P_2 is gradual, whereas the transition from P_2 to P_3 is generally abrupt, except in rabbits.[158]

To confuse matters further, the morphology of the subdivisions differs not only from each other but also among species, including mice,[159] rats,[156] rhesus monkeys,[160] rabbits,[158] and dogs.[161] For a detailed description of a particular species, the reader should consult the original studies. Segmentation of human proximal tubules has not been studied as recently or thoroughly because of a lack of availability of well-fixed normal human kidney and, therefore, has been divided only into convoluted and straight regions.[162]

In general, cells of the P_1 region are tall, have a well-developed apical microvillus border, an elaborate cell shape with well-developed lateral interdigitating processes containing abundant, large mitochondria, and a well-developed endocytic apparatus (Fig. 1.16). P_2 cells decrease in cell height from those seen in P_1, have a shorter microvillus border, and are less elaborately shaped cells with smaller mitochondria (Fig. 1.17). The P_3 cells are more cuboidal in shape (less elaborate) and their microvillus border is generally less elaborate. The cells of rats are an exception and have a well-developed brush border of very long microvilli (Fig. 1.18).[156] This cytologic segmentation of the proximal tubule is maintained in superficial, midcortical, and juxtamedullary nephrons.

Proximal Convoluted Tubule (P_1 and Part of P_2)

The proximal convoluted tubule is the longest and largest segment of the mammalian nephron. The tubule is lined by cells that have an elaborate cell shape based on extensive basolateral interdigitations (Figs. 1.19 to 1.21), a well-developed microvillus border, a prominent intracellular digestive tract (endocytic apparatus and lysosomes (Fig. 1.15), and numerous large peroxisomes (microbodies). The single ovoid nucleus lies in the middle to basal region of the cytoplasm.

Cell Shape and Mitochondria

The cells are characterized by an extensive system of lateral cell processes that interdigitate with lateral processes from adjacent cells (Figs. 1.19 to 1.21). These lateral processes can extend the entire height of the epithelium, especially in the P_1 segment, but become more elaborate toward the basal regions of the lateral surface (Fig. 1.16). The complex shape of these cells serves to increase the lateral cell surface area manyfold, which provides a greater area for transporters, above all of the Na^+-K^+-ATPase. These lateral extensions usually contain one or two layers of mitochondria (Fig. 1.20). The mitochondria are long, narrow rods that branch and double back on themselves. They are oriented perpendicular to the basement membrane and lie adjacent to the cell membrane, to which they presumably supply energy for transport processes.

The lateral extensions and their mitochondria cause the pattern of basal striations that are typical for numerous transporting cells. The lateral processes of proximal convoluted tubule cells in humans are not as elaborate as those seen in rats (compare Figs. 1.15 and 1.16). In rabbits, the lateral cell surface is increased 20 times over that of the basal cell surface.[163] The lateral extensions also establish a complex and extensive surface labyrinth of lateral intercellular spaces ("basal labyrinth").

Cell Junctions

The proximal convoluted tubular cells have an apical junctional complex that consists of a shallow, beltlike, tight junction next to the tubular lumen; a deeper, beltlike intermediate junction (the zonula adherens); and only small and infrequently seen desmosomes. The proximal tubular tight junctions are shallow and consist of only one or two lines of fusion of the outer leaflet of the cell membrane (Fig. 1.22). Freeze-fracture studies of normal proximal tight junctions, however, reveal focal discontinuities. During volume expansion, striking increases in the length of discontinuities were found.[164] Transmission micrographs also show multiple areas of nonfusion of tight junctions associated with renal venous constriction and increased ureteral pressure.[165] These sites of nonfusion may explain the increased permeability seen in these situations. Proximal tubular cells are electrically coupled by gap junctions (Fig. 1.22).[166]

Microvilli

A layer of slender (approximately 80 to 90 μm), finger-shaped processes extends into the tubular lumen, forming the microvillus, or brush border. The length and number of processes vary with the segment and species. The luminal surface of the pars convoluta is increased 40 times in rats.[157] The luminal surface is increased 36 times in the pars convoluta and 15 times in the pars recta in rabbits.[163] Each microvillus has a core of microfilaments that extend into the apical cytoplasm connecting them to the cytoskeleton.

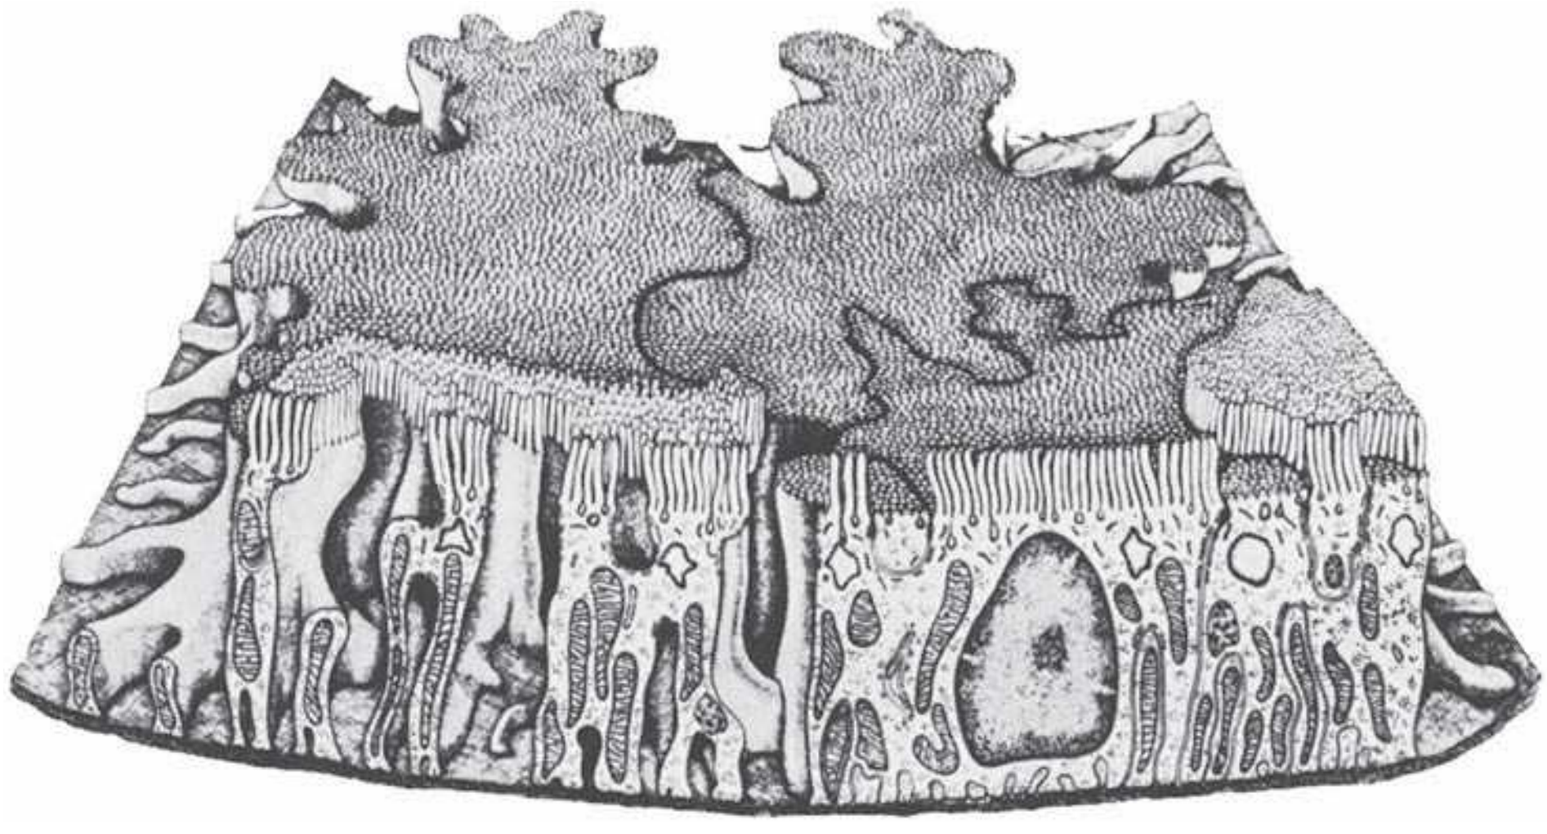

FIGURE 1.21 Diagram of a proximal convoluted tubular cell showing the elaborate shape of these cells. Some interdigitating processes extend the full height of the cells. The apical and basal cytoplasmic regions also have smaller, more elaborate interdigitating processes. (From Bulger RE. The shape of rat kidney tubular cells. *Am J Anal.* 1965;116:237, with permission.)

Cytoplasm

The cells contain a very prominent vacuolar apparatus (see later text), a Golgi apparatus, free ribosomes, and cisternae of rough and smooth surface endoplasmic reticulum. The latter forms specialized cisternae, called the perimembranous cisternal system, near the lateral cell membranes.[80] In addition, the cells contain many peroxisomes that frequently have eyecatching shapes.[167] Peroxisomes are limited by a single membrane and contain a dense matrix, frequently exhibiting crystalloid nucleoids (Fig. 1.17); platelike inclusions at the peroxisomal edge, which are called marginal plates, are also frequently encountered. Peroxisomes are invariably wrapped by elements of the smooth-surfaced endoplasmic reticulum. In the kidney, large peroxisomes are exclusively found in the proximal tubule, most frequently in the P_3 segments[167]—all other nephron portions contain only microperoxisomes. Peroxisomes contain enzymes from a primitive respiratory chain in which oxidases produce hydrogen peroxide, which is, in turn, destroyed by the catalase, hence the name peroxisome.[168] Peroxisomes participate in the breakdown of very-long-chain fatty acids by lipid β-oxidation; in addition, they may play a protective role by destroying hydrogen peroxide produced by free radicals.

Straight Part of the Proximal Tubule (Last Part of P_2 and All of P_3)

The straight part of the proximal tubule (pars recta) begins in the medullary ray and penetrates into the outer stripe of the outer zone of the medulla (Fig. 1.18). The proximal pars recta converts into the thin limb near the junction of the inner and outer stripe. In rats, the pars recta includes the final region of both P_2 and P_3,[169] and the transition

between the two segments occurs at various levels in the medullary ray. This region is marked by a sudden increase in microvillar length, a decrease in endocytic apparatus, and a decrease in interdigitation between adjacent cells. The microvilli of the pars recta cells decrease in height and number in rabbits[158] and humans[162] but remain high in rats (Fig. 1.18).

In general, the P_3 pars recta cells have been described as lower in height with a less elaborate shape. In humans, the pars recta cells have a convex apical surface, and some lipid droplets are found in the basal cytoplasm. The mitochondria are fewer and no longer closely applied to the cell membrane. The lysosomes are smaller and the Golgi and endocytic apparatuses are less well developed. Peroxisomes are more numerous in the pars recta.[80,162] The tight junctions of P_3 can be more complex in shape, consisting of several junctional strands in rats, dogs, and cats.[170]

Structure–Function Correlations

The functional relevance of the proximal tubule is manifold and quantitatively enormous. It reabsorbs about 70% of filtered Na^+, Cl^-, and water; 95% of bicarbonate; 60% of Ca^{2+}; and sodium phosphate. Reabsorption of the filtered glucose is complete, whereas reabsorption of amino acids is almost complete. This occurs either by transcellular transport via specific channels and transporters in both membranes (water, sodium, phosphate, glucose, amino acids, and bicarbonate in a specific enzyme-mediated mode) or predominantly by paracellular transport through the leaky tight junctions (Ca^{2+}, Cl^-). Furthermore, filtered macromolecules undergo reuptake by a prominently developed endocytotic apparatus. In addition, the proximal tubule (predominantly S_3 segments) secretes organic cations and anions, which constitute an extraordinarily diverse array of compounds of physiologic, pharmacologic, and toxicologic importance. The transepithelial transport involves separate entry steps at the basolateral membrane and exit steps at the luminal membrane with specific transporters at both sites.[171–174] Other potentially toxic xenobiotic compounds are metabolized within the well-developed smooth endoplasmic reticulum of S_3 segments.[175]

Unique to the proximal tubule is the reabsorption and degradation of filtered protein and peptides (Figs. 1.15 and 1.16). As discussed previously, all proteins smaller than albumin leak through the glomerular filter; even albumin, in small amounts, is always contained in the filtrate. All these diverse macromolecules are taken up by proximal tubule cells via receptor-mediated endocytosis and degraded in lysosomes. In proteinuric states, this function is greatly enhanced. The uptake and digestion include the following steps.[176,177]

1. Binding of the filtered protein to two multiligand receptors, megalin and cubulin, which are densely accumulated within clathrin-coated pits in the intermicrovillar areas of the apical membrane.

   Megalin is a 600-kDa transmembrane protein belonging to the LDL-receptor family (see reviews).[176,177] The extracellular domain contains four clusters of cysteine-rich, complement-type repeats, constituting the ligand-binding regions. Cubulin is a 416-kDa peripheral membrane protein identical to the intrinsic factor vitamin B_{12} receptor, known from the small intestine. It contains 27 CUB domains, which are responsible for the ability to interact with a great variety of ligands.
2. Small apical vesicals pinch off from the tubular invagination at the intermicrovillar areas to ferry the protein to the next component.
3. Large apical vacuoles located in the apical cytoplasm are formed by fusion of small vesicles representing the early endocytotic compartment.
4. Condensing vacuoles form in which the protein is condensed. These vacuoles move basally in the cell and acquire hydrolytic enzymes by fusion either with primary or secondary lysosomes. The proteins sequestered within lysosomes appear to be broken down into amino acids that are reused by the cell.
5. Already sequestered in the early endosomal compartment, the receptors are concentrated in dense, apical tubules by which they are returned to the apical plasma membrane.

This process of megalin-mediated internalization appears to be of even much wider relevance. As mentioned previously, the proximal tubule reabsorbs phosphate, representing a key element in phosphate homeostasis. Depending on the amount of sodium phosphate cotransporters present in the brush border cell membrane, the reabsorption varies. Internalization of the phosphate transporter type II (e.g., PTH induced to downregulate reabsorption) occurs via megalin-mediated endocytosis.[178,179] The proximal tubule has also endocrine relevance. In response to stimulation by PTH, it produces, by adding a second hydroxyl group, the active vitamin D_3, calcitriol.

Thin Limbs of the Loop of Henle (Intermediate Tubule)

Thin limbs can be short, occurring only along the descending limb, or they can be long, reaching varying distances into the inner medulla. In the long-looped variety, thin limb segments compose part of both the descending and ascending limbs. Four types of thin limb segments are routinely identified: (1) descending thin limbs of short-looped nephrons (SDTL) (Figs. 1.23 to 1.25), (2) upper portions of descending thin limbs of long-looped nephrons (LDTL up), (3) lower portions of descending thin limbs of long-looped nephrons (LDTL lp), and (4) ascending thin limbs of long-looped nephrons (ATL) (Figs. 1.24 and 1.25). This pattern has been observed in rats,[180,181] mice,[182] syric hamsters,[183] the desert rodent Psammomys obesus,[184,185] and the rabbit.[158] Thin limbs have not been studied as carefully in humans as

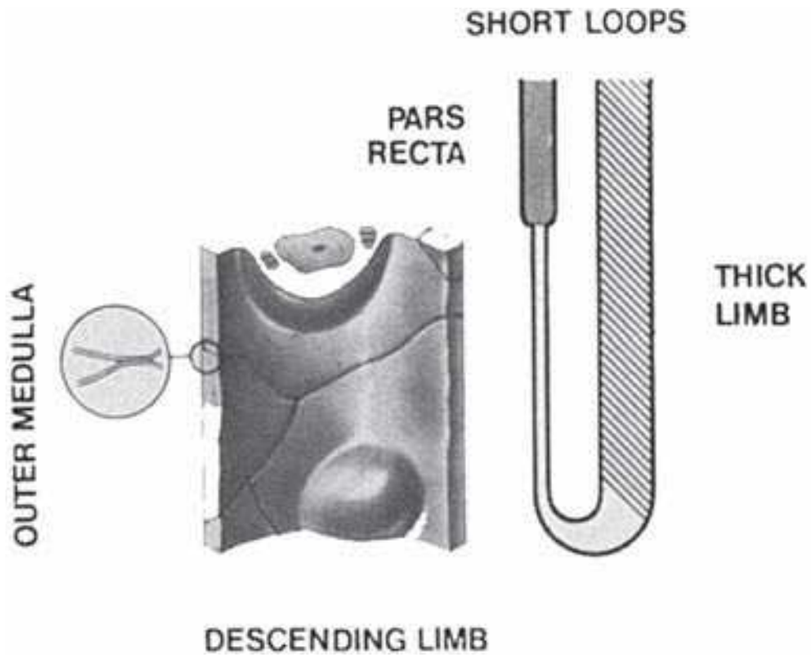

FIGURE 1.23 Diagrammatic representation of thin limb structure in short loops of Henle showing the shapes of constituent cells and the morphology of the occluding junctions (*inset*). (From Schwartz MM, Venkatachalam MA. Structural differences in thin limbs of Henle: physiologic implications. *Kidney Int*. 1974;6:193, with permission.)

in several other animal species.[13,186,187] An additional subsegment of thin limbs has been identified in chinchillas.[188]

Surprisingly, as seen by light microscopy, these simple looking epithelia are strikingly different from each other—not only the ascending from the descending limbs but, most remarkably, the descending limbs of short from those of long loops. Furthermore, within the descending segments, the proximal portion, although structurally not different from the distal portion, express a different pattern of transporters than the distal portion. Even islets or interposed limb pieces of functionally different cells are encountered within an otherwise homogenous thin limb segment.[189,190] Beyond all of these heterogeneities, there are prominent differences among species. This situation may explain the doggedly persistent discussion about the integrated function of thin limbs in the urine-concentrating process; a generally accepted concept of how the final concentration of the urine in the inner medulla occurs is lacking.

The type-1 epithelium lining (SDTL) is composed of flat, noninterdigitating cells, joined by tight junctions that consist of several anastomosing strands. Cell organelles are exceedingly sparse. Functionally, this segment contains aquaporin 1 (AQP1) and the urea transporter UT-A2 in its membranes.[191–194] Thus, it is water and urea permeable. However, these properties are unequally distributed; within the proximal part, the water permeability is high, whereas, within the distal part, the urea permeability is high.[191,193,195] In species with complex vascular bundles (rat, mouse, etc.), the SDTLs lie within vascular bundles[187]; in these surroundings, the thin limbs are in an ideal position to recycle urea from the ascending vasa recta into the short-loop nephrons.

The descending limbs of long loops (LDTL) are generally much larger in diameter and have a thicker epithelium than those of short loops (Fig. 1.25). Moreover, these thin limbs segments are heterogeneous; those of the longest long loops begin in the inner stripe as a much thicker tubule than those of shorter long loops. The character of the epithelium gradually changes as the limbs descend toward and into the inner medulla. The subdivision of the long descending thin limbs into an upper part (type-2 epithelium) and a lower part (type-3 epithelium) is an approximation and reflects the gradual change

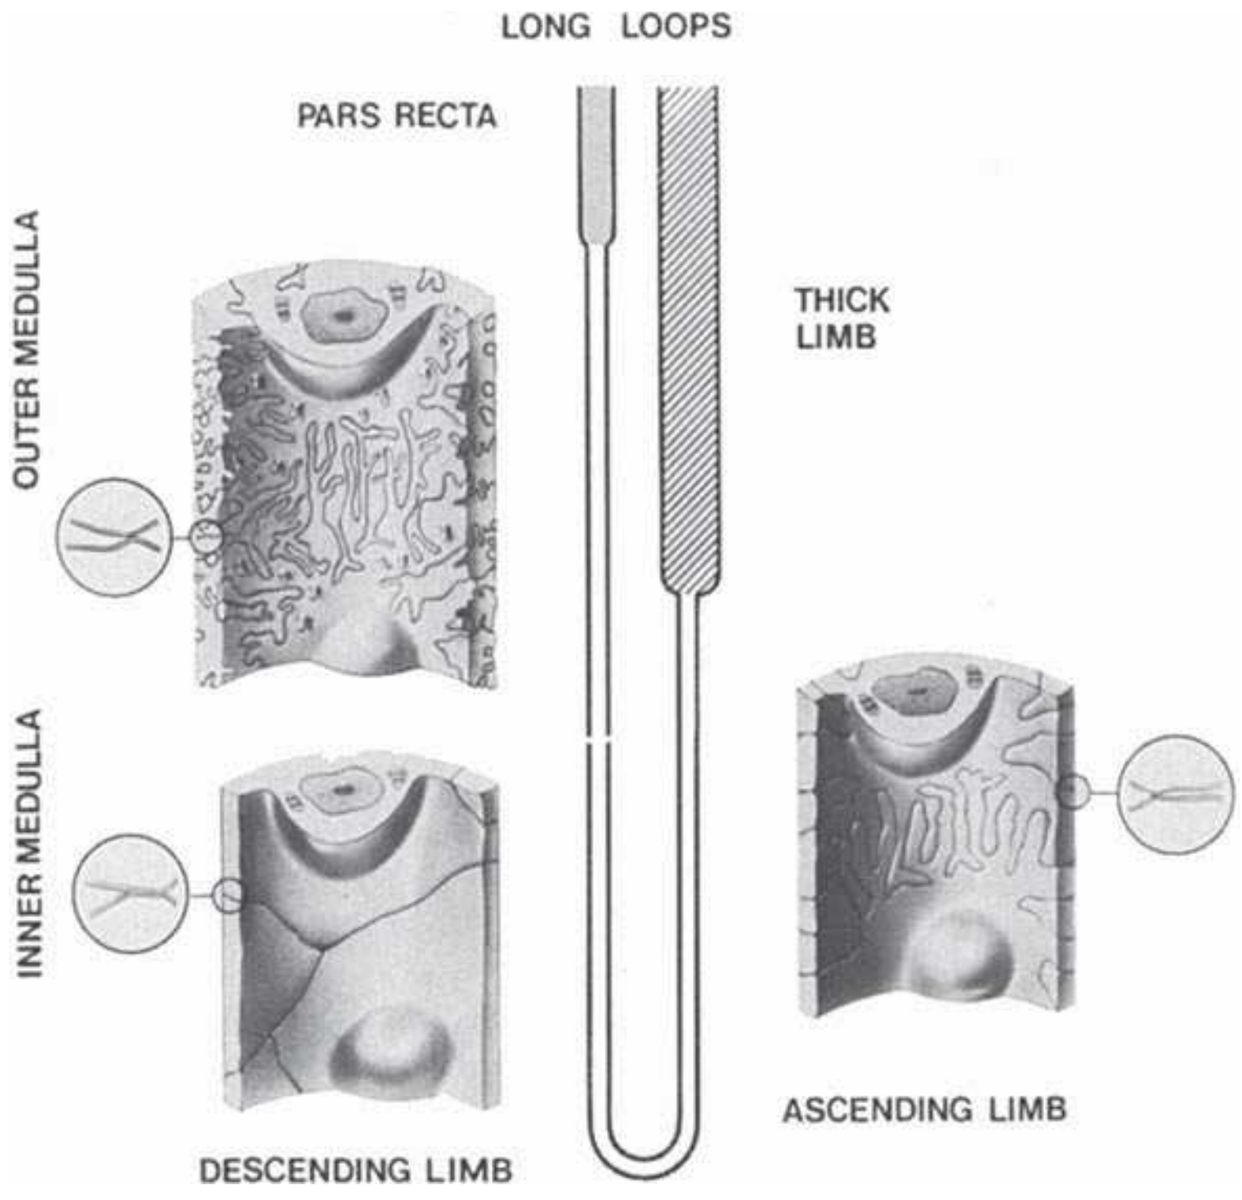

FIGURE 1.24 Diagrammatic representation of thin limb structure in long loops of Henle, showing the shapes of constituent cells and the morphology of the occluding junctions (*inset*). (Magnification ×900.)

between the two epithelia. Moreover, this process of epithelial transformation appears to be related to the length of each loop. It occurs earlier and more quickly in short long loops and is delayed in the longest long loops.[158,159,181,182,187,189,196]

Furthermore, considerable interspecies differences, particularly prominent in type 2 epithelia, complicate the situation. Two patterns of type-2 epithelium may be distinguished.[187,197] In one group of species (mouse, rat, Psamomys, etc.),[159,184,185,198,199] the type-2 epithelium is characterized by an extremely high degree of cellular interdigitation and a shallow tight junction consisting of only one junctional strand pointing to prominent paracellular transports. In addition, the epithelium has numerous apical microvilli, considerable numbers of mitochondria, and exhibits a high expression of Na^+-K^+-ATPase.[200,201] In a second group of species (rabbit, minipig, and, possibly, man),[202,203] the type-2 epithelium is much more simply organized. The prominent paracellular pathway is lacking; the cells do not interdigitate and are joined by deep tight junctions. In other respects, however, the epithelia are similar in the two groups: numerous luminal microvilli, many mitochondria, and a dense assembly of intramembrane particles in luminal and basolateral membranes are present in both groups. The high density of intramembrane particles may, at least, be partially due to the high density of AQP1 channels in both membranes—corresponding to the decrease of particle density along its descending course. The density of AQP1 channels also decreases and finally terminates completely.[195,204,205] Because structurally a clear cut border between the upper and the lower segment of the LDTL cannot be defined, it may be reasonable to discriminate both segments by the absence of AQP1 in the lower segments.[189,195,204]

Type-3 epithelium (found in LDTL lp) is comparably simple; interspecies differences are no longer prominent. The epithelium consists of flat, noninterdigitating cells, joined by tight junctions of intermediate apico-basal depth[181]; it lacks AQP1 and may, accordingly, have a very low water permeability. Regarding the permeability to urea and the distribution of the urea transporter, UT-A, conflicting data are published, especially when comparing data from different species.[190,191,204,206–208]

The ascending thin limb (ATL) is present only in long-loop nephrons and is uniformly organized among mammals. Generally the transition from the type-3 epithelium of the DTL to the type-4 epithelium of the ATL occurs in a short, but fairly constant, distance before the bend ("prebend segment").[180,185,189] Therefore, functionally, the entire bend should be regarded as part of the ATL. The type-4 epithelium is characterized by very flat but heavily interdigitating cells joined by shallow tight junctions, consisting of only one, but prominent, junctional strand. This leaky organization of the paracellular pathways correspond with functional studies,[209,210] which all demonstrate that the ATLs are highly permeable for ions.

The change from the type-3 epithelium to the type-4 epithelium coincides with the full disappearance of the urea transporter UT-A and the abrupt beginning of the expression of the chloride channel ClC-K1[189,204]; aquaporins are also lacking. Thus, the ATL is water and urea impermeable, but highly permeable for Cl^- and also Na^+.

In humans,[211,212] dogs,[161] and minipigs,[203] a gradual transition is seen from the thin limb to the ascending thick limb; however, an abrupt transition is seen in most other species.[158,213,214]

THE DISTAL TUBULE OVERVIEW

The distal tubule of mammalian kidneys has been defined in many and conflicting ways. For morphologists, the distal tubule is divided into several serial segments with differing locations in the kidney and of varying ultrastructural patterns[215] (Fig. 1.2). The first morphologic segment of the distal tubule for long-looped nephrons begins at the boundary between the inner zone of the medulla and the inner stripe of the outer zone of the medulla. At this boundary, the cells lining the ascending thin limbs of long-looped nephrons increase in height, forming the MTAL. The MTALs of short-looped nephrons are encompassed within the inner stripe of the outer zone in which the descending thin limb of short-looped nephrons converts into a descending thick limb, which then makes a hairpin turn and ascends as an MTAL. The MTAL traverses the inner stripe of the outer zone of the medulla and continues toward the cortex through the outer stripe of the outer zone of the medulla. The MTAL then enters the cortex, ascending within the medullary ray as the CTAL. These two segments, the MTAL and CTAL, are also called the straight part of the distal tubule. The CTAL then leaves the medullary ray and enters the pars convoluta of the cortex, running between the afferent and efferent arteriole of the renal corpuscle from which that tubule was derived. A plaque of taller, but narrower, cells is found in the wall of the CTAL in this region; this plaque of cells forms the macula densa (JGA). In humans, the cells of the MTAL are not as elaborately shaped as those described in the majority of laboratory animals that have been studied.[212]

After a short post macula densa region of the CTAL, the distal tubule becomes more convoluted and it is now lined by epithelial cells that increase in height from the CTAL, which forms the distal convoluted tubule (DCT) (see Fig. 1.27).[214,216] In rabbits, the DCT contains one type of cell known as the distal convoluted tubular cell.[158] In this species, the DCT is abruptly replaced by the connecting tubule (CNT). In other species, such as rats and mice,[217] humans,[218] or minipigs,[203] the transition is more gradual with intermixing of cells so that in the late DCT of these species connecting tubule cells and intercalated (IC) cells begin to dominate, although DCT cells and principal cells of the collecting duct also can be identified. This segment is then defined as the CNT. The CNT of superficial nephrons begin as unbranched segments, each emptying into a collecting duct (some investigators call the first part of the collecting duct the initial collecting duct). In midcortical and juxtamedullary nephrons, the change from the DCT to the CNT occurs a few cells before the fusion of the two tubules.[158] These CNT segments join to form branching connecting tubule segments called arcades, which arch upward in the cortex and then empty into a CCD.[7] The number of each type of CNT architecture varies with the species.

Medullary Thick Ascending Limb

The MTAL is lined by cells of one type that has extensive basal interdigitating processes filling the basal three-fourths of the cytoplasm (Fig. 1.26). The larger cell processes contain large mitochondria that are elongated on an axis perpendicular to the tubular basement membrane. In addition to their normal contents, the mitochondria contain prominent intramitochondrial granules and occasional filamentous bodies.[219] The epithelium lining the MTAL is approximately 7 μm in height.[213,220]

The apical surface of the MTAL cells does not have an elaborate shape in rabbits[158]; it is more elaborate in rats.[221] Tisher and associates,[213,216,220] using scanning electron microscopy, have described two surface configurations of the MTAL cells, with variations in apical cell outlines and in the number of apical microplications. Some cells have smooth apical surfaces with a few microprojections, whereas others have a rough surface with numerous microprojections. The MTAL cells have both extensive invaginations of the basolateral plasma membrane, as well as a large lateral interdigitating process of adjacent cells.[220] Because a main function of the TAL is the reabsorption of sodium and chloride from the tubular lumen to the interstitium, these basolateral processes have Na^+-K^+-ATPase activity.[222] In addition, they have an apical bumetanide-sensitive sodium-potassium-2 chloride cotransporter called NKCC2 located in the apical

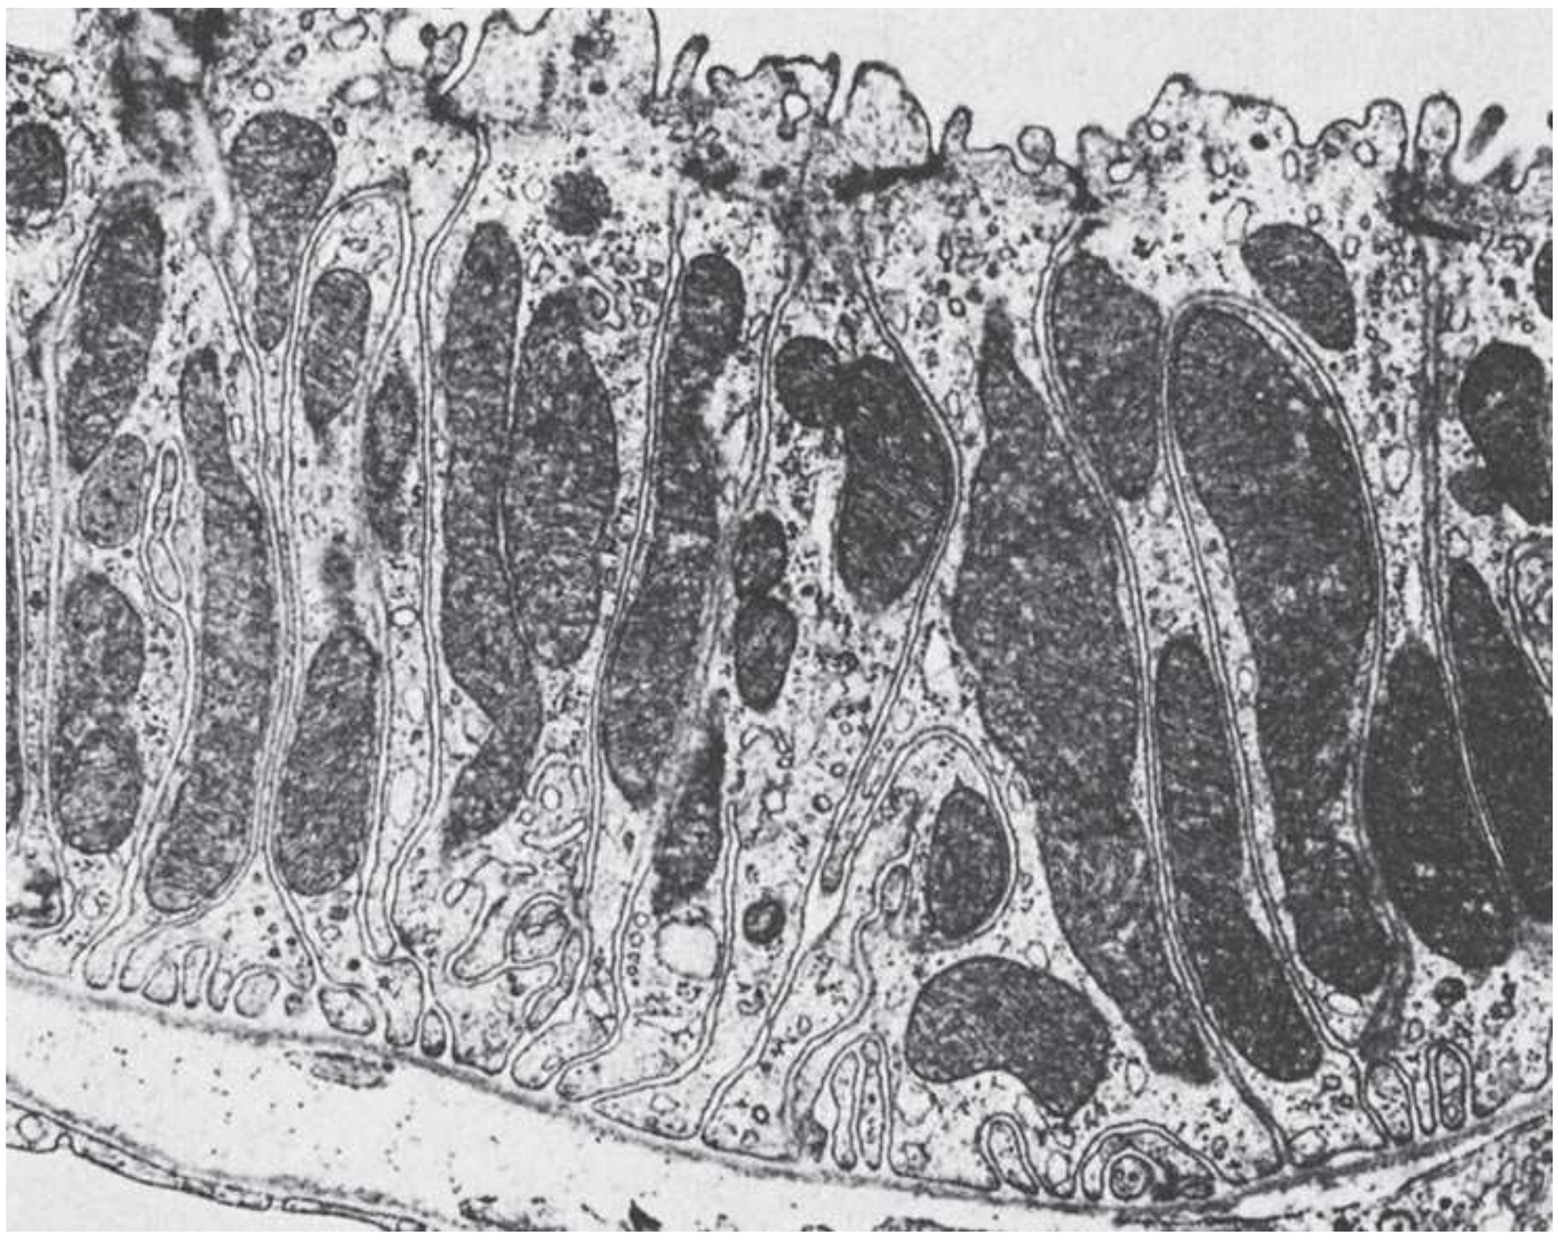

FIGURE 1.26 Transmission electron micrograph of the pars recta of the distal tubule from a rat showing the interdigitating cellular processes. (Magnification ×15,000.)

membrane (see the discussion of the membrane amplification principle later in this chapter). The MTAL demonstrates a low permeability for water so the active transport of the sodium ions out of the basolateral membranes of the cells in exchange for potassium ions participates in forming the hypertonicity of the medullary interstitium. The apical cytoplasm contains a variable number of vesicles and a prominent Golgi apparatus. Cisternae of rough-surfaced endoplasmic reticulum can be seen throughout the cytoplasm. The tight junction is of low to intermediate apical–basal depth, consisting of several parallel strands.[223] These tight junctions appear to be related to the relative impermeability to water (see discussion later in this chapter of tight junction structure and their role in transepithelial solute and water transport). As the MTAL traverses the outer stripe in rats, it decreases in cell height, but retains its prominent lateral interdigitations. In rabbits, the apical surface becomes more elaborate in this region.[158]

The administration of vasopressin (antidiuretic hormone) to rats that have hereditary diabetes insipidus causes hypertrophy of the MTAL in Brattleboro rats.[224] This effect can also be shown by water restriction in normal rats[225] and after high protein intake.[226,227]

Cortical Thick Ascending Limb

The cells of the CTAL are lower in height than those of the MTAL in the rat, measuring about 5 μm in height[221] and 2 μm in the rabbit.[2] The cells still have prominent basolateral interdigitating cell projections, which increase the basolateral cell membrane approximately tenfold over the apical or basal cell surface.[228] These interdigitating processes are more prominent in a circumferential direction.[228] Mitochondria are still prominent in the basolateral cell processes, but somewhat smaller than those of the MTAL. The apical cell border becomes more tortuous in this segment, having more prominent invaginations of the entire lateral cell margins, including the apical region of the cell,[158] and has more microvilli along its surface.[213] Tamm–Horsfall glycoprotein has been identified covering the plasma membrane in the TAL of rat.[229,230]

The MTAL and CTAL differ from each other physiologically, especially in hormone responsiveness.[231,232] The MTAL has a high density of Na^+-K^+-ATPase.[233] Hebert et al.[222] have shown in mice that antidiuretic hormone (ADH) increases the transepithelial voltage and net chloride reabsorption in the medullary, but not the cortical, region of the ascending thick segment. The ascending thick region functions in flow-dependent absorption of NaCl mediated by the furosemide (bumetanide)-sensitive cotransport NKCC2.[234,235] Nielsen et al.[236] and Obermuller et al.,[237] using immunohistochemistry, have demonstrated bumetanide-sensitive Na-K-2Cl labeling in the apical plasma membrane and the subapical intracellular vesicles of MTAL and CTAL in the rat and rabbit. The apical plasma membrane of the macula densa region also had distinct labeling consistent with a role in tubuloglomerular feedback.

The TAL in the inner stripe has a greater reabsorptive capacity for NaCl than the cortical segment,[238] but the cortical segment can maintain a higher concentration gradient[239] (see the discussion of Na^+-K^+-ATPase and the basolateral membrane area later in this chapter). The sodium chloride

reabsorbed by the TAL contributes to the hypertonicity of the medullary interstitium. As the CTAL ascends toward the renal corpuscle from which it was derived, there is an increase in apical plasma membrane surface area, both by an increase in apical microvilli and by an increase in lateral cell margins.[221]

The macula densa region is formed by a plaque of cells in the wall of the CTAL (see Fig. 1.35), where the ascending thick tubule runs between the afferent and efferent arterioles of the renal corpuscle from which the tubule is derived. A group of extraglomerular mesangial cells (lacis cells, Polkissen cells) fills the cone-shaped area formed by those three structures.[240] These four elements—the afferent and efferent arterioles, the extraglomerular mesangium, and the macula densa—constitute the juxtaglomerular apparatus, which will be discussed separately in more detail later in this chapter.

Distal Convoluted Tubule

The DCT (distal pars convoluta) is shorter than the proximal convolution, being about 1.2 mm in length in the rat.[217] Therefore, fewer profiles are seen in sections of the renal cortex. The DCT begins with a rather marked increase in the height of the lining cells from those of the TAL, although the cells are similar to those lining the TAL. In the rabbit, DCT cells are three to four times taller in the DCT than the cells lining the CTAL.[214] The DCT tubule has a variable diameter and contains one type of cell with more nuclear profiles than are seen in the proximal convoluted tubule (Fig. 1.27). The DCT extends from the CTAL to the CNT. The cells lining the DCT have short, bulbous luminal microvilli, but no regular brush border. The microvilli are more numerous than seen on the TAL cells, the CNT cells, or the principal cells of the CCD.[241] In humans, small lipid droplets are seen in the cytoplasm.[212] The endocytic apparatus is not well developed, but some vacuoles and numerous small vesicles are seen in the apical region. Dorup[241] describes four types of vesicles in these cells: intermediate vesicles (80 to 200 μm), which are generally uncoated; small vesicles with a mean diameter of 50 μm that are continuous with these intermediate vesicles; large vesicles (>200 μm); and tubular profiles (these being less frequent in DCT cells). Some rough-surfaced endoplasmic reticulum and lysosomes are also present in this segment. The cell nuclei occupy an apical position, because the basal two thirds of the cytoplasm is filled with extensive lateral interdigitating processes surrounded by basolateral cell membranes. These basolateral processes are filled with large elongated mitochondria that have their longitudinal axis perpendicular to the basement membrane. The presence of the large mitochondria lying adjacent to the basolateral cell membranes is consistent with the need for ATP for the continued active reabsorption of solute that occurs in this tubule (see Fig. 1.27). The volume of mitochondria in the DCT cells is larger than in the CNT cells or cortical collecting duct (CCT) cells.[241] An increased delivery of sodium to the DCT brings about an increase in the volume of the cell, in the mitochondrial volume, and in the proliferation of the basolateral membranes in the cells of the DCT, as well as in the CNT cells and the principal cells of the collecting ducts.[242–244]

The apical membrane of the DCT cells has numerous small microprojections. The tight junctions between the cells of the distal tubule are elaborate and are composed of multiple lines of membrane fusion,[245] a characteristic that correlates with the ability of the cells to maintain a large

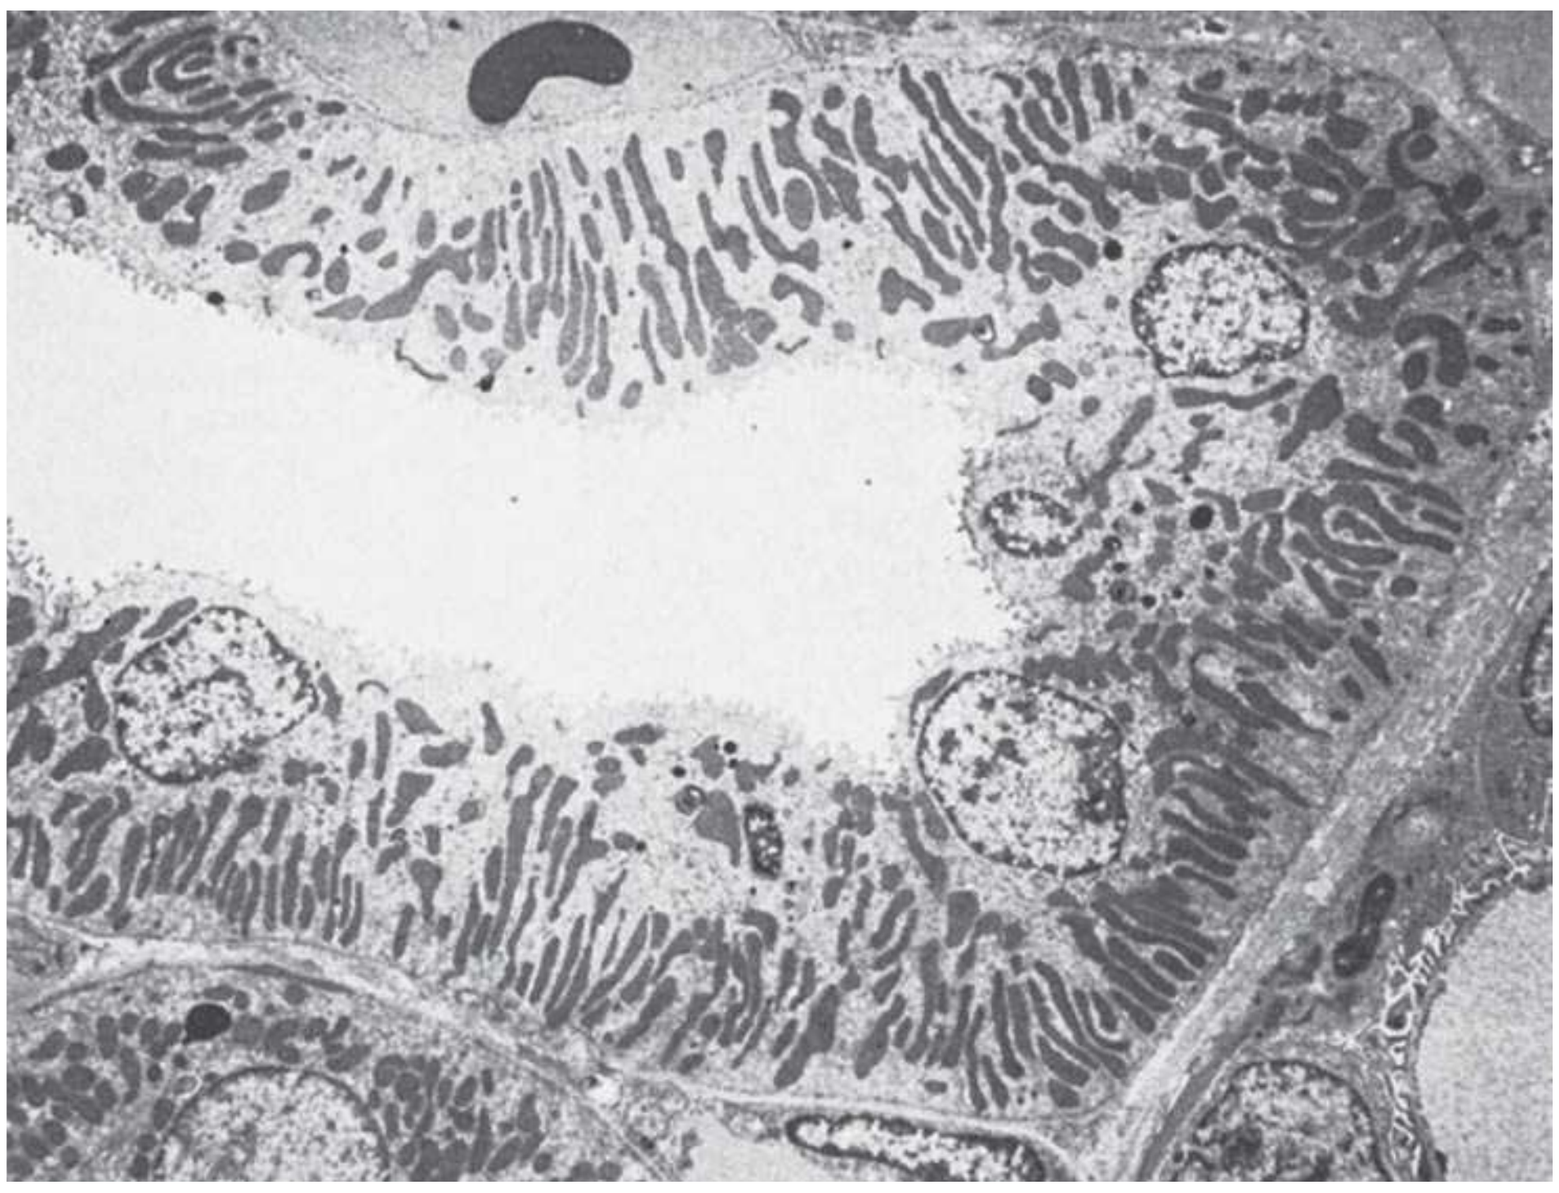

FIGURE 1.27 Transmission electron micrograph from a rat distal convoluted tubule showing the numerous mitochondria within interdigitating processes. (Magnification ×2,850.)

electrochemical gradient. The DCT reabsorbs NaCl against a steep chemical gradient and, as expected for such a sodium-absorbing epithelium, contains abundant Na^+-K^+-ATPase on its basal lateral cell membrane.[233,246,247] DCT proliferation and basolateral membrane amplification occur when active sodium reabsorption increases.[248,249] Kaissling et al.[250] increased the NaCl load to this segment by administering furosemide and demonstrated a marked adaptive increase in the basolateral membrane in the DCT.

In rabbits, an abrupt transition is seen from the distal tubule to the connecting piece of the nephrons.[158] The situation is less clear in other species, in which the transition does not appear to be either as abrupt or as completely studied. Recent studies by Biner et al.[251] used immunohistochemistry to localize the various transport systems along the human cortical distal nephron. The DCT demonstrates luminal thiazide-sensitive sodium-chloride cotransporter (NCC). The NCC overlaps with epithelial sodium chloride channels (ENaC) for a short region at the end of the DCT. IC cells were interspersed among the DCT cells near the end of the DCT. (For more detailed information, see recent reviews from the groups of Kaissling[251,252] and Bachmann.[253])

The Connecting Tubule

The CNT forms the next region of the distal nephron and lies between the DCT and the collecting duct system. At the present time, the CNT may be best classified as part of the DCT because it appears to be derived from the metanephric blastema.[4] Peter[7] believed that the arcades arise from the ureteric bud, whereas Oliver,[5] Potter,[254] and, more recently, Neiss,[4] all believe that the metanephric blastema is the correct source. However, Howie et al.,[255] using immunohistologic methods with substances related to the ABO blood groups, various cytokines, and Tamm–Horsfall protein, found that the ureteric bud and the connecting piece express the same antigens. The morphology of the CNT cells appears to have features of both the DCT cells, such as some degree of lateral interdigitations that contain mitochondria, but also has features of the CCD cells, such as the presence of more true basal infoldings (Fig. 1.28). Because of the intermixing of DCT cells, CNT cells, IC cells, and principal cells of the CCD in some species, such as rats and mice, there is a gradual transition from the DCT to the CNT in these species.[213,217] Neiss[4] demonstrated that IC cells (also called dark cells) in the CNT arose from the metanephric blastema, whereas the IC cells found in the collecting duct arose from the ureteric bud. Kim et al.,[256] using specific antibodies to carbonic anhydrase II, H^+-ATPase, and band-3 protein, demonstrated that IC appeared simultaneously in both the CNT and the medullary collecting duct. These IC cells differentiated from separate foci: one in the nephron (developing from the metanephric blastema) and one in the collecting duct (developing from the ureteric bud). When first identified, cells with distinct apical staining for H^+-ATPase (presumed to be type A intercalated cells), as well as cells with distinct basolateral H^+-ATPase labeling

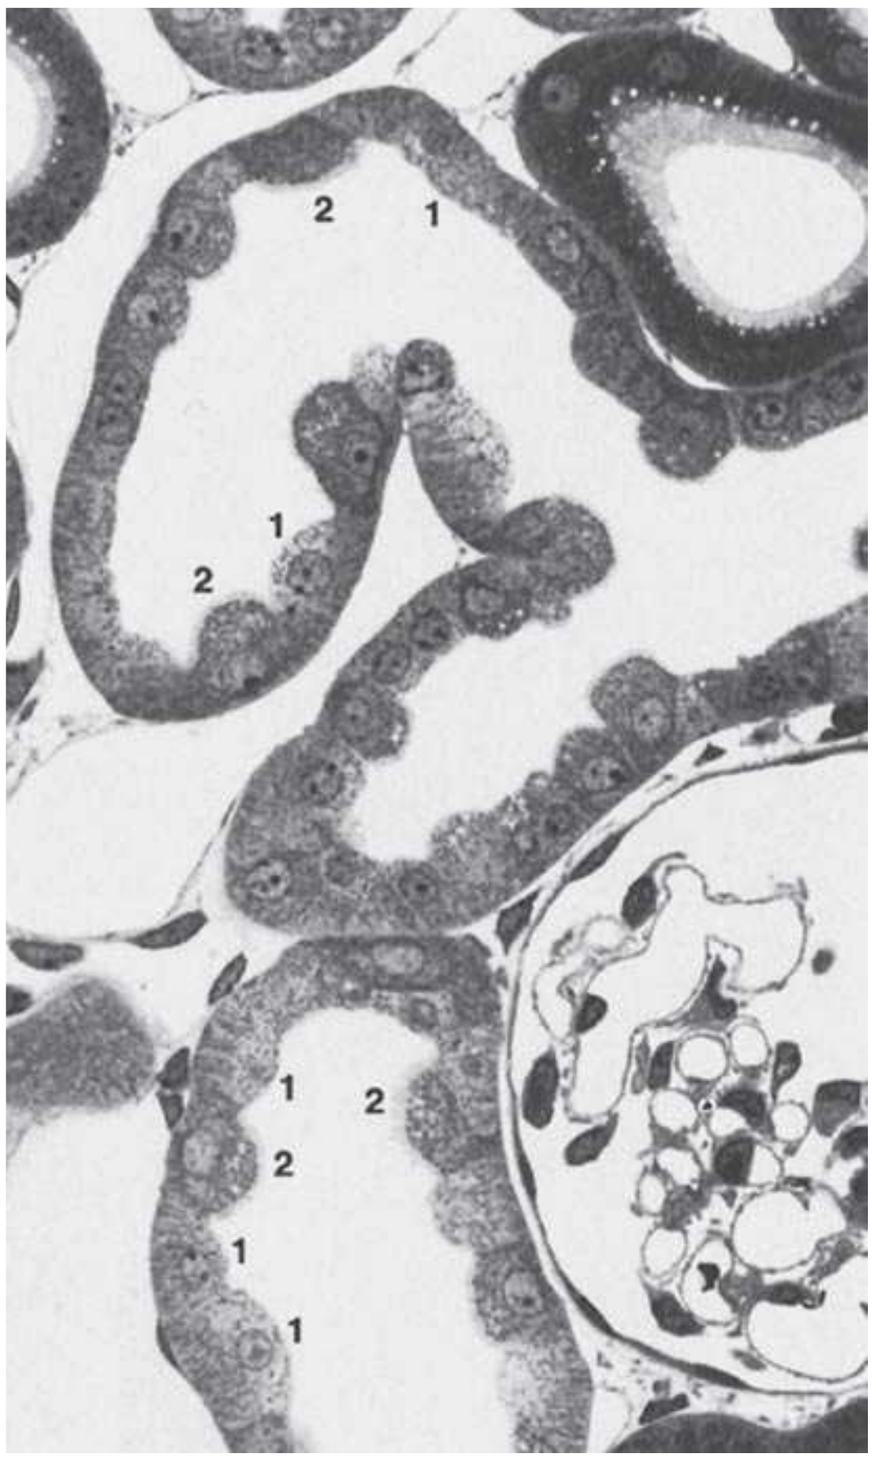

FIGURE 1.28 Light micrograph of the renal cortex (rabbit) showing a connecting tubule composed of connecting tubule cells (*1*) and intercalated cells (*2*). (Magnification ×900.) (From Kaissling B, Zurich, with permission.)

(presumed to be type B intercalated cells), were observed seemingly being developed from two embryologically distinct parts of the kidney. Some of these IC cells in certain locations subsequently disappeared.[256]

The CNT of superficial nephrons are short and drain individually into the collecting duct (some classify the point of junction as the initial collecting duct). CNTs of juxtamedullary and some midcortical nephrons generally form arched collecting ducts in many species. The arched duct starts deep within the cortex with the conversion and confluence of several DCT into the arcade and then ascends, while collecting parts of other nephrons, before the duct turns and enters a medullary ray. This arched duct results from an early embryonic type of nephron induction.[4,7] The number of nephrons that empty directly into the CCD, compared with the number that enter first into an arched tubule, varies with the species.[5] Both types occur in humans.

Two types of cells generally line the CNT, although intermixing of these two cell types with cells of other cell types, such as the DCT cells and the principal cells of the CD, are seen in some species. The two main types of cells

seen are CNT and IC cells (Fig. 1.28). The CNT cells appear to be characterized mainly by extensive true infoldings of the basal cell membrane, which can extend quite deeply into the cytoplasm. However, basolateral interdigitations have also been described, but are less pronounced than seen in DCT cells.[241] In rabbits, the plicated membranes can reach the apical cytoplasm.[158] Stanton et al.[244] demonstrated a striking increase in basolateral membranes in the rat CNT and the initial CCD of potassium-adapted animals, indicating that potassium is secreted by the CNT cells, as well as the principal cells of the (initial) collecting duct. In this study, no changes were seen in the IC cells. This suggests that potassium is secreted by the CNT cell and the principal cell of the initial collecting duct.[244,257]

The basolateral membranes of CNT cells are partially separated by mitochondria, which are smaller, more randomly distributed, and less numerous than those found in the DCT. The volume density of mitochondria in rat CNT cells was significantly lower than in the DCT cells.[241] This arrangement differs from principal cells of the collecting duct, in which the mitochondria are found mainly above the basal infoldings, not among the basolateral membranes. Microvilli on the apical surface tend to be slender and infrequent. Apical vesicles were about as frequent as seen in the DCT cells.[241] Mitochondria, the nucleus, and other cell organelles fill the apical cytoplasm. The CNT cells appear to exist in most species, including rats, mice,[212,217] and humans.[212]

Biner et al.[251] demonstrated an ENaC along the entire CNT in humans. The major part of the CNT also coexpresses aquaporin 2 with the ENaC. IC cells were identified interspersed among the CNT cells in the human. Loffing and Kaissling[258] reviewed the transport pathways along several mammalian distal nephrons and showed that ENaC was present along the CNT from the rabbit, rat, mouse, and human. Frindt et al.,[259] using patch clamp techniques in rat kidney tubule segments, demonstrated that the CNT could reabsorb sodium at a rate 10 times higher than that of the CCT. Using immunogold labeling and electron microscopy, aquaporin 2 (apical), 3, and 4 (basolateral) were all shown to be colocalized in CNT cells of rat.[260]

The CNT cell displays an amplification of basal cell membrane in rats[244] and rabbits[249] in situations in which there is a low Na^+ and high K^+ intake. This effect is axial along the tubule, being greatest at the early segment of the CNT and decreasing along its length.[249] The axial change in structure is paralleled by similar changes in Na^+-K^+-ATPase.[261]

The second cell type is the IC cells (or dark cells). Three types of IC cells have been described: type A involved with the secretion of protons into the lumen; type B involved with the secretion of bicarbonate into the tubular lumen; and non-A–non-B, which may be able to secrete both protons and bicarbonate into the tubular lumen. IC cells will be discussed under the collecting ducts, because these cells comprise such an important number of the cells lining the tubule in that region. Electrophysiologic studies in rabbits suggest that approximately 98% of the IC cells in the connecting tubule are the HCO_3^--secreting B type.[262]

THE COLLECTING DUCTS

The collecting ducts extend from the CNT through the medullary rays as CCDs. They then cross the outer and inner stripe of the outer medulla as well as the inner medulla, to empty their contents at the tip of the renal papillae. They include the CCDs (including the initial collecting ducts), the outer medullary collecting ducts (OMCDs), and the inner medullary collecting ducts (IMCDs).

The collecting ducts are the final regulators of fluid and electrolyte balance, playing roles in the handling of Na^+, Cl^-, K^+, and acid and base. Although there has been great emphasis on the role of the collecting ducts as the main controllers of urinary sodium and potassium excretion, Meneton et al.[263] stress the pivotal role played by both the late part of the DCT and the CNT, especially in situations that prevail in our current environment, in which the dietary sodium intake is high and the potassium intake is low. They propose that a large proportion of the aldosterone-regulated sodium reabsorption and potassium secretion occurs before the tubular fluid reaches the collecting duct. The difference between the function of the late DCT and the CNT compared to the collecting duct seems to be more quantitative than qualitative, with a large proportion of the aldosterone-regulated sodium reabsorption and potassium secretion being done in the late DCT and CNT. The collecting duct would function mainly when the requirement for sodium and water conservation is maximal and the upstream segments are overloaded by diet or some genetic defect.

The collecting ducts are lined by two types of cells: collecting duct principal (light) cells and intercalated (dark) cells (Figs. 1.29 and 1.30). About 30% of CCD cells are IC cells in rat.[264] Kaissling and Kriz[158] estimate that rabbits have 33% IC cells in the CCD and 50% in the outer medullary collecting duct. About one-third of the cells lining the outer medullary collecting duct in the rat are IC cells.[265] The number of IC cells decreases as the collecting duct descends into the medulla and are absent below the first portion of the IMCD. The principal cells of the collecting duct gradually change in morphology as they descend toward the papilla. They increase in cell height and have more complex tight junctions, whereas the amount of basal infoldings and the number of mitochondria decrease. Fusions of the collecting ducts occur in the inner renal medulla to form the large papillary collecting ducts (ducts of Bellini). These large collecting ducts exit at the papillary tip in an area known as the area cribrosa.

The principal cells of the collecting duct in the cortex are cuboidal in humans[218] and low cuboidal in rats (see Fig. 1.29). They form the most numerous cell types. They have a simple cell shape, with fairly straight lateral cell borders that have small interlocking projections. Their

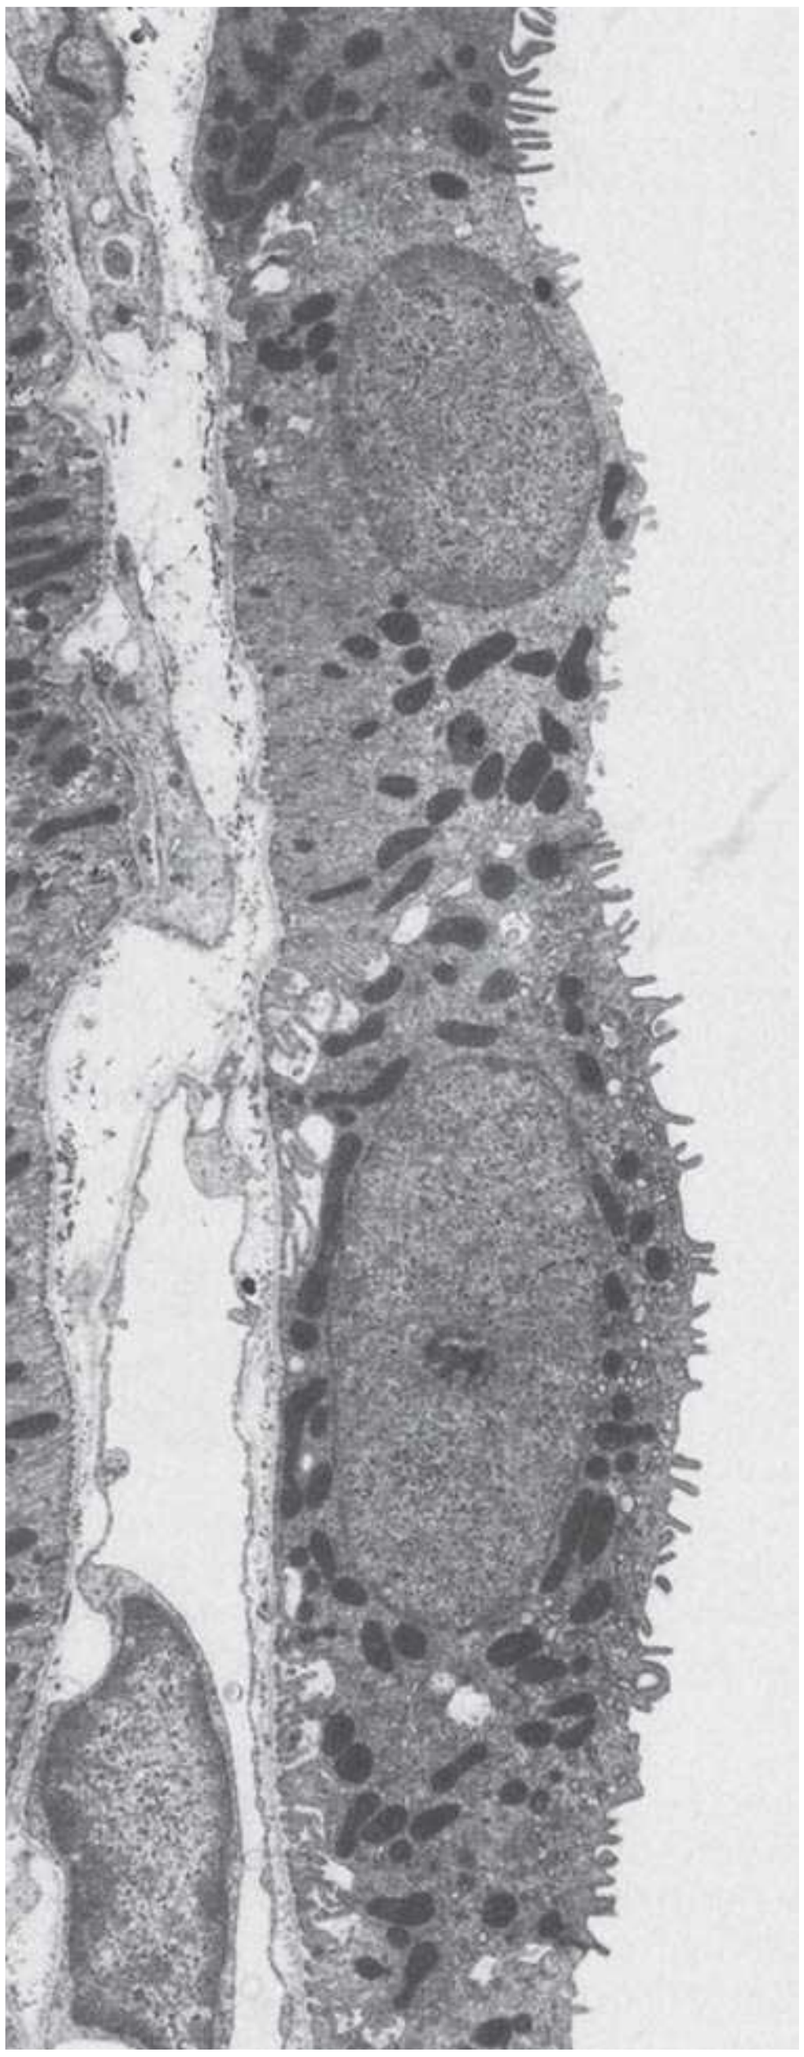

FIGURE 1.29 Transmission electron micrograph of the epithelium of a cortical collecting duct (rat) showing a collecting duct cell (principal cell) (*above*) and an intercalated cell (A-type) (*below*). pale-staining cytoplasm contains a few small, oval, randomly oriented mitochondria and other organelles, and the nucleus is situated in the middle to upper one-half of the cell in the cortex. The luminal surface is generally smooth with a few short microvilli and a single cilium. The basal surface is characterized by true basal infoldings, with few lateral interdigitations. The amplification factor of basolateral membranes was significantly lower than in the CNT cells.[241] Because these infoldings are short and closely spaced, they do not have mitochondria lying between them. The mitochondria are located mainly above the infoldings and in the apical cytoplasm, which contained few intermediate and small vesicles, tubular profiles, and large vesicles.[241] The tight junctions are deep,[223,266] and the apical surface has a prominent glycocalyx.[267]

Conditions that increase potassium secretion, such as potassium adaptation or high endogenous or exogenous mineralocorticoid levels, bring about dramatic increases in these basal cell membrane infoldings.[249,262,268,269] For example, striking increases in the basolateral membranes of the principal cells of the initial segment of the collecting duct have been demonstrated in potassium-adapted animals.[244] In addition, the principal cells in rats showed a 35% decrease in the basolateral membranes in adrenalectomized animals that was restored to control levels by the administration of physiologic amounts of aldosterone, but not of glucocorticoids.[270] In addition, increasing the dose of aldosterone over control levels caused an increase in the basolateral membranes by 111% compared with controls. They did not note changes in the luminal membranes of the principal cells.[270] These

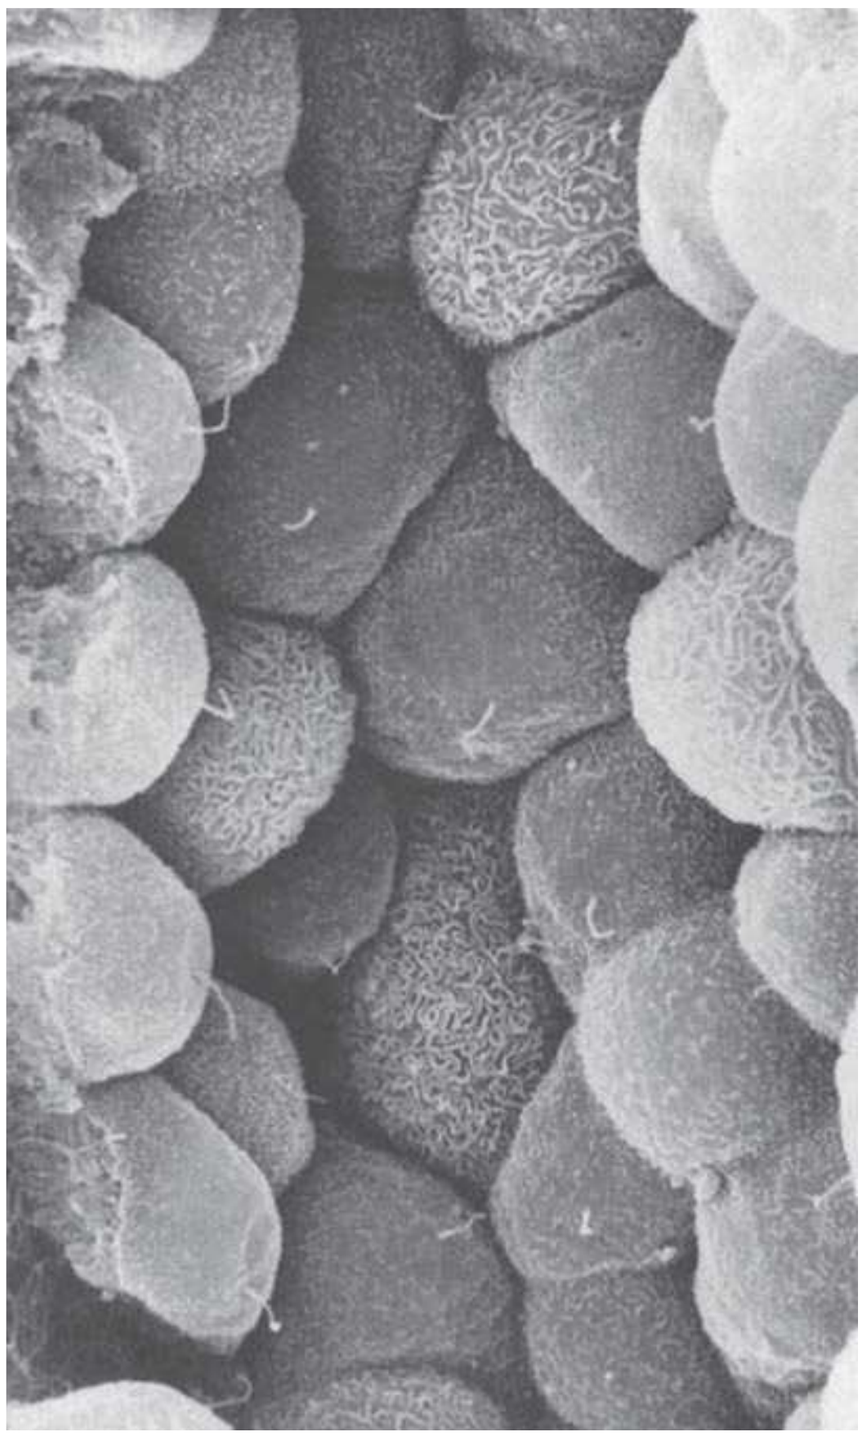

FIGURE 1.30 Scanning electron micrograph of a cortical collecting duct (rat) showing the apical aspect of collecting duct cells (with an apical cilium) and intercalated cells (with apical microfolds). (Magnification ×2,400.)

studies provide evidence that principal cells in the collecting duct are involved with potassium secretion.

The collecting duct responds to ADH by an increase in water permeability. The principal cells are vasopressin sensitive and show dramatic increases in water permeability of the apical membrane. Sun et al.[271] have demonstrated direct evidence that AQP2 on principal cells is located in clathrin-coated pits that recycle between the plasma membrane and intracellular vesicles in response to the availability of ADH. The mechanisms underlying these changes are discussed in detail later in this chapter.

Biner et al.,[251] using immunohistochemical localization techniques on human kidney, demonstrated the presence of an amiloride-sensitive ENaC and AQP2 activity on collecting duct principal cells. Loffing et al.[272] using immunohistochemistry in rabbit kidney cortex, demonstrated that ENaC is found in the CNT cells and the CCD cells. The ENaC shifted from the apical membrane in the upstream CNT cells to a cytoplasmic location downstream in the CNT and CCD cells. In the rabbit, the AQP2 was seen only on the CCD cells. The apical membranes of the collecting duct principal cells of humans contain ENaC and AQP2, whereas the basal membranes contain Na^+-K^+-ATPase and aquaporins 3 (AQP3) and 4 (AQP4); hence, the CCD plays a critical role in the concentration of urine. The CCD also responds to the mineralocorticoid aldosterone.[273]

The collecting duct cells undergo gradual, although considerable, changes from the cortex downstream to the upper one-third of the inner medulla.[158,218] The cells of the outer medulla include principal cells similar to those seen in the cortex; however, the cells become taller with decreasing concentrations of several cellular organelles and basal infoldings. IC cells similar to type A are found in the outer medulla. From the deeper cortical levels downward into the inner medullary region, the basal labyrinth of the principal cells continues to decrease gradually, with a steeper reduction within the outer stripe.[158,215,218] The number of mitochondria also continues to decrease, whereas lysosomal elements and apical-coated vesicles seem to increase. The density of the cytoskeletal network lying under the apical cell membrane becomes more prominent and the tight junctional belt becomes deeper.[158]

From the second one-third of the inner medulla, collecting duct cell size increases steeply. These tall IMCD cells are distinct from collecting duct cells upstream according to several criteria[213,220,274] (Fig. 1.31). Their luminal membrane is covered by numerous stubby microvilli and lacks the central cilium. The lateral intercellular spaces are more extensively developed and are prominent by their dense assembly of microvilli and microfolds projecting from the lateral cell membranes. A prominent feature of principal cells of the last one-third of IMCDs is the expression of the ADH-sensitive

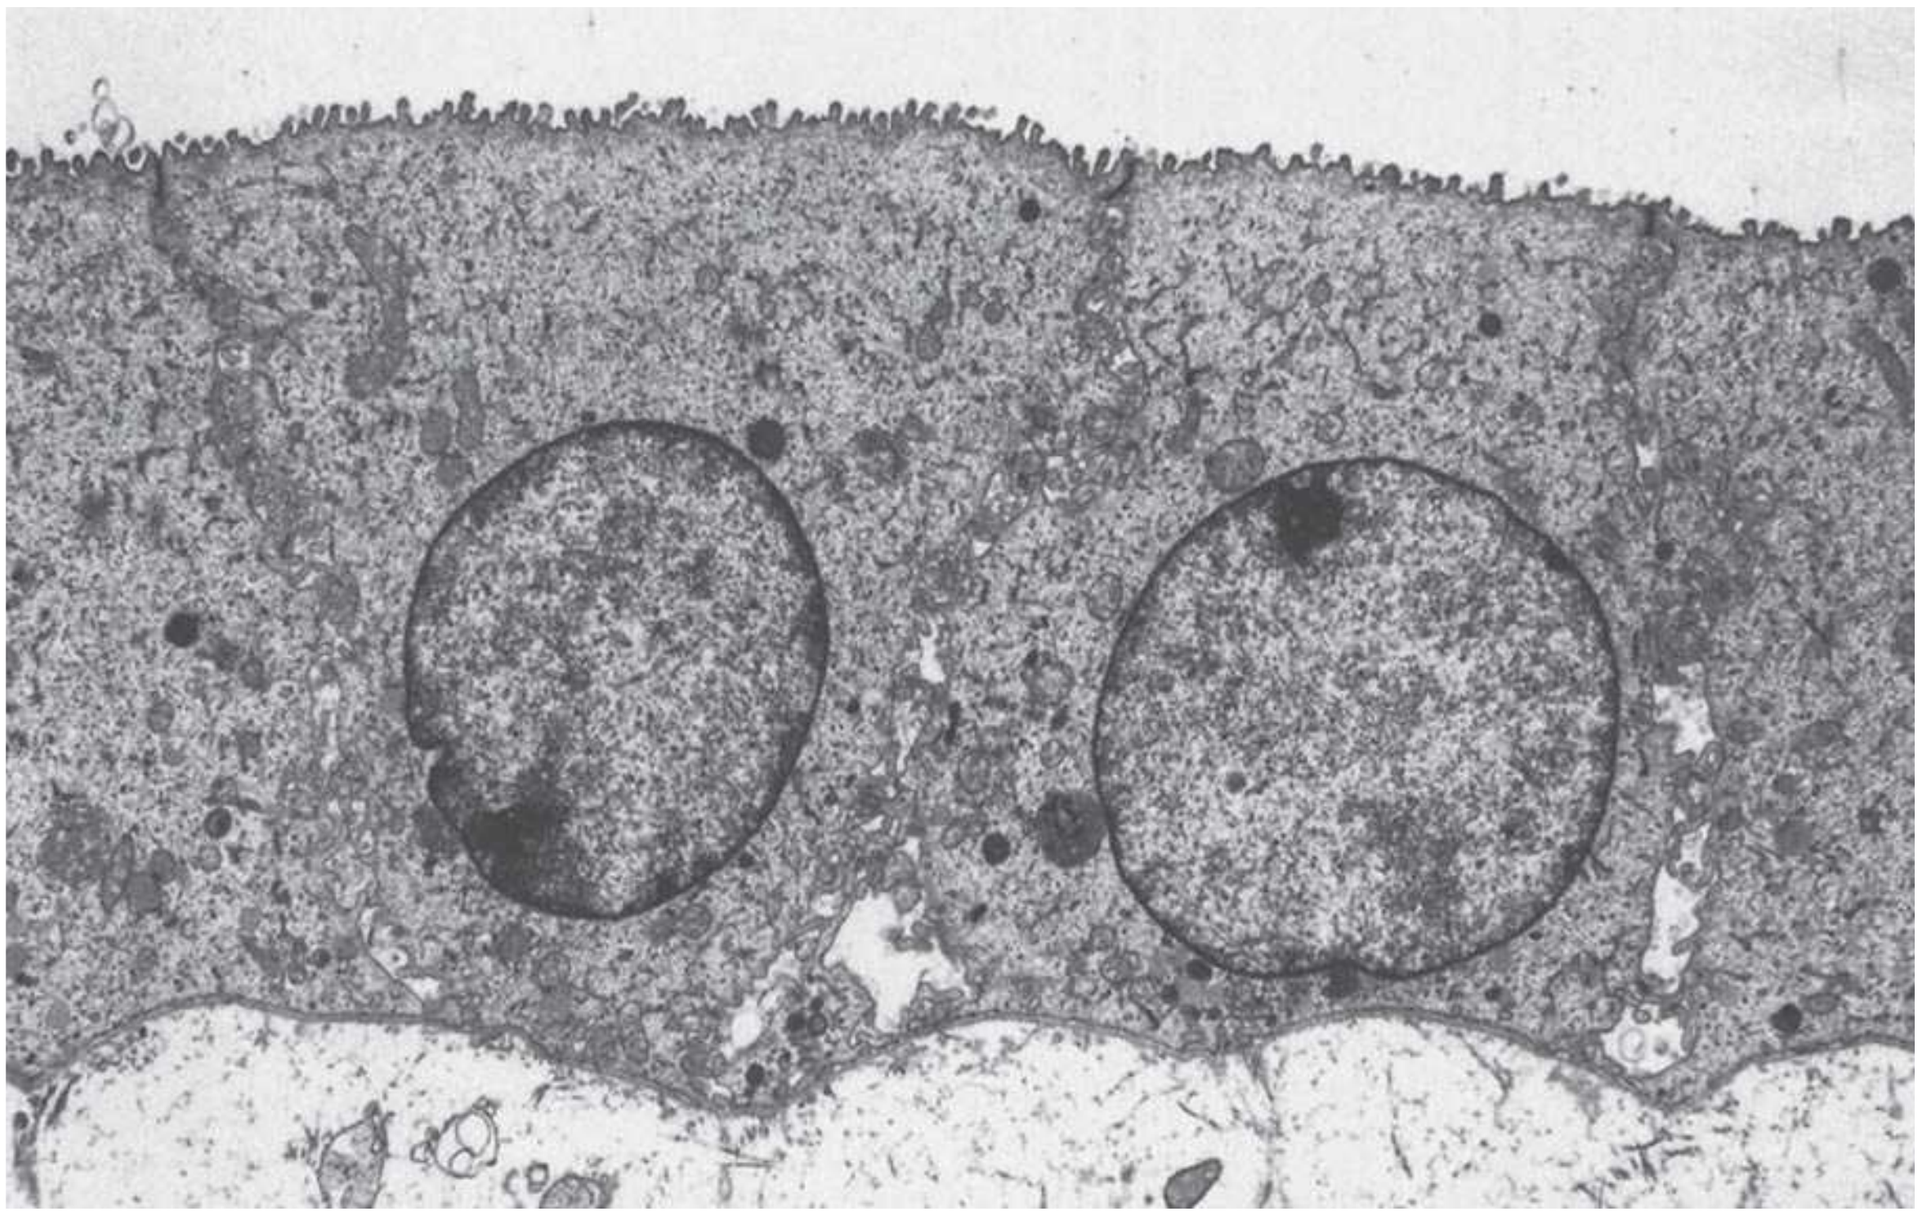

FIGURE 1.31 Transmission electron micrograph of the inner medullary collecting duct epithelium (rat) showing the high inner medullary collecting duct cells with many stubby microvilli of the luminal membrane and prominent lateral intercellular spaces filled with lateral microfolds. FIGURE 1.32 Summary diagram, showing cells from the various regions of the urinary tubule.

urea transporter UT-A1.[193,275] In most other respects, IMCD cells resemble the other collecting duct cells. The morphology of the various regions of the renal tubule is summarized in Figure 1.32.

Intercalated Cells

IC cells have long been identified in CCDs in a variety of species such as rats,[213,217,264,276–279] mice,[264,280] humans,[218,251] and rabbits[158,248,256,281–283] (Figs. 1.29 and 1.33). It has become obvious that IC cells are not only found in the CCD but, depending on the species, in the latter region of the DCT in humans[218,251,278] and rat,[217,241,265,278] in the connecting tubule in rabbits[158,248] and humans,[251] in the CCD (as listed previously), in the outer medullary collecting ducts in rats,[265] and in the upper part of the inner medullary cells in rats and rabbits.[158] IC cells constitute about 37% to 40% of the cells in CCD in rats and rabbits.[265,280,283] Kaissling and Kriz[158] estimate that rabbits have 33% IC cells in the CCD and 50% in the outer medullary collecting duct, whereas Hansen et al.[265] estimate that 36% to 40% of IC cells are present in the outer medullary collecting ducts in rat. IC cells show a slow decrease in the upper part of the IMCD in rats.[283]

IC cells (Fig. 1.33) are sometimes called dark cells because their cytoplasm stains more densely. They exhibit

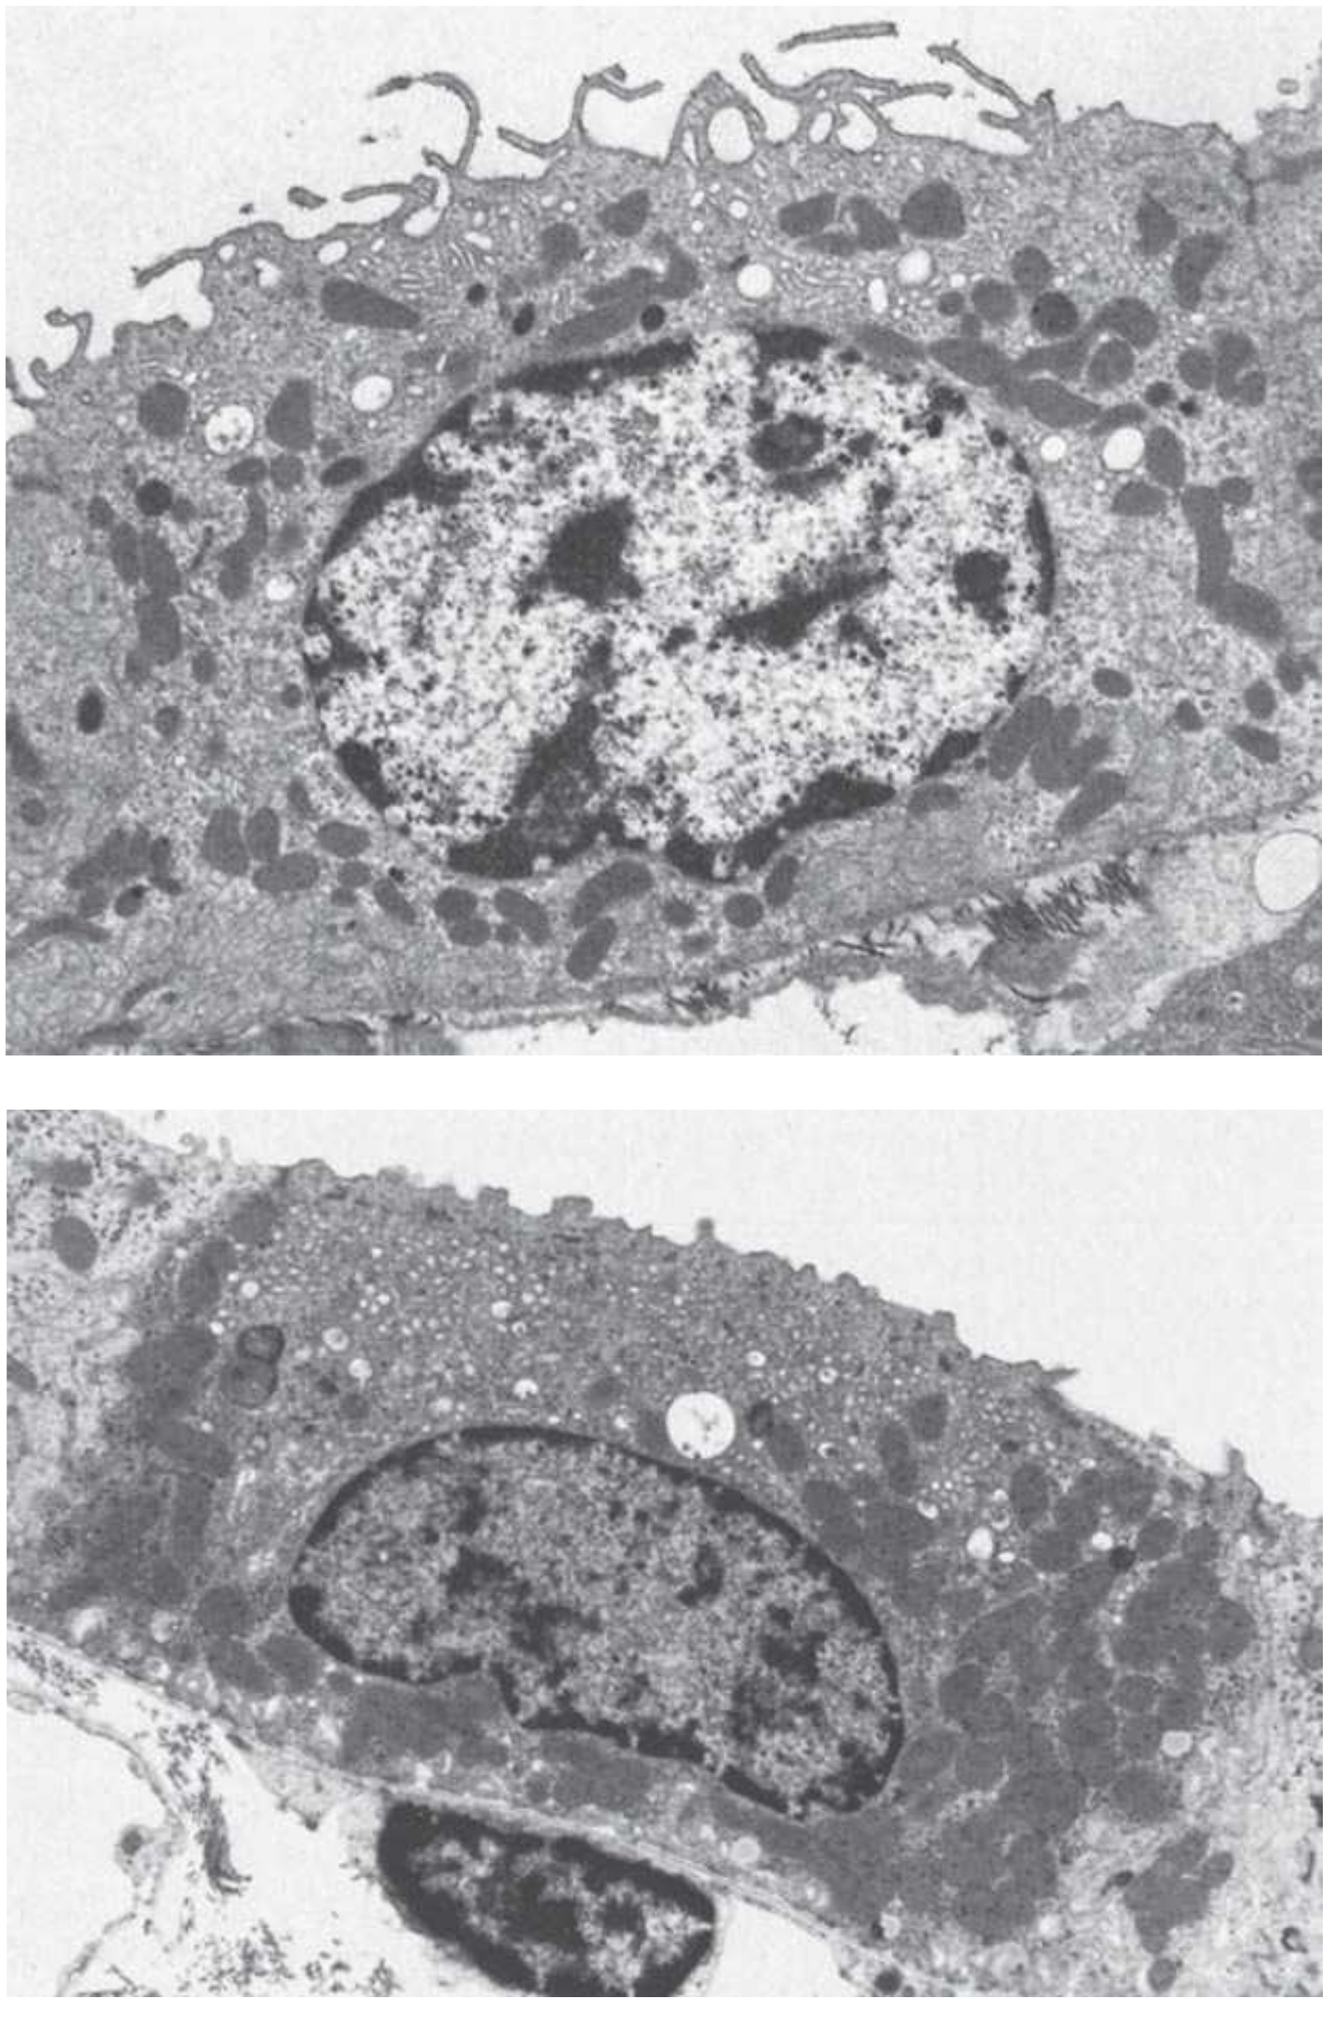

FIGURE 1.33 Transmission electron micrographs of intercalated cells (rat). **A:** Type A exhibiting apical microfolds and flat vesicles in the apical cytoplasm. (Magnification ×6,800.) **B:** Type B showing a rather smooth apical surface, many small round vesicles, and mitochondria located predominantly in the lateral and basal parts of the cell. (Magnification ×6,800.)

significant structural heterogeneity even within a single segment of the collecting duct. IC cells can also be distinguished from principal cells by differences in cell shape, cytochemical staining, and uptake of the pH-sensitive fluoroprobe, 2′,7′-bis(carboxyethyl)—5,6-carboxyfluorescein (BCECF). IC cells have a more circular, rather than hexagonal, profile that bulges into the tubule lumen when observed in isolated perfused tubules by means of interference-contrast optics. In rabbits, IC cells can be identified by positive staining with peanut lectin[284,285] and by luminal uptake of acetoxymethyl BCECF.[285] The apical surface of the IC cell is frequently adorned by luminal extensions, which include microvilli and microridges (called microplicae). Basal membrane infoldings resemble those of the collecting duct cell.

Three types of IC cells have been defined morphologically and by immunohistochemical staining, including type A, type B, and non-A–non-B.[264,280] However, there is a striking difference in the number and distribution of the various types of IC cells from animal to animal and among the nephron segments of a particular species.[264] Carbonic anhydrase II immunoreactivity was seen in all IC cells, but type A stained more intensely than type B. The immunostaining in type A cells was pronounced in the apical cytoplasm and apical microprojections. In type B cells, the staining was more diffuse throughout the cytoplasm. In the non-A–non-B cells, the staining was also diffuse.[286]

Type A IC cells tend to have a more circular apical cell profile,[278] a centrally placed nucleus, prominent apical microvilli and microplicae extending from the apical plasma membrane, and prominent apical cytoplasmic tubulovesicular

profiles (see Fig. 1.33A). Mitochondria are numerous and can be located above the nucleus, as well as between the nucleus and the basal membrane infoldings. Using freeze-fracture techniques, there are rod-shaped particles and studs present on the cytoplasmic face of the apical plasmalemma and on the tubulovesicular profiles in the IC cells of the CCD and the outer medullary collecting ducts.[280,287,288] H^+-ATPase is expressed on the apical plasma membrane and in the cytoplasmic tubulovesicular and vesicular profiles of type A IC cells. (See review of renal vacuolar H^+-ATPase.[289])

Verlander et al.[278] showed that IC cells in animals with respiratory acidosis show a striking increase in apical microprojections and tubulovesicular profiles as well as an increase in surface density of the apical plasma membrane. However, no changes were seen with the number of IC cells. When there was a stimulation of bicarbonate secretion in rats, Verlander and associates[288] documented a withdrawal of the marker for H^+-ATPase from the apical plasma membrane with its storage in apical cytoplasmic vesicles in IC cells in both the CCD and the OMCD. H^+-ATPase activity appeared to be inserted into the basal plasma membrane of type B IC cells.[288]

Luminal and/or tubulovesicular membranes exhibit two specific types of particles. Large club-shaped particles called "studs" have been observed on the cytoplasmic surface of the tubulovesicular structures on the cytoplasmic side of the apical plasma membrane; the rapid-freeze, deep-etch technique shows 10-μm spherical structures composed of multiple subunits and arranged in paracrystalline hexagonal arrays.[290] Brown et al.[291] have presented evidence that the studlike material coating the vesicles contains cytoplasmic domains of the proton-pumping H^+-ATPase. On the basis of both morphologic characteristics and immunocytochemistry, the structures appear to be (or related to) the vacuolar-type H^+-ATPase.[277,291] In addition, freeze-fracture studies have shown the presence of rod-shaped particles in vesicles and cell surface membranes,[292] which may form a component of this H^+-ATPase. Changes in membrane structure have been shown to be related to proton secretion.[248,261] When H^+ secretion is stimulated, cytoplasmic vesicles bearing rod-shaped intramembranous particles (IMPs) fuse with the apical plasma membrane, inserting IMPs into the membrane.

This supports the idea that type A IC cells demonstrate net excretion of protons into the tubular lumen that is accomplished by the vacuolar H^+-ATPase located in the apical plasma membrane and apical tubulovesicular profiles.[264,277,280,288,293,294] For this process, it has been suggested that the hydrogen ions are produced by cytosolic carbonic anhydrase in CNT cells and CCD cells of the mouse and rat[264,280,286,294,295] and human.[251,296,297] The bicarbonate that is generated is released by a band 3-like Cl^-/HCO_3^- exchanger AE1, located in the basolateral plasma membrane, into the interstitium at the base of the cell.

Medullary IC cells from rats fed a diet with a high K^+ content had a small luminal membrane area and a cell apex with numerous vesicles. The ingestion of a low K^+ diet led to an increased luminal membrane area with few apical vesicles.[268] It has, therefore, been postulated that IC cells function in potassium reabsorption.

A similar increase in the apical plasma membrane with a decrease in tubulovesicular profiles was seen in IC cells of the outer medulla in chronic metabolic acidosis[298] and acute respiratory acidosis in rats.[299] In respiratory acidosis, a marked increase in apical microprojections was seen as was an increase in the surface density of the apical membrane of type A cells. No changes were seen with type B cells in rat CCD.[278] Madsen and Tisher[213] postulated that hydrogen ion pumps located in the apical vesicles had been inserted into the apical cell membrane by vesicle fusion with the apical membrane.

Type B IC cells are present in the CCD and the CT of rats,[276,278,286,300] mice,[264,280] and rabbits.[230,256,281,301] The type B cell (Fig. 1.33B) has an angular outline[278] and a relatively smooth apical plasma membrane with short sparse microvilli (without rod-shaped studs in the apical membrane).[280] The apical membrane generally lacks studs, but the basolateral membrane exhibits studs.[278] The nucleus lies in an eccentric position and the numerous small mitochondria are densely packed and are concentrated at the basal part of the cytoplasm. The cytoplasm and the organelles stain more densely in light and electron microscopy. Cytoplasmic vesicles (mostly noncoated) are seen throughout the cell cytoplasm. In the type B cells, the H^+-ATPase is expressed in the basolateral plasma membrane and in the cytoplasmic vesicles throughout the cells.[277,280,291,300,302–305] Using freeze-fracture techniques, rod-shaped rectangular particles are found on the basal membranes in these cells and not on the apical plasma membrane.[277,300] The basal hydrogen ion secretion is thought to mediate HCO_3^- secretion into the luminal fluid by an apical Cl^-/HCO_3^- exchanger different from AE1.[256,264]

One candidate for this anion exchanger is pendrin, a Na^+-independent Cl^-/HCO_3^- exchanger. Quentin et al.[306] have shown that the Cl^-/HCO_3^- exchanger pendrin in rat kidney is specifically regulated in response to chloride balance independent of sodium and acid/base balance. Using a mouse model, Wall et al.[307] demonstrated that pendrin protein was localized in the apical cytoplasmic vesicles in both type B and non-A–non-B IC cells from a subset of cells in the DCT, the type B cells in the CNT, and the CCD. Pendrin mRNA was expressed mainly in the cortex. Pendrin immunoreactivity was highest in the apical cytoplasmic vesicles, although there was little immunogold staining along the apical plasma membrane of type B IC cells, but non-A–non-B IC cells had intense pendrin immunoreactivity along the apical plasma membrane. Kim et al.,[308] using immunoelectron microscopy, demonstrated pendrin in both the apical plasma membrane and intracellular vesicles throughout the cell. Kim et al.[286] found the carbonic anhydrase activity more diffuse in the cytoplasm of type B than type A cells.

The third type of IC cell is non-A–non-B cells that have been identified in the CT and the CCD of rats[264,276,286,309] and mice.[264,276,280] Non-A–non-B cells have vacuolar

type H^+-ATPase in both apical plasma membranes and apical vesicles, but do not have the basolateral band 3-like immunoreactivity of AE1.[264] In rabbits and mice, most non-A–non-B cells in the collecting duct have an electroneutral Na-independent Cl^-/HCO_3^- exchanger in the apical membrane.[264] Pendrin immunoreactivity is intense along the apical membrane, as well as being present in apical vesicles in some cells in the DCT, in the CNT, and CT.[307] Because both pendrin immunoreactivity and pendrin-mediated HCO_3^- secretion are present in the apical plasma membrane and apical intracellular vesicles in type B and non-A–non-B IC cells, Kim et al.[308] suggest that HCO_3^- secretion could be regulated by trafficking of pendrin between the two membraneous compartments. In addition, since non-A–non B cells seem capable of both apical HCO_3^- and H^+ secretion, the simultaneous secretion of both HCO_3^- in exchange for Cl^- and proton secretion mediated by electrogenic H^+-ATPase, would cause chloride reabsorption with no change in acid/base status.[308]

THE JUXTAGLOMERULAR APPARATUS

At the vascular pole of the renal corpuscle, the macula densa region of the CTAL comes into close proximity to the efferent and afferent arterioles and a group of cells called the extraglomerular mesangium.[310,311] The juxtaglomerular apparatus consists of four parts (Figs. 1.5 and 1.34): (1) a plaque of cells in the wall of the CTAL of the distal nephron in the region of the vascular pole of a renal corpuscle, called the "macula densa"; (2) the termination of the afferent arteriole as it enters this renal corpuscle; (3) the initiation of the efferent arteriole as it exits from the same renal corpuscle; and (4) a cone-shaped region of extraglomerular mesangial cells (also called the lacis, Polkissen, or Goomaghtigh cells) lying in the space between the macula densa and the two arterioles. This area receives a rich supply of sympathetic nerve endings.

In the human kidney, 40% of the basal lamina region of the macula densa lies adjacent to the base of the cone-shaped extraglomerular mesangium, 10% of the macula densa basal lamina is in contact with the afferent arteriole, and 5% is in contact with the efferent arteriole.[308]

The MD consists of the cells in the wall of the CTAL of the distal tubule, which lies adjacent to the glomerular vascular pole. The MD appears as a dense spot upon hematoxylin and eosin staining because the cells are narrow and the nuclei are close together. MD cells (Fig. 1.35) are not interdigitated with each other by large lateral cell processes, as in other regions of the distal tubule. In contrast, the lateral intercellular spaces between MD cells extend very straight in an apical–basal direction—their width appears to vary according to function.[312] The mitochondria are shorter and more randomly arranged. The Golgi apparatus lies on the basal side of the nucleus. The basal aspect of the MD touches

FIGURE 1.34 Light micrograph of a renal corpuscle with both urinary and vascular poles in the section. (Magnification ×1,900.)

the extraglomerular mesangium. Additional, but variable, contacts are found with the efferent as well as the afferent arterioles.[13] The most conspicuous difference of MD cells to any other cells of the nephron is the occurrence of nitric oxide synthase I (see Fig. 1.37C).[313,314] A prominent feature of the MD is also the expression of cyclooxygenase-2.[315]

Modified smooth muscle cells in the wall of the afferent arterioles, called granular cells (formerly also called juxtaglomerular cells), contain specific membrane-bound granules (Fig. 1.36). In situ hybridization[316] and immunocytochemistry [317] have shown that these cells synthesize renin (Fig. 1.37A), which is then stored in granular form (Figs. 1.36B and 1.37B). The granules stain with the Bowie method and have a positive periodic acid-Schiff reaction. Like other smooth muscle cells, the juxtaglomerular cells also contain intracellular filaments and dense bodies, but they have more cisternae of rough-surfaced endoplasmic reticulum, a large Golgi apparatus, and mature and immature secretory granules in their cytoplasm, consistent with the ability of these cells to synthesize small peptides. The immature granules appear to have a paracrystalline structure.[80,318] The secretory product is released by exocytosis into the extracellular space within or surrounding the wall of the arteriole.[319,320] Processes of the juxtaglomerular cells contact the surrounding cells as well as the endothelial cells by means of gap junctions.[321]

The extraglomerular mesangium[310] (Goormaghtigh cells, polar cushion, Polkissen cells, and lacis cells) fills the area between the afferent and efferent arterioles and the MD (see Figs. 1.5 and 1.35). It is composed of nongranulated cells that are continuous with granular cells and smooth muscle cells of the arteriolar walls and with the intraglomerular mesangial cells.[310] The extraglomerular mesangial cells are "flatly pressed" cylinders with both ends splitting into a group of parallel processes. These extraglomerular mesangial cells are surrounded by abundant extracellular matrix. Numerous gap junctions occur between the processes of the same cell, with adjacent smooth muscle cells, with granular cells, and at the renal hilus with intraglomerular mesangial cells.[240,322,323]

The initmate and systematic juxtaposition of tubular and vascular cells within the JGA has given rise to early

speculations about a functional connection in which a signal related to the composition of the tubular fluid at the MD affects glomerular vascular tone and the glomerular filtration rate.[324] It has now become clear that the JGA serves two different functions: it regulates the flow resistance of afferent arterioles in the so-called tubuloglomerular feedback mechanism and it participates in the control of renin synthesis and release from granular cells in the afferent arteriole.[325] Researchers originally assumed that the two responses might be related to each other in that renin released from the granular cells not only has systematic relevance, but locally triggers the formation of angiotensin II and thus is responsible for the afferent vasoconstriction as well; however, it now appears that the final activation of smooth muscle and granular effector cells occurs through largely independent pathways. Renin release from granular cells is the major source of systemic angiotensin II and thus plays an essential role in controlling extracellular volume and blood pressure, whereas the vasoconstriction of the afferent arteriole locally serves to modulate the filtration of this nephron.

For both mechanisms, it is well established that changes in the chloride concentration of the tubular fluid at the MD cause graded releases of mediators that reach their target by diffusion, thus acting in a paracrine fashion.[326] Note that the extraglomerular mesangium that mediates the contact between the MD and the effector cells is not vascularized, so that the buildup of any paracrine agent would not be perturbed by blood flow.

With respect to renin release, the most likely paracrine mediators of this process are prostaglandin E_2 and nitric oxide.[314,327,328] With respect to the vasoconstrictor response purinergic mediators,, either ATP or adenosine, as first suggested by Oswald and colleagues in 1980,[329] appear to play the major role.[325,330,331] For an up-to-date discussion of the function of the JGA, see the reviews by Schnermann and Levine,[325] Persson and colleagues,[332] and Komlosi et al.[333]

RENAL BLOOD VESSELS

The renal arteries arise from the lateral region of the abdominal aorta at the level of the first and second lumbar vertebrae. Each artery divides into an anterior and posterior division before traversing the renal hilus. These divisions usually form a total of five segmental branches. The anterior division gives rise to the upper, middle, and lower segmental arteries, whereas the posterior division becomes the posterior segmental artery. The apical segmental artery can arise from either division. The segmental arteries give rise to interlobar arteries within the renal sinus. The interlobar arteries enter the renal columns adjacent to the renal pyramids.

The intrarenal microvaculature has been extensively studied by several groups[10,11,158,334]; a basic pattern is established throughout the mammalian kidneys that may be described as follows. At the corticomedullary junction, the interlobar artery branches into several arcuate arteries that

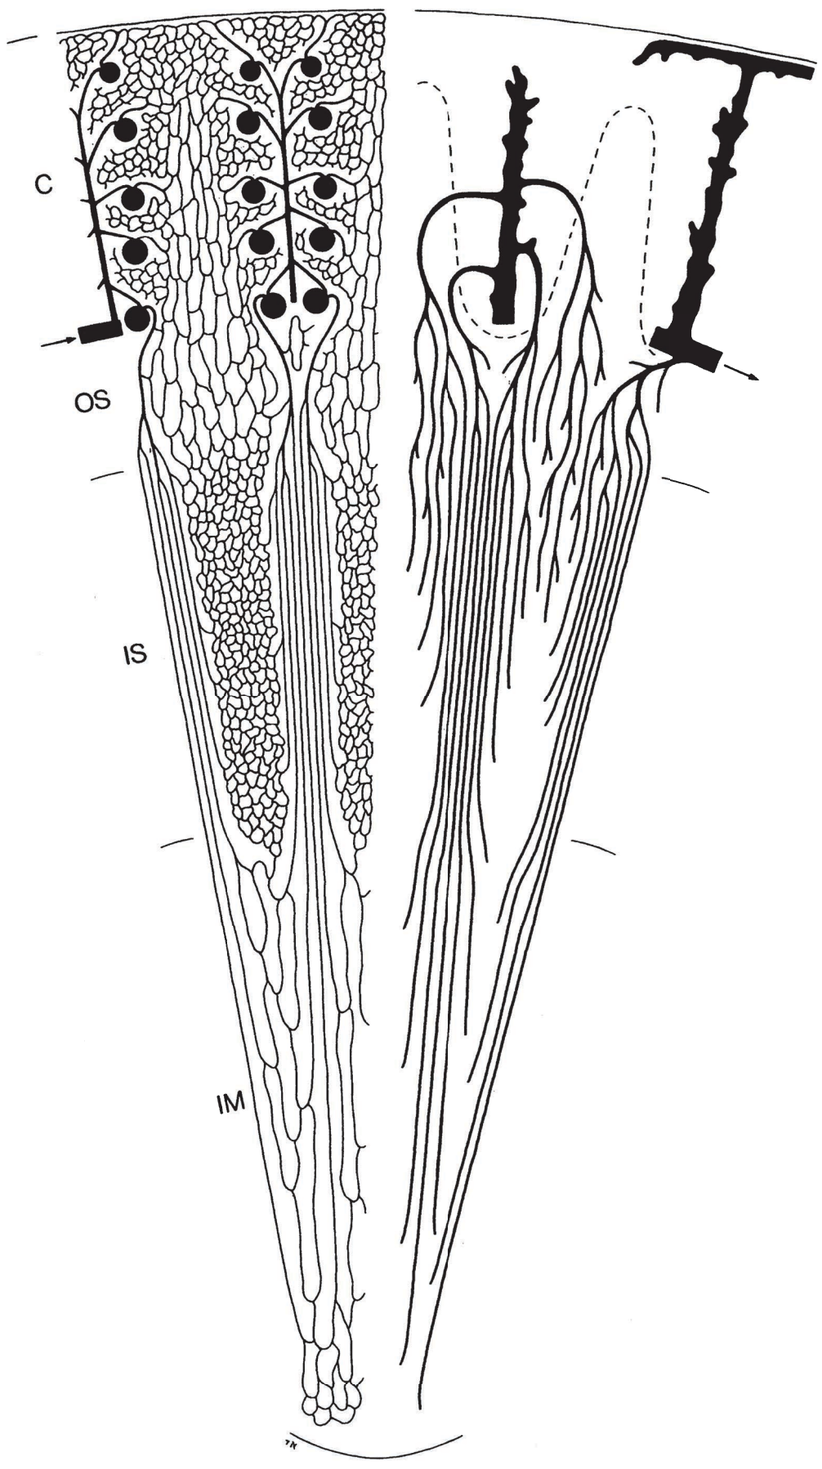

FIGURE 1.38 A basic pattern of renal microvasculature. *C*, cortex; *OS*, outer stripe; *IS*, inner stripe; *IM*, inner medulla. The *left panel* shows the arterial vessels and capillaries. An arcuate artery (*arrow*) gives rise to cortical radial arteries from which the glomerular afferent arterioles originate. Efferent arterioles of juxtamedullary glomeruli descend into the medulla and divide into the descending vasa recta, which, together with ascending vasa recta, form the vascular bundles. At intervals, descending vasa recta leave the bundles to feed the adjacent capillaries. The *right panel* shows the venous vessels. The cortical radial veins start within the superficial cortex; in the human kidney, some of them start as stellate veins on the surface of the kidney (shown on the right side). They all drain into arcuate veins. The venous drainage of the medulla is carried out by venous vasa recta; those from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the venous vasa recta from the inner stripe ascend outside the bundles. After traversing the outer stripe as wide tortuous channels, the ascending vasa recta drain into arcuate or cortical radial veins. (From Rollhäuser H, Kriz W. Das Gefäss-system der Rattenniere. *Z Zellforsch*. 1964;64:381, with permission.)

arch across the base of the renal pyramid (Fig. 1.38). The arcuate arteries give rise to interlobular arteries (cortical radial arteries) that course peripherally, between the medullary rays and, thus, within the cortical labyrinth. The interlobular arteries also branch, and the branches give rise to afferent arterioles that supply the renal corpuscles.

Glomerular capillaries are derived from the afferent arteriole, which—strictly at the entrance level—divides into several (two to five) primary capillary branches.[335–337]

Each of these branches gives rise to an anastomosing capillary network that runs toward the urinary pole and then turns back toward the vascular pole. Thereby, the glomerular tuft is subdivided into several lobules, each of which contains an afferent and efferent capillary portion. The lobules are not strictly separated from each other—some anastomoses between lobules occur. The capillaries converge to form the more centrally located efferent arteriole, which is already established inside the glomerular tuft. Thus, the efferent arteriole has a significant intraglomerular segment that runs through the glomerular stalk (Fig. 1.5).[337] At this site a mesangial layer surrounds the vessel. After leaving the glomerulus, the efferent arteriole is reestablished as a proper arteriole.

The efferent arterioles of superficial (or subcapsular) glomeruli perfuse convoluted tubules through long pathways extending to the kidney surface or through intermediate branches near the renal corpuscle. In the midcortex, the efferents either branch near the glomerulus and perfuse convoluted tubules in that region or extend directly to the long meshed network of the medullary ray. Efferent arterioles from juxtamedullary nephrons extend downward to form the descending vasa recta (Fig. 1.38), and occasional branches to regions between the bundles. The early divisions give rise to capillaries located in the outer stripe of the outer medulla. The descending vasa recta then descend within the vascular bundles to the inner stripe and inner medulla (Fig. 1.39).[10] The medulla is drained by venous (ascending)

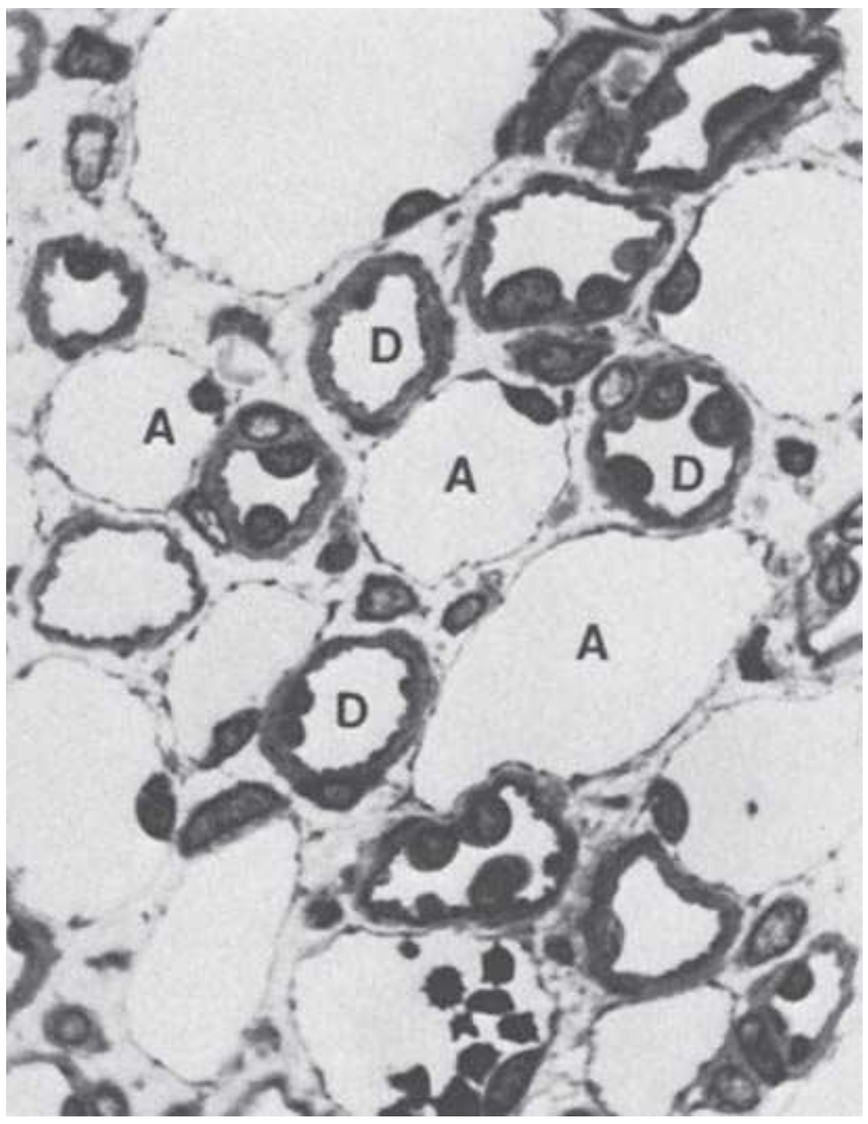

FIGURE 1.39 Light micrograph of a vasa recta bundle, showing descending (*D*) and ascending (*A*) vessels. (Magnification ×950.)

vasa recta, which lie adjacent to descending vasa recta, forming the vascular bundles that function as a countercurrent exchanger. Venous vasa recta that drain the inner medulla remain in the vascular bundles through the inner and outer stripe region. The venous vessels that drain the region of the upper and middle inner stripe ascend within the interbundle region to the outer stripe, there joining the vessels leaving the bundles to form together the major part of the blood supply to this region by a network of venous vessels. The density of capillaries that are derived directly from efferent arterioles is debated.[338] Finally, the ascending vasa recta empty into arcuate or interlobular veins (Fig. 1.38).

The cortical venous system is subject to some variation. In the human, the venous drainage starts on the renal surface beneath the capsule with small venules (stellate veins) that converge to form the interlobular veins (cortical radial veins); in most other species, the interlobular veins begin deeply beneath the cortical surface and stellate veins are lacking. Interlobular veins receive tributaries from the cortical peritubular capillary network (Fig. 1.38) and finally empty into arcuate veins that accompany the arcuate arteries. The arcuate veins receive blood from the venous vasa recta, as described in the preceding section. Interlobar veins form by confluence of arcuate veins and the latter finally form the renal vein. In contrast to the arcuate arteries, which are terminal arteries, the arcuate veins form true anastomosing arches at the corticomedullary border.

The morphology of the descending and ascending parts of the vasa recta differs markedly (Fig. 1.39).[187,339,340] The descending vasa recta are lined by a continuous nonfenestrated endothelium, with cells oriented longitudinally along the cell axis, forming 10 to 20 cell profiles in a single cross-section.[187,340] The endothelium contains the urea transporter UT-B1.[193] Pericytes are seen encircling the descending vasa recta, but they become less frequent as the vessels descend into the inner medulla, where these vessels finally convert into capillaries. As long as the descending vasa recta have pericytes nerve terminals are seen in their neighborhood.

The capillaries and the ascending vasa recta are lined by a thin fenestrated epithelium. The fenestrae are similar to those seen in peritubular capillaries, as well as in most regions of the body, being 40 to 70 μm in diameter[187] and bridged by a thin diaphragm. Uniquely, fenestrated endothelium can line quite large vessels in the kidney.

Lymphatic vessels are seen only in the cortex accompanying the arteries within the periarterial tissue sheaths (see below). The medulla has no lymphatic drainage.[341]

INTERSTITIUM

The interstitium of the kidney comprises the extravascular intertubular spaces of the renal parenchyma, with their attendant cellular elements and extracellular substances.[342,343] It is bounded on all sides by tubular and vascular basement membranes. The lymphatics are considered as part of the interstitium.

In functional studies, the interstitial volume of the kidney has been estimated to amount to 13% of the total kidney volume, whereas stereologically derived values for the cell-free interstitial space of the cortex and outer medulla of the rat range between 3% and 5%.[344–346] Thus, the functional interstitium includes more than just the peritubular spaces; the prominent periarterial connective tissue sheaths (see the following) may, in fact, account for one-half of the entire interstitial volume.[347]

The interstitium is differently developed within the various regions regions of the kidney.[342,343] In the cortex, the peritubular interstitium is distinguished from the periarterial connective tissue (Fig. 1.40). The peritubular interstitium consist of the narrow spaces between tubules and

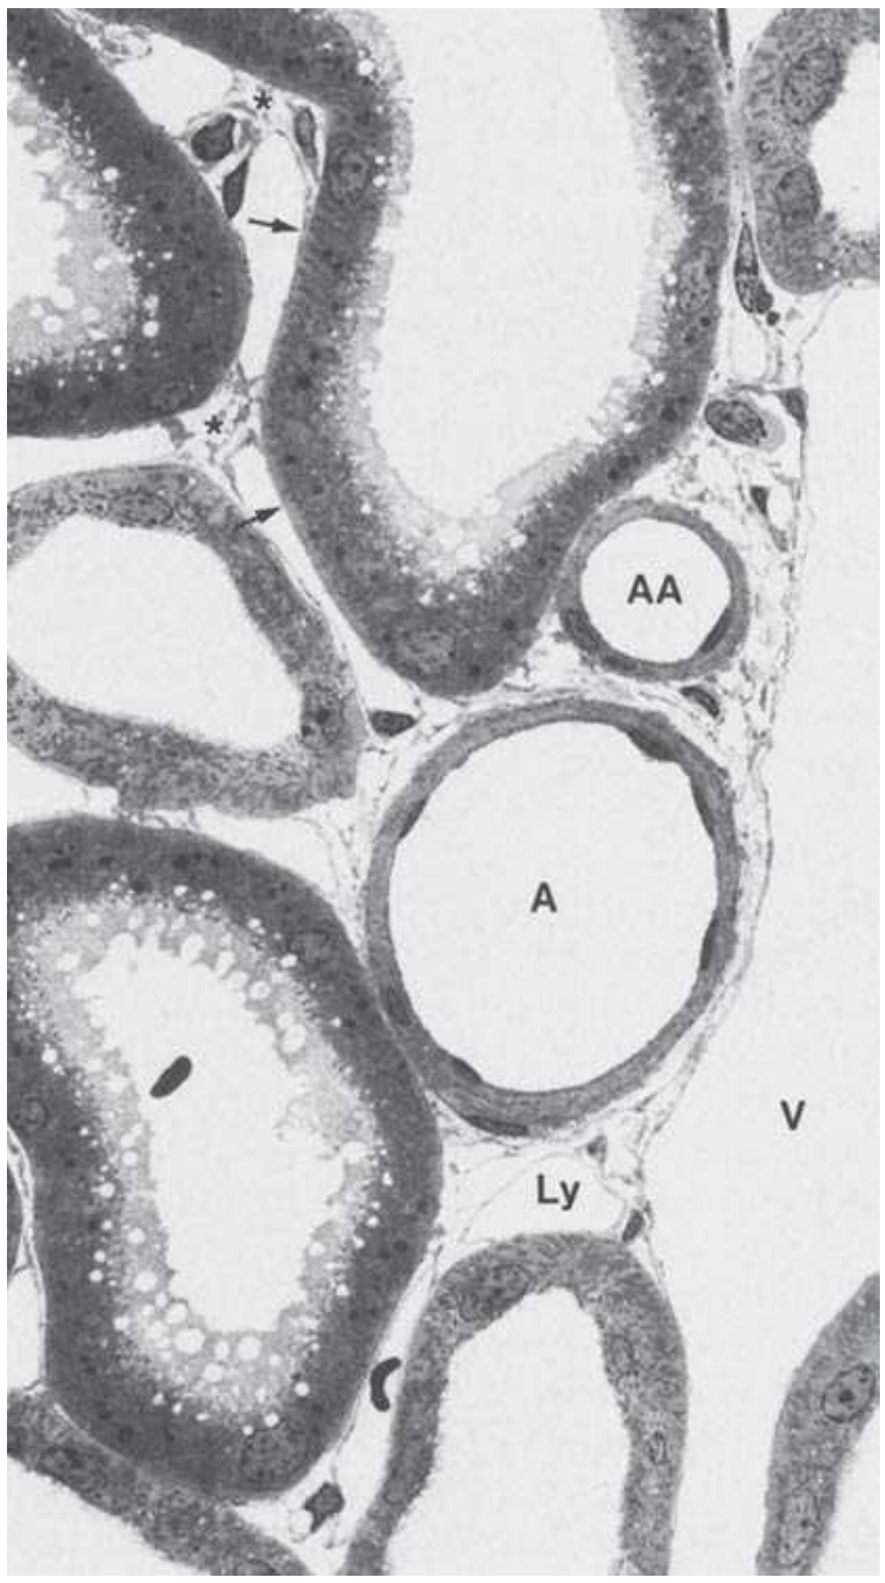

FIGURE 1.40 Low power electron micrograph of a cross-section through the renal cortex (rat). A cortical radial artery (*A*) and vein (*V*), an afferent arteriole (*AA*), and several tubular profiles are seen. The arteries are surrounded by the loose connective tissue sheath that contains the intrarenal lymphatics (*Ly*); the interstitial spaces of this sheath are continuous with the peritubular interstitium, which includes wide (*stars*) and narrow (*arrows*) portions. (Magnification ×1,000.)

around glomeruli. Sometimes, the peritubular capillaries are considered as part of the peritubular interstitium. Capillaries may abut directly to the the outer surface of tubules accounting for 54% to 67%[348] of the capillary surface, whereas only 26% of the tubular surface is directly adjacent to peritubular capillaries.[349] Thus, most of the exchanges among tubules and vessels have to pass through the interstitial compartment.

The periarterial connective tissue forms a fluid-rich loose connective tissue sheath that surrounds the intrarenal arteries and contains the lymphatic vessels of the kidney (Figs. 1.40 and 1.41).[341,347,350] The periarterial lymphatic sheath extends along the intrarenal arteries as far as the afferent arteriole, where it becomes quite attenuated. It is particularly well developed around the arcuate and cortical radial arteries. It contains the renal nerves.

The lymphatic capillaries begin within these sheaths; lymphatics do not, in general, penetrate the renal parenchyma proper and are not found in the medulla.[341,351] The lymphatic vessels converge along with the intrarenal arteries to emerge at the renal hilus. The peritubular interstitium of the cortex freely communicates with the periarterial tissue sheaths. Within the sheaths, fluid and solutes gradually may enter the lymphatic vessels as they converge toward the hilus (Fig. 1.41). In addition to lymphatic drainage, the periarterial connective tissue sheaths probably participate in the distribution of vasoactive substances alongside of the intrarenal arterioles and arteries.[350] It also serves for the intrarenal distribution of inflammatory cells.

In the medulla, the interstitium is differently developed within the three medullary regions[342]: outer and inner stripes and inner medulla. The relative interstitial volume exhibits a pronounced axial gradient from cortex to the inner medulla. The outer stripe has a very narrow, sparse interstitium, occupying 3% to 5% of outer stripe volume.[342,352] Also the vasa recta within the bundles of the inner stripe are very narrowly packed. The interstitial volume of the interbundle regions of the inner stripe is somewhat greater (10% in rats). The most elaborate and distinctive type of regional interstitium is that of the inner medulla. Here, the interstitium constitutes a much larger part of the total tissue volume (30% to 40%),[345,352] and shows a particular arrangement of its fibroblasts (see later).

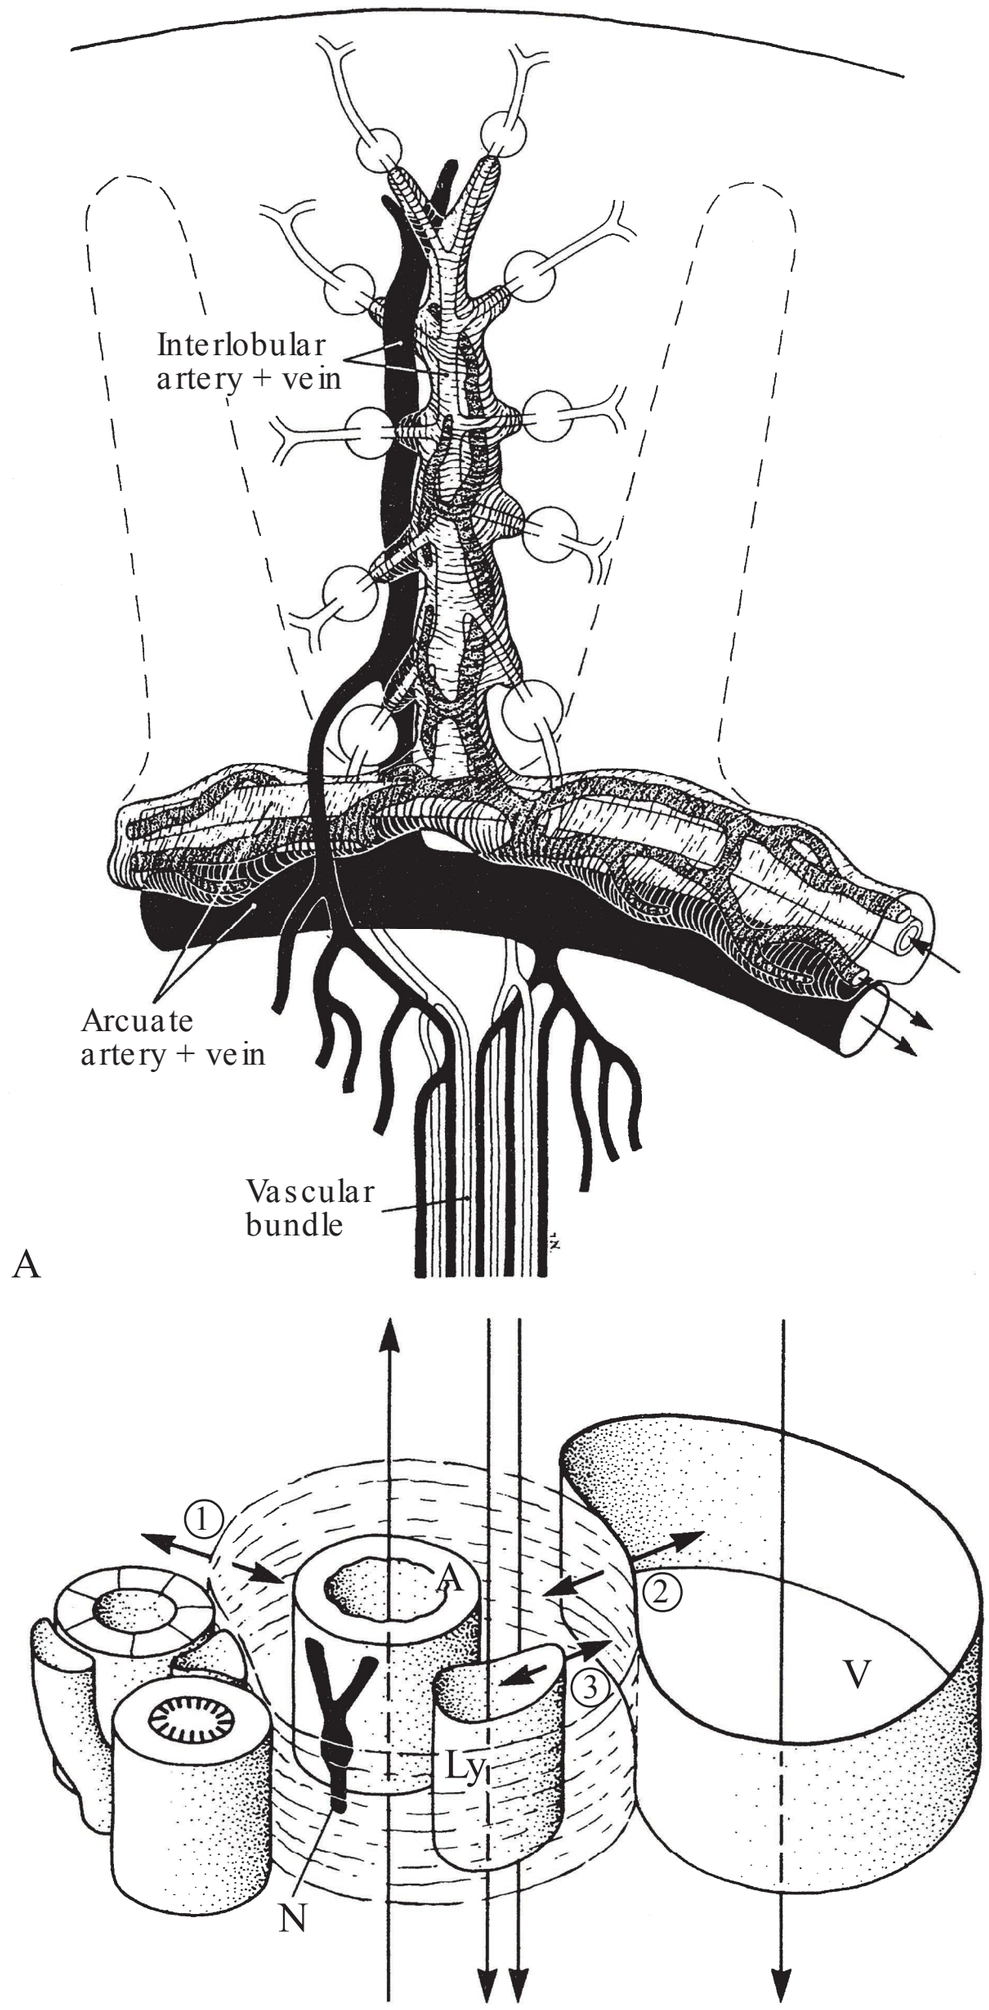

FIGURE 1.41 Schematics showing **(A)** the distribution and **(B)** the relationships of periarterial connective tissue sheath. The periarterial sheath is schematically indicated as a wide "stocking" drawn over the intrarenal arteries. In reality, there is no limiting membrane between the sheath and the surrounding interstitium. The lymphatics (*stippled area*) originate and travel within the periarterial sheath. The medullary rays are indicated by a broken line. The traverse section in **(B)** shows possible relationships between the sheath and the surrounding structures (*double-headed arrows*): (*1*) with the peritubular interstitium, (*2*) with the accompanying vein (*V*), and (*3*) with lymphatics (*Ly*). The *single-headed arrows* indicate the flow of the respective fluid. *N*, nerve. (From Kriz W. A periarterial pathway for intrarenal distribution of renin. *Kidney Int*. 987;31:551, with permission.)

The Cells of the Interstitium

The renal interstitium contains two types of cells: *fi*broblasts and dendritic cells. The fibroblasts are quite differently developed in the cortex and medulla.[342,353–356] Let us first consider the cortex. Within the peritubular interstitium roughly 50% of the cells normally present are fibroblasts and the other 50% dendritic cells, which cannot be separated from each other by simple light microscopy. The *fi*broblasts in this region are extensively branched, with long, often sheetlike processes (Fig. 1.42).[343,357,358] They contain abundant rough endoplasmic reticulum. Mitochondria,

FIGURE 1.42 Transmission electron micrograph of interstitial cells in the cortical peritubular interstitium. Two types are seen: fibroblasts (*1*) with many processes and a dendritic cell (*2*). *C*, capillary. (Magnification ×5,800.)

Golgi complexes, lysosomes, and microfilament bundles are regularly encountered. Fibroblasts perform a scaffolding function interconnecting the nephrons and the peritubular capillaries. They perform this function by focal contacts of their cytoplasmic processes with neighboring fibroblasts as well as with capillaries and tubules.[343,356,357] In addition, they produce the fibrous matrix, which serves together with these cells as a common scaffold throughout the renal parenchyma. These fibroblasts can be unequivocally detected by electron microscopy and fluorescence microscopy by their strong expression of ecto-5′-nucleotidase (CD73),[343,356,357,359,360] as well as of the PDGF receptor beta (PDGFRβ).[361]

Fibroblasts of the renal cortex with their enzyme ecto-5′-nucleotidase[362,363] can generate adenosine within the cortical interstitium. In addition, a subfraction of cortical interstitial cells synthesize erythropoietin.[364–366]

In the inner medulla, the fibroblasts represent a particular variety. They contain numerous homogeneous osmiophilic lipid droplets. Hence, they are generally called lipid-laden interstitial cells (Fig. 1.43).[353,355,367] These star-shaped cells interconnect loops of Henle and vasa recta, spanning these axial structures like the rungs of a ladder.[342,358] They increase in number toward the tip of the papilla and have an abundant rough endoplasmic reticulum, with cisternae that are often dilated and filled with flocculent material. A cytoskeleton is especially well developed in their most peripheral cell processes. These cells possess receptors for angiotensin II and bradykinin.[368,369] They are responsible for

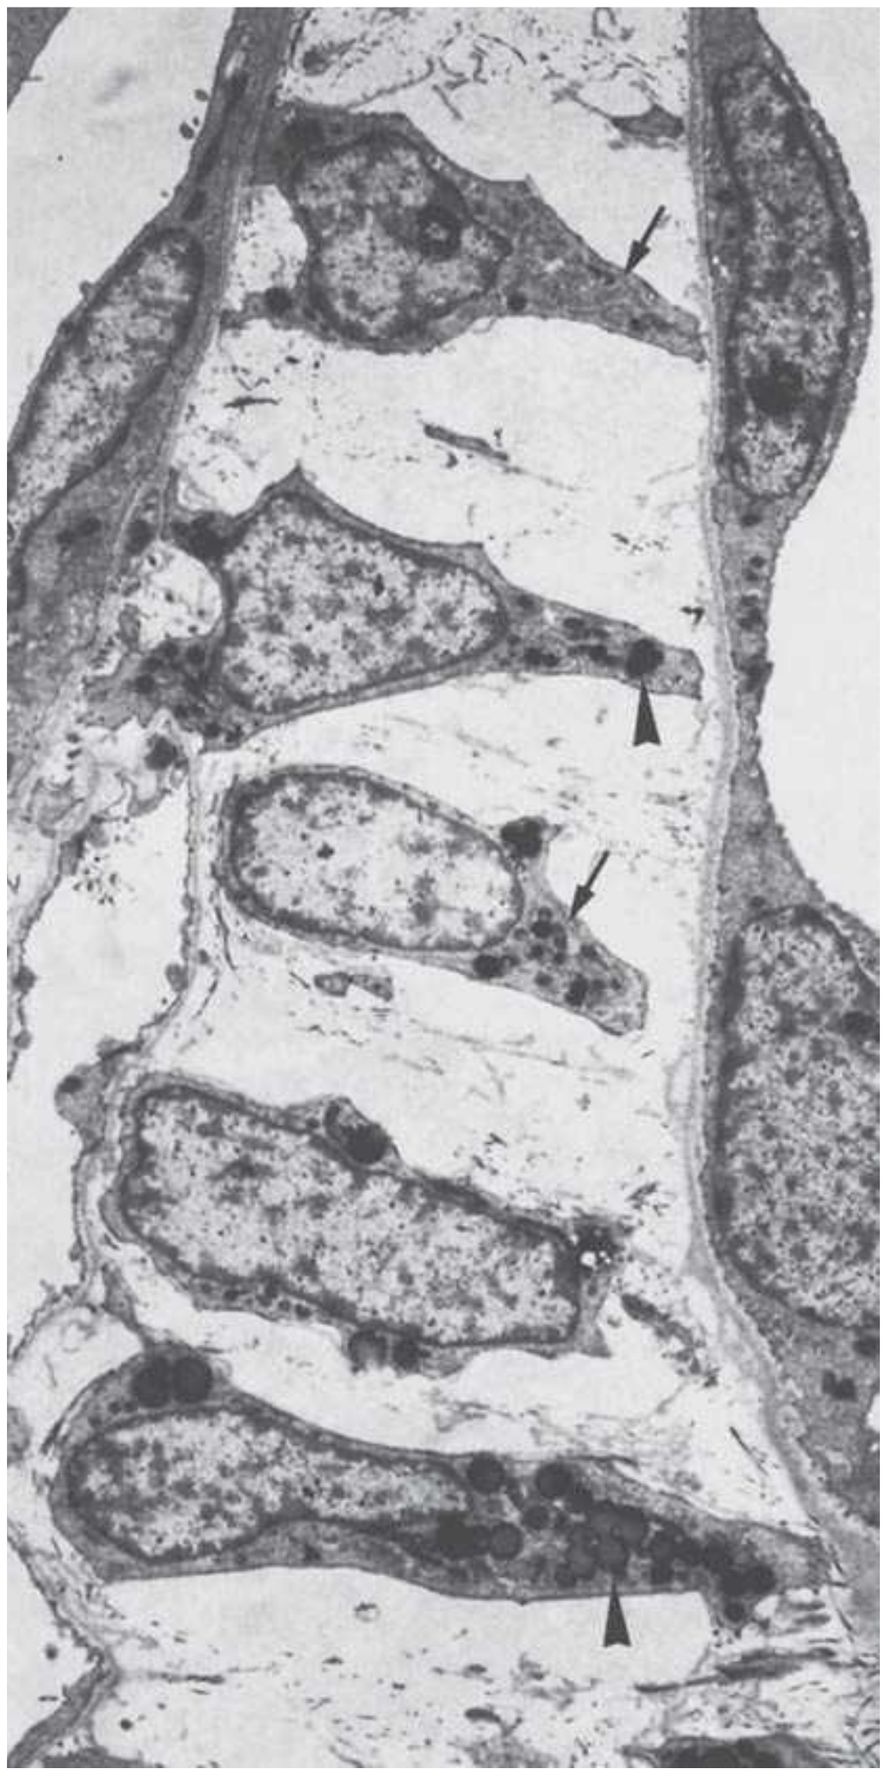

FIGURE 1.43 Transmission electron micrograph of a longitudinal section of the inner medulla (rat) showing lipid-laden interstitial cells arranged like the rungs of a ladder between parallel running tubes or vessels. Note the numerous lipid droplets (*arrowheads*) and the prominent endoplasmic reticulum (*arrows*). (Magnification ×3,300.)

the production of extracellular fibers and ground substance, including the abundant glycosaminoglycans and hyaluronic acid of the inner medulla.[370]

The lipid-laden interstitial cells participate in producing the medullary prostaglandins. The lipid droplets of these cells contain polyunsaturated fatty acids that appear to be precursors of prostaglandins and other lipid-derived hormones.[368,369] The cells produce vasodepressing lipids, in particular, prostaglandin E_2.[371,372]

The second abundant cell type in the renal interstitium is the dendritic cell (Fig. 1.42). They originate from the bone marrow and, as in other organs, are subject to a vivid turnover.[373] In the kidney, dendritic cells are found in the interstitium throughout the cortex and the outer medulla.[343,356,357] They enter the interstitium from the blood, reside for some days in interstitial spaces, and leave the interstitium with the lymph flow.

The extracellular components of the interstitium form a matrix that may be thought of as a hydrated gel of ground substance within a fibrillar reticulum.[342] Several fibers make up the interstitial reticulum. Collagen fibers (types I, III, and VI) are present in the matrix, both in isolation and in bundles. Type I collagen forms typical cross-banded fibers, generally more than 30 μm in diameter. Type III fibers (10 to 40 μm in diameter) and type VI fibers (6 to 10 μm in diameter) are often seen associated with type I fibers. In addition, unbanded microfibrils with a diameter of 15 to 30 μm and an electron-lucent core have been described.[342,354]

Myofibroblasts are absent from healthy kidneys. They differ from fibroblasts by their high production of extracellular matrix, expression of vimentin, and α-smooth muscle actin (αSMA).[343,374] The accumulation of myofibroblasts in a diseased kidney is generally suggested to occur by transformation of fibroblasts into myofibroblasts in response to stimuli from locally produced cytokines.[374,375] An alternative hypothesis postulates that myofibroblasts may develop by "epithelialmesenchymal transition" (EMT) from tubular cells[376]; however, the evidence for this origin is not conclusive.[377]

Macrophages (histiocytes) are also rarely found in the healthy kidney, except for the periarterial tissue sheaths[356] (Fig. 1.42). These round cells demonstrate primary and secondary lysosomes and characteristic surface folds. Along with interstitial affections, the number of macrophages may dramatically rise.

STRUCTURE–FUNCTION RELATIONSHIPS WITHIN THE RENAL MEDULLA

During phylogeny, the renal medulla has developed in response to the necessity to conserve water by excreting a concentrated urine.[378] Loops of Henle, collecting ducts, and a specific blood supply through vascular bundles have developed into a complex structural system that accounts for this function. Whereas the mechanisms to produce a concentrated urine up to a concentration of about 600 mOsmol/L in the outer medulla are fairly well known, the mechanisms underlying the final urine concentration in the inner medulla are still poorly understood.

Within the outer medulla the reabsorption of NaCl from the MTAL represents the driving force to produce a corticomedullary osmotic gradient that provokes the osmotic water withdrawal from the collecting duct passing through this region. ADH initiates the insertion of AQP2 channels into the apical plasma membrane of collecting duct principal cells. Together with the constitutive AQP3 and AQP4 channels in the basolateral membrane of these cells, this allows osmotic water withdrawal into the hypertonic interstitium of the outer medulla.[192] The reabsorbed water is brought back into the systemic circulation by venous vasa recta.[2]

The final step of the urine concentrating process in the inner medulla is basically identical insofar as water is reabsorbed by osmosis through ADH-stimulated water-permeable collecting ducts into a hypertonic interstitium. However, the mechanisms for creating the osmotic gradient in the inner medulla up to 1200 mOsmol/L in humans and much higher in many rodent species are much more complex than in the outer medulla and are insufficiently understood. A driving force like the sodium pump in MTALs in the outer medulla is lacking. This has led to several "passive" models,[379,380] which take into account the specific transport properties of thin limbs, collecting ducts, and vasa recta to elucidate, by mathematical modeling, how part of the osmotic energy produced by the function of MTALs in the outer medulla may be transferred into the inner medulla, leading there to an osmotic gradient toward the tip of the papilla. A review of these models is far beyond the scope of this chapter. From a structural point of view, two features appear most relevant.

1. **The shape of the inner medulla.** The inner medulla has a particular shape, tapering from a broad basis to a tiny papilla. The mass of the inner medulla is, therefore, unevenly distributed along the longitudal axis. A reconstruction study in the rat[2,381,382] has shown that the inner medulla is shaped like a mushroom, consisting of a broad head and a thin stalk. Calculations in the model have shown that the first one-half of the inner medulla comprises roughly 80% of the total inner medullary volume and, consequently, only 20% are left for the second, papillary, half. Thus, the decrease of the mass in the inner medulla along the longitudal axis is almost exponential. This shape perfectly reflects what happens with the structures within the inner medulla: loops of Henle, collecting ducts, and vasa recta all decrease rapidly in number from the base to the tip of the papilla.[381,382] It has been calculated that of an estimated 10,000 long loops entering the inner medulla at its base, only about 1,500 reach the papillary one-half

of the inner medulla.[2] Thus, the majority of thin limbs (the "short" long thin limbs) turn back shortly after entering the inner medulla; a smaller, but still substantial, number of thin limbs reach the middle part of the inner medulla; and only a small population of "long" long loops really reach the papilla.

This has led to the proposal[383] and, later, mathematical models[204,384] that this arrangement might account for a cascadelike transport of solutes toward the tip of the papilla. The large fraction of "short" long loops, by some way or another, manages the transport of solutes into the first one-third of the inner medulla, the intermediate fraction of long loops brings a proportion of these solutes further down into the middle part, and finally the small fraction of "long" long loops completes the transport of a still much smaller solute fraction down into the papilla.

2. **Structural arrangements in the renal medulla that allow the recycling of urea into the inner medulla via short loops of Henle.** The descending thin limbs of short loops in the outer medulla are arranged in a pattern that allows the shifting of urea from the venous blood coming up with the venous vasa recta from the inner medulla into tubular fluid of descending thin limbs of short loops. This possibility is perfectly developed in the complex vascular bundles in the outer medulla of rodents with high urine-concentrating abilities.[159,187,197,198] Within these vascular bundles, the SDTLs are arranged in a countercurrent fashion with ascending vasa recta coming up from the inner medulla. Thus urea, by countercurrent exchange, may directly enter the descending thin limbs through the urea transporter UT-A2[193,275] (the fenestrated endothelium of venous vasa recta may readily be expected to be highly permeable for urea). In a renal medulla with "simple" vascular bundles (as they are found in most species), countercurrent exchange of urea first occurs from ascending to descending vasa recta (which contain the urea transporter UT-B1), which, afterward, will deliver their blood to the capillary plexus of the interbundle region surrounding the thin limbs of short loops on their descending direction. Thus, even if probably less effectively, urea from the inner medulla has access to the SDTLs.[193,197,385,386]

Starting with the MTAL, thus abruptly at the end of the ATL, the uriniferous tubule is impermeable to urea until the terminal collecting duct in the inner medulla, which, starting abruptly, expresses the ADH-dependent urea transporter UT-A1.[193,275] Because of water reabsorption upstream from this segment, urea becomes concentrated within the tubular urine to levels always higher than the adjacent interstitium. In the terminal CD segment, a major part of this urea diffuses into the papillary interstitium and where it mixes with other solutes (NaCl), contributing to the osmotic driving force that reclaims water from the collecting duct. The locus of urea delivery in the papilla (i.e., at the "ultimate bend" of the complex countercurrent exchange system of the inner medulla) is optimal because (1) by countercurrent exchange in vasa recta and thin limbs, urea is largely trapped and distributed in a longitudinal gradient within the inner medulla and (2) the fraction of urea that escapes the inner medulla is subject to recycling via short loops back into the inner medulla. Thus, this latter fraction of urea is available another time within the papillary interstitium ready to withdraw and/or to balance water reabsorption from the collecting duct. Recycling is not simply trapping because this fraction of urea on its nephron way back into the inner medulla is concentrated a second time, essentially by the work of the sodium pump in the MTALs. In essence, urea recycling by short loops (not by long loops) represents an effective transport of osmotic energy from the outer into the inner medulla.

Whether these mechanisms are sufficient to build an osmotic gradient up to several osmoles in desert rodents, or whether there are additional sources complementing the solute gradients (e.g., continuous production of osmotic active substances), is presently unknown. Even if this question does not belong to the most urgent problems in medicine, it represents a highly challenging biologic enigma.

CHAPTER

2 Clinical Importance of Nephron Mass

Valerie A. Luyckx • Thomas F. Mueller

INTRODUCTION

The relationship between renal salt handling, intravascular volume homeostasis, and hypertension is well established, which points to the kidney as the central organ in the development of hypertension.[1] Based on the concept of developmental programming, where an environmental stimulus experienced during a critical period of early development can induce long-term structural and functional adaptive changes in the developing organism, Brenner et al. proposed that a low nephron number, acquired during fetal life, may predispose an individual to hypertension and renal disease.[2,3] This hypothesis was attractive because low birth weight, a marker of an adverse intrauterine environment, if associated with a congenital reduction in nephron number, could potentially explain the variability in hypertension and renal disease prevalence observed among populations of different ethnicity where those with lower birth weights tend to have a higher burden of renal disease.[4–7] The initial hypothesis suggested that a kidney with fewer nephrons would have a reduced filtration surface area with a limited capacity to excrete sodium, thereby contributing to the development of hypertension. Although this "nephron number" hypothesis was initially quite controversial, and with time has proved to be not entirely this straightforward, the association between nephron number and predisposition to hypertension and renal disease has been borne out in many animal experiments and human studies.[8–12] In this chapter we put forward the existing evidence comprising animal and human studies, which link nephron mass, birth weight, and other clinical variables with clinical outcomes. Extrapolation from animals to humans has many limitations and, therefore, where possible we have included human studies to corroborate or refute animal findings. Although this field has grown significantly within the last decade and many questions remain unanswered, a clearer and consistent picture is emerging that shows nephron mass does have clinical importance.

An individual's nephron mass is determined by a complex interplay between genetics and environment, evolving throughout their lifetime, bearing the imprint of their past, being reflected in their present, and affecting their future risk of hypertension and renal disease. Although traditionally it has been thought that all kidneys have about 1 million nephrons, recent studies have found that total glomerular number varies up to 13-fold in human kidneys, much more, for example, than height or weight (Table 2.1).[13] The terms "nephron endowment," implying number of nephrons present upon completion of nephrogenesis; "nephron number," implying the number of intact nephrons at the time of measurement; and "glomerular number," including the number of tubular and atubular glomeruli, have all been used interchangeably.[13] In this chapter we use the term "nephron number" more generally to describe the total number of nephrons in a kidney at the time of discussion. The term nephron mass is used more broadly as a clinical term to incorporate nephron number, kidney weight, kidney size, and kidney volume. A discussion of the importance of acquired reduction in nephron mass in later life is beyond the scope of this chapter.

DEVELOPMENTAL DETERMINANTS OF NEPHRON NUMBER

Low Nephron Number

Kidney development in humans proceeds from the 9th to the 36th week of gestation.[9,14] Accurate determination of nephron number is difficult because nephron number cannot be determined in humans in vivo. The unbiased fractionator-sampling/dissector method is thought to be the most objective nephron counting method, and is currently utilized in most human studies.[15,16] This method, however, requires postmortem kidney samples and is very labor intensive. An in vivo glomerular counting method comparing the fractionator technique with a combined renal biopsy/magnetic resonance imaging (MRI) method in explanted canine kidneys has been attempted.[17] This study found a good correlation of glomerular number on average between the two methods, but, within kidneys, there was a 36% variance, calling individual applicability into question. Large-scale human

studies of nephron number and association with phenotype are therefore not easily feasible.

Average nephron number has been reported to range from 617,000 (range 331,000–1,424,000) to 1,429,200 (range 884,485–1,959,914) per kidney among normal adult Caucasian Europeans.[10,18] Other studies including subjects of multiple ethnic origins from the United States, Africa, and Australia showed somewhat similar results, with a mean number around the mid 800,000 glomeruli per kidney, with a very wide range, from 210,332 to 2,702,079 as shown in Table 2.1.[13] The range appears widest in kidneys from subjects of African origin.[13,19] In general, nephron numbers are lower in older subjects, attributed to age-related glomerulosclerosis and obsolescence.[18,20] Whether the high variability in nephron number across populations reflects true differences or is confounded by small sample sizes or limitations of counting methods will become clearer with time as more studies accumulate or as better techniques evolve.

Various animal models have been used to study the impact of developmental programming on nephrogenesis. The details and pathophysiology of these models, and mechanisms whereby nephron numbers are reduced, are beyond the scope of this chapter and are outlined in detail elsewhere.[8,21,22] Extrapolating from the animal studies, from a clinical point of view, the factors associated with development of low nephron number can be divided into two groups: modifiable and nonmodifiable, as outlined in Table 2.2.

Modifiable Factors

Modifiable factors associated with low nephron number include prenatal events—factors occurring during gestation and postnatal events occurring in the neonate.

Prenatal Factors. Maternal diets deficient in protein, total calories, or iron have all been shown to reduce nephron numbers in offspring of experimental animals, most often in association with low birth weight.[12,23–26] Figure 2.1 shows a reduction in nephron numbers in low birth weight rats that were subjected to maternal low protein diets during gestation. Maternal dietary deficiencies are common in pregnant mothers in developing countries and therefore likely clinically relevant in a large proportion of the world.[27] Maternal vitamin A deficient diets are associated with a dose-dependent reduction in nephron number in animals.[28]

2.2 Factors Associated with Charges in Nephron Number and Kidney Size

REDUCED NEPHRON NUMBERS OR KIDNEY SIZE

Timing	Condition	Source of Data	Effect on Nephron Number (NNx)/Kidney Size	References
Prenatal, modifiable	Maternal low protein diet or total calorie restriction	Animal	↓ NNx, 16%–40%	12, 246
	Maternal vitamin A restriction	Animal	↓ NNx, in proportion to reduction in vitamin A	28, 29
		Human	Small infant kidney size	
	Maternal iron restriction	Animal	↓ NNx, 22%	25
	Gestational glucocorticoid exposure	Animal	↓ NNx, 20%–38%	37, 180
	Uterine artery ligation/ embolization	Animal	↓ NNx, 20%–30%	81
	Maternal diabetes/ hyperglycemia	Animal	↓ NNx, 10%–35%	50, 51, 247
	Gestational drug exposure	Animal		
	■ Gentamicin		↓ NNx, 10%–20%	40–45, 248
	■ β lactams		↓ NNx, 5%–10%	
	■ Cyclosporine		↓ NNx, 25%–33%	
	■ Ethanol		↓ NNx, 10%–20%	
	■ COX2 inhibitors		↓ NNx	
	■ Indomethacin		↓ NNx	
Prenatal, nonmodifiable	Genetics			
	■ RET(1476A) polymorphism	Human	10% ↓ newborn kidney volume	63, 64
	■ PAX2 AAA haplotype	Human	10% ↓ newborn kidney volume	
	Prematurity	Human	NNx ↓ with gestational age, limited post natal nephrogenesis	54, 69, 132
			Reduced kidney size in growth restricted children	
Postnatal	Nutrition	Animal	NNx ↓ with postnatal nutrient restriction alone	32
	Renal failure	Human	? cause or consequence of NNx ↓	54

NORMALIZATION OR INCREASE IN NEPHRON NUMBER

Vitamin A deficiency was examined in a cohort of Indian compared to Canadian mothers and found to be associated with significantly smaller newborn renal volume, which the authors suggest likely reflects lower nephron number.[29] Retinoic acid, the active metabolite of vitamin A, functions as a transcription factor regulating expression of Ret, a tyrosine kinase receptor critical for kidney development.[30] Interestingly, vitamin A levels are reduced by smoking and alcohol intake, both known to reduce birth weight.[31] Uteroplacental insufficiency, induced by uterine artery ligation late in gestation, also results in low offspring birth weight and low nephron number.[32,33] This model may share some similarities

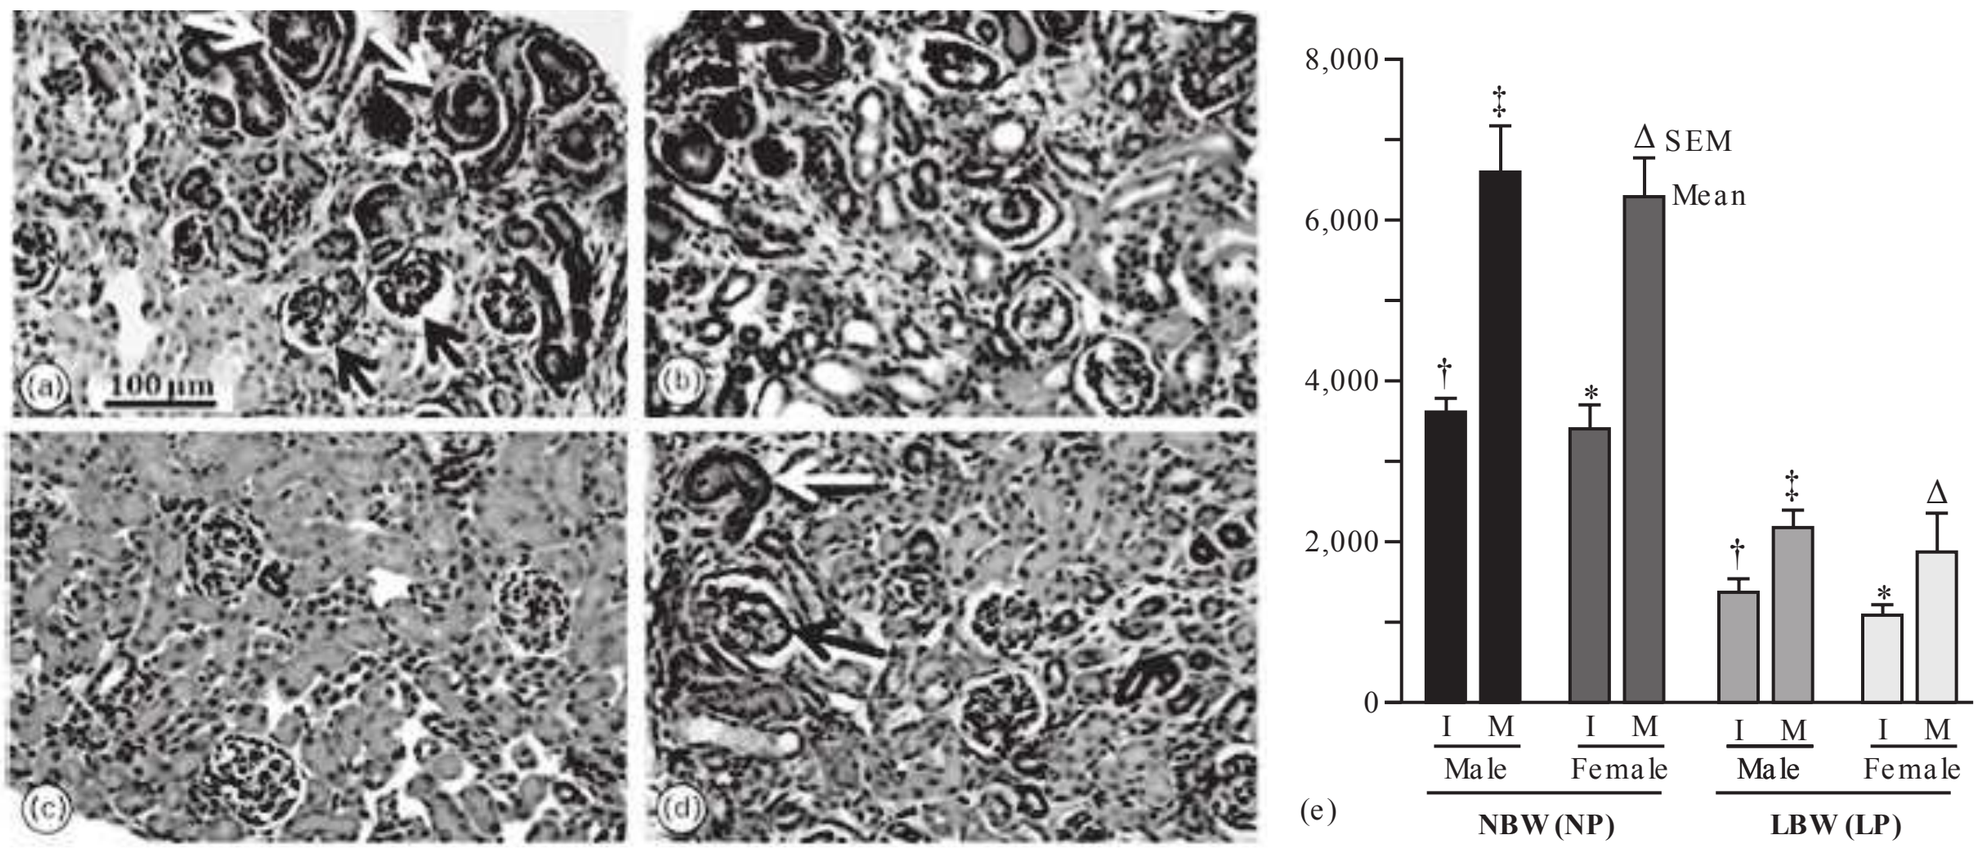

FIGURE 2.1 Relationship between glomerulogenesis, nephron number, and birth weight in rats subjected to maternal normal (NP) or low (LP) protein diets. Renal cortex at days 0 (d0) and 10 (d10) in rat offspring of NP-fed dams (normal birth weight, NBW) and LP-fed dams (low birth weight, LBW). *(a)* Normal glomerulogenesis in NBW offspring at d0, with comma-shape structure (immature renal corpuscle, *white arrow*) and inner vascularized structure (mature renal corpuscle, *black arrow*); *(b)* LBW d0 with fewer corpuscular structures and moderately dilated tubules; *(c)* NBW d10 showing only mature renal corpuscles; *(d)* LBW d10 showing immature and mature renal corpuscles; and *(e)* number of glomerulus-like structures (immature [I] and mature [M]) measured in NBW and LBW offspring ($n = 5$ per group). Symbols indicate group comparisons, $P < 0.05$. (Reprinted with permission from Villar-Martini VC, Carvalho JJ, Neves MF, et al. Hypertension and kidney alterations in rat offspring from low protein pregnancies. *J Hypertens Suppl.* 2009;27:S47–51.)

with preeclampsia in humans in terms of the reduction of uterine blood flow and the restriction of fetal nutrient supply.

Increased fetal glucocorticoid exposure is a likely mechanism whereby maternal low protein diet reduces nephron number, via reduced activity of placental 11β-hydroxysteroid dehydrogenase activity, shown in both animals and humans.[34,35] Similarly, administration of glucocorticoids during gestation in rats and sheep leads to reduced nephrogenesis, although this effect was not seen in the Marmoset monkey.[36–38] Glucocorticoids are thought to reduce nephron number by impacting ureteric bud invasion of the metanephric mesenchyme, thereby limiting branching morphogenesis.[8] The impact of maternal glucocorticoid utilization during pregnancy on human nephrogenesis is not known. Ingestion of other medications during pregnancy may also impact nephrogenesis in many ways.[39] Gestational administration of aminoglycosides, beta lactams, cyclosporine, cyclooxygenase inhibitors, and nonsteroidal anti-inflammatory drugs have all been associated with reduced nephron number in experimental models.[39–43] Similarly, chronic and acute gestational exposure to alcohol impairs embryonic ureteric bud branching, resulting in fewer nephrons in offspring.[44,45] In humans one abstract suggested an impact of maternal alcohol consumption on kidney development in Australian Aboriginal children.[9]

Conceivably, therefore, all of these prenatal experimental conditions may impact human nephrogenesis and minimization of these exposures prior to and during pregnancy would optimize fetal nephrogenesis. The timing of an insult during gestation is also relevant to its impact on nephrogenesis, with the greatest effect in animals generally seen with interventions in the latter half of gestation.[8]

Maternal factors also impact fetal development during gestation. Low birth weight is associated with multiple maternal factors although nephron number has not specifically been examined in most cases.[46,47] Manalich et al. found a strong correlation between low birth weight and low nephron number in a cohort of Cuban newborns.[48] Maternal hypertension and maternal smoking were correlated with low birth weight, although direct correlation with nephron number was not reported. In experimental animals, maternal diabetes or hyperglycemia has been shown to result in approximately 30% lower offspring nephron number in some, but not all, studies, although differences in methods of nephron number counting may account for some of the variability.[49–51] In other studies, maternal diabetes was associated with smaller kidneys, higher blood pressures, microalbuminuria, and reduced glomerular filtration rates in rat offspring.[51,52] In young adults, renal functional reserve was found to be reduced in those who had been exposed to maternal diabetes during gestation, compared to those with paternal diabetes (i.e., excluding a genetic component), or those with nondiabetic parents.[53] The reduced renal functional reserve was interpreted by the authors as a possible surrogate for a reduced nephron number acquired in utero in the offspring of diabetic mothers.

Postnatal Factors. Although nephrogenesis is thought to be complete at birth in humans, this may not be the case for babies born prematurely, and therefore a window in which nephrogenesis may still be vulnerable likely exists soon after birth in these infants.[54] Consistent with this possibility, early postnatal growth restriction alone in normal birth weight rats was associated with a reduction in nephron number, demonstrating the importance of early postnatal nutrition on nephrogenesis.[32] The relevance of these findings to the human, however, is questionable because nephrogenesis normally proceeds for 10 days after birth in rodents and therefore this period is analogous to late gestation in humans. These data may, however, have relevance to humans born prematurely. Indeed, in a cohort of children born either very low birth weight (<1,000 g) or premature (<30 weeks gestation), extrauterine growth restriction was associated with significantly lower glomerular filtration rates at a mean of 7.6 years of age, suggesting an impact of postnatal nutrition on renal development.[55] Another study of postmortem kidneys from premature infants who died after 40 days of life found glomerular number to be significantly lower in those who developed renal failure compared to those who did not. These findings may suggest that renal failure itself inhibits glomerulogenesis; however, it is also possible that fewer glomeruli made these extremely ill infants more susceptible to renal failure. In another cohort of critically ill premature infants, renal failure was a significant complication and associated with a high mortality, although not associated with birth weight.[56] In contrast, another study did find neonatal acute kidney injury to be an independent predictor of mortality in very low birth weight infants.[57] Prematurity itself is a recognized risk for renal failure in infants, and has been shown to be associated with increased risk of subsequent hypertension and chronic kidney disease (CKD).[58] Taking these human studies together, postnatal events do impact renal development in premature infants and may have potentially adverse short- and long-term consequences.

Nonmodifiable Factors

Nonmodifiable factors also impact nephrogenesis, and may occur in isolation or together with other potentially modifiable factors described previously (Table 2.2).

Genetics. Rare congenital and genetic abnormalities associated with abnormal kidney development manifest with renal dysfunction, often presenting very early in life.[11,59] Approximately 40% to 60% of childhood end-stage renal disease (ESRD) results from some form of congenital renal hypoplasia.[60] More subtle renal developmental abnormalities—which may not manifest as overt syndromes but, rather, with later life renal dysfunction—may well be the result of gene polymorphisms impacting nephron number. Renal hypoplasia and reduced nephron number have been described with full or partial deletion of over 25 genes in mice, which are reviewed in detail elsewhere.[13,21,61] The important steps in kidney development

include specification of the metanephric blastema from the intermediate mesoderm, formation of the ureteric bud and its outgrowth from the wolffian duct, and ureteric bud branching. Genes participating in specification of the metanephric blastema from the intermediate mesoderm include Odd-1, Eya 1 Pax 2, Wt-1, Six 1, Gdnf, and Sall 1, of which Odd-1 and Eya -1 are critical.[21,60] Genes regulating formation of the ureteric bud and its outgrowth from the wolffian duct include Pax2, Liml, Bmp4, and Gdnf. [21,60] Gdnf (glial cell-derived neurotrophic factor) signals through the Gfrα1 receptor and the c-Ret receptor tyrosine kinase and, during branching, morphogenesis is only expressed on the tips of ureteric branches, selectively inducing branching at this location.[21] Among the most important pathways impacting nephrogenesis, therefore, are Gdnf/Ret and Pax2. In mice, deletion of Gdnf and c-Ret leads to renal agenesis or severe hypoplasia.[21,60] Deletion of Pax2, the "master organizer" of renal development, is incompatible with life.[60] The impact of genetic polymorphisms in these pivotal genes has been studied in humans. Haploinsufficiency of the PAX2 gene causes the autosomal dominant renal coloboma syndrome, associated with significant reduction in nephron number and "oligomeganephronia."[60,62,63] Taking this finding further, looking for a more subtle impact in the wider population, Quinlan et al. found that the common AAA haplotype of PAX2, present in 18.5% of newborns in a Canadian cohort, was associated with reduced allele-specific mRNA expression in vitro, and a 10% reduction in newborn kidney volume, compared with the GGG haplotype.[63] Similarly, a polymorphic variant of RET, RET(1476A), was also associated with reduced mRNA synthesis, an almost 10% reduction in kidney volume, and higher levels of the renal function marker cystatin C at birth compared with the RET(1476G) variant in Caucasian newborns.[64] These authors found that newborn kidney volume is proportional to nephron number, therefore PAX2 and RET polymorphisms are likely associated with reduced nephron number in humans.[64] Among 15% of Caucasians inheriting both alleles, newborn kidney sizes were 23% smaller.[65] Surprisingly, however, none of 19 common GDNF gene variants or three single nucleotide polymorphisms related to a putative GDNF-PAX binding site were associated with small kidney size among 163 Caucasians newborns.[65] One rare coding GDNF variant (R93W) was not found in any subject and therefore, the clinical impact of this potential mutation is not known.[65] These early and small studies suggest that genetic polymorphisms in genes that are critical in nephrogenesis may contribute to the wide spectrum of nephron number found in the general population.

Prematurity. Unlike in rodents, postnatal nephrogenesis does not occur in humans, except in extremely premature infants; therefore, nephron number is predominantly determined in utero. Rodriguez et al. examined kidneys from 56 extremely premature infants compared with 10 full-term infants at autopsy.[54] Radial glomerular counts were lower in premature compared with full-term infant kidneys and glomerular number correlated with gestational age, as has been reported previously.[54,66] In addition, they found evidence of active glomerulogenesis (indicated by the presence of basophilic S-shaped bodies under the renal capsule in kidneys) in premature infants up to, but not beyond, 40 days of life.[54] This was the first study to demonstrate ongoing nephrogenesis in humans postnatally. Similarly, in preterm baboons, nephrogenesis was found to continue after birth and nephron number was within the normal range; however, there was a greater proportion of abnormal glomeruli in the superficial cortex compared to full-term controls, suggesting compromised nephrogenesis after premature birth.[67] In contrast, Hinchliffe et al. did not find an increase in nephron number in growth restricted infants who died as stillbirths at varying gestations, or at 1 year of age, suggesting a lack of nephrogenesis after birth.[66,68] Gestational age was found to correlate with nephron number, which reached a maximum around 36 weeks.[69]

Gender. Gender likely plays a complicated role in developmental programming. In the largest series of kidneys analyzed to date, glomerular number in adult females was found to be reduced by up to 12% compared to males.[13,70] In a cohort of Cuban newborns, however, nephron number was not affected by gender.[48] In experimental models, reviewed in detail elsewhere, males generally tend to be more severely affected than females in terms of reduction in nephron number, as well as subsequent manifestation of hypertension and renal dysfunction.[71,72] These differences may in part result from differences in postnatal growth rates between males and females, gender-specific differences in adaptation to adverse events, and gender-specific regulation of genes and pathways impacting renal development, function, and hypertension.[33,72] Similarly, a large study in humans found an association of CKD with low birth weight in adult males, but not in females, suggesting a possible impact of gender on subsequent disease expression, although mechanisms are not yet clear.[73]

Ethnicity. Hoy and colleagues have shown a reduction in nephron number among Aboriginal compared with non-Aboriginal Australians (Table 2.1).[70] Among African Americans and Caucasian Americans, nephron number was not significantly different in both groups and correlated with birth weight, although the distribution appeared to be more bimodal in the African American cohort.[74] No low birth weight subjects were included in this study, but low birth weight is more prevalent among African Americans; therefore, in the general U.S. population, a greater proportion of African Americans may have lower nephron number. This remains to be studied. Nephron number among Senegalese Africans and African Americans was similar.[75] Among Cuban neonates, nephron number was again not different between black compared with white subjects.[48] To our knowledge kidneys of subjects from other ethnic groups have not been studied. Ethnicity, therefore, may have an impact on nephron number, although it is difficult to dissect out an impact independent of its association with birth

weight, socioeconomic factors, genetic polymorphisms, and many other potential confounders.

Intergenerational Factors. Among both white and African American women, mothers who had been of low birth weight had a significantly increased risk of having low birth weight offspring, independent of economic environment, suggesting a cross-generational effect of maternal low birth weight.[76] Similarly maternal, but not paternal birth weights, were associated with offspring birth weight, arguing for an intergenerational programming effect of the maternal environment.[77] Interestingly, in a large population-based study, mothers experiencing preeclampsia, especially when associated with premature birth and low birth weight in the offspring, are at increased risk of subsequent need for renal biopsy and/or ESRD.[47,78] A reduced maternal glomerular filtration rate (GFR) <90 mL per minute and hypertension are significant risk factors for preeclampsia, small for gestational age infants, and premature delivery.[79] The question arises why the mother herself may have been predisposed to these adverse pregnancy-related and renal outcomes. It is conceivable that a vicious cycle may occur where a low birth weight mother would be predisposed to programmed adverse pregnancy outcomes, in turn impacting fetal nephrogenesis and thereby future pregnancy outcomes and renal health of the subsequent generations. To our knowledge this specific association has not been studied in humans. In rats, the first generation offspring of mothers fed low protein diets during gestation had low birth weights, low nephron number, and developed spontaneous hypertension at 8 weeks of age. Offspring of these first generation females, although maintained on normal diets throughout gestation, also exhibited low nephron number and hypertension, demonstrating intergenerational programming.[80] Interestingly the effect was lost by the third generation, suggesting that the intergenerational cycle can be interrupted by optimization of risk factors such as maternal nutrition.

Strategies for Augmentation of Nephron Number

Although total filtration surface area in individuals with fewer nephrons may not be reduced, as a result of compensatory hypertrophy of the existing nephrons (see later), low nephron number is still associated with an increased risk of hypertension and renal dysfunction in later life. Strategies to optimize nephron number may therefore have an important impact on clinical disease (Table 2.2). Interventions would likely need to be applied during gestation to have an optimal effect. Ideally, optimization of all modifiable risk factors prior to pregnancy would appear the simplest and most widely applicable intervention. Clinically feasible interventions are being studied to potentially "rescue" nephron number and reduce subsequent hypertension.

Postnatal Nutrition

Provision of adequate postnatal nutrition in low birth weight rat pups, achieved by cross-fostering onto normal lactating females at birth, led to restoration of nephron number and prevented the development of subsequent hypertension compared to pups with continued growth restriction.[81]

Vitamin A Supplementation

Because vitamin A deficiency is associated with a nephron deficit, administration of a single dose of retinoic acid during early nephrogenesis restored nephron number to control levels in rat pups exposed to low protein diet in utero.[82] Postnatal administration of retinoic acid to preterm baboons, however, was not able to stimulate nephrogenesis compared to preterm controls, suggesting a more proximal window for the effect of vitamin A on nephrogenesis, although these results may have been confounded by routine antibiotics given to all animals, which may have negatively impacted nephrogenesis, confounding a potentially small vitamin A effect.[30]

Genetics

In a cohort of Caucasian newborns, a common variant of the ALHD1A2 gene involved in retinoic acid metabolism, ALHD1A2rs7169289(G), was associated with a 22% increase in newborn kidney size, and higher cord blood retinoic acid levels, compared to the wild-type ALDH1A2 rs7169289(A) allele.[83] These authors suggest this gene polymorphism could be protective for nephrogenesis in the setting of vitamin A deficiency.

Prevention of Low Nephron Number

The ubiquitous plasma membrane protein Na^+/K^+-ATPase functions as an ion pump as well as a signal transducer. Ouabain is a highly specific Na^+/K^+-ATPase ligand that triggers the release of calcium waves, which are important regulators of early development.[84] Interestingly, erythrocyte membrane Na^+/K^+-ATPase activity was found to be reduced in a cohort of low birth weight males at age 20, making this a potentially relevant pathway.[85] The impact of ouabain administration was studied experimentally as a modulator of nephrogenesis under protein-deficient conditions in vitro and in vivo.[86] Ouabain was found to abrogate the effect of serum starvation on ureteric bud branching in cultured metanephroi, and to prevent reduction in nephron number in offspring of low protein diet-fed dams.[84] The ouabain was administered throughout pregnancy in this study and, therefore, the potential of ouabain to rescue or restore nephron number once an adverse event is already established has not been studied. Similarly, supplementation of maternal diet during gestation with glycine, urea, or alanine prevented the reduction in nephron number induced by maternal low protein diet in all offspring, but blood pressure was only normalized in those receiving glycine.[24] Interestingly, nephron number in the offspring of mothers subjected to water restriction during gestation was increased, but also did not abrogate development of subsequent hypertension—again suggesting possible divergent programming mechanisms for nephron number and blood pressure in some models.[87]

Maternal Nephrectomy

Uninephrectomy in rat mothers prior to pregnancy has been associated with an increase in offspring nephron number at birth; however, at 6 weeks, nephron numbers were not different from offspring of nonnephrectomized dams.[88,89] These authors suggest a possible circulating renotrophic factor in response to maternal uninephrectomy, possibly inducing hypertrophy of the contralateral kidney, which may accelerate nephrogenesis in the fetus but may not affect ultimate nephron number. These observations may be relevant in human cases such as maternal renal transplantation or maternal kidney donation, although timing of pregnancy in relation to nephrectomy may be an important variable. This area deserves more investigation.

CLINICAL SURROGATES FOR NEPHRON NUMBER

In vivo, nephron number can only be grossly estimated by MRI or kidney biopsy.[18,70,90] Associations of nephron number with readily available clinical variables have been described and are outlined in Table 2.3.

Anthropomorphic Features

Birth Weight

Low birth weight is defined by the World Health Organization as a birth weight under 2,500 g. Very low birth weight is usually defined a below 1,500 g. Low birth weight could result from prematurity itself (i.e., birth before the 37th week of gestation with an appropriate weight for gestational age), or from intrauterine growth restriction (IUGR) at any gestation.[46] A small for gestational age infant is defined as having a birth weight below the 10th percentile of normal for that gestational age.[46] Full-term IUGR is the most strongly associated with adult disease.[91] Risk factors for low birth weight are diverse and, in poorer countries, maternal malnutrition, poor prenatal care, and infections are common, whereas in the developed world, factors such as high risk pregnancies, assisted reproduction, multiple gestations, and advanced maternal age are becoming more frequent.[46,92] High birth weight is defined variably as a birth weight >4,000 g or >4,500 g, and is associated with maternal obesity, maternal diabetes, prolonged gestation, and reduced maternal smoking.[93] High birth weight has also been associated with adverse renal outcomes in the offspring, especially as a consequence of maternal diabetes.[94,95]

2.3 Clinical Surrogates for Low Nephron Number

Clinical Feature	Association with Nephron Number	Population	Reference
Low birth weight	↑ of 257,426 glomeruli per kg increase in birth weight	U.S. white and black, children and adults	19
Prematurity	↓ glomerular number in premature compared to term infants	U.S. premature and full term neonates	54, 68
Gender	Nephron number is 12% lower in females	U.S. white and black Aboriginal Australian	70
Age	↓ 3,676 glomeruli per kidney per year of age >18 years	U.S. white and black Aboriginal Australian	70
Adult height	↑ 28,000 glomeruli per centimeter increase in height	Australian Aboriginal German, white	10, 70
Kidney mass	↑ 23,459 glomeruli per gram of kidney tissue	Infants <3 months of age	64
Glomerular volume	Inverse correlation between glomerular volume and nephron number	U.S. white and black Aboriginal Australian German adults, Cuban infants	10, 13, 48
Ethnicity	↓ Aboriginal Australians compared to U.S. white and black	U.S. white and black Aboriginal Australian	70

↑, increase; ↓, decrease.

Low birth weight is the strongest current clinical surrogate for nephron number. Nephron number has consistently been shown to correlate strongly with birth weight in humans, with an extrapolated increase of 257,426 glomeruli per kilogram increase in birth weight.[19,48,54,70] The relationship of birth weight to nephron number is preserved among Australian Aboriginals, African Americans, and Whites and therefore may be generalizable to other populations.[19,70] The specific relationship between nephron number and low birth weight has only been examined in infants. Low birth weight was associated with lower nephron number than normal birth weight, and was similar among black and white subjects.[48,68] In experimental animals, however, not all low birth weight animals have been found to have reduced nephron number and, conversely, low nephron number has been reported in the absence of low birth weight.[96,97] Birth weight alone, therefore, is not a universal surrogate for nephron number. To our knowledge, nephron number has not been specifically studied in high birth weight humans or animals. Other anthropomorphic correlates that have been associated with nephron number are highlighted in Table 2.3.[18,20,70,98]

Kidney Size

Renal Mass

From autopsy studies, nephron number has been found to correlate directly with kidney weight in both adult and infant cohorts.[18,64] Zhang et al. calculated a predicted increase of 23,459 glomeruli per gram of kidney mass in infants under 3 months of age.[64] In living subjects, kidney weight is not routinely obtainable, but donor kidney mass measured prior to transplantation, as a measure of nephron "dose," has been shown to have clinical relevance (see later).

Kidney Volume

Kidney volume can be measured in vivo, making it an attractive potential surrogate for nephron number. Renal volume is dependent on nephron number, but is also strongly

2.4 Differences in Nephron Number, Glomerular Volume, and Total Glomerular Surface Area in the Right Kidney, U.S./Australian Adults (18+ years), Means (SD)

		All	No hypertension	Hypertension	No Hypertension versus Hypertension

correlated with current body size.[18] In fetuses and at birth, kidney volume is presumed to be directly proportional to nephron number; however, once normal kidney growth and adaptation occurs after a few months of life, impacted by body surface area, age, gender, glomerular hypertrophy, or nephron loss through injury, the relationship likely becomes less linear.[63] Despite this caveat, several authors have investigated utility of renal volume in relation to birth weight. Evaluation of fetal renal function by ultrasound in growth restricted fetuses in utero found reduced hourly urine output, greater oligohydramnios, reduced renal perfusion, and smaller kidney volume compared to normally growing fetuses.[99–101] Although these findings could simply reflect globally reduced renal perfusion, abnormal renal development cannot be excluded. Another study utilizing serial ultrasounds in a cohort of small for gestational age compared to appropriate for gestational age fetuses found that kidneys were smaller in the small for gestational age cohort, although kidney length was relatively preserved compared to width and circumference after 26 weeks of gestation.[102] Follow-up of kidney size and growth postnatally in 178 premature or small for gestational age children, compared with 717 term appropriate for gestational age controls, at 0, 3, and 18 months found that weight for gestational age correlated with kidney volume at all three time points.[103] Slight catch-up in kidney growth was observed in the growth-restricted, but not the premature infants. Among a cohort of low birth weight Australian Aboriginal children aged 5 to 18, renal volumes were found to be lower when adjusted for body size compared to normal birth weight children.[104] These authors also found that the reduction in kidney volume was driven more by a shorter depth than length of the kidney. Kidney length and volume were also both found to be smaller in a cohort of low birth weight children aged 10 to 12 years, and correlated weakly with lower GFR (Fig. 2.2).[105] In contrast, others found no difference in kidney volume, adjusted for body surface area and gender, between individuals who had been appropriate weight for gestational age at term, small for gestational age at term, or preterm at age 9 to 12 years.[106] Among young adults born premature (either appropriate or small for gestational age) compared with term age-matched controls, prematurity was associated with smaller kidneys at age 20 years, whereas IUGR had only a small, nonsignificant effect.[107] Kidney volume may therefore be less reliable as a surrogate for nephron endowment as subjects age. In addition, as a note of caution, renal volumes were not comparable between ultrasound and MRI in a neonatal population, suggesting that the same imaging modality should be used if measurements are to be compared.[108]

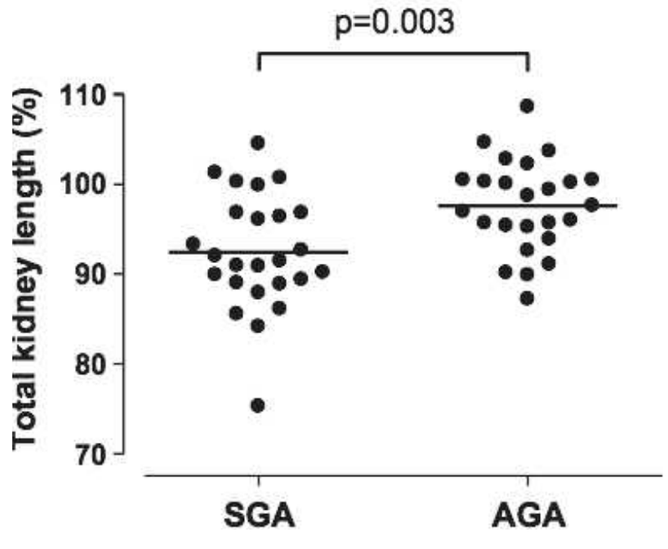

FIGURE 2.2 Correlation between growth restriction and kidney length. Kidney length (expressed as percent expected from the literature) is significantly shorter in Caucasian children aged 11.3 ± 2.1 years who were born small weight for gestational age (SGA) compared with appropriate weight for gestational age (AGA) at birth. Histologic Features

Glomerular Volume

Glomerular number has been found to vary up to 13-fold among all the cohorts studied, and glomerular volume has been found to vary up to 6.7-fold (Table 2.1).[13] Because nephron number is fixed at birth, glomerular size is likely the major variable determining adaptation of filtration capacity to match the body's demands.[19,20,48,98,109,110] Indeed, calculated total filtration surface area in kidneys with varying nephron number tends to be very similar, suggesting compensatory hypertrophy in those with fewer nephrons as shown in Table 2.4.[9] Consistent with this, mean glomerular volumes vary directly with body size, and inversely with nephron number and birth weight in all populations studied (Fig. 2.3).[10,48,70,111] Most studies, however, report mean glomerular volumes for a whole kidney. Further investigation into glomerular heterogeneity has found significant inter- and intraindividual variability in glomerular size.[13,112] Individual glomerular volume was found to vary up to eightfold within a single subject.[13] Glomerular size tended to be larger and more variable in the outer cortex compared to those deeper within the kidney.[13] In multiple analyses, hypertension, obesity, age, and low nephron number emerged as major predictors of larger glomeruli and greater heterogeneity.[13,70,75,111–113] Interestingly, consistently, African American and African subjects have higher mean glomerular volumes and greater heterogeneity of glomerular volume compared to white subjects, independent of nephron number (Fig. 2.4).[13,75] Furthermore, between Senegalese and African American subjects, glomerular volumes were higher in the U.S. cohort after controlling for body size.[75] Increased glomerular volume and heterogeneity therefore may result from different mechanisms among African origin populations compared to Caucasians. Whether this may have posed an evolutionary survival advantage which may be maladaptive in the current environmental circumstances given the greater burden of renal disease among African Americans, or whether this may reflect differences in glomerular perfusion, circulating glucose concentrations, or chronic inflammation, remains to be elucidated.[75,114] It is possible that the

greater average adult height among African American subjects may augment final nephron number, diminishing the relationship with birth weight, but may not compensate for, or may exacerbate, other potentially programmed changes such as glomerular size. Compensatory hyperfiltration may be adequate in the short term to augment glomerular filtration, but sustained hyperfiltration, especially in the setting of additional renal stresses (e.g., rapid growth, hypertension, diabetes) will eventually become maladaptive and contribute to ongoing nephron loss. A kidney starting with fewer nephrons would therefore reach a critical deficit within a shorter time. Consistent with this, evaluation of glomerular size in donor kidney biopsies again found higher maximal planar area of glomeruli to be a predictor of poorer transplant function and, again, glomerular size was higher in African American subjects.[115] From a clinical point of view, therefore, an otherwise unexplained increased in glomerular volume should raise the suspicion of a coexisting reduction in nephron number, although this relationship is less clear in African origin populations.

Pathologic Changes

Most renal biopsy results in subjects with lower nephron number have commented on glomerular size. In general the degree of glomerulosclerosis present in kidneys with low nephron number has been found to increase with age and hypertension, but has not been a prominent feature in most studies.[116] The pattern of glomerulosclerosis has been described as a global ischemic collapse rather than classical focal and segmental glomerulosclerosis that might have been expected with hyperfiltration causing cumulative glomerular injury.[74] A recent case series of six very low birth weight subjects, aged 15 to 52 years, who had been born prematurely, however, did find evidence of secondary focal and segmental glomerulosclerosis, associated with glomerulomegaly in all biopsies.[117] Although all biopsies were performed because of a clinical indication, and therefore may not be a generalizable sample, the authors suggest that low birth weight was a common denominator predisposing to hyperfiltration and glomerulosclerosis. Analyses of histologic changes in human biopsies may be confounded by multiple factors. In kidneys of rats exposed to gestational low protein diet, fewer and more immature glomeruli were present on day 10 at the end of nephrogenesis, exhibiting a markedly thickened glomerular basement membrane and abnormal podocyte structure (Fig. 2.1).[118] Similarly, in prehypertensive Gdnf heterozygous mice, which have a 30% reduction in nephron number, glomerular enlargement was observed, associated with an increase in cellular proliferation, thickened glomerular basement membrane, reduced podocyte density, and a mild expansion of the tubulointerstitium.[119] In rats rendered diabetic at 12 weeks, and followed until 40 weeks, glomerular changes associated with diabetes were similar in those that had been of low birth weight compared to normal birth weight. However, again, in addition to lower nephron number, podocyte density was reduced and the area covered by each podocyte was greater in the low birth weight diabetic animals.[120] Interestingly, proteinuria tended to be higher in the low birth weight group, likely suggesting a greater degree of hyperfiltration. Taken together, these authors postulate that early subtle structural abnormalities in kidneys with reduced nephron number may enhance susceptibility to subsequent renal injury.

CLINICAL IMPACT OF NEPRHON MASS

Blood Pressure

Birth Weight and Blood Pressure

Many studies in humans and animal models have supported the observation that low birth weight is associated with higher blood pressures in later life (Fig. 2.5).[12,121–127] Higher blood pressures have been reported in newborns of lower birth weight, therefore this programming effect is evident early and tracks through to adulthood (Fig. 2.6).[127] Importantly, low birth weight children tend to have higher blood pressures, although not in the hypertensive range, compared to normal birth weight children. With increasing age, however, blood pressure differences between low birth weight and normal birth weight subjects become amplified and do reach hypertensive levels with time.[128,129] Prematurity and gestational age have also been associated with higher blood pressures in young adults; however, low birth weight for gestational age was a more significant predictor of blood pressure at birth and 18 years of age than low birth weight of prematurity.[107,130–133] This observation suggests that ongoing intrauterine stress may have a greater impact than premature birth. Consistent with this possibility, abnormal placental morphology, a marker of adverse intrauterine conditions, has been associated with higher blood pressures in children at 7 years of age.[134] The importance of the intrauterine environment has also been highlighted in both monozygotic and dizygotic twin studies, where the lower birth weight twin has been found to have a greater increase in blood pressure in infancy and higher blood pressure in adulthood.[135,136] These data have been interpreted to suggest that genetic factors play a smaller role than fetal growth in developmental programming. Although this may be the case, a significant modulation of the relationship between birth weight and blood pressure has been found by genotype of beta adrenergic receptors, suggesting possible developmental interaction with gene expression as well.[137] The relationship between birth weight and blood pressure has not been universally found, however, and in particular appears to be weaker, but not always absent, in African American children.[128,138–142] However, interestingly, the association between low birth weight and higher blood pressures does appear preserved in African and Caribbean black children, suggesting that early childhood growth rates, genetic, and/or other environmental factors are also important.[143–145] Current body mass index (BMI) is a frequent confounder in these studies, and may play a greater role among black compared to white subjects.[137]

Nephron Number and Blood Pressure

The association between low birth weight and later life hypertension has been well documented in various animal models utilizing gestational interventions such as maternal dietary protein restriction, dexamethasone administration, or uterine artery ligation, as described previously.[12,28,37,146–150] The link between low birth weight and subsequent spontaneous hypertension in these models appears to be, at least in part, attributable to an inborn nephron deficit.[12,37,148] Most interventions result in a 20% to 30% reduction in glomerular number in offspring, and hypertension emerges by early adulthood.[12,151] Conversely, optimization of postnatal nutrition after growth restriction has been found to normalize nephron number and abrogate the development of hypertension in rats, suggesting that nephron number per se is an important contributor to the pathogenesis of hypertension.[24,81,152] In contrast, however, augmentation of nephron number does not always protect against high blood pressure. Restoration of nephron number by supplementation of maternal low protein diet with glycine, urea, or alanine only normalized blood pressure in the offspring supplemented with glycine.[24] Similarly, a 20% increase in nephron number, induced by postnatal overfeeding in normal birth weight rats, did not prevent hypertension and glomerulosclerosis with age, although concomitant obesity may have been a confounder in this study.[152] Based on these studies, therefore, developmental programming of hypertension is dependent on more than a reduction in nephron number, although under certain circumstances nephron number does appear to be the predominant predisposing factor.

Evidence in humans suggests a similar association between nephron number and risk of hypertension. In a cohort 35- to 59-year-old European Caucasians who died in accidents, mean nephron number was significantly lower, and glomerular volume significantly higher in the 10 subjects with a history of essential hypertension, compared to 10 normotensive matched controls.[10] There was no evidence of disproportionate glomerulosclerosis or renal injury, leading the authors to suggest that an intrinsic deficit in nephron number was the most likely factor associated with development of essential hypertension. Birth weights were not available in this study, therefore potential associations with nephron number could not be speculated. A possible limitation of this study is the high mean glomerular number in the nonhypertensive group compared to that reported in other Caucasian populations; however, mean nephron number in the hypertensive group was similar to that in a hypertensive U.S. Caucasian cohort. Similarly, lower nephron numbers have been associated with higher blood pressures among Caucasians and Australian Aboriginal subjects, although the relationship is not as consistent among subjects of African origin (Fig. 2.7).[10,70,98] Conversely, the prevalence of hypertension was found to be lower among Caucasians and Australian Aboriginals with higher nephron numbers, suggesting a protective effect of higher nephron numbers in these populations.[70,113] An important caveat is that these studies are all performed on postmortem kidney samples mostly from adults of varying ages, and therefore may not reflect nephron endowment at birth. Much larger sample sizes would be required to control for all possible confounding variables between subjects, which are not easily feasible. In addition, associations have been well described between birth weight and nephron number, nephron number and hypertension, and birth weight and hypertension but, to date, to our knowledge, no study has analyzed nephron number, birth weight, and hypertension in individual subjects.

Timing of nephron loss appears to impact subsequent risk of hypertension and renal disease. In humans, congenital conditions associated with significant reductions in nephron mass (e.g. unilateral renal agenesis or bilateral renal hypoplasia) result in worsening proteinuria, hypertension, and renal dysfunction with time.[11] In contrast, nephrectomy later in life, resulting in a comparable loss of nephron mass, does not necessarily result in progressive renal functional decline.[153] Similarly, nephrectomy in adult animals in varying experimental settings does not invariably lead to hypertension and renal dysfunction.[154] Removal of a kidney on postnatal day 1 in rats, or fetal uninephrectomy in sheep (i.e., loss of nephrons during active nephrogenesis), however, does lead to adult hypertension in the absence of evidence of renal injury.[155–157] Taken together these animal and human observations suggest that loss of nephrons during renal development, as opposed to after nephrogenesis is completed, may have a more critical impact on the long-term risk of hypertension.

In support of this hypothesis, glomerular numbers in adult rats were similar after uninephrectomy at day 3 or day 120 of age; however, a greater proportion of immature glomeruli were present in kidneys of rats having undergone removal of the contralateral kidney at day 3.[158] In addition, mean glomerular volume compared to controls was 59% higher in rats undergoing neonatal nephrectomy compared with 20% higher in rats nephrectomized as adults, suggesting more vigorous compensatory hypertrophy and hyperfunction in response to neonatal nephrectomy, which may become maladaptive over the long term. Developmentally acquired low nephron mass may, therefore, be considered along the broader continuum of renal hypoplasia and associated with long-term consequences.[13]

Glomerular Volume and Blood Pressure

Glomerular volume varies inversely with nephron number and, in U.S. White, Black, and Australian Aboriginal subjects, is associated with increased risk for high blood pressure (Fig. 2.8).[70] In addition, among the U.S. Black and Australian Aboriginal populations, large glomeruli on renal biopsy are associated with poorer renal outcomes in native and transplanted kidneys.[98,115,159,160] Among Black subjects, glomerular size appears to be an independent predictor of higher blood pressure, whereas in White and Australian Aboriginal subjects, the relationship appears also dependent on low nephron number.[113]

The observation that in some animal models normalization of nephron number did not prevent development of subsequent hypertension, argues against nephron number being the sole programmed link between early developmental stress and higher blood pressures.[161,162] Given that the filtration surface area in kidneys with low nephron numbers has not been found to be significantly lower than in kidneys with a higher number of nephrons, and may even be increased in subjects with hypertension (Table 2.4), other nonglomerular contributors to sodium avidity in low birth weight kidneys have been investigated.[8,10,70] Blood pressure is dependent on renal, neuroendocrine, and vascular factors, all of which may be subject to simultaneous developmental programming.[8] Programmable vascular factors which have been studied include altered structure and function of large vessels, impaired vascular reactivity, and endothelial dysfunction, which are reviewed in detail elsewhere.[163–165] Neuroendocrine factors include altered stress responsiveness, cortisol levels, insulin resistance, and sympathetic nervous system activity.[71,166,167] Within the kidney, in addition to programming of nephron

number, alterations in sodium transport and modulation of the renin-angiotensin system have also been well described.

Renal Programming of Blood Pressure

Salt Sensitivity and Birth Weight

The original programming hypothesis postulated a reduction in filtration surface area and limitation in sodium excretory capacity in a kidney with fewer nephrons.[2] Consistent with this, prenatal dexamethasone administration in rats was associated with lower GFR, higher urine albumin excretion, reduced urinary sodium excretion, and higher tissue sodium content compared to controls.[37] Interestingly, in a study of Caucasian men aged 20 years, those who had been of low birth weight had an increase in systolic blood pressure and no change in GFR, but an increase in fractional excretion of sodium compared to normal birth weight controls.[85]

Salt-sensitive hypertension has subsequently been shown in low birth weight rats (induced by uterine artery ligation), and in adult rats that had been exposed to maternal gestational diabetes.[52,168,169] In contrast, however, blood pressures did not increase more in low birth weight rats (induced by maternal protein restriction) compared to normal birth weight rats on a high salt diet.[170] Timing of the dietary sodium challenge may have an impact, however.[171] Blood pressure rises more consistently in response to a high salt diet in older rats, suggesting loss of potential adaptive mechanism with age, or greater susceptibility to salt sensitivity as nephron numbers decline with age.[172] Plasma volume and blood pressures were found to be higher in low birth weight compared to normal birth weight juvenile rats on normal diets, however, suggesting positive sodium balance at baseline.[173] Interestingly, although a further increase in sodium intake did not increase blood pressures or plasma volume expansion more than in normal birth weight rats, GFR was significantly increased in the low birth weight rats on a high sodium diet, suggesting a shift in the pressure natriuresis curve.[173] These rats were subjected to global malnutrition in utero, therefore a low sodium diet during gestation, which also may have modulated their renal sodium handling. Interestingly, manipulation of sodium intake postnatally was found to impact long-term blood pressure in young low birth weight rats.[174] Low birth weight rats were placed on either low, normal, or high salt diets from weaning to 6 weeks of age, followed by normal diets thereafter. Later life hypertension was abrogated by early low salt diet and worsened by early high salt diet. In addition, salt sensitivity after 40 weeks was lost in the rats subjected to early low salt diets.[174] Early low salt diet therefore appears to be able to "re-program" the kidney and prevent hypertension in low birth weight rats.

Filtration surface area, blood pressure, and response to sodium loading was assessed in GNDF heterozygous mice in which nephron numbers are reduced, and 20% of animals have unilateral renal agenesis.[175] Total nephron number was reduced by 25% in mice with two kidneys (HET2K) and 65% in mice with single kidneys (HET1K) compared to the wild type. The degree of glomerular hypertrophy was similar in HET1K and HET2K, resulting in normalization of glomerular surface area in HET2K but a persistent reduction in the HET1K. In this model, reduced nephron number alone was not associated with increased blood pressures, but both groups of HET mice became significantly hypertensive on a high sodium diet, with blood pressures being highest in the HET1K mice.[175] Interestingly, at baseline urine sodium excretion was progressively higher in HET2K and HET1K mice, suggesting augmented natriuresis that maintained normal blood pressures. In the same model, tubule sodium transporters were not found to be increased, in contrast to other programming models. This suggested a different adaptation in baseline sodium handling in this genetic model, which may be overwhelmed in the face of a high sodium diet.[119,175]

In healthy human adults, salt sensitivity was found to correlate inversely with birth weight, independent of GFR (Fig. 2.9).[176] Similarly, in low birth weight children, the prevalence of salt sensitivity was found to be high and to correlate

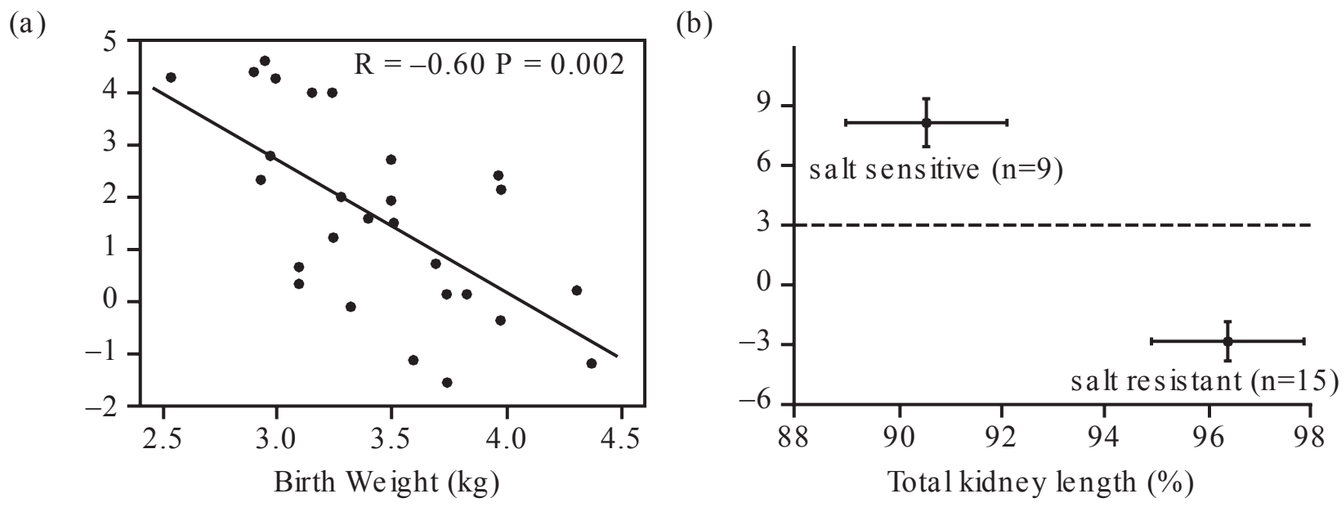

FIGURE 2.9 Salt-sensitivity in humans relative to birth weight and kidney length. **A:** Correlation between birth weight and salt sensitivity in 27 normotensive subjects aged 37.2 ± 14.5 years. **B:** Correlation between salt sensitivity and percent expected kidney length in children aged 11.3 ± 2.1 years. Kidney lengths were smaller in children who had been small weight for gestational age (SGA) compared to appropriate weight for gestational age (AGA) children at birth, suggesting a correlation of salt sensitivity with birth weight. (**A**, reprinted with permission from de Boer MP, Ijzerman RG, de Jongh RT, et al. Birth weight relates to salt sensitivity of blood pressure in healthy adults. Hypertension 2008;51:928–932. **B**, reprinted with permission from Simonetti GD, Raio L, Surbek D, et al. Salt sensitivity of children with low birth weight. *Hypertension*. 2008;52:625–630.)

inversely with kidney size, again independent of GFR, suggesting that renal function itself was not a confounder (Fig. 2.9).[105] Developmental programming of blood pressure in most animal models and humans does, therefore, appear to be associated with altered sodium handling by the kidney.

Renal Sodium Transport

The expression of renal sodium transporters has been investigated in several animal models of developmental programming as a contributor to salt sensitivity. In offspring of mothers fed a low protein diet or given dexamethasone during gestation, chloride transport in the thick ascending limb (mTAL) and the lumen positive transepithelial potential difference were significantly higher compared to control rats, demonstrating increased bumetanide sensitive Na^+-K^+-2 Cl^- (NKCC2) transporter activity in the mTAL.[177] Rats were already hypertensive at the time of study and, consistent with these findings, administration of furosemide reduced blood pressure in the prenatal low protein diet group compared to controls, demonstrating that the increased NKCC2 activity was contributing to the higher blood pressure.[177] Interestingly, in this study, at 6 weeks of age, expression of the NKCC2 was increased in the medulla of the low protein diet group but not the prenatal dexamethasone group, despite changes in sodium chloride transport being evident in both.[177] Similarly, NKCC2 and thiazide sensitive Na^+-Cl^- cotransporter (NCC) protein levels were significantly elevated in low birth weight, induced by maternal low protein diet, rat kidneys at 4 weeks of age—that is, before the manifestation of hypertension. This occurred even though expression of the proximal tubule sodium hydrogen exchanger (NHE3) and the epithelial sodium channel (ENaC) expression were not changed.[178]

In another study, prenatal dexamethasone was associated with increased NKCC2 protein expression at 8 weeks, along with NCC and NHE3, but not ENaC, and their expression was reduced by renal denervation, suggesting modulation of sodium transporter expression by the renal nerves.[179] Other investigators found mRNA expression of the glucocorticoid receptor, and the glucocorticoid responsive α1- and β1-subunits of Na^+/K^+-ATPase to be increased in offspring of rats fed low protein diets during gestation.[180] Similarly, in animals subjected to maternal diabetes, renal Na^+/K^+-ATPase expression was increased, as well as the β and γ subunits of ENaC.[168] When these animals were subjected to a high salt diet, expression of NHE3 and NCC increased, but expression of NKCC2 decreased.[168] In yet another model of low nephron endowment, there was no difference in NCC or ENaC expression by immunohistochemistry in kidneys of Gdnf heterozygous compared to wild type mice.[119] Various programming models of low nephron number and hypertension, therefore, are associated with some disparities in renal sodium transporter expression, but in general it appears sodium transporters are upregulated and likely contribute to increased blood pressures. Whether the alteration in sodium transport is a direct result of reduced nephron numbers, single nephron hyperfiltration and glomerulotubular balance, or is an independent simultaneously programmed change in the renal tubules is not yet clear.

The intrarenal renin-angiotensin system is important for nephrogenesis as well as blood pressure regulation.[8,72] Administration of inhibitors of the renin-angiotensin system during renal development results in abnormal kidneys and reduced nephron numbers.[8] Maternal low protein diet, prenatal dexamethasone, and uterine artery ligation all induce intrauterine growth restriction and have been associated with altered expression of components of the renin-angiotensin system.[8,181–185] The observed alterations in renal renin, angiotensinogen, angiotensin converting enzyme activity, angiotensin II, and angiotensin receptor subtype 1 and 2 levels all appear to be modulated at different times of development with some changes being present at birth and others manifesting in later life, as reviewed elsewhere.[8] In addition, some of the observed variation likely results from differences in timing and nature of the programming insult. The observation that programmed hypertension could be modulated by postnatal administration of inhibitors of the renin-angiotensin system supports a role for this system in generation of increased blood pressures, potentially involving altered sodium transport, reduced nitric oxide activity, and reactive oxygen species generation.[183,185] Furthermore, evidence of lack of suppression of this system in the setting of increased renal sodium transport and plasma volume expansion also suggests dysregulation by prenatal programming.[8] To our knowledge, levels of renin-angiotensin system activity have not been investigated in low birth weight humans.

Catch-up Growth and Blood Pressure

Developmental programming does not only encompass the intrauterine period but, as discussed previously, early postnatal events may also be critical in renal development. Similarly, early childhood growth, especially after intrauterine growth restriction, is emerging as a significant risk factor for subsequent hypertension and cardiovascular disease.[186]

In low birth weight male rats with reduced nephron numbers, induced by maternal gestational protein restriction, postnatal overfeeding resulted in accelerated development of hypertension and a significant reduction in GFR in adulthood.[187] The rapid postnatal weight gain in the low birth weight overfed rats therefore exacerbated the programmed risk of hypertension, acting as a "second hit" superimposed on the low nephron number. Interestingly, appetite, obesity, and energy expenditure are also developmentally programmed, compounding the risk of cardiovascular disease in growth restricted individuals.[188] In a cohort of adolescents, rapid weight gain in the first 2 weeks of life was associated with reduced flow-mediated dilation of the brachial artery measured at ages 13 to 16, underscoring the long-term impact of early nutrition on vascular function.[189] Similarly, weight gain within the first 5 months of life was associated with increased systolic and diastolic blood pressures at 25 years of age, although only systolic blood pressure was inversely associated with birth weight.[190] The combination of low birth

2.5 Difference in Systolic Blood Pressure (mm Hg) at 22 Years per SDs Increase in Birth Weight, Infant Weight Gain (First Year), and Early Childhood Weight Gain (1–5 Years)[a]

weight followed by accelerated childhood growth has also been consistently found to be associated with higher blood pressures in childhood and adulthood (Table 2.5).[191,192]

Several potential mechanisms have been investigated to explain this amplification of cardiovascular risk by rapid weight gain after growth restriction. In obese sheep that had been exposed to maternal nutrient restriction during gestation, adipose tissue showed an increase in number of necrotic cells, increased secretion of pro-inflammatory factors, and increased evidence of endoplasmic reticulum stress compared to obese controls.[188] In addition, the nutrient restricted obese sheep exhibited abnormal myocardial structure and function.[188] One possible connection between growth restriction and accelerated catch-up growth is the development of premature senescence.[193] Chronic diseases such a hypertension, chronic kidney disease, and cardiovascular disease have all been associated with increased expression of senescence markers. In animal models, low birth weight followed by accelerated postnatal growth was associated with more rapid telomere shortening and accelerated senescence in kidneys and aortas, as well as premature death.[194–196] These markers were not correlated directly with blood pressures and nephron numbers in the same animals. However, investigators utilized a standard programming model of maternal dietary protein restriction, therefore low birth weight animals were expected to have low nephron numbers and high blood pressures.

In another study, there was no difference in expression of the senescence marker p16 between low birth weight and normal birth weight rats, suggesting that senescence is not likely a contributor to the reduced nephron numbers.[193] p16 was significantly increased by weaning in kidneys and hearts of low birth weight rats, and continued to rise progressively with age, suggesting ongoing tissue stress and accelerated senescence precipitated by catch-up growth. Increased senescence in the low birth weight kidneys may result from ongoing hyperfiltration injury in kidneys with fewer nephrons, exacerbated by a rapid increase in body size. Interestingly in humans, leukocyte telomere length was not different between small for gestational age and appropriate for gestational age newborns, but by 5 years low birth weight children had significantly shorter telomeres than normal birth weight children, consistent with accelerated senescence.[197,198] However, growth trajectories of these children were not reported. Markers of endoplasmic reticulum and mitochondrial stress were increased in low birth weight rat kidneys after rapid catch-up growth, which points to increased reactive species generation as a possible mediator of increased senescence.[193] Consistent with these animal findings, in humans there is evidence of increased oxidative stress in children born small for gestational age compared to controls, which was relatively higher in those who experienced catch-up growth.[199,200] The link between nephron mass, catch-up growth, premature senescence, and the development of hypertension and renal disease in humans after developmental programming has not been studied.

Renal Function and Nephron Mass

Glomerular Filtration Rate

A reduction in nephron number, and therefore filtration surface area, in the absence of compensatory hyperfiltration, would be expected to be associated with a reduced whole kidney GFR. Consistent with this possibility, amikacin clearance, as a surrogate for GFR, was lower in premature or growth restricted neonates on day 1 of life (i.e., before

any adaptation would have occurred).[201] Similarly, nephron number and GFR were measured in newborn growth restricted piglets.[202] GFR was reduced in proportion with nephron number, suggesting a lack of glomerular adaptation early after birth. With increasing age, however, as the single nephron GFR increased with hyperfiltration, differences in total GFR have not been consistently seen between normal and low birth weight subjects. Among 6- to 12-year-olds, estimated creatinine clearance was lower and serum creatinine higher in very low birth weight compared to age-matched normal birth weight subjects.[203] In contrast, estimated GFRs were not different between three groups of 9- to 12-year-olds born with low gestational age or either small for gestational age or appropriate for gestational age at term.[106] Interestingly, estimated GFR calculated using cystatin C showed a significant linear trend with birth weight compared to creatinine-based GFR in a cohort of children divided into quartiles by birth weight. This suggested the potential pitfalls with creatinine measurements and/or the need to adapt GFR calculation formulae in young low birth weight subjects.[204]

Utilizing iothalamate clearance, GFR was measured in a cohort of children at a mean age of 7.6 years who were born with a birth weight under 1,000 g or before 30 weeks of gestation, and stratified according to whether they had experienced either intrauterine or extrauterine growth restriction or normal perinatal nutrition.[55] GFRs were significantly lower in both pre- and postnatally growth restricted children, although still within the normal range for their age. This observation further highlights the potential negative impact of poor extrauterine nutrition on early renal development in premature infants. In young adults born very premature, the creatinine-based Cockroft-Gault GFR was found to correlate positively with birth weight.[131] GFRs measured by 24-hour urine creatinine clearance within adult twin pairs were lower in the lower birth weight twin, again suggesting an independent effect of the intrauterine environment on programming of renal function.[205] Overall, from several studies, GFRs were estimated to increase by 3.8 to 7.2 mL per minute in males and 2.6 to 5.7 mL per minute in females per 1-kg increase in birth weight.[206,207]

An interesting small study evaluated total GFR, effective renal plasma flow, and filtration fraction before and after low dose dopamine or an oral amino acid load to test renal functional reserve in 20-year-olds born (1) premature with appropriate weight for gestational age, (2) premature and small for gestational age, or (3) term and appropriate for gestational age. Intriguingly, although the changes did not reach statistical significance, the stimulated increase in GFR was less in small for gestational age compared with appropriate for gestational age and control subjects. Effective renal plasma flow was lower in both small for gestational age and appropriate for gestational age preterm subjects, suggesting at least a small decrease in renal functional reserve capacity.[208]

GFR and effective renal plasma flow were also studied before and after an intravenous amino acid infusion in young adults who had diabetic mothers (i.e., had been exposed to maternal diabetes during gestation) compared to those with diabetic fathers. Subjects were matched for age, gender, BMI, and birth weight. The offspring of diabetic mothers had a significantly reduced renal reserve capacity, suggesting a renal programming effect due to maternal diabetes.[53] Evaluation of renal functional reserve may therefore be a sensitive method to detect subtle changes in renal function due to a reduced nephron number that may not be evident with baseline GFR measurements.

Proteinuria is a marker of glomerular hyperfiltration and renal injury and, as such, has been investigated in several low birth weight populations. Among children aged 8 to 11 years of age, low birth weight was associated with significantly higher blood pressures and 24-hour urine albumin excretion compared to normal birth weight controls.[209] Multiple other studies have also shown a largely consistent relationship between low birth weight and proteinuria, although in some studies albuminuria was associated with thinness at birth, an indicator of intrauterine stress, rather than birth weight.[94,131,207,210,211] Among Australian Aborigines, albuminuria was strongly associated with low birth weight and the relationship was amplified with increasing age.[212] Macroalbuminuria in this cohort was also associated with a high risk of renal failure and death.[213] In a Finnish population with type 1 diabetes, however, after a mean duration of diabetes of 19 years, no association was found between proteinuria and birth weight stratified as low, <10th percentile; high, >90th percentile; and intermediate, between 10th and 90th percentiles.[214]

In a similar study, among Danish women with type 1 diabetes, with a median duration of 27 years, 75% of those with birth weight under the 10th percentile had nephropathy, defined as persistent urine albumin excretion >300 g per day, compared with 35% of those with birth weights above the 90th percentile.[215] The effect was not present in men, although in another study, short stature in men was associated with a higher risk of macroalbuminuria.[216] A U-shaped association between birth weight and proteinuria was found among Pima Indians with type 2 diabetes in the United States, suggesting that high birth weight and low birth weight are both risk factors for renal disease in this population.[94] Interestingly 64% of subjects with high birth weight were offspring of diabetic mothers versus none of those with low birth weight. The association of high birth weight with proteinuria was lost after adjustment for maternal diabetes, suggesting potentially different programming mechanisms in low birth weight and high birth weight with respect to proteinuria.[94]

Differences between these studies in diabetic subjects may reflect altered genetic susceptibility to renal disease in the Pima population, differences between type 1 and type 2 diabetes, as well as different durations of diabetes. As mentioned previously, podocyte abnormalities are present in kidneys with developmentally programmed low nephron numbers, which may contribute to the development of proteinuria in low birth weight subjects.[118]

Chronic Kidney Disease

Although GFRs have been found to be statistically lower in low birth weight populations, this has not always been outside of the normal range, calling into the question true clinical relevance.[55,131] A recent meta-analysis examined 31 studies that reported risk of CKD—including various end points, including proteinuria, diabetic nephropathy, and reduced GFR—relative to birth weight.[207] Overall they found a 70% increased risk of CKD in low birth weight individuals, regardless of end point studied.[207] Again, the effect was stronger in males. Among 12,364 participants in the Kidney Early Evaluation Program, among men a U-shaped curve was found for risk of CKD, defined as an estimated GFR <60 mL per minute or albumin excretion ≥30 g per g, and birth weight, with increased risk with birth weights <2,500 g and ≥4,500 g.[73] No association was found among female participants, however.

The clinical relevance of the risk of CKD with low or high birth weights is borne out in studies examining risk of ESRD. Retrospective analysis in over 2 million Norwegians found the relative risk of ESRD to be 1.7 in males and females born below the 10th percentile in weight.[217] Interestingly, when looking at absolute birth weights and risk, the relative risk for ESRD was 2.0 with birth weights <2.5 kg, but was only increased in females with birth weights ≥4.5 kg.[217] In a predominantly black, southern U.S. population, a U-shaped curve was again described for risk of ESRD with low and high birth weights, this time in both men and women.[218]

Growing numbers of epidemiologic studies therefore support the relationship between high birth weight or low birth weight and risk of subsequent renal disease (Table 2.6). A direct link between nephron number and renal disease in individual human subjects has not been made, however. Nephron number is unlikely to be the sole cause of renal dysfunction in most patients, and other susceptibilities likely compound the risk. A low nephron number, however, may lower the threshold to reach a critical loss of renal function in response to superimposed renal injury or stress. In support of this possibility, low birth weight has been associated with poorer renal outcomes in patients with nephrotic syndrome, membranous nephropathy, IgA nephropathy, minimal change disease, and diabetic nephropathy.[95,219–222]

Interestingly in a model of diabetes superimposed on low nephron number, the increase in glomerular volume in response to hyperglycemia was more exaggerated and maladaptive in the low compared to normal birth weight rats.[223] Similarly, mesangioproliferative glomerulonephritis was associated with significantly increased glomerulosclerosis in low birth weight animals with reduced nephron numbers.[224] Potential molecular mechanisms whereby kidneys with fewer nephrons adapt differently than normal kidneys include an imbalance between apoptosis and cell proliferation, accelerated senescence, reactive oxygen species generation, and mitochondrial dysfunction.[162,193]

RELEVANCE OF NEPHRON MASS IN TRANSPLANTATION

Impact of Kidney Donation

In experimental models of low birth weight, as described previously, nephron numbers are often reduced by 25% to 30%, and animals develop spontaneous hypertension and

2.6 Clinical Findings Associated with Birth Weight, Nephron Number, and Kidney Size in Humans

Low Birth Weight/ Prematurity	Low Nephron Number	Reduced Renal Size	High Birth Weight/ Maternal Diabetes
↑ Blood pressure[127] Salt sensitivity[105,176] Proteinuria[131,210] ↓ GFR[55,131,201] ↓ Renal functional reserve[208] Accelerated progression of primary renal disease[219–222] Chronic kidney disease[73,207] End-stage kidney disease[217,218] Death[210]	↑ Blood pressure[70] ↑ Glomerular volume[13] ? Predisposition to renal failure in neonates[54]	↑ Blood pressure[105] Salt sensitivity[105] ↓ GFR[105] ↓ Renal allograft survival if small kidney into large recipient[237]	Proteinuria[95] ↓ Renal functional reserve[53] End-stage kidney disease[217,218]

↑, increase; ↓, decrease; ?, unknown.

renal dysfunction.[12,37] In humans, donation of a kidney implies loss of 50% of nephron mass, and therefore may carry some long-term risk. However, many studies have shown that kidney donation is safe and former kidney donors have similar or even better life expectancy and lower risk for ESRD than the general population.[153] This paradox might be due to the very thorough screening of potential donors and the selection of only the very healthiest subjects. In addition, the studies on long-term outcomes have predominantly been done in Caucasians, are limited by significant loss to follow-up, and do not use similarly selected, healthy control groups for their comparative analysis.

An early retrospective study of 52 kidney donors followed after at least 10 years did find a higher risk of hypertension and mild proteinuria compared to age-matched controls and other potential donors, although creatinine clearance did not deteriorate as a function of time.[225] Interestingly the risks of hypertension and proteinuria were greater in men. In contrast, subsequent studies in predominantly Caucasian donors did not find a significantly increased risk of hypertension and proteinuria, suggesting that uninephrectomy is safe.[153] Concerns have been raised, however, about possible harm of living kidney donation in other ethnic groups. After a median of 16 years postdonation, the incidence of new onset hypertension, CKD, and ESRD was significantly higher among Australian Aboriginal kidney donors compared to Caucasians.[226] Similarly, among Canadian donors, hypertension was present in 42% of Aboriginals compared with 19% of Caucasians by a mean of 14 years of follow-up, and in 100% of Aboriginal donors by 20 years postdonation.[227] Estimated GFR was not different between Caucasians and Aboriginals, but proteinuria was more common among Aboriginal donors. In U.S. cohorts, black kidney donors were found to have significantly more hypertension and CKD compared to white donors.[159,228]

In all of these cohorts donors are presumed to have been screened and found healthy prior to donation, therefore, uninephrectomy in populations with high susceptibility to hypertension and kidney disease may carry more risk than has thus far been appreciated. Aboriginal Australian and U.S. black populations have lower birth weights than their Caucasian counterparts, and Canadian Aboriginals have higher birth weights (World Health Organization). This suggests that programming of nephron number may be a factor contributing to increased hypertension and renal risk postnephrectomy. Birth weight and early development history should therefore be incorporated into a potential donor's evaluation, and consideration given to measurement of renal functional reserve, although at present it is likely premature to suggest that decisions on donor eligibility be based on this information.

Impact on Allograft Function

The importance of nephron mass as a nonimmunologic determinant of long-term transplant outcomes has been debated since the nephron number hypothesis was first put forward.[229] Indeed, in rat models it has been elegantly shown that transplanted nephron mass (i.e., kidneys with varying nephron numbers) has a significant impact on allograft outcome, independent of immunologic barriers.[230] As nephron numbers cannot be determined in vivo, various surrogates have been examined in humans to assess the impact of transplanted nephron mass, measurable to some degree ex vivo, relative to recipient demand, on allograft outcomes (Table 2.7). Such surrogates include ratios of recipient to donor body surface area (BSA) or body weight, of kidney volume to recipient BSA, and of kidney weight to recipient body weight.[231–235] As mentioned previously, kidney mass and kidney volume do reflect nephron number to some degree, but these data should be interpreted with caution, realizing that BSA is not always proportional to kidney weight, and that two kidneys of the same size may differ in nephron number.

Despite these caveats and the variability of methods employed, the evidence shows fairly consistently that small kidneys, or kidneys from small donors, transplanted into larger recipients, tend to have poorer outcomes.[231–235] Duration of follow-up, however, is also a crucial variable, as seen in the donor literature, where differences in hypertension and proteinuria emerge only after many years. Interestingly, an early report in a cohort of renal allograft recipients, with a mean of 32 months of follow-up, failed to find any impact of graft weight on short-term graft survival.[236] With longer follow-up, however, in the same cohort, subjects with a low donor kidney weight to recipient body weight ratio (DKW/RBW) showed a greater adaptive early increase in GFR, which remained stable for 7 years, followed by a more rapid loss of GFR as compared to the high DKW/RBW group, thus demonstrating the importance of long term follow-up.[237] These data suggest that smaller kidneys transplanted into larger recipients underwent early hyperfiltration that could not be sustained indefinitely, resulting in ongoing nephron loss. Over time, the low DKW/RBW group required more antihypertensives, had more proteinuria, and on kidney biopsy showed a greater degree of glomerulosclerosis. Overall, the risk of transplant failure was 55% higher in low DKW/RBW compared to the high DKW/RBW group at 2 years.[237] The authors conclude that mismatch between allograft and recipient weight is an independent predictor of long-term graft survival.

These results are consistent with another analysis, which was restricted to recipients of living donor kidneys who had not experienced any complications within the first year of transplantation. Progressively higher levels of urine protein excretion and lower GFRs occurred as DKW/RBW fell.[238] Similarly, a large retrospective analysis of 32,083 recipients of a first cadaveric kidney transplant, utilizing the ratio of donor to recipient BSA, found that large recipients of small kidneys had a 43% increased risk of late allograft failure compared to the reference group which was medium sized recipients receiving kidneys from medium sized donors.[234]

Another study examined the outcomes of kidneys from donors over age 60, presumed to have fewer nephrons by

2.7 Impact of Donor and Recipient Mismatch on Renal Allograft Outcomes

Measurement	Allograft Outcome	Donor	Reference
Donor kidney weight : recipient body weight	↑ Risk of late allograft loss, proteinuria, hypertension, and glomerulosclerosis at 6.2 years with lower ratios	Cadaveric	237
Donor kidney weight : recipient body weight	↓ Creatinine clearance and ↑ proteinuria at 3 years with lower ratios	Living	238
Donor–recipient body weight ratio	↓ Graft survival at 5 years in low ratio group	Living	232
Donor : recipient BSA	↑ Late allograft loss in large recipients who received kidneys from small donors	Cadaveric	234[a]
Transplant cross-sectional area (ultrasound): recipient body weight (Tx/W)	↓ Creatinine, trend toward improved outcome with larger ratios at 12 months	Cadaveric	241
Kidney weight (g)	↑ Creatinine clearance with higher kidney weight at 12 months	Living	231

[a]More studies reviewed in this reference.
↑, increase; ↓, decrease; BSA, body surface area.

virtue of increased age, relative to recipient BMI, and found that 5-year allograft survival was significantly lower in recipients with higher BMI or BSA, again suggesting an impact for mismatch between fewer transplanted functioning nephrons and higher donor demand on long-term outcomes.[239] Not all studies have found consistent results, however, with some failing to find an impact of differing donor to recipient BSA ratios on outcomes of paired cadaver kidneys.[233] The high and low ratios did overlap in this study, however.

A more recent study of paired kidneys did find a donor–recipient size mismatch to be a risk factor for delayed graft function.[240] Other investigators have examined the ratio of transplanted kidney cross-sectional area, as measured by ultrasound, relative to recipient weight as a predictor of outcomes. They found lower serum creatinines and a trend toward improved graft survival at 5 years in those with higher ratios.[241] Overall, therefore, transplanted nephron mass does appear to have a long-term impact on allograft function. Clinically, however, nephron mass at transplantation is likely impacted by many other factors in addition to nephron endowment (e.g., loss through peritransplant injury, immune-mediated injury, donor age, and other donor factors). Kidneys transplanted with fewer nephrons are likely to have less functional reserve and therefore are at risk of declining function over time. Awareness of this association may impact a clinician's decision about medication choices, peritransplant interventions, and ultimately potentially organ allocation.

THE IMPACT OF PROGRAMMING ON RELATED ORGAN SYSTEMS

The interaction of gestational diabetes exposure, birth weight, and proteinuria, for example, demonstrates that developmental programming may impact multiple organ systems simultaneously.[53,95,215] In a Swedish cohort of 18,230 twins, low birth weight was found to increase the risk of adult type 2 diabetes with an adjusted odds ratio of 1.44 per 500 g decrease in birth weight.[242] Similarly, in a Chinese cohort, low birth weight was found to be inversely associated with risk of type 2 diabetes, and both high and low birth weights were associated with increased risk of hypertension and abdominal obesity.[243] Low birth weight combined with abdominal obesity was the strongest predictor of diabetes. Obesity and diabetes are both risk factors for CKD and, therefore, their interaction with low birth weight likely augments this risk. Interestingly, low birth weight rats, induced by maternal low protein diet, suffered more severe cardiac dysfunction after myocardial ischemia and reperfusion compared to normal birth weight rats.[244] In another study, graded surgical reduction in nephron number in normal rats was associated with progressively

higher systolic blood pressures, left ventricular hypertrophy, and left ventricular systolic and diastolic dysfunction compared to sham operated controls.[245] In sheep, fetal uninephrectomy resulted in hypertension and more severe renal dysfunction and albuminuria with age.[156] In addition, cardiac functional reserve, measured in response to dobutamine infusion, was significantly reduced by 6 months of age in the neonatally nephrectomized sheep and left ventricular mass was significantly increased. In the clinical arena, patients with CKD often have coexisting diabetes and/or cardiac dysfunction, and CKD itself is a known cardiac risk factor. Whether some of this association is related to the consequences of renal dysfunction per se—that is, hypertension, volume expansion, proteinuria—or may reflect parallel programming of multiple organ systems in the same individual has yet to be elucidated.

CONCLUSION

The concept that nephron mass, at least in part, is determined during the perinatal period and has a long-term impact on an individual's subsequent risk of hypertension and renal disease is now accepted (Fig. 2.10). Nephron number alone is not often enough to result in overt disease, but does appear to be a strong modifier of risk in various ethnic groups, as well as under certain clinical conditions (e.g., diabetes mellitus). As such, surrogate markers for low nephron number and adverse perinatal conditions should be screened for in the clinical setting and appreciated as risk factors that may not be modifiable in the adult. However, they may highlight the need to minimize further insults and optimize other risk factors for hypertension and renal disease. Low birth weight is currently the most useful clinical surrogate for low nephron mass and the developmentally determined risk of hypertension and renal disease.

Much more work is needed to determine the impact of high birth weight. The exciting experimental findings that low nephron numbers can be rescued under some circumstances points to the importance of improving maternal health before and during gestation, optimizing of neonatal nutrition, and avoiding nephrotoxins in the early perinatal period, as well as raising hope for potential translation of therapeutic interventions to the human in the future. From a public health point of view, close attention should be paid to improving perinatal care and early childhood nutrition as potential tools to stem the growing tides of renal and cardiovascular disease in future generations.

CHAPTER

3 Renal Circulation and Glomerular Hemodynamics

William J. Arendshorst • L. Gabriel Navar

The capability of the kidneys to achieve their sophisticated homeostatic function is optimized by an intricate microvascular system that adjusts vascular resistance to maintain an appropriate control of the intracapillary and interstitial forces that govern renal blood flow in the cortex and medulla as well as the glomerular filtration rate. A combination of intrinsic and extrinsic regulatory mechanisms are responsible for controlling the one-fifth of the cardiac output that circulates through the kidneys. Essentially all the renal blood flow (RBF) traverses through the glomerular capillaries, where about 20% of the plasma is filtered. The complex glomerular filtration apparatus is truly unique in having both a very high hydraulic conductivity and a remarkably low permeability to plasma proteins. One major function of the renal vasculature is to regulate the intraglomerular forces so that an adequate, yet not excessive, volume is filtered into the urinary tubules. In this chapter, we discuss the characteristics of the filtering and the reabsorbing microcirculatory structures in the normal kidney. Particular emphasis is placed on the dynamic interactions among the intrarenal paracrine and extrarenal homeostatic mechanisms that participate in regulating these processes. To allow a better appreciation of basic mechanisms, some structural relationships and fundamental concepts related to vascular smooth muscle, endothelial cells, and other components of the renal microvascular network are discussed. A detailed discussion of the anatomic features of the kidney is provided in Chapter 1.

THE MAGNITUDE OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

The multiple intrarenal parallel arteriolar pathways provide the kidneys with a very low vascular resistance. They normally receive about 20% of the cardiac output. This amounts to a blood flow of 1,000 to 1,200 mL per minute in a 70- to 75-kg person. RBF is even more impressive when considered per unit of kidney weight, because the kidneys account for only 0.5% of the total body weight, or about 300 g. Thus, as shown in Table 3.1, blood flow per gram of kidney weight is about 4 mL per minute, which is 5 to 50 times greater than the flow through other organs and circulatory beds. Based on a total of 1 million glomeruli in each kidney or a glomerular density of 7,000 glomeruli per gram, the average blood flow and glomerular filtration rate (GFR) per glomerulus is 570 nL per minute and 62 nL per minute, respectively. This large flow, coupled with the maintenance of a high hydrostatic pressure in glomerular capillaries, allows the filtration of about 20% of the plasma, which amounts to an average GFR of 120 mL per minute, or 170 L per day.[1,2]

The extraordinarily high RBF is in marked excess of that simply required to provide the renal parenchyma with adequate supplies of oxygen and nutrients. For this reason, it is generally recognized that RBF is regulated primarily to maintain the glomerular and peritubular intrarenal hemodynamic environments at levels compatible with the optimum delivery of filtrate to the nephrons and appropriate reabsorption of fluid back into the systemic vasculature.

The Relationship of Renal Blood Flow to Oxygen Consumption

Although oxygen (O_2) use is not a major determinant of RBF, O_2 consumption by the kidneys is still quite high because of the very high metabolic activity of the tubules. Over 99% of the filtered fluid, electrolytes, and essential organic nutrients are normally reabsorbed by the tubules and returned to the circulation via the peritubular capillaries. The tubular reabsorptive processes depend on the integrity of the epithelial transport systems, in particular the energy requiring Na-K-ATPase. Such tubular enzyme systems account for the majority of the O_2 consumption by the kidneys.

RBF is about 400 mL/min/100 g of tissue, and the arteriovenous O_2 difference is relatively low, only 1 to 2 mL per deciliter of blood. Thus, O_2 consumption by the kidney is about 8 mL of O_2 per minute or 400 μm of O_2/min/100 g, which amounts to 6% to 8% of the whole body O_2 consumption. This level of O_2 use is relatively constant and is not reduced by moderate hypoxemia. Under physiologic conditions, there is a consistent relationship between RBF

3.1 Renal Hemodynamic Function in Humans

	Total	Per Kilogram Body Weight	Per Gram Kidney Weight
Renal blood flow	1,200 mL/min	17 mL/min	4 mL/min
Renal plasma flow	670 mL/min	9.6 mL/min	2.2 mL/min
Glomerular filtration rate	130 mL/min	1.9 mL/min	0.45 mL/min
Number of glomeruli	2 million	28,500	7,000
Oxygen consumption	1,200 μMO_2/min	17 μMO_2/min	4 μMO_2/min

and renal O_2 consumption. However, this relationship is a consequence of the associated changes in GFR and filtered sodium load, reflecting a direct causal relationship between tubular sodium reabsorption and O_2 consumption, as shown in Figure 3.1. The rate of actively transported sodium appears to be the primary determinant of the rate of O_2 consumption. About 20% of the consumption, or approximately 100 μm of O_2/min/100 g of kidney, is used for basal metabolic purposes and continues even in the absence of filtration. Above this basal rate, there is a linear relationship. Approximately 27 to 35 mEq of sodium is reabsorbed per millimole of O_2 consumed, depending on the contribution of passive transport via paracellular pathways, which may be about 40%. In contrast to other organs, the kidneys do not have a hyperemic response to hypoxia, making them more susceptible to hypoxemia.[3,4]

The balance of O_2 consumption for sodium reabsorption and O_2 delivery is reflected by the tissue pressure of O_2 (pO_2). A cortical–medullary gradient of oxygenation exists in the kidney. In the superficial cortex, pO_2 in efferent arterioles is 40 to 45 mm Hg, with values of 40 mm Hg recorded in other cortical structures (proximal tubule, distal tubule, superficial cortical tissue), and 30 mm Hg in the deep cortex. The fact that pO_2 in the renal vein exceeds that of any site in the cortex indicates precapillary shunting of O_2 from artery to vein. Renal medullary pO_2 is about 20 mm Hg, with cells functioning in a climate of constant relative hypoxia. Recent mathematical analysis indicates that arteriovenous O_2 shunting in the cortex is substantial. The shunting contributes to the stabilization of tissue pO_2 levels. Cortical ischemia may exacerbate medullary hypoxia even when medullary perfusion is maintained.[5–8]

In the renal medullary microcirculation, the net amount of O_2 reabsorbed from vasa recta into the interstitium is significantly lower than estimated medullary O_2 requirements based on active sodium reabsorption. Low inner medullary pO_2 results from the countercurrent arrangement of vasa recta and high vascular permeability to O_2, as well as high metabolic needs. Diffusional shunting of O_2 between descending and ascending vasa recta explains why a 20-mm Hg decrease in initial pO_2 at the corticomedullary border only leads to a small drop in pO_2 at the papillary tip (<2 mm Hg with baseline parameter values). In contrast, small decreases in medullary blood flow, hematocrit, and O_2 consumption by tubules markedly reduce interstitial pO_2. Without erythrocytes, papillary tip pO_2 cannot be maintained above 10 mm Hg, even when O_2 consumption is zero. An increase in medullary blood flow during water diuresis improves medullary O_2 delivery.

The renal medulla normally functions in an hypoxic environment. Tissue hypoxia impacts on O_2-regulated genes and leads to the renal production of adrenomedullin and erythropoietin. Hypoxia-inducible factor-1alpha (HIF-1α) is a transcription factor that regulates the O_2-dependent expression of many genes. This transcription factor may contribute to gene expression in renal medullary cells that

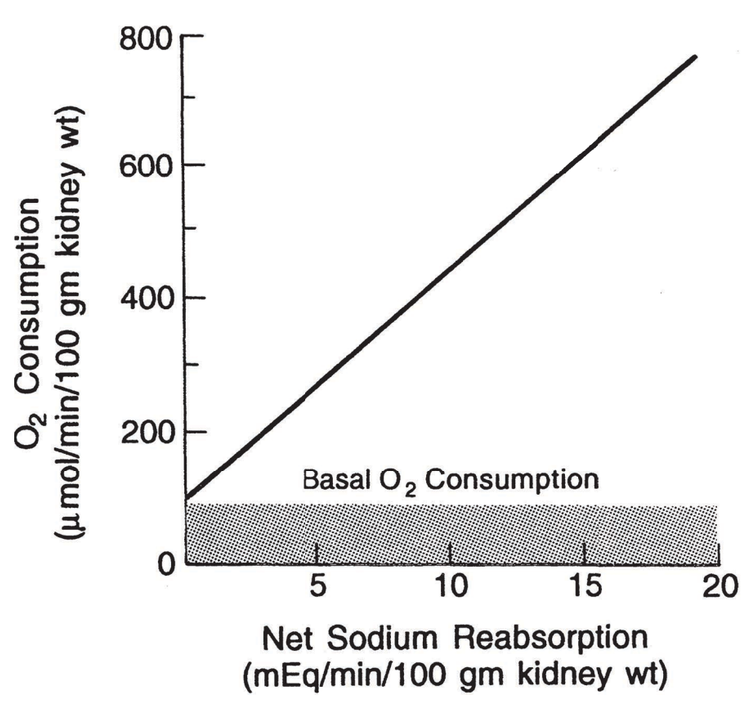

FIGURE 3.1 The relationship between tubular sodium reabsorption and oxygen consumption by the kidney. The primary determinant of oxygen consumption above basal levels is the rate of active sodium transport.

function normally under hypoxic conditions. In this regard, the loop diuretic furosemide markedly increases renal medullary pO_2 levels (20 to 50 mm Hg) in association with the inhibition of reabsorption along the ascending limb of Henle loop and a reduction in HIF-1α.[9,10]

The efficiency of coupling between tubular transport and O_2 consumption is modified by paracrine/autocrine factors. Nitric oxide (NO) normally suppresses O_2 consumption by epithelial mitochondria. The inhibition of NO synthesis increases O_2 extraction and O_2 consumption and reduces the efficiency of sodium transport. The regulation of renal O_2 consumption by NO may become impaired during oxidative stress when superoxide production is excessive. Oxidative stress and decreased availability/activity of NO can lead to reduced intrarenal pO_2 due to enhanced O_2 usage relative to tubular sodium transport. A low sodium intake leads to increased renal medullary oxygenation.[11]

Endothelial-dependent NO plays a role in the regulation of renal O_2 consumption in normal kidneys. Baseline cortical O_2 consumption is about 600 nmol per minute per gram of tissue. Stimulation of NO production by bradykinin or administration of a NO donor reduces O_2 consumption 25% to 30% in the renal cortex and 30% in the medulla. Superoxide scavenging of NO attenuates the stimulatory effect of bradykinin or NO donors.[3,5,8]

CHARACTERISTICS OF THE CONTRACTILE PROCESS

Structural–Functional Aspects

There are important interactions among various cell types in the microvasculature that determine the caliber of the small diameter resistance vessels. The complex vasculature of the kidney (Fig. 3.2) allows the fine regulation of the intrarenal hemodynamic environment. Smooth muscle cells surround all vascular structures from the main renal artery to the individual afferent and efferent arterioles. The preglomerular vasculature also has extensive innervation and responds to renal nerve stimulation and many different hormonal, paracrine, and physical stimuli. Nevertheless, most of the fine control of preglomerular resistance occurs in the small diameter afferent arterioles. The afferent arterioles vary in length and in the angle at which they branch from the interlobular arteries; those in juxtamedullary portions branch at a much sharper angle. In addition, smooth muscle cells of the afferent arterioles are modified as the vessels approach the glomerulus. The proximal portions of afferent arterioles possess typical elongated smooth muscle cells, whereas cells closer to the glomerulus are more rounded and many possess renin-containing granules.[1,2]

As is shown in Figure 3.3, the magnitude of the hydrostatic pressure drop along the arterial tree is relatively small up to the terminal segments of the afferent arterioles. About 70% of the preglomerular pressure drop occurs in the terminal portion of the afferent arteriole. In rodents, the arteries and the larger arterioles leading to the superficial nephrons contribute more to this pressure drop. Overall, the pressure drop up to the glomerular capillary tuft is much lower than in other vascular beds. This allows for high hydrostatic pressure in the glomerular capillaries, which is much greater than the plasma colloid osmotic pressure and is thus responsible for the ultrafiltration of fluid into the Bowman space.[1]

The terminal portion of an afferent arteriole contains modified granular epithelioid cells that form part of the juxtaglomerular apparatus. The granules contain renin and other components of the renin–angiotensin system; the extent of granulation varies inversely with sodium intake. There is a reciprocal relationship between the amount of renin and actin, and the granular cells may have reduced contractile capability. As is shown in Figure 3.4, the juxtaglomerular granular cells are adjacent to the tubular macula densa segment at the end of the ascending loop of Henle, and they are associated with the nongranular extraglomerular mesangial cells between the afferent and efferent arterioles. The appearance of the macula densa cells with large nuclei along with their close apposition to the glomerular vessels provide the

(Drawing by Dr. Daniel Casellas.)

morphologic basis for the influence of alterations in flow or composition of the tubular fluid to generate signals that are transmitted to the afferent arteriole or juxtaglomerular cells to control vascular tone and renin release.[12–14]

As an afferent arteriole approaches a glomerulus, the muscle cells surrounding the vessel intermingle with extraglomerular and intraglomerular mesangial cells. As it enters the glomerulus, the arteriole expands into a manifold lined by endothelial cells, which, in turn, gives rise to a series of glomerular capillary loops. The loops subdivide further into a branching system of exchange channels. Finally, the channels coalesce into a small number of terminal capillaries, which join to form the efferent arteriole. Greater structural detail regarding the glomerular capillaries subserving the filtration process is provided in Chapter 1.

Efferent arterioles originate deep within the glomeruli and vary with regard to length, diameter, and density of smooth muscle cells. In the outer cortex, these vessels are relatively short, have a smaller diameter, and have a less well-developed muscular wall than efferent arterioles in deeper cortical regions. The smooth muscle cells of the superficial efferent arterioles resemble pericytes that often extend onto the peritubular capillaries. In the midcortex, the efferent arterioles are usually longer and have a greater degree of smooth muscle development. In the deeper portion of the cortex, the efferent arterioles are more variable in length. Some efferent arterioles of juxtamedullary nephrons give rise to typical cortical peritubular capillary systems, whereas others are much longer and descend toward the medulla. These two distinct capillary networks subserve the reabsorptive functions of the cortex and medulla, respectively, and may be subject to independent regulation. At the corticomedullary border, the efferent arterioles break up into vascular bundles that branch into numerous descending vasa recta. Vasa recta branch to form a capillary plexus at each level within the medulla. There are three distinct capillary plexuses, with the densest found in the inner stripe of the outer medulla. The ascending vasa recta are morphologically distinct from the descending vasa recta and ascend within vascular bundles to drain into the arcuate veins. The ascending vasa recta are more numerous and have a highly fenestrated, thin endothelium, whereas the descending vasa recta have a continuous thick endothelium. These anatomic differences suggest that the ascending vasa recta have a much greater permeability to macromolecules than the descending vasa recta.[1,2,15,16]

Each glomerular resistance segment contributes to the regulation of glomerular blood flow and pressure in a unique manner because the glomerular capillary is "nested" between the afferent and efferent arterioles. Although a more quantitative analysis of their respective roles is presented in a following section, it should be appreciated that alterations in preglomerular resistance produce changes in glomerular blood flow, pressure, and GFR, which are directionally similar. In contrast, selective changes in efferent arteriolar resistance cause more complex GFR responses because glomerular pressure and blood flow change in opposite directions. The maintenance of appropriate efferent arteriolar tone serves to keep glomerular capillary pressure sufficiently high to provide an adequate hydrostatic pressure for filtration. The efferent arterioles also are responsible for the marked decrease in pressure at the peritubular capillaries, which allows the reabsorptive force of the plasma colloid osmotic pressure to predominate.[1]

There are important regional differences in the circulation within the kidney, which have considerable functional significance. The relative distribution of glomerular and postglomerular blood flow is depicted in Figure 3.5. Glomerular blood flow is proportional to the size of the glomeruli. The larger deep juxtamedullary nephrons have higher flows than the superficial or midcortical glomeruli. These juxtamedullary glomeruli give rise to muscular efferent arterioles that descend toward the medulla and branch into the vasa recta bundles, which are intimately associated with the surrounding concentric rings of loops of Henle and collecting ducts. With regard to the postglomerular blood flow, about 75% to 85% of the total RBF is distributed to the peritubular capillaries in the cortex, whereas 15% to 25% goes to the medullary region. Blood flow throughout the cortex is much higher than in the medulla and is higher in the outer cortex than in the inner cortex. Overall cortical blood flow averages 4 to 6 mL/min/g of tissue. Medullary blood flow ranges from 2.0 to 3.5 mL/min/g in the outer medulla to much lower values of approximately 0.2 to 1.0 mL/min/g of tissue in the inner medulla and papilla. Regional mean transit times of intravascular indicators are 1 to 3 seconds for the cortex,

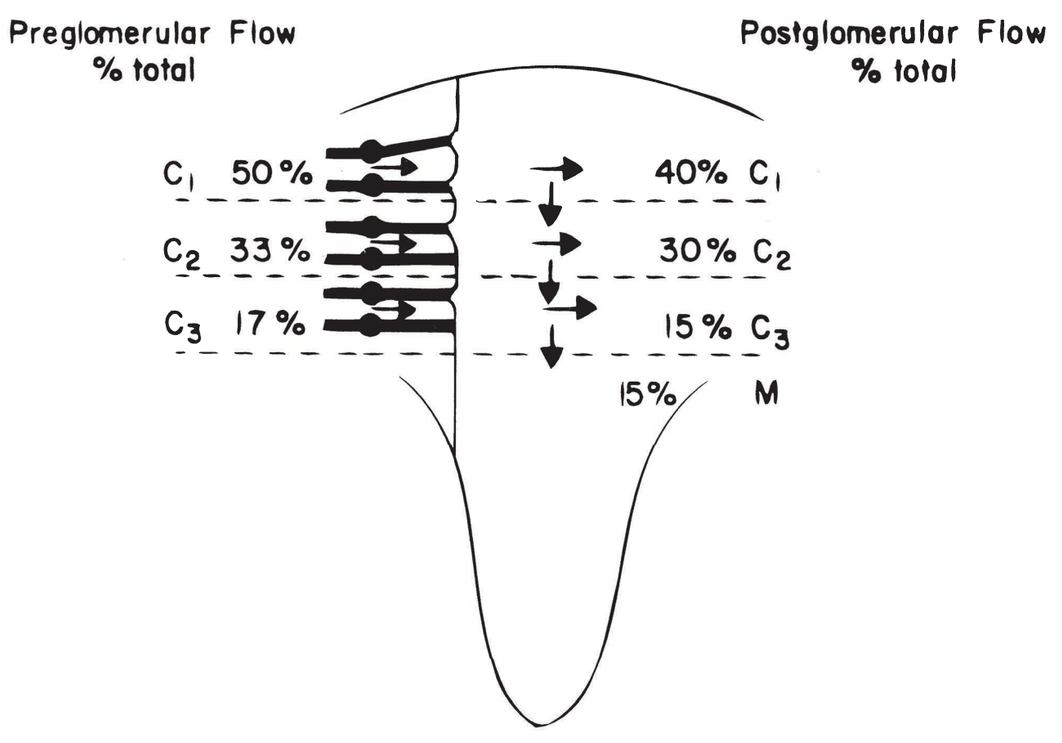

FIGURE 3.5 The distribution of glomerular and postglomerular flow and of cortical (C_1, C_2, C_3) and medullary (M) blood flow. The distribution of glomerular flow is expressed as a percentage of total blood flow; preglomerular flow is presented on the left, and postglomerular flow on the right. The deep cortical flow is subdivided to account for medullary flow distribution. As noted from the *arrows*, there is a general shift of the postglomerular blood flow toward deeper areas.

4 to 6 seconds for the outer medulla, and 10 to 30 seconds for the inner medulla.[15,17–19].

Receptor Activation and Intracellular Signaling

Contractile responses at various sites along the vascular network have different functional characteristics, depending on the expression of receptor populations and/or activation mechanisms. The actions of circulating hormones and neural stimuli combined with local paracrine factors from endothelial and epithelial cells are expressed through different effector mechanisms to provide a highly integrated regulation of the renal microcirculation and the interstitial environment. Many vasoactive agents interact with membrane receptors on the vascular smooth muscle and the endothelial and mesangial cells.

Plasma membrane surface receptors can be subdivided into three main groups in which the receptor is coupled to a guanine nucleotide binding protein (Gα protein), regulates enzyme activity, or serves as part of an ion channel. Examples of the latter two groups are the atrial natriuretic peptide (ANP) receptor, guanylate cyclase, in vascular smooth muscle, and the nicotinic-acetylcholine receptor that directly activates a cation channel at the neuromuscular junction. Almost all known vasoactive agents affect vasomotor tone via receptor coupling to G proteins. G protein-coupled receptors (GPCR) share several common structural features with seven transmembrane domains with three extracellular and three intracellular loops. The extracellular loops act in concert with the transmembrane domains to bind the agonist. The intracellular loops function to activate a G protein. G proteins are heterotrimeric proteins consisting of α, β, and γ subunits. The Gα subunit is unique for each receptor and is responsible for generating a specific intracellular signal. The β and γ subunits share a high degree of homology among G proteins; together they function to modulate the ability of the α subunit to generate the signal.

G proteins undergo a conformational change following agonist binding to a membrane receptor, which in turn enables guanosine triphosphate (GTP) to replace guanosine diphosphate (GDP) on the α subunit. The Gα-GTP complex then dissociates from the β and γ subunits and interacts with an effector such as an enzyme or a channel. The intrinsic GTPase activity of the Gα subunit then hydrolyzes GTP to GDP, and the Gα-GDP complex reassociates with the β and γ subunits, which terminates the response. G proteins linked to adenylate cyclase are classified as $G\alpha_s$ or $G\alpha_i$, depending on whether they stimulate or inhibit adenylate cyclase and cyclic adenosine monophosphate (cAMP) generation. $G\alpha_{q11/12}$ activate membrane-bound phospholipase C (PLC) or activate membrane Ca^{2+} channels, or both. An example of multiple effects an agonist can produce depending on receptor coupling to different G proteins (e.g., $G\alpha q_{11/12}$) is provided by norepinephrine. The binding of norepinephrine to an α_2-adrenoceptor inhibits adenylate cyclase, reduces the formation of cAMP, and attenuates activity of protein kinase A (PKA), whereas binding to a β_1- or β_2-adrenoceptor activates adenylate cyclase to increase cAMP/PKA signaling. Norepinephrine also binds to α_1-adrenoceptors and activates a $G\alpha_q$ protein, which is coupled to PLC, leading to the formation of inositol triphosphate (IP_3) and the release of Ca^{2+} from the sarcoplasmic reticulum. α_1-Adrenoceptors also stimulate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to increase superoxide oxide production and adenosine diphosphate (ADP) ribosyl cyclase generation of cyclic ADP ribose that sensitizes ryanodine receptors to release Ca^{2+} from sarcoplasmic reticular stores.[20–24]

GPCRs and/or their immediate signaling partners (G proteins) are concentrated in caveolae, flask-shaped plasma membrane invaginations (50 to 100 nm in diameter) that are subcellular microdomains of lipid rafts and caveolae, enriched in glycosphingolipids and cholesterol and the protein caveolin. Caveolae are complexes with a high concentration of signaling molecules. Caveolin is a scaffolding protein that anchors receptors (e.g., angiotensin II subtype 1 [AT_1], endothelin [ET-1], epidermal growth factor [EGF]) signaling and trafficking proteins ($G\alpha_{q/11}$) as well as ion channels (K^+ and transient receptor potential [TRP] channels) and enzymes (endothelial nitric oxide synthase [eNOS], protein kinase C [PKC], phospholipase C [PLC], NADPH oxidase, ADP ribosyl cyclase) involved in controlling vasomotor tone. Endothelial cells and fibroblasts are rich in caveolins 1 and 2; smooth muscle cells express all three caveolins (Cav-1, -2, and -3). In vascular smooth muscle cells, Cav-1 serves as a scaffold or chaperone to target AT_1 receptors to caveolae to activate downstream signaling; Cav-1 is required for efficient coupling of $G\alpha_{q/ll}$ proteins and PLC_β to promote Ca^{2+} mobilization from the sarcoplasmic reticulum. Cav-1 links AT_1 receptors to NADPH oxidases and promotes recruitment of Rac1 to activate reactive oxygen species (ROS) formation. Cav-1 couples IP_3 receptors and TRPC3 channels for store-operated Ca^{2+} entry. It also suppresses K_{ATP} channel activity and negatively regulates Ang II–induced EGF receptor transactivation. Most caveolae in vascular smooth muscle cells have nanocontacts with the sarcoplasmic reticulum, providing a direct link to intracellular Ca^{2+} mobilization and excitation–contraction coupling.

In endothelial cells, Cav-1 binds eNOS, limiting the translocation and activation of eNOS. Caveolin-deficient animals exhibit unusual endothelial dysfunction in that NO production is unopposed, leading to marked vasodilation. Cav-1 knockout animals display attenuated vasoconstriction to phenylephrine and a lack of myogenic tone, largely due to excessive NO production. Mice lacking caveolin show that caveolae and caveolins play a prominent role in various pathophysiologic conditions, especially those related to the cardiovascular system. These disease phenotypes include atherosclerosis, cardiac hypertrophy, cardiomyopathy, diabetes, and neointimal hyperplasia (smooth muscle cell proliferation).[25–28]

GPCR desensitization reduces receptor downstream signaling and effector response. G-protein coupled receptor kinases (GRKs), a family of serine/threonine protein

kinases, initiate receptor-specific, homologous desensitization that curtails receptor signaling by phosphorylating the C-terminal tail of agonist-bound GPCR to promote docking with inhibitory β-arrestins. β-Arrestins not only uncouple receptors from heterotrimeric G-proteins, they also target GPCRs to clathrin-coated vesicles for internalization. Endocytosed receptors are either resensitized and recycled to the plasma membrane or degraded in lysosomes. GPCRs internalize as a stable complex with β-arrestin with signaling potential and gene transcription.[22,29–31]

Although GRKs regulate GPCR activity, regulators of G protein signaling (RGS) proteins directly control the activity of Gα-protein subunits, functioning as endogenous negative regulators of GPCR signaling by accelerating GTP hydrolysis by Gα-subunits and thereby attenuating signaling. The most well-characterized RGS proteins (e.g., RGS2, PGS4, PGS5 of the R4 family) determine signaling specificity of $G\alpha_q$- and $G\alpha_i$-coupled receptors. RGS2 is a GTPase activating protein that binds to both $G\alpha_{q/11}$ and $G\alpha_i$ subunits of GPCRs to accelerate their intrinsic GTPase activity. As a result, they are deactivated with a reduced stimulation of PLC_β-mediated Ca^{2+} release and subsequent vasoconstriction. RGS2 and/or RGS5 reduce Ca^{2+} signaling initiated by AT_1 and ET-1 and α1-adrenoceptors and subsequent contraction. RGS5 mRNA, a regulator of vascular remodeling, is expressed in medial smooth muscle of afferent arterioles and the main renal artery in nonhuman primates. RGS proteins may play a role in mechanosensation and stretch-induced myogenic responses, as well as coordinating actions of vasoconstrictor hormones and paracrine agents.

RGS2 activity is acutely stimulated by NO and cGMP signaling to promote vascular relaxation by attenuating Ca^{2+} signaling in response to vasoconstrictor agents. RGS2 expression in vascular smooth muscle is upregulated by Ang II and is downregulated in hypertension. RGS2 knockout mice are hypertensive with enhanced vasoconstriction produced by Ang II and α1-adrenoceptor agonists. The exaggerated $G\alpha_{q/11}$ signaling in mutant animals is associated with renovascular abnormalities, exaggerated vasoconstriction, hypertension, thickening of the vascular wall of the aorta and renal interlobular arteries, and cardiac hypertrophy. Kidney cross-transplantation studies demonstrate that a specific loss of RGS2 in the kidney causes hypertension, whereas the absence of RGS2 from all extrarenal tissues, including the peripheral vasculature, does not affect arterial pressure. Isolated perfused kidneys of RGS4 knockout mice show increased renal vasoconstrictor responses to ET-1.[21,32–34]

Regulation of Microvascular Contractility

Changes in vascular perfusion are mediated by smooth muscle cell contraction or relaxation that elicits a change in vessel radius and in vascular resistance. Multiple steps and enzymatic cascades are involved in the contractile process, and many of these mechanisms interact with one another to modulate the contractile response. A pivotal step in mediating the contractile response in vascular smooth muscle cells is an increase in the cytosolic concentration of free ionized calcium ($[Ca^{2+}]_i$) above its very low basal value of 10^{-7} M. (This is approximately 0.01% of the ionic Ca^{2+} levels of plasma and extracellular fluid, 1 mM). As shown in Figure 3.5, cytosolic Ca^{2+} binds with calmodulin. The Ca^{2+}-calmodulin complex activates myosin light chain (MLC) kinase, leading to the phosphorylation of MLC that interacts with actin and adenosine triphosphate (ATP) to elicit tension development. Increased $[Ca^{2+}]_i$ also phosphorylates CPI-17, a phosphoprotein that inhibits MLC. GPCR activation of PKC enhances Ca^{2+} sensitivity of the contractile apparatus by potentiating the efficiency of Ca^{2+} stimulation of CPI-17. In addition, GPCR couples to the $G\alpha_{q/11}$ signal through the monomeric GTPase RhoA/Rho kinase pathway to decrease the activity of MLC phosphatase, resulting in increased Ca^{2+} sensitivity of myofilaments and enhanced vasoconstriction for a given level of cytosolic Ca^{2+} concentration. Relaxation occurs as a consequence of the removal or sequestration of Ca^{2+} from the cytosol and/or MLC dephosphorylation. Decreases in Ca^{2+} signaling occur following dissociation of ligand from GPCR surface receptor, receptor inactivation, or internalization.[2,35]

Various hormones and drugs activate plasma membrane receptors to induce contraction by eliciting an increase in $[Ca^{2+}]_i$. Cytosolic Ca^{2+} is increased through a combination of Ca^{2+} entry from the extracellular environment and mobilization of Ca^{2+} from internal stores. Ca^{2+} can be released from intracellular stores via release channels, activated by IP_3 or by a ryanodine (Ry)-like ligand. Ca^{2+} is released from a common sarcoplasmic reticular pool, with uptake mediated by a common sarcoplasmic–endoplasmic reticular Ca^{2+} ATPase (SERCA). Many vasoconstrictor agents increase intracellular Ca^{2+} by activating a Gα protein that stimulates PLC to break down membrane-bound phosphatidylinositol 4,5-diphosphate (PIP_2) into IP_3 and 1,2-diacylglycerol (DAG). The soluble IP_3 binds to an IP_3 receptor located on the sarcoplasmic reticulum, leading to the activation of Ca^{2+} channels and the release of Ca^{2+} into the cytoplasm. The lipophilic DAG remains within the membrane environment and activates PKC isoform that phosphorylates various regulatory proteins. DAG may also be generated by the actions of phospholipase D on phosphatidylcholine that is not accompanied by concurrent IP_3 generation and the associated increase in $[Ca^{2+}]_i$. Agents that activate PKC, such as phorbol esters, induce slowly developing, sustained contractions or enhance contractile responsiveness to other stimuli.[2,36]

Activation of cell surface GPCRs also leads to the stimulation of plasma membrane-bound ADP-ribosyl cyclase that converts the substrate nicotinamide adenine dinucleotide (NAD+) to adenosine 5′-cyclic diphosphate (cADP)-ribose, a potent Ca^{2+} mobilizing agent that acts on a RyR to trigger Ca^{2+} release from the sarcoplasmic reticulum. cADP-ribose is a calmodulin-dependent Ca^{2+}-mobilizing second messenger system that acts independently of IP_3, with RyR-mediated Ca^{2+} release to amplify IP_3-mediated

Ca^{2+} mobilization. Ryanodine receptors are extremely sensitive to $[Ca^{2+}]_i$ and exhibit Ca^{2+}-induced Ca^{2+} release (CICR), a form of autopotentiation. Concentrations of Ca^{2+} over a wide range (5 to 100 μM) enhance the open probability of RyR, which contrasts with a narrower range (180 to 220 nM) for the IP_3R.[20]

Calcium entry occurs through a variety of pathways, including voltage-operated channels (VOCs) that are activated upon membrane depolarization and voltage-independent receptor-operated channels (ROCs) and store-operated channels (SOCs). Membrane depolarization downstream of GPCR activation results from the activation of Cl^- channels or the inactivation of K^+ channels. Voltage-independent ROCs and SOCs also contribute to agonist-induced Ca^{2+} entry in both preglomerular and efferent arterioles. ROCs are activated downstream of cell surface GPCR, independent of Ca^{2+} mobilization, via signaling mechanisms involving DAG and calmodulin, and other possible intermediates. SOCs are known to contribute to agonist-induced Ca^{2+} entry in renal vascular smooth muscle cells; they are also termed capacitative as they respond to depletion of Ca^{2+} stores.[37,38]

Among the identified families of TRP proteins, the canonical TRP (TRPC) family (TRPC1 through TRPC7) is thought to be involved in Ca^{2+} entry in vascular smooth muscle cells, most likely functioning as voltage-independent SOCs and/or ROCs. TRPC1 proteins in vascular smooth muscle cells form tetrameric channels in association with TRPC4 or TRPC5. TRPC3, -6, and -7 are activated by DAG and thus are attractive possibilities as ROCs. TRPC6 is an essential component of α1-adrenoceptor–activated cation channels in portal venous smooth muscle cells. Preglomerular arterioles have a predominance of TRPC3 and -6 subunits that may comprise SOCs and/or ROCs in these vessels. Evidence to support TRPC channel function is attenuation of Ca^{2+} responses of the afferent arteriole to norepinephrine by the blockers of voltage-insensitive Ca^{2+} entry Gd^{3+} and SKF 96365. Activation of TRPC6 in the afferent arteriole leads to increased $[Ca^{2+}]_i$. The Ca^{2+} permeable TRPC6 is a key signaling component in a functional slit diaphragm formed by podocytes in the glomerular filtration barrier. Gain-of-function mutations in TRPC6 are the cause for progressive kidney failure with urinary protein loss and focal segmental glomerular sclerosis. SOCs are activated by Ca^{2+} mobilization to specifically restore Ca^{2+} content in sarcoplasmic reticulum. Current interest focuses on stromal interaction molecules (STIM) in the sarcoplasmic reticulum, which sense SR Ca^{2+} depletion and then translocate to junctions near the plasma membrane to organize Orai proteins, the Ca^{2+} release-activated Ca^{2+} channels, to form a pore and increase Ca^{2+} entry.[37,39–47]

Na^+/Ca^{2+} exchange (NCX) contributes to the regulation of $[Ca^{2+}]_i$, working reversibly in the exit mode to extrude Ca^{2+} or in the entry mode to facilitate Ca^{2+} entry. Exchanger activity is normally higher in afferent then in efferent arterioles. Ang II stimulates $[Ca^{2+}]_i$ in afferent arterioles by activating NCX to promote Ca^{2+} entry. Consistent with this observation, genetic deletion of Na^+/Ca^{2+} exchanger NCX1 in smooth muscle cells reduces Ang II–induced renal vasoconstriction in vivo, presumably due to less Ca^{2+} entry into smooth muscle cells. Nevertheless, the pharmacologic blockade of NCX or lowering extracellular Na^+ concentration causes renal vasoconstriction and exaggerated Ang II–induced constriction of the isolated perfused kidney. Smooth muscle Na^+/Ca^{2+} activity responds to Na^+/K^+-ATPase inhibition by an endogenous ouabainlike glycoside to extrude the high cellular Na^+ in exchange for Ca^{2+} entry in hypertensive states.[43,48–50]

Several different K^+ channels have been identified; the most prominent are Ca^{2+}-activated and ATP-dependent K^+ channels, which mediate relaxation by hyperpolarizing the cell membrane and reducing Ca^{2+} entry through voltage-gated Ca^{2+} channels. Importantly, increases in intracellular ATP inhibit K^+ channels, thus causing depolarization. Channel activity is reduced by intracellular ATP concentrations normally present, suggesting that the activity of this channel is quite low in normal cells and may serve a primary protective role during the depletion of energy reserves.[2,51–54]

At the whole kidney level, Rho-kinase inhibition dilates the renal vasculature under basal conditions and attenuates renal vasoconstriction produced by intrarenal infusion of Ang II, arginine vasopressin (AVP), or norepinephrine, as well as increased renal perfusion pressure. Frequency analysis of renal vascular admittance indicates that Rho-kinase strengthens the myogenic response. Ca^{2+} sensitivity of the afferent arteriole is increased by adenosine and norepinephrine. Adenosine increases Ca^{2+} sensitivity by PKC, Rho-kinase, and p38 mitogen activated protein (MAP) kinase signaling pathways. This provides a mechanism by which different vasoactive agents can modulate reactivity to other stimuli. Interestingly, adenosine enhances Ang II–induced afferent arteriolar contraction but does not potentiate the contractile responses to ET-1 or norepinephrine. Reactivity to Ang II is enhanced by the ability of norepinephrine to increase Ca^{2+} sensitivity with increased MLC phosphorylation.

Rho-kinase participates in pressure-induced interlobular arterial and afferent arteriolar myogenic behavior and vasoconstrictor responses evoked by Ang II, adenosine A_1, endothelin ET_B, and purinergic P_2X_1 receptor activation as well as membrane depolarization. Ca^{2+} sensitization due to Rho-kinase also contributes to Ang II–induced constriction of efferent arterioles. Rho-kinase inhibition dilates preglomerular and postglomerular arterioles and attenuates vasoconstriction elicited by adenosine A_1 or endothelin ET_B receptor stimulation. Ang II, AVP, and TxA_2 constrict preglomerular arcuate and interlobular arteries in the hydronephrotic kidney in part via Rho-kinase. The afferent arteriolar myogenic response in this preparation is markedly attenuated by Rho-kinase inhibition.[55–59]

As mentioned earlier, cAMP also activates Ca^{2+} translocation mechanisms that increase extrusion of Ca^{2+} out of the cell, return Ca^{2+} to the sarcoplasmic reticulum, or inhibit IP_3-mediated mobilization of Ca^{2+} from sarcoplasmic

Agents that increase cytosolic calcium:

Ang II, AVP, Epinephrine (α), TXA_2, Leukotrienes, Norepinephrine, Endothelin, ATP

Agents that increase cAMP (or cGMP):

Epinephrine (β), PTH, PGI_2, PGE_2, ANP, Dopamine, Bradykinin, Nitric Oxide, Adenosine (A_2)

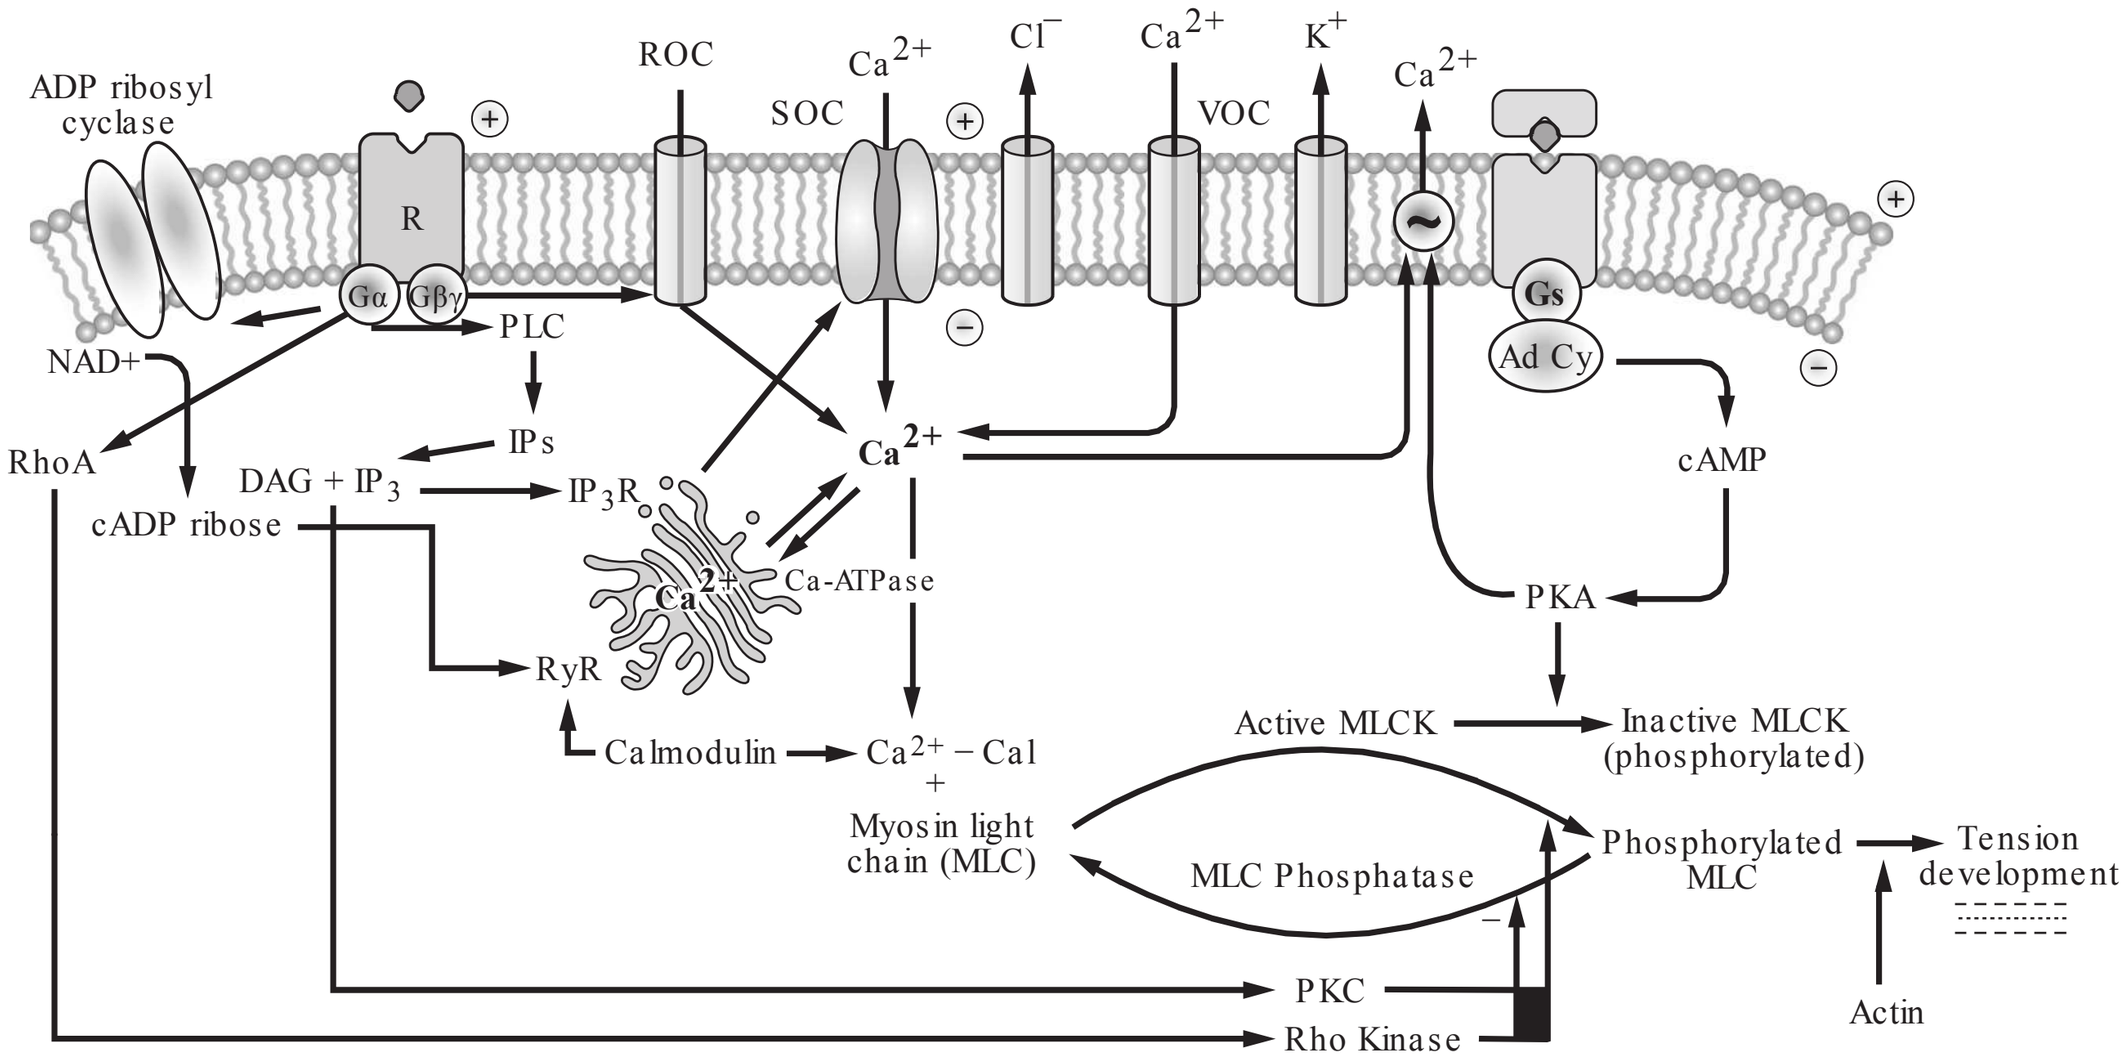

FIGURE 3.6 Primary intracellular signaling systems mediating smooth muscle cell or mesangial cell contraction, with effects of various hormones and vasoactive agents on the two major types of receptor systems. For ease of presentation, only two receptor mechanisms are depicted, but each agent acts on its own receptor system.

reticulum stores (Fig. 3.6). Drugs or agents such as PGE_2 and PGI_2 that increase cAMP via $G\alpha_s$ signaling produce increases in RBF and GFR. Small amounts of such ligands can buffer the action of vasoconstrictor agents without affecting baseline vascular tone. In contrast, ligand-receptor complexes coupled to the inhibitory G protein ($G\alpha_i$) reduce cAMP levels and cause greater contraction for a given level of $[Ca^{2+}]_i$. $G\alpha_i$ proteins are reported to activate PLC and mobilize Ca^{2+} in the afferent arteriole.[60,61]

Another family of receptors operates through the G protein-dependent activation of guanylate cyclase, the generation of cGMP, and the activation of protein kinase C to mediate vasodilation. In addition, two major guanylate cyclase activators are not G protein-dependent. NO derived from endothelial cells directly interacts with soluble guanylate cyclase. Also, ANP directly activates particulate guanylate cyclase in vascular smooth muscle cells. The mechanisms mediating cGMP-dependent vasorelaxation are similar to those used by cAMP. cGMP-dependent kinases lead to the inhibition of voltage-gated L-type Ca^{2+} channels, activation of a Na^+/Ca^{2+} exchanger, stimulation of Ca^{2+}-ATPase, inhibition of IP_3 formation, and phosphorylation of phospholamban, resulting in increased Ca^{2+}-ATPase activity in the sarcoplasmic reticulum. Ca^{2+} desensitization of the contractile machinery, independent of $[Ca^{2+}]_i$ changes, takes place because cGMP/PKG can block RhoA activation and can reduce MLC activity by inhibiting CPI-17 phosphorylation and activating MLC phosphatase. cGMP also may stimulate Ca^{2+}-activated K^+ channels, which leads to hyperpolarization.[33,62]

The arachidonic acid pathways constitute another intracellular signaling system. Increased $[Ca^{2+}]_i$ can activate phospholipase A_2 and can release arachidonic acid from membrane phospholipids, resulting in the production of various metabolites that lead to vasodilation or vasoconstriction. Arachidonic acid metabolites exert effects through multiple pathways, including cAMP, cytosolic Ca^{2+}, and inhibition of K^+ channels. Arachidonic acid itself may increase Ca^{2+} entry via a noncapacitative Ca^{2+} entry channel. These actions will be discussed in detail later in this chapter.

Differences in cellular sites and mechanisms of smooth muscle activation may be partially responsible for the large variety of renal hemodynamic responses produced by different vasoactive agents. There is a major difference in the mechanisms leading to Ca^{2+} activation in the vascular smooth muscle cells of the afferent and efferent arterioles. Preglomerular vessels have a strong dependence on L-type voltage-gated Ca^{2+} channels, whereas their influence is not readily apparent in efferent arterioles. Antagonists of Ca^{2+} influx through L-type, dihydropyridine-sensitive Ca^{2+} channels selectively block agonist-induced constriction of

the preglomerular arterioles, including the afferent arteriole, without affecting efferent arteriolar contraction. This is the case for Ang II, ET-1, norepinephrine, and potassium chloride–induced depolarization. Agents that block L-type Ca^{2+} channels such as nifedipine, diltiazem, and verapamil primarily cause afferent vasodilation and impair autoregulatory responses to changes in renal perfusion pressure, affecting both myogenic and tubuloglomerular feedback (TGF responses). In contrast, T-type Ca^{2+} channels are active at both afferent and efferent arteriolar sites and influence vascular responsiveness. T-type Ca^{2+} channel blockers vasodilate afferent and efferent arterioles and prevent contractile responses to various stimuli at both sites. In afferent arterioles, T-type channels may act cooperatively with L-type channels to bring about membrane depolarization and Ca^{2+} entry. A primary action on the preglomerular vasculature also explains the increases in GFR and glomerular capillary pressure produced by Ca^{2+} entry blockers as well as inhibition of the TGF system. An example of a hormone that exerts its effects through different mechanisms is Ang II. Its effects are mediated by at least two mechanisms. Afferent arteriolar responses are highly dependent on Ca^{2+} entry via L-type channels, whereas the efferent arteriolar response is influenced by Ca^{2+} mobilization and Ca^{2+} entry via T-type channels and through store-operated channels in the absence of any entry through voltage-gated L-type channels. NO may suppress voltage-sensitive Ca^{2+} entry in both afferent and efferent arterioles. Ca^{2+} entry in outer medullary vasa recta is mediated by a combination of L- and T-type Ca^{2+} channels as well as store-operated cation channels.[63–67]

In addition to the smooth muscle cells of the resistance vessels, the mesangial cells within the glomerular tufts possess contractile capability, which may contribute not only to the regulation of blood flow through the glomerulus but also to the filtering capacity. Mesangial contraction is postulated to reduce the glomerular filtration coefficient (K_f) by decreasing the radius of capillaries or the surface area available for filtration, or both, but the precise mechanism is not clear. Many agents, including Ang II and vasopressin, reduce K_f. Low K_f values have also been observed during sodium depletion when plasma and local concentrations of endogenous Ang II are elevated. These responses reflect specific receptor-mediated effects on mesangial cells, because the response can be reversed by selective receptor antagonists in vivo and in cultured mesangial cells. However, podocytes are closely associated with mesangial cells in vivo and also respond to Ang II, suggesting that part of the actions of Ang II on K_f could be due to responses by podocytes. Some mesangial cell receptors exert stabilizing effects on mesangial cell contraction and counteract the influence of excessive levels of vasoconstrictor agents or serve metabolic functions. β-Adrenergic agonists and vasodilator prostaglandins (PGE_2 and PGI_2) increase cAMP in isolated glomeruli and mesangial cells and they directly oppose the apparent contractile effects of Ang II. Nevertheless, the structural mechanism by which mesangial cell contraction actually alters K_f remains unclear.[2,68–70]

Endothelial Interactions with Vascular Smooth Muscle

The vasculature is lined with a continuous layer of endothelial cells, which has many functions including serving as a diffusion barrier and preventing vascular thrombosis. Endothelial cells are dynamic metabolic units having membrane receptors and membrane-bound enzymes, which allow them to respond to and contribute to changes in the concentration of humoral agents. Membrane-bound ectoenzymes form or degrade, circulating vasoactive substances such as Ang II (angiotensin converting enzyme [ACE]), ET-1 (endothelin converting enzyme and metallopeptidase), bradykinin (kininase II), and adenonucleotides (three ectonucleotidases convert ATP, ADP, and AMP). Localization of ACE in preglomerular vessels allows the conversion of systemically delivered Ang I, an inactive decapeptide, to the biologically active octapeptide Ang II, that can then induce vasoconstriction locally or in downstream segments.[2]

The vascular endothelium serves an important paracrine role (Fig. 3.7). Endothelial cells participate in contractile and dilator mechanisms by responding to a variety of stimuli and increasing or decreasing formation of potent vasoactive substances that act locally to modulate the tone of adjacent smooth muscle cells. General classes consist of endothelium-derived relaxing factors (EDRF) and endothelium-derived contracting factors (EDCF). Specific examples of relaxing factors that cause renal vasodilation are NO, PGE_2, and PGI_2 (prostacyclin), carbon monoxide (CO), and an epoxyeicosatrienoic acid (EET), a hyperpolarizing factor that is a metabolite of the cytochrome P450 pathway. Examples of EDCF include Ang II, ET-1, thromboxane (TxA_2), and oxygen-free radicals. These paracrine factors act on smooth muscle cells to modify vasomotor tone, proliferative state, and provide a balance between antioxidant defense mechanisms and excess generation of O_2-derived free radicals. Thus, the endothelial cells are intimately involved in controlling the renal microcirculation.[71,72]

One of the most studied interactions between endothelial cells and smooth muscle cells involves the ability of the endothelium to modify the vascular responses to acetylcholine and other agents. Acetylcholine is a powerful vasodilator in vivo and also in isolated smooth muscle preparations that have an intact endothelium because it stimulates endothelial cells to produce vasodilatory paracrine substances. However, when applied to vascular preparations whose endothelium has been removed, acetylcholine induces vasoconstriction by acting directly on muscarinic receptors on smooth muscle cells. Many other substances have now been shown to stimulate the release of endothelium-derived vasoactive factors.

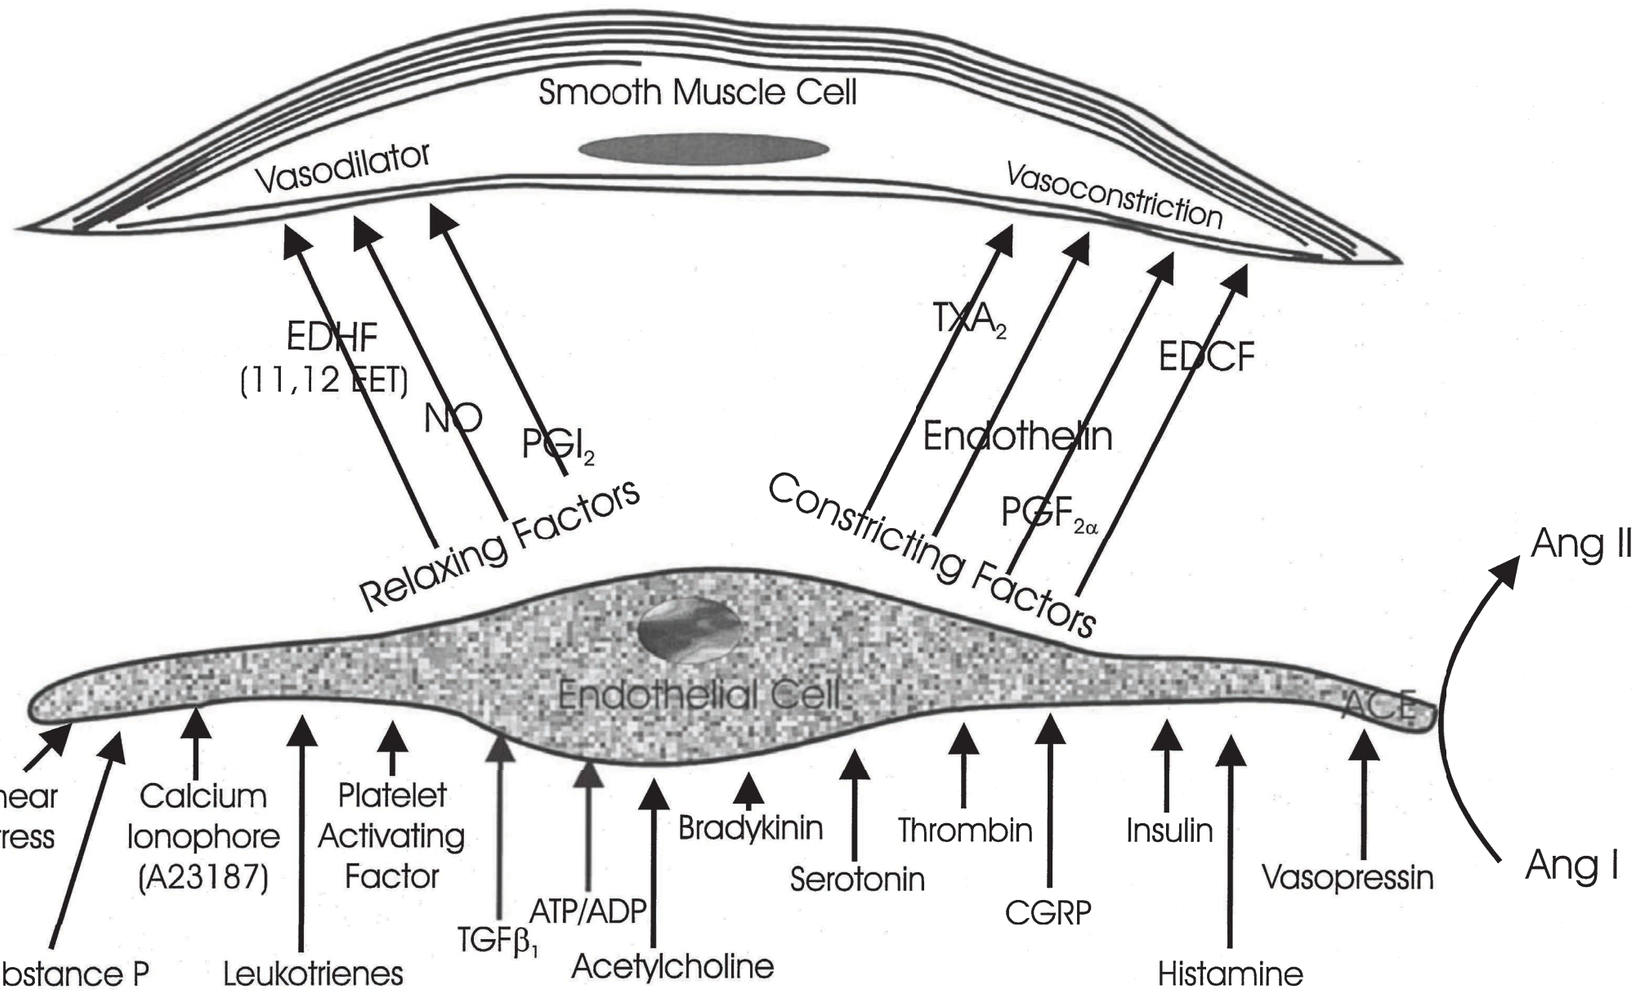

FIGURE 3.7 The interaction of endothelial cells with smooth muscle or mesangial cells. Agents that are known to influence endothelial-derived relaxing factors or nitric oxide (*NO*) and endothelial-derived constricting factors (EDCF) production by endothelial cells are shown. Endothelial cells also produce several vasoconstrictor and vasodilator agents, as shown in the figure and described in the text.

One of the major relaxing factors is NO derived from L-arginine. These paracrine systems will be discussed in later sections.[2,73,74]

Endothelial cells have a remarkable capability to transport substances across their layers through a variety of mechanisms. One of the most impressive features of endothelial cells lining the vasculature is their ability to form fenestrations that serve as extracellular channels. This feature occurs predominantly in capillary structures having large rates of transcapillary volume flux. Both glomerular and peritubular capillary systems have fenestrations. The glomerular capillaries have abundant, well-rounded fenestrations that are 50 to 100 nm in diameter and lack a diaphragm. These fenestrations constitute highly permeable pathways for the large volume of plasma filtrate that continuously traverses from the glomerular capillaries into the Bowman space. Although it is not clear whether subtle changes in the size of the fenestrations contribute to the regulation of the hydraulic conductivity of the glomerular capillary barrier, it is apparent that their integrity is essential for the maintenance of glomerular filtration.[2,75]

The fenestrations of the peritubular capillaries are bridged by a thin diaphragm and are smaller in diameter (20 nm). Considering the total number of capillaries, there is much more peritubular than glomerular capillary surface area. However, because the overall reabsorptive rate by the peritubular capillaries is nearly equal to the GFR, the average hydraulic conductivity of the peritubular capillaries per unit of surface area is estimated to be less than that of glomerular capillaries. Fenestrations also exist in the terminal segments of afferent arterioles, and they may provide a pathway for renin entry into the circulation from juxtaglomerular granular cells.[2,76]

TRANSCAPILLARY EXCHANGE IN RENAL MICROCIRCULATION

Forces Governing Ultrafiltration at the Glomerulus

Bulk movement of fluid across capillary membranes of the renal microcirculation is passive in nature, driven by physical forces. As blood flows from the afferent arterioles into the glomerular capillary tufts, the high hydrostatic pressure predominates over the counteracting forces caused by Bowman space hydrostatic pressure and plasma colloid osmotic pressure. Therefore, fluid is driven from the glomerular capillaries through the endothelial fenestrations, across the basement membrane, and between the podocyte foot processes into the Bowman space. This movement of fluid can be described quantitatively by the Starling filtration-reabsorption principle, which is based on the premises that (1) water and solutes flow through extracellular channels or pathways and (2) the diameters of these channels are large with respect to water molecules, hydrated ions, and solutes of low-molecular weight, such as urea, glucose, and amino acids. Thus, except for the larger solutes, mainly plasma proteins that approach or exceed the size of the channels, the filtrate is translocated without substantive compositional alterations. Detailed consideration of the structure and biochemical composition of the glomerular filtration barrier is provided in Chapter 1.

The physical forces acting across the glomerular membrane are glomerular capillary pressure (P_g), Bowman space

pressure (P_B), glomerular plasma colloid osmotic pressure (π_g), and colloid osmotic pressure of filtrate in the Bowman space (π_B). The filtering capacity of the filtration barrier is expressed as the glomerular filtration coefficient (K_f), which is the product of the hydraulic conductivity of the glomerular membrane (L_p) and the total filtering surface area (S_f). Because the net forces change as fluid is filtered along the length of the glomerular capillaries, total GFR can be expressed by the equation:

$$GFR = K_f \int_0^1 [(P_{g(x)} - P_B) - \sigma (\pi_{g(x)} - \pi_B)]\, dx \qquad (1)$$

where x represents the normalized length of the glomerular capillaries, with 0 designating the afferent end and 1 designating the efferent end; σ (sigma) is the reflection coefficient, which has a range of 0 to 1. When sigma is 1, proteins are completely "reflected" by the capillary wall, and the colloid osmotic pressure is maximally effective. Normal glomerular capillaries are extremely efficient in restricting the passage of macromolecules, and the amount of protein present in the normal filtrate in the Bowman space is less than 0.1% of the plasma protein. For practical considerations, the effective colloid osmotic pressure is considered equivalent to that of the plasma in the glomerular capillaries (π_g). As is shown in Figure 3.8, this value increases progressively along the length of the capillaries as a function of the relative volume of protein-free fluid that is filtered. Because colloid osmotic pressure is the major force retarding glomerular filtration, filtration is greatest in the initial segments of the glomerular capillaries and decreases progressively along the length of the capillaries.[1,2,77]

The exact hydrostatic pressure drop along the glomerular capillaries is uncertain because experimental assessment is not possible. Nevertheless, there are abundant parallel capillaries that collectively have a large cross-sectional area relative to that of the afferent and efferent arterioles; thus, the hydrostatic pressure drop along the glomerular capillaries is small as compared with the pressure drops across the afferent and efferent arterioles. Computations based on the number and dimensions of the glomerular capillaries yield estimates that are in the range of 1 to 4 mm Hg. Thus, P_g is usually treated as a constant value. With these simplifying assumptions and the use of average values for hydrostatic and colloid osmotic pressures in glomerular capillaries, the more commonly used formulation for GFR results:

$$GFR = K_f (P_g - P_B - \pi_g) \qquad (2)$$

The net, or mean, effective filtration pressure (EFP) is calculated as

$$EFP = P_g - P_B - \pi_g \qquad (3)$$

The increase in plasma protein concentration is a direct function of the filtration fraction, defined as the quotient of GFR and renal plasma flow. Because of the nonlinear relationship between plasma protein concentration and colloid osmotic pressure, the rate of increase in colloid osmotic pressure from the afferent to the efferent arteriole increases progressively (Fig. 3.9). Empirically derived relationships allow the prediction of colloid osmotic pressure (π) from the total plasma protein concentration (C) when the albumin-to-globulin (A/G) ratio is known. The commonly used Landis-Pappenheimer relationship

$$\pi = 2.1\, C + 0.16\, C^2 + 0.009\, C^3 \qquad (4)$$

applies to an A/G ratio of about 1.2, which is considered normal for humans.[2]

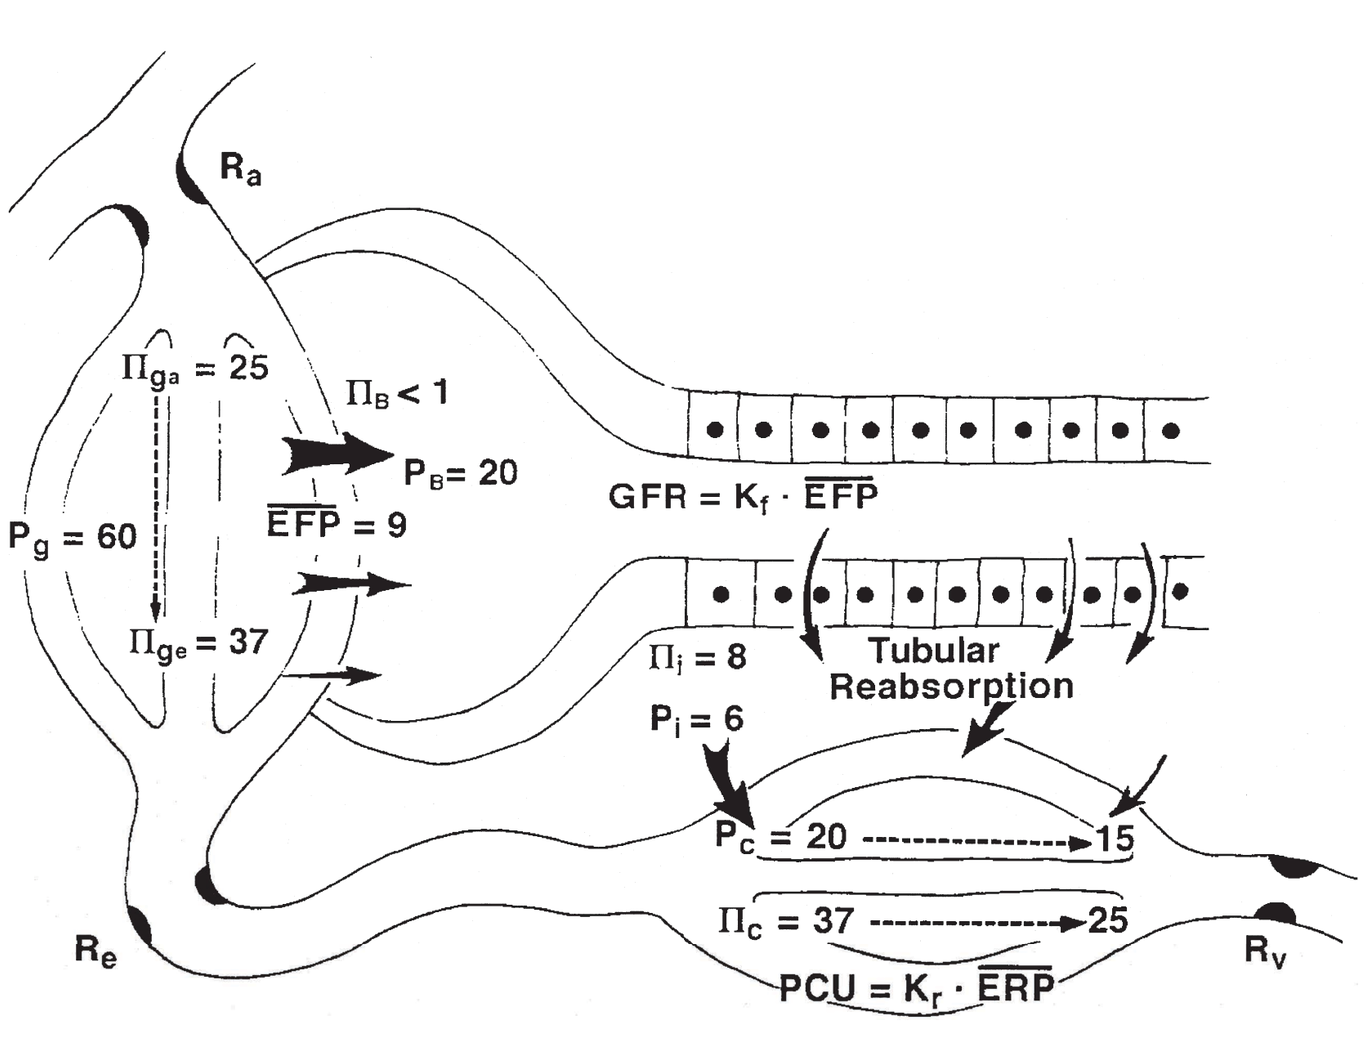

FIGURE 3.8 A schematic diagram of the forces responsible for the filtration of fluid from the glomerular capillaries and the reabsorption of fluid into the peritubular capillaries. The values are considered representative of forces in humans. R_a, afferent arteriole resistance; R_e, efferent arteriole resistance; $P_{g,B,c,i}$, pressure in glomerular capillaries, Bowman's space, peritubular capillaries, and renal interstitium; $\Pi_{g,B,C,i}$, colloid osmotic pressure in glomerular capillaries, Bowman's space, peritubular capillaries, and renal interstitium; EFP, effective filtration pressure; K_f, filtration coefficient; GFR, glomerular filtration rate.

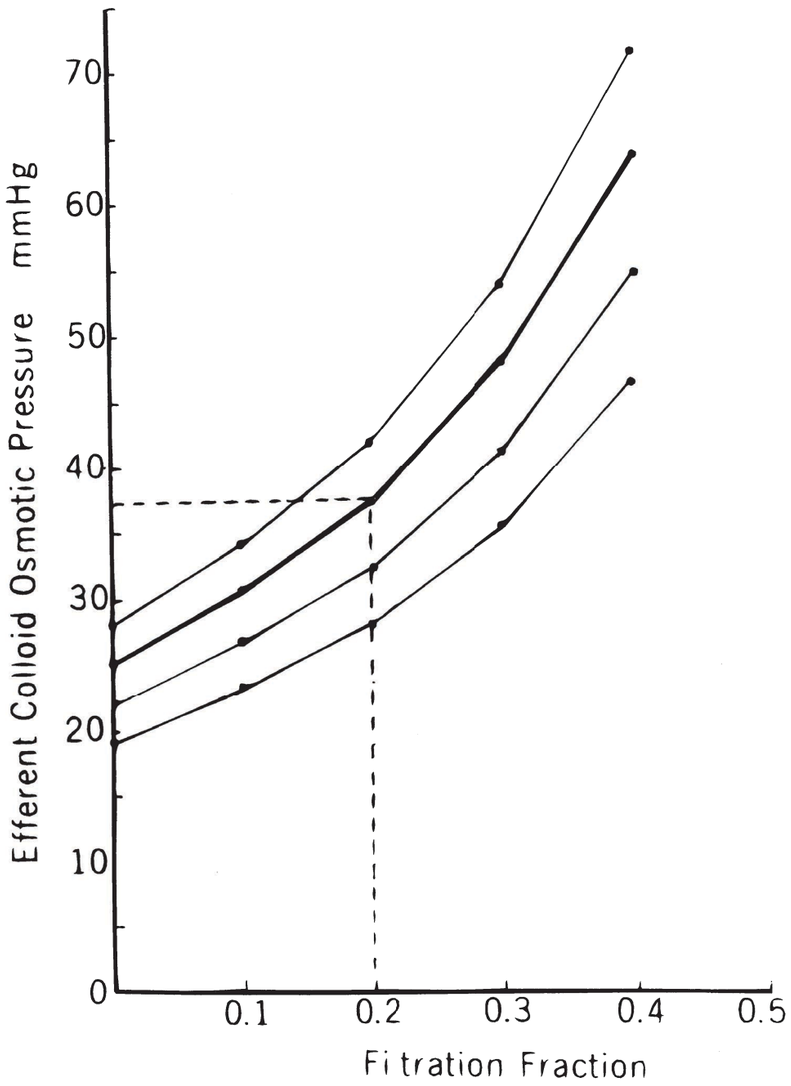

FIGURE 3.9 Anomogram relating the efferent arteriolar colloid osmotic pressure to the initial plasma colloid osmotic pressure and the filtration fraction. Normal afferent arteriolar colloid osmotic pressure, 25 mm Hg, is indicated by the *thicker curve*. An example of how to estimate efferent arteriolar colloid osmotic pressure for any given filtration fraction and plasma colloid osmotic pressure is shown by the *dashed lines*.

The efferent arteriolar colloid osmotic pressure is determined by the initial plasma value and the filtration fraction. The nomogram in Figure 3.9 allows for the estimation of the efferent arteriolar colloid osmotic pressure and is independent of A/G ratios. For example, at a normal filtration fraction of 0.20 and normal plasma colloid osmotic pressure of 25 mm Hg, the predicted value for efferent colloid osmotic pressure is 37 mm Hg.

The hydrostatic pressure in Bowman space (P_B) in humans has not been measured directly. In laboratory animals, P_B is equal to proximal tubular pressure, which ranges from 11 to 15 mm Hg in rats and from 18 to 22 mm Hg in dogs. Also, proximal tubular pressure is slightly higher than the pressure in adjacent peritubular capillaries. Peritubular capillary pressure has also not been measured directly in humans, but it can be estimated from intrarenal venous pressure measurements obtained by retrograde passage of a renal vein catheter. Values obtained in humans are 20 to 25 mm Hg and provide reasonable estimates of proximal tubular pressure. This pressure plus an average efferent colloid osmotic pressure of 37 mm Hg provides a minimal glomerular pressure in humans in the range of 57 to 62 mm Hg; actual values are higher to the extent that there is net filtration pressure at the terminal end of the glomerular capillaries.

Micropuncture studies in animals also indicate that glomerular pressure is 50 to 60 mm Hg and approximately 40 mm Hg greater than the opposing hydrostatic pressure in the Bowman space. From this difference in transglomerular capillary hydrostatic pressure, it can be calculated that EFP ranges from 15 mm Hg at the afferent end of the glomerular capillaries to about 3 mm Hg at the efferent end, yielding an average EFP of 9 mm Hg (Fig. 3.8). Using this value and one of 120 mL per minute for total GFR, a K_f of 13 mL/min/mm Hg for the total nephron population is calculated. Assuming there are 2 million nephrons in both human kidneys, the K_f for a single glomerulus is approximately 6 to 7 nL/min/mm Hg. This value generally agrees with micropuncture measurements, which indicates that K_f for an individual glomerulus is 4 to 5 nL/min/mm Hg in dogs and 2 to 5 nL/min/mm Hg in rats. The large variation in K_f among rats is due in part to differences observed among different strains.[2,77]

The filtration process can operate under one of two conditions. The first condition is the case described previously, in which filtration continues throughout the entire length of the glomerular capillaries and a finite positive EFP remains at the efferent end of the glomerular capillaries. This pattern of disequilibrium is shown by the solid lines in the left panel of Figure 3.10. The second condition occurs when the increase in colloid osmotic pressure is so rapid that the forces favoring and opposing filtration become equal at some point within the capillary system, a condition termed *filtration pressure equilibrium* (Fig. 3.10, solid lines in right panel). Under equilibrium conditions, the latter part of the available filtering surface area is not used and becomes a functional reserve. Studies in some strains of rats have suggested that the normal condition is one of filtration equilibrium. Data from other strains of rats and dogs indicate that, under normal circumstances, glomerular capillary hydrostatic pressure is sufficiently high and the K_f is sufficiently low to prevent the achievement of filtration equilibrium within the glomerular capillaries, and thus filtration occurs along the entire length of the glomerular capillaries.[2]

A physiologic consequence of the equilibrium or disequilibrium of filtration pressures is the influence of plasma flow on GFR. Using a mathematical model presented later, the specific effect of plasma flow can be predicted for both conditions when the transcapillary hydrostatic pressure gradient is kept constant. As shown by the dashed line in Figure 3.10 (right panel), an increase in plasma flow to a system in filtration equilibrium diminishes the rate of increase of colloid osmotic pressure along the length of the glomerular capillaries. The EFP is not dissipated as quickly, and the point of equilibration of hydrostatic and colloid osmotic forces is moved distally, which, in effect, results in the recruitment of additional filtering surface area (S_f) and an increase in the functional K_f. Consequently, increases in plasma flow can increase the GFR proportionately even when glomerular capillary pressure is unchanged. In the case of filtration

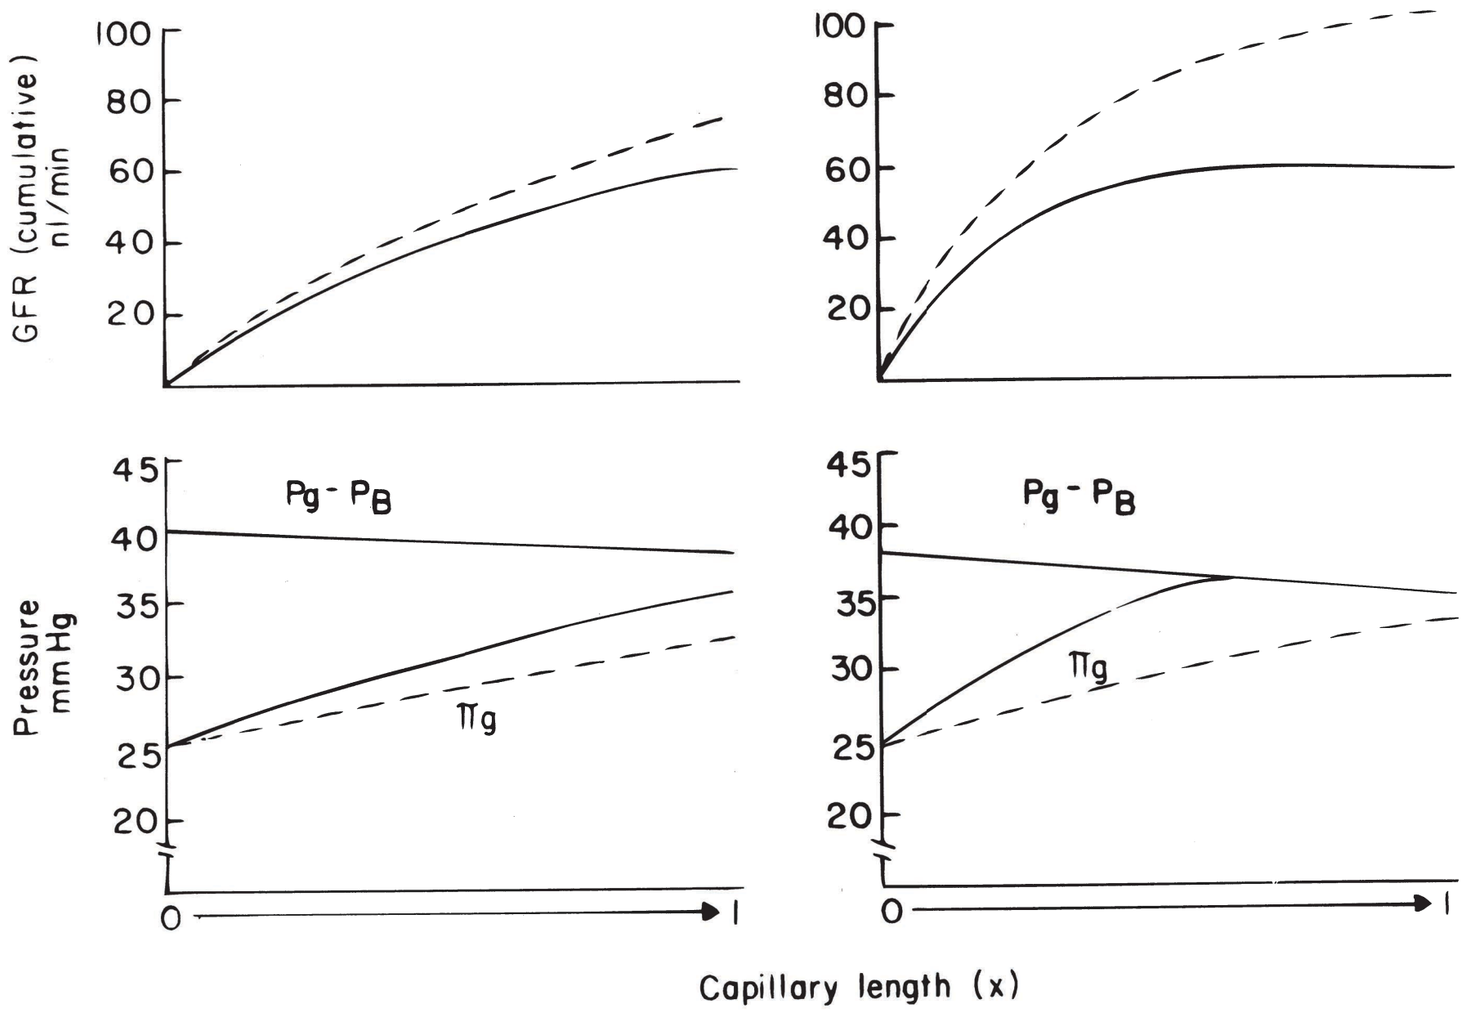

FIGURE 3.10 A comparison of filtration dynamics in conditions of filtration equilibrium (*right*) and disequilibrium when filtration occurs throughout the length of capillary (*left*). The lower panels represent the changes in the transcapillary hydrostatic pressure gradient ($P_g - P_B$) and the glomerular plasma colloid osmotic pressure (π_g), and the upper panels represent the cumulative GFR along the length of the glomerular capillary. The *dashed lines* indicate the changes occurring in response to doubling of plasma flow under both conditions. P_g, glomerular capillary hydrostatic pressure; P_B, hydrostatic pressure in Bowman's space.

pressure disequilibrium, increases in plasma flow increase GFR only modestly as a consequence of a reduced colloid osmotic pressure profile, and there is no net recruitment of previously unused surface area (see Fig. 3.10, dashed lines in left panel). Thus, the magnitude of a selective plasma flow effect is smaller during filtration pressure disequilibrium than during equilibrium. In humans, the low filtration fraction and the relative lack of plasma flow dependence of GFR suggest that the filtration process continues throughout the entire length of the glomerular capillaries (i.e., disequilibrium, as shown in the left panel of Fig. 3.9).[1,2,77]

Glomerular Permeability to Macromolecules

Experiments examining the filterability of test molecules of different sizes, shapes, and charges have been used to characterize the hydrodynamic properties of the filtration barrier. A sieving coefficient (Φ), or fractional clearance of a test molecule, is obtained relative to that of a freely filtered reference molecule such as inulin. Accurate determinations can be made when both substances enter the urine by means of filtration and are not subjected to tubular reabsorption or secretion. Such data have been fitted to various theoretic models based on limiting membrane structures, consisting of an impermeable matrix that is perforated with cylindrical pores, rectangular slitlike openings, or a meshwork of fibrous or granular gel-like structures. An evaluation of molecular sieving or steric restriction in each model, however, is based on the principle of geometric exclusion of large solute molecules from a portion of the membrane that is accessible to water and small solutes. In essence, the larger molecules that approach or exceed the effective size of the channels are restricted or "sieved." Conceptually, the simplest model that is applicable to the glomerular barrier consists of a size-discriminating membrane with a large population of fluid-filled cylindrical pores of about 5 nm in radius, which totals approximately 5% of the total surface area. There may also be a very small population of much larger pores.[2,75]

Studies involving quantitative consideration of macromolecular passage through capillary membranes have relied on the thermodynamic approach developed by Kedem and Katchelsky. Derivations for solute flux (J_s) across a constraining membrane include a convection term, which is the solute flux that occurs as a consequence of the bulk volume flow (J_v), and a diffusion flux, which is a function of the concentration gradient of the solute. In its most elementary form, solute flux due to convection is

$$J_s = J_v C_s (1 - \sigma) \tag{5}$$

and solute flux due to diffusion is

$$J_s = PS (\Delta C_s) \tag{6}$$

where J_v is the volume flow (in this case the GFR), and C_s is the average concentration across the membrane; sigma (σ) is the reflection coefficient previously discussed. ΔC_s is the concentration difference across the capillary wall, and PS is the diffusional, permeability surface-area product coefficient. With small uncharged molecules, such as glucose, sigma approaches zero and thus glucose flux is simply defined by the product of GFR and the plasma glucose concentration. For very large molecules that are restricted with almost complete efficiency, sigma approaches 1 and thus solute flux due to convection is negligible. The most relevant example is for plasma albumin. Using a value of 1 to 3 mg per deciliter for albumin concentration in early tubular fluid and a systemic plasma albumin concentration

of 3,600 mg per deciliter, sigma is greater than 0.99. Furthermore, the PS coefficient is so low (0.001 mL per minute) that solute flux due to diffusion also approaches zero. These quantitative considerations also highlight the difficulty in attempting to evaluate mechanisms of proteinuria. Theoretically, protein passage across the glomerular membrane could increase more than 100-fold, which could be accounted for by a change in sigma from 0.99 to 0.95. Such small changes in membrane permeability would not be expected to be associated with discernible morphologic changes.[2,75]

Passage of macromolecules across capillary membranes is dependent on several factors in addition to the effective radius. These factors include the electrical charge and the structural conformation and rigidity of the molecule. As shown in Figure 3.10, the glomerular sieving coefficient or fractional clearance (usually determined as C_D/C_{IN}) of graded sizes of electrically neutral dextran molecules declines progressively as effective radius and molecular weight increase. Water, electrolytes, and other small, uncharged solute molecules with an effective Stokes-Einstein radius of less than 1.8 nm freely permeate. As the effective radius increases, there is a progressive restriction. The fractional clearance of macromolecules the size of immunoglobulin G (IgG) (5 nm) is essentially zero. For the same equivalent radius, the fractional clearances of albumin (3.6 nm) and negatively charged dextran sulfate are considerably lower than the clearances of uncharged molecules. In addition, polycationic macromolecules are filtered more readily than neutral molecules. These differences in transport of electrically charged macromolecules are due to the membrane-bound polyanionic glycoproteins that are rich in sialic acid and heparin sulfate residues, which set up a negative electrostatic field that repels polyanions. These are associated with the glycoprotein coat that covers the endothelial fenestrations, the basement membrane, and the podocytes. Partial loss of these anionic sites on the glomerular capillary wall can lead to albuminuria in the absence of any gross structural abnormalities and in cases of mild glomerulonephritis. Such a loss has been induced experimentally by neutralization of the electrostatic barrier with the polycation protamine. In more severe glomerular injury–associated proteinuria, a larger fraction of the filtrate appears to pass through a population of large diameter, nonselective pores.

In addition to size and charge, molecular configuration influences the sieving coefficient (Fig. 3.11). Rigid or globular molecules such as horseradish peroxidase or ficoll have lower sieving coefficients for any given molecular size than neutral dextran polymers with highly deformable linear structures. Thus, it is likely that the curve for neutral dextrans in Figure 3.11 overestimates the true permeability characteristics of more rigid, globular-structured macromolecules such as plasma proteins. Because shape, flexibility, and deformability contribute to the quantitative relationship between molecular size and transglomerular solute flux, it is difficult to establish the true dimensions of the extracellular

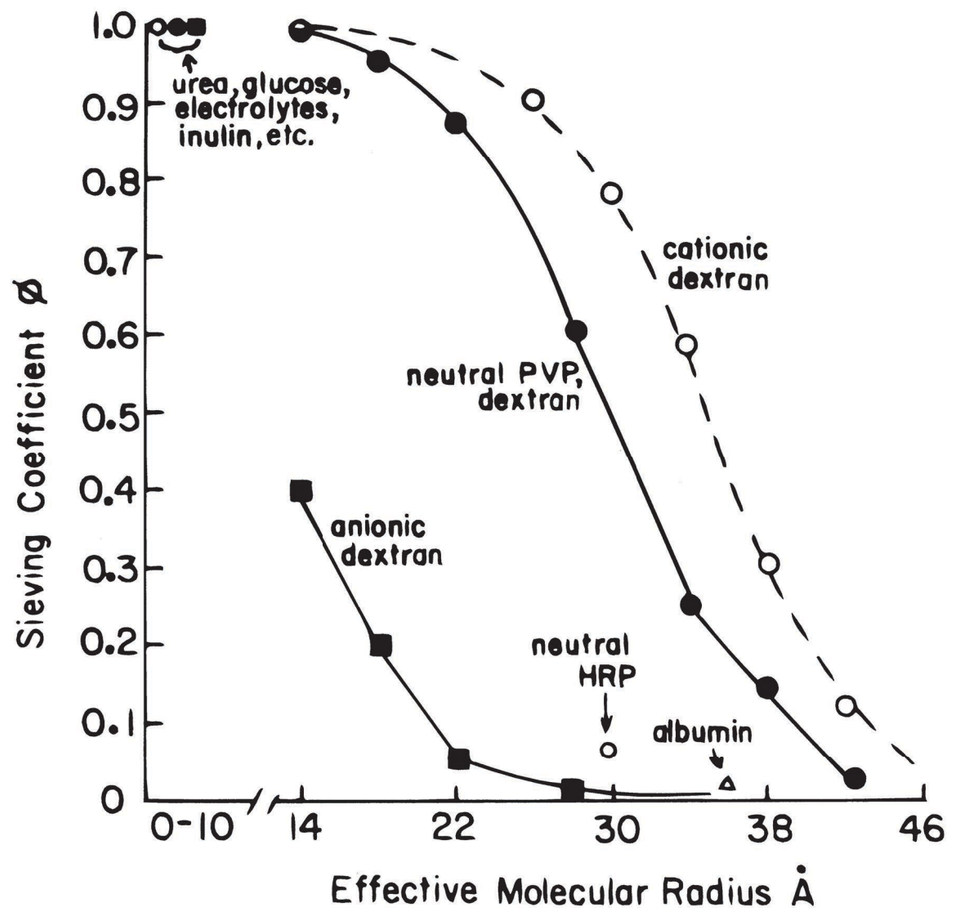

FIGURE 3.11 Representative sieving curves for several test molecules in the glomerular circulation. The curve representing neutral molecules is based on data obtained with the use of polyvinylpyrrolidone (PVP) and neutral dextran. The curves for anionic and cationic molecules are based on studies with charged dextrans. Also shown are the sieving values for neutral horseradish peroxidase (*neutral HRP*) and for albumin. The smaller molecules are shown to have a sieving coefficient of 1.0. See text for details.

channels. Data currently available indicate that the effective radius of the channels in the glomerular membrane is in the range of 4.5 to 6 nm.[2,75]

Recent studies have challenged the generally held notions described previously regarding glomerular permeability and have suggested that much greater amounts of albumin are filtered across the glomerular capillaries and that most of it is then reabsorbed in the proximal tubules by megalin and other macromolecule transporters. Studies based on measurements of glomerular permeability of fluorescent labeled albumin suggest that even normal glomerular capillaries allow passage of albumin that is avidly bound and retrieved by proximal tubules. This concept has been met with substantial resistance and alternative studies have failed to indicate such high levels of albumin passage across normal glomerular capillaries. Advanced multiphoton determinations have yielded a glomerular sieving coefficient of 0.001, a value consistent with the view that the primary determinant of albuminuria is of glomerular origin and that charge does play a significant role.[78–83]

The controversy about glomerular permselectivity highlights important recent findings regarding the extremely complex nature of the glomerular barrier because it consists of three distinct layers in series; each having its own selectivity characteristics. Gene targeted mouse models illustrate the

important role that podocytes have in restricting macromolecules. In particular, studies of the structural and molecular characteristics of the slit diaphragms between adjacent podocytes reveal an extremely complex network of molecular interactions that serve to maintain the normal structure of the podocytes and their close relationship with the basement membranes. The structure of the glomerular membrane is described in detail in Chapter 1. With regard to macromolecular permeability, the podocyte slit-diaphragm layer and its complex array of proteins, including nephrin, podocin, cadherin, and integrins, are clearly identified as the final barrier responsible for the extremely high degree of restriction. Nevertheless, the emerging consensus is that all of the three major restriction sites make a contribution. In essence, when the endothelial glycocalyx is compromised, proteinuria develops. Disorganization of the basement membrane also leads to proteinuria. Furthermore, disruption of the nephrin-actin cytoskeleton complex of the podocyte layer and foot process effacement are associated with the greatest degree of proteinuria. Conceptually, it is attractive to attribute a progressively greater reflection coefficient (sigma) to the three layers in series.[81,84]

Hemodynamics in Peritubular Capillaries and Its Role in Fluid Reabsorption

Virtually all of the peritubular capillary network stems from efferent arterioles. About 85% of the postglomerular blood flow is distributed to peritubular capillaries in the cortex, and the remaining 15% goes to the medulla and papilla (Fig. 3.5). The overall density of peritubular capillaries and the total surface area are considerably greater than those of glomerular capillaries. The peritubular capillary wall consists of a fenestrated endothelial layer covered by a thin basement membrane. Per unit of surface area, it has a lower hydraulic conductivity and a slightly higher permeability to large molecules than the glomerular wall.

In a manner analogous to the process of filtration, the peritubular capillary reabsorption (PR) of interstitial fluid that is reabsorbed by the renal tubules is determined by the imbalance of hydrostatic and osmotic forces between the interstitial space and adjacent peritubular capillaries. If one considers the forces responsible for reabsorption into the capillaries, then

$$PR = K_r [(\pi_c - \pi_i) - (P_c - P_i)] \quad (7)$$

where K_r is the reabsorptive coefficient, π_c and π_i represent the average colloid osmotic pressures in the capillaries and in the interstitial fluid, and P_c and P_i represent the corresponding hydrostatic pressures.

As plasma emerges from the glomerular capillaries, it has a colloid osmotic pressure of 35 to 37 mm Hg (Fig. 3.8). Furthermore, the hydrostatic pressure drops about 40 mm Hg along the efferent arteriole (Fig. 3.3), yielding an initial peritubular capillary pressure of about 20 mm Hg. With regard to the interstitial compartment, π_i and P_i are about 6 to 8 mm Hg and tend to cancel each other out. Thus, the mean effective reabsorption force is 15 mm Hg at the beginning of the peritubular capillary bed. As fluid is reabsorbed into the capillaries, plasma proteins are diluted and the colloid osmotic pressure progressively decreases to the original value entering the kidney. There is also a small decline in capillary hydrostatic pressure along the peritubular capillaries. Thus, there is an effective reabsorptive force over the entire length of the peritubular capillaries, which falls from about 15 mm Hg to about 8 mm Hg (Fig. 3.8). The hydraulic reabsorptive coefficient, K_r, for the peritubular capillaries is about 9 to 10 mL/min/mm Hg, which is slightly lower, overall, than the glomerular K_f. This suggests a lower hydraulic conductivity, which is compensated by the larger surface area of the peritubular capillaries.

With regard to macromolecular permeability, the situation existing in the peritubular circulation contrasts with that in the glomerulus because the convective component is directed inward in association with the continuous fluid reabsorption. Thus, the loss of macromolecules from the postglomerular capillaries occurs only as a consequence of diffusion of macromolecules from the plasma into the interstitial compartment. Although significant amounts of protein accumulate in the interstitium, the actual permeability is still quite low because of the low removal rate by the lymphatics in the renal cortex. Some studies indicate that the postglomerular circulation constrains molecules that can readily pass through the glomerular membrane. There also may be a small population of pores with diameters greater than 5 nm. Nevertheless, most of the channels have a high degree of efficiency in restricting albumin and other plasma proteins, so their reflection coefficients are very close to 1. This occurrence is due, in part, to an electrostatic barrier similar to that found in the glomerular capillaries such that negatively charged macromolecules permeate more slowly than neutral molecules of the same size. Thus, plasma proteins exert almost their full osmotic pressure across the peritubular capillaries. In spite of these high reflection coefficients, the concentration of albumin in the renal lymph, and presumably in the interstitial fluid, is about one-fourth that in systemic plasma. Although this concentration seems rather high, it should be noted that lymph flow is very low and less than 1% of net protein is lost from the plasma flowing through the peritubular capillaries.[2]

Maintaining the high density of peritubular capillaries is of critical importance in providing adequate oxygenation to the surrounding tubules. Renal interstitial inflammation may lead to reduced peritubular capillary density and the impairment of renal function, resulting in salt-sensitive hypertension. Peritubular capillary loss in renal transplant patients is associated with interstitial fibrosis and tubular atrophy, leading to reduced renal function.[85,86]

Lymphatic capillaries, primarily distributed throughout the cortex, are very permeable to protein and fluid. They

serve to return the proteins that leak out of the peritubular capillaries back to the circulation, and it is usually assumed that the protein concentration in the lymph reflects the protein concentration in the interstitial fluid. The normal renal lymph flow in humans is estimated to be about 2 to 5 mL per minute, or less than 1% of the plasma flow. Lymph flow is increased by elevations in interstitial hydrostatic pressure, such as those accompanying diuretic states, ureteral obstruction, or increases in renal venous pressure.[87,88]

Capillary Uptake by the Vasa Recta

Efferent arterioles of juxtamedullary nephrons provide the vascular supply to the medulla. These efferent arterioles branch into long-looped capillaries, termed the vasa recta, which descend into the medulla in vascular bundles. The vasa recta bundles are intimately associated with and are surrounded by concentric rings of loops of Henle and collecting ducts. The medullary circulation has the important function of removing water and solutes reabsorbed from descending and ascending loops of Henle and collecting ducts without disrupting the large longitudinal osmotic gradients that exist in the inner medulla during water conserving states. This delicate balance is achieved by virtue of the low blood flow and an efficient countercurrent diffusion of fluid and small molecular-weight solutes, which occur because of the specialized structures of the hairpin-shaped parallel loops of the descending and ascending vasa recta. The end result is passive equilibration and shunting of fluid across the vasa recta loops, from the descending to the ascending limbs, and the trapping of solute at the bends. The descending vasa recta have a continuous thick endothelium but aquaporin-1 channels allow for water efflux. Because protein permeability is low, the high plasma protein concentration of the efferent arteriolar blood is preserved. In contrast, the ascending vasa recta have a highly fenestrated thin endothelium, which greatly facilitates passive reabsorption. The ascending vasa recta also have a higher permeability to protein. However, the hydrostatic pressure in the ascending vasa recta is relatively low, about 10 mm Hg, and probably not much higher than interstitial hydrostatic pressure. In the face of a very small outward hydrostatic pressure gradient, the transcapillary colloid osmotic pressure gradient provides an important reabsorptive force, favoring capillary fluid uptake throughout these specialized capillaries. Importantly, the outer medullary descending vasa recta are encircled at points by contractile pericytes that provide a means to locally regulate blood flow.[2,15,19,89,90]

A Quantitative Analysis of Filtration and Reabsorption Dynamics

The mechanisms regulating GFR involve complex interactions among the individual determinants. To achieve a better understanding of the singular effects of each determinant, one can examine the theoretical influence of selective changes in an idealized situation where the other determinants are held constant. Such theoretical predictions can be made from the simple mathematical model shown in Figure 3.12, which analyzes fluid flow dynamics along the length of a single filtering capillary and the resistances of the afferent and efferent arterioles.

This model can be used to analyze the effects on GFR of singular perturbations, such as changes in the transcapillary hydrostatic pressure gradient, the systemic plasma protein concentration, the glomerular plasma flow, and the filtration coefficient. As shown in Figure 3.13 (panel A), changes in the transcapillary hydrostatic pressure difference produce striking responses in GFR. An increase of 10% causes a greater relative increase in EFP leading to an increase in GFR of 19%. GFR is inversely related to plasma colloid osmotic pressure; as can be seen in panel B, a 10% increase of the plasma protein concentration reduces GFR by 25%. The influence of changes in K_f and in plasma flow on GFR are more complex because they affect the rate of rise of plasma colloid osmotic pressure along the capillary bed and thus EFP. Panel C in Figure 3.13 shows that GFR is affected more by decreases than by increases in K_f. The reduced effect of increases in K_f above the normal values reflects the achievement of filtration–pressure equilibrium. Once filtration equilibrium is reached, further increases in K_f enhance ultrafiltration in early portions of the capillary, which causes protein concentration to increase more rapidly. However, this effect is offset because the colloid osmotic pressure equilibrates with the

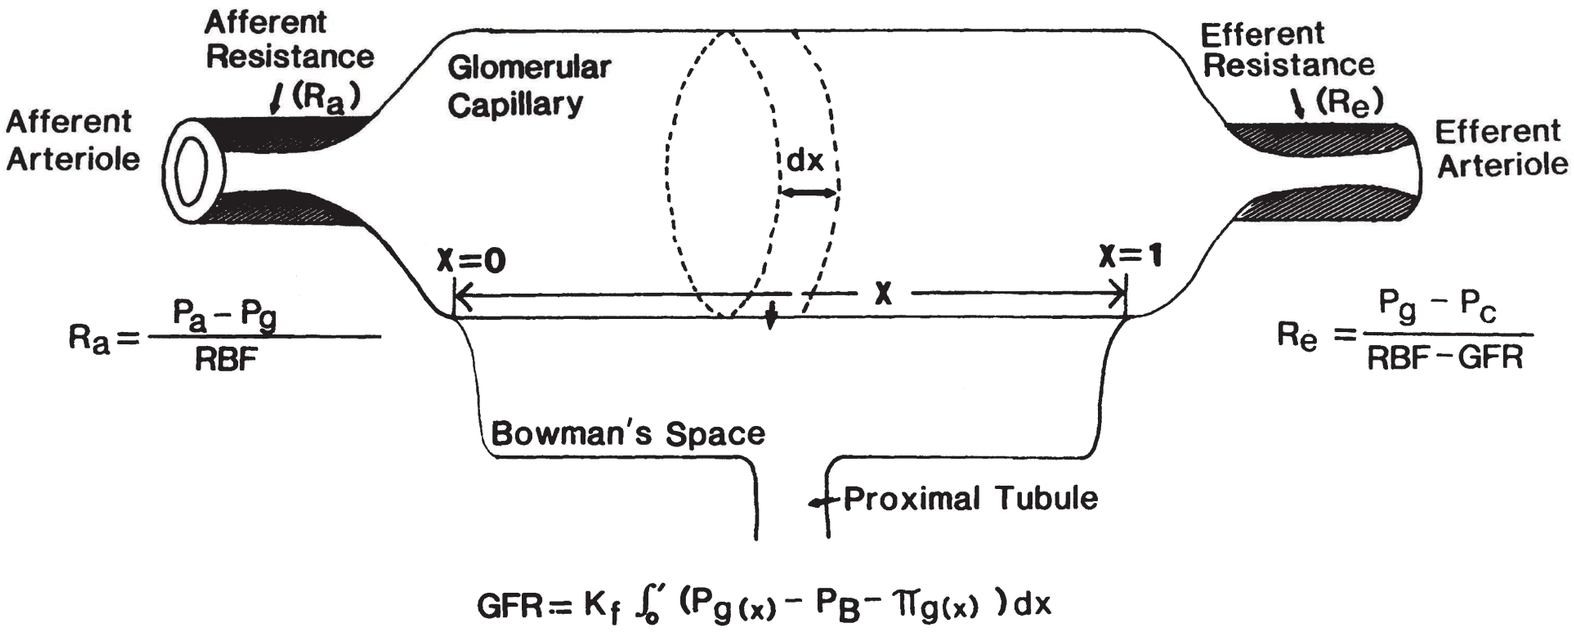

FIGURE 3.12 A "single capillary" model of glomerular filtration dynamics and afferent arteriolar (*R*a) and efferent arteriolar (*R*e) resistances. P_a, arterial pressure; P_g, glomerular capillary pressure; P_c, peritubular capillary pressure; P_B, Bowman's space pressure; *RBF*, renal blood flow; *GFR*, glomerular filtration rate.

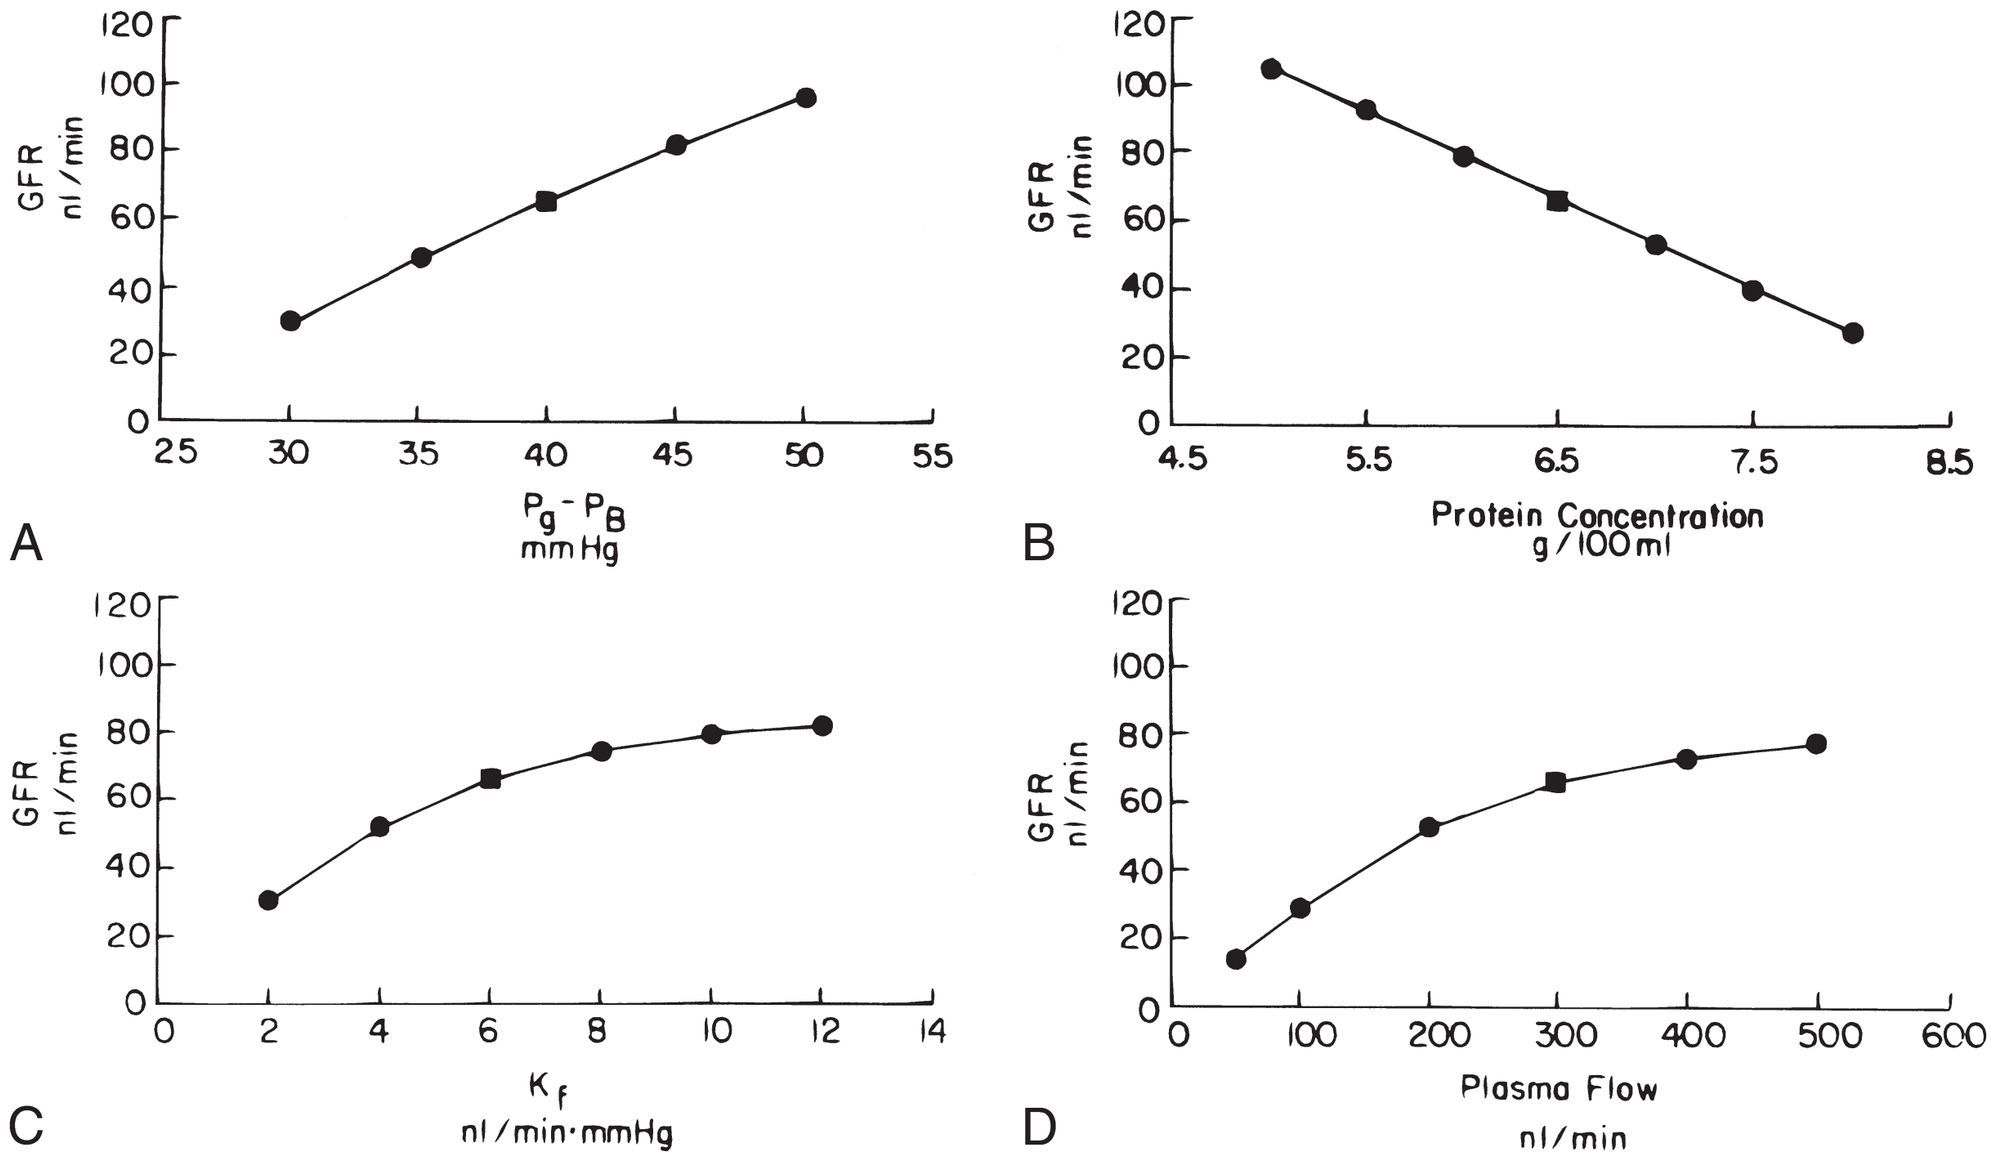

FIGURE 3.13 Theoretical effects of singular perturbations in **(A)** the transcapillary hydrostatic pressure gradient ($P_g - P_B$), **(B)** the plasma protein concentration, **(C)** the filtration coefficient (K_f), and **(D)** the plasma flow at entry to glomeruli. For these simulations, control values (*squares*) estimated to be representative of single nephron function in humans were used: GFR = 65 nL/min; plasma flow = 300 nL/min; ($P_g - P_B$) = 40 mm Hg; plasma protein concentration = 6.5 g/dL. *GFR*, glomerular filtration rate.

hydrostatic pressure difference at a more proximal site along the capillary. Thus, the mean EFP and the total GFR remain the same, although the locus of equilibrium is shifted to an earlier site.

Panel D of Figure 3.13 demonstrates that the effects of glomerular plasma flow on GFR are also nonlinear. In the absence of changes in the other determinants, GFR increases only modestly with increases in plasma flow. On the other hand, decreases in plasma flow below 200 nL per minute produce roughly proportional decrements in GFR. This increase in sensitivity is again due to the attainment of filtration equilibrium at the lower values of plasma flow. Glomerular plasma flow exerts these effects by modifying the intraglomerular profile of colloid osmotic pressure and thus mean EFP. The effects of increases in plasma flow during filtration equilibrium and not in equilibrium were discussed earlier and are shown in Figure 3.10. Changes in plasma flow have a relatively small effect on the colloid osmotic pressure profile during filtration disequilibrium (Fig. 3.10). A decrease in plasma flow increases the fraction of plasma being filtered per unit of capillary length in proximal segments. As a result, the rate of rise of colloid osmotic pressure is increased progressively. During filtration pressure equilibrium, GFR is highly plasma flow dependent. Thus, there are two major functional consequences of filtration pressure equilibrium. GFR is insensitive to increases in K_f and is strongly influenced by changes in plasma flow. In contrast, GFR is directly responsive to K_f and is less plasma flow dependent under disequilibrium conditions. In either situation, glomerular capillary pressure is quantitatively a much more powerful determinant of GFR than plasma flow.

A mathematical analysis that is of more physiologic relevance involves an integrated consideration of changes in preglomerular and efferent arteriolar resistance on glomerular dynamics. The predicted effects of constriction and dilation of either afferent or efferent arterioles under idealized conditions are presented in Figure 3.14, when the other resistances as well as other inputs are maintained at normal values. A selective increase in afferent resistance reduces plasma flow and hydrostatic pressure in glomerular and peritubular capillaries. GFR decreases proportionately more than plasma flow and thus the filtration fraction falls. In contrast, an increase in efferent arteriolar resistance reduces plasma flow but increases glomerular pressure. GFR initially increases slightly but then reaches a plateau. The plateau region of mean EFP is due to the counteracting effects of the increases in glomerular capillary and colloid osmotic pressures. From these quantitative considerations, it is apparent that the preglomerular resistance is ideally suited to control GFR. Efferent arteriolar resistance contributes to subtle alterations in GFR but exerts major effects on the dynamics of the postglomerular circulation. It is important to

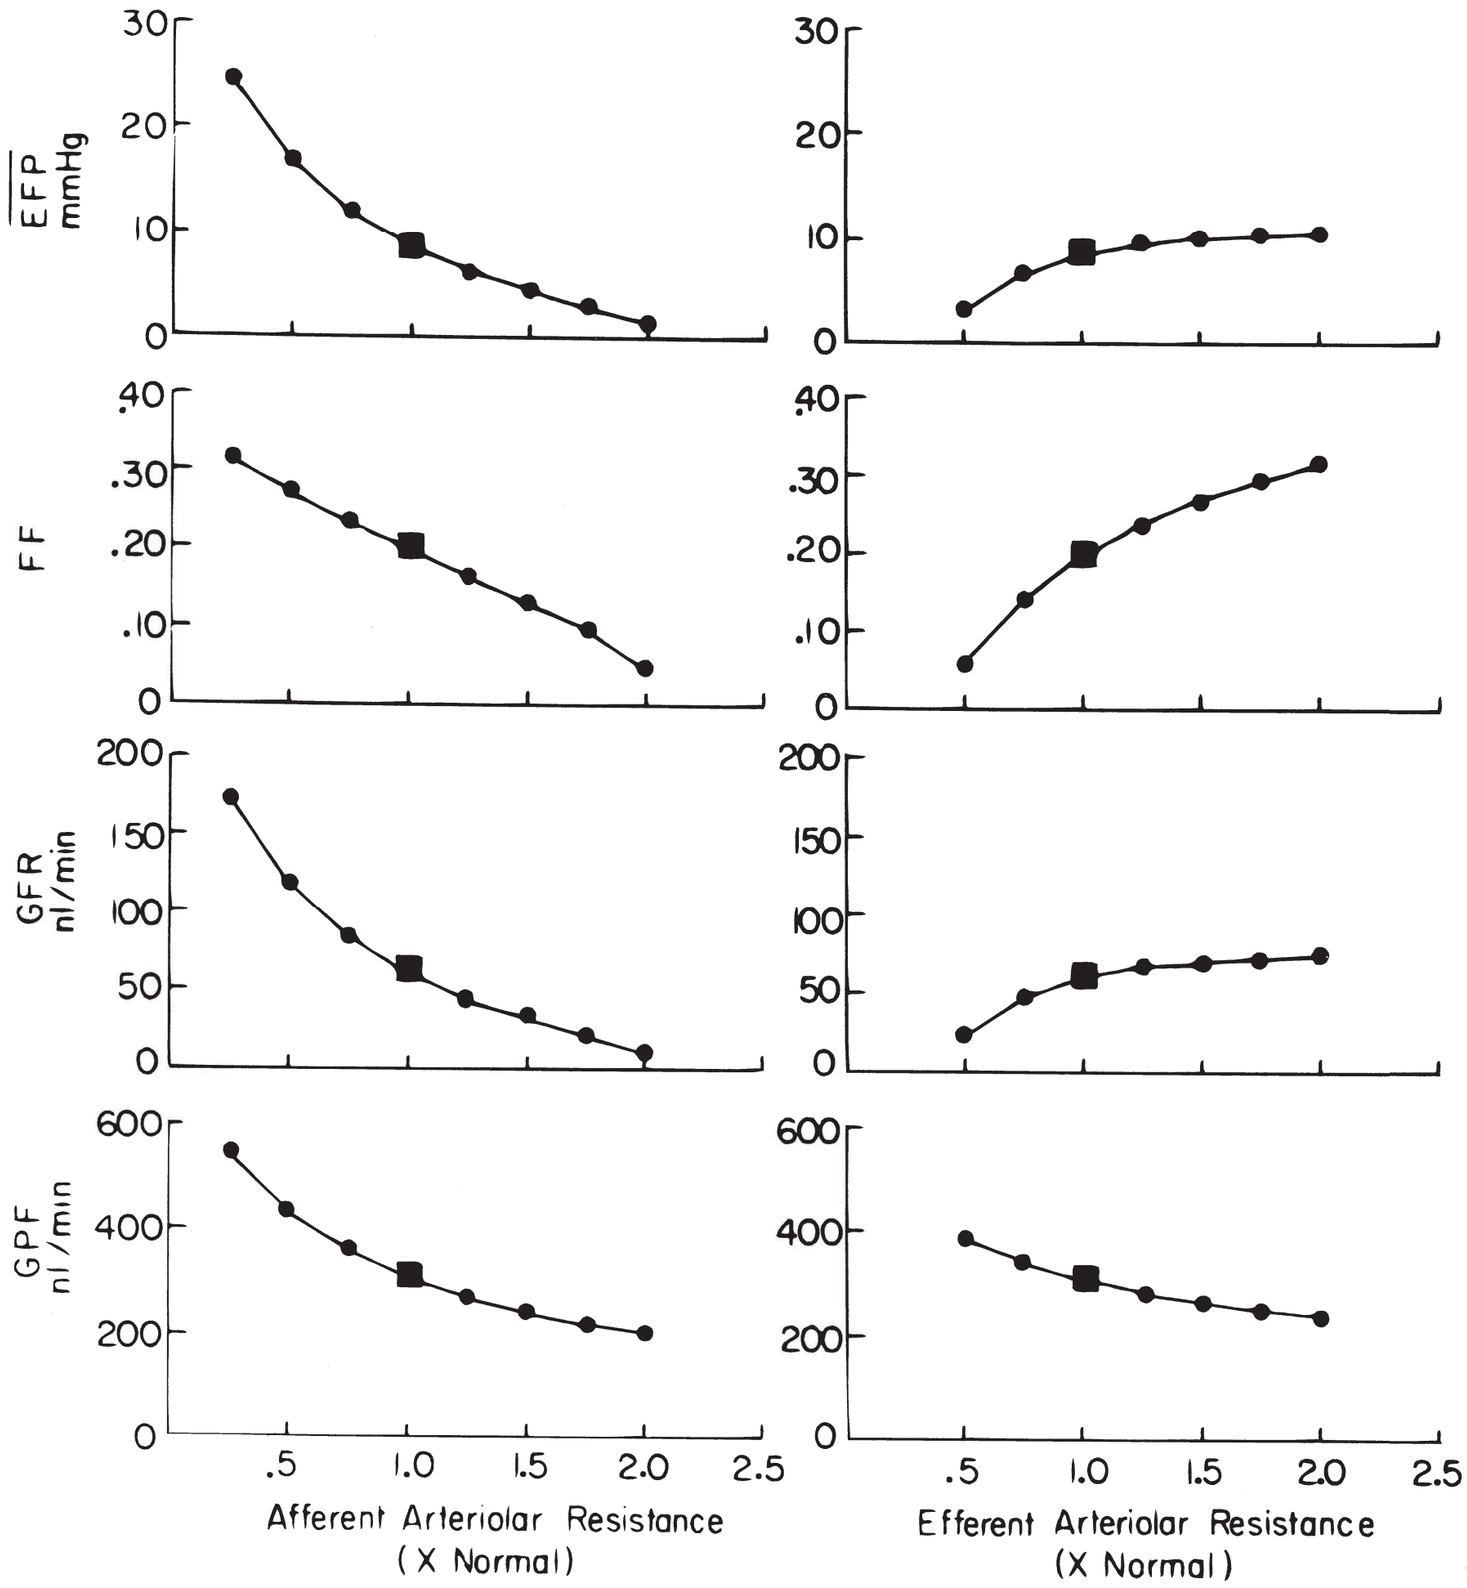

FIGURE 3.14 Effects of increases and decreases in afferent and efferent arteriolar resistance on the glomerular filtration rate (*GFR*), plasma flow (*GPF*), the filtration fraction (*FF*), and the mean effective filtration pressure (*EFP*).

emphasize that changes in filtration fraction alone cannot be used to determine the localization of resistance changes to a specific manipulation, condition, or drug. For example, combined increases in afferent and efferent resistances reduce the plasma flow proportionately more than the GFR, and the filtration fraction increases. Likewise, combined decreases in afferent and efferent arteriolar resistances increases blood flow proportionately more than GFR and filtration fraction falls. These changes in the filtration fraction have often been interpreted incorrectly as being indicative of selective change in efferent arteriolar resistance.

Control of Glomerular Dynamics by the Filtration Coefficient

In addition to the regulation of capillary flow and pressure by resistance changes of the preglomerular and postglomerular vascular segments, K_f and K_r may be influenced by many factors. Alterations in the size of the capillaries or closure of a fraction of the capillaries may reduce the available filtering surface area and thus influence K_f. The hydraulic conductivity may be altered by adjustments in the size and number of endothelial fenestrations, the thickness or permeability of the basement membrane, and the number or structural configuration of the slit pores between the foot processes. Recent attention has been focused on the role of the podocytes in control of GFR. Changes in any of these properties could be manifested as changes in K_f.[91]

Animal studies suggest that vasoconstrictor hormones and some vasodilators are capable of reducing K_f. Also, K_f may be reduced drastically in disease states that involve sclerosis of glomerular capillaries or thickening of the basement membrane. K_f may be increased slightly in certain circumstances, such as increased plasma colloid osmotic pressure. Differences in basal K_f are reported among different species and different strains and colonies of rats. Agents such as Ang II and catecholamines decrease K_f. Blockade of the vascular effects of Ang II negates the K_f lowering effect of prostaglandins E_2 and I_2 and parathyroid hormone (PTH). In addition, several vasodilators (acetylcholine, bradykinin, and histamine) decrease K_f in rats through a mechanism that is not clear. Although the vasodilator actions are primarily due to NO release, it is not apparent how this would decrease K_f. In contrast to the effects observed in rats, vasodilator

agents do not affect K_f appreciably in dogs. The reason for this apparent species difference is not known. Nevertheless, it seems clear that a variety of paracrine agents, including NO and ET-1, can influence K_f and filtration dynamics.[1,36,77]

With regard to the postglomerular vasculature, the major regulator of hydrostatic pressure in the peritubular capillaries is the efferent arteriolar tone. For a given flow, an increase in efferent arteriolar resistance increases the pressure drop along this vessel and thus reduces the pressure in peritubular capillaries. An increase in downstream resistance due to venous obstruction or elevated tubular pressure increases hydrostatic pressure in the capillaries. Interstitial hydrostatic pressure changes in the same direction as pressure in the peritubular capillaries. Colloid osmotic pressure of blood entering the peritubular capillaries is primarily regulated by the filtration fraction. A higher colloid osmotic pressure exerts a greater reabsorptive force in the postglomerular circulation. The colloid osmotic pressure in interstitial fluid is determined by a balance of protein entry from circulating plasma and protein exit by means of the lymphatic circulation. In general, stimuli promoting efferent arteriolar constriction reduce hydrostatic pressure in peritubular capillaries and increase efferent arteriolar colloid osmotic pressure, changes that favor increased fluid reabsorption from the renal interstitium into the peritubular capillaries. Vasodilating stimuli have the opposite effects and are often accompanied by natriuretic and diuretic responses. In all cases, however, there is a very intimate coupling between the rate of fluid reabsorption from the tubules into the interstitium and fluid reabsorption from the interstitial compartment into peritubular capillaries.[87]

THE REGULATION OF RENAL HEMODYNAMICS

The high sensitivity of glomerular and peritubular capillary dynamics to variations in the intrarenal pressures and flows emphasizes the importance of regulatory mechanisms that maintain the intrarenal hemodynamic environment. Overall control is shared by several mechanisms that exert specific effects on various segments of the renal vasculature. Some of these mechanisms are intrinsic to the kidney, whereas others depend on extrarenal signals mediated by neural or hormonal stimuli.

Mechanisms of Autoregulation

Intrinsic paracrine signals can adjust intrarenal vascular resistance in response to a variety of extrarenal perturbations. Alterations in vascular resistance serve to counter the effect of the extrarenal disturbance to stabilize RBF and GFR. The most widely studied manifestation of these intrinsic mechanisms is the phenomenon of renal autoregulation. In response to alterations in renal arterial pressure over a wide range, the kidney adjusts its vascular resistance to maintain, or "autoregulate," RBF. This range encompasses the physiologically relevant arterial pressures, both above and below normal. In response to reductions in arterial pressure, which may occur during situations such as sleep or recumbence, intrarenal mechanisms decrease renal vascular resistance (RVR) to maintain RBF and GFR at optimum levels. Likewise, increases in arterial pressure, which might occur during exercise or acute episodes of stress, elicit intrarenal signals that increase vascular resistance and thus maintain RBF and GFR at or near control levels. In addition to RBF and GFR, the microvascular and tubular pressures exhibit autoregulatory behavior. Because glomerular pressure and GFR are autoregulated, the predominant adjustments of vascular resistance are localized to the preglomerular arterioles. Figure 3.15 shows representative relationships between the renal arterial pressure and RBF, GFR, and segmental vascular resistances. The responses of vascular resistance to changes in perfusion pressure represent the most commonly investigated aspect of the renal autoregulatory mechanism, but other stimuli, such as increases in ureteral or renal venous pressure or changes in plasma colloid osmotic pressure, also elicit autoregulatory responses. The response serves a negative feedback function to counteract the effect of the disturbance and restore RBF or GFR back toward normal.[1,2,92–94]

Although complex interactions with multiple signaling pathways are involved in the total response, the autoregulatory component of the vasculature requires activation of voltage-dependent Ca^{2+} channels and is prevented by L-type Ca^{2+} channel blockers. Much of the research oriented toward understanding this basic response is focused on the mechanisms by which messages are initiated, transmitted to, and received by the smooth muscle cells to affect the requisite alterations in vascular resistance. The two basic mechanisms that contribute to the autoregulation phenomenon are the myogenic and the TGF mechanisms. A third possible contributor has been identified recently, but the underlying mechanism is not known.[2,92–94]

The myogenic mechanism responds to a distending force on the vessel wall caused by an increase in arterial pressure. The actual distending force can be calculated from the law of Laplace that relates tangential wall tension (T) to the inner radius of the vessel (r) and the transmural pressure difference:

$$T = r\,(P_a - P_i) \tag{8}$$

where P_a is intra-arteriolar hydrostatic pressure, and P_i is the interstitial fluid pressure. When the transmural pressure difference increases, wall tension is increased, which activates Ca^{2+} channels and leads to constriction and a reduction of the radius allowing the tension to return to normal. A myogenic response occurs in preglomerular vessels but not postglomerular efferent arterioles. This may be due to the differential activating mechanisms in these vessels because efferent arterioles do not normally have functional L-type Ca^{2+} channels. In addition to the afferent arteriole, the arcuate and interlobular arteries also display myogenic responses.

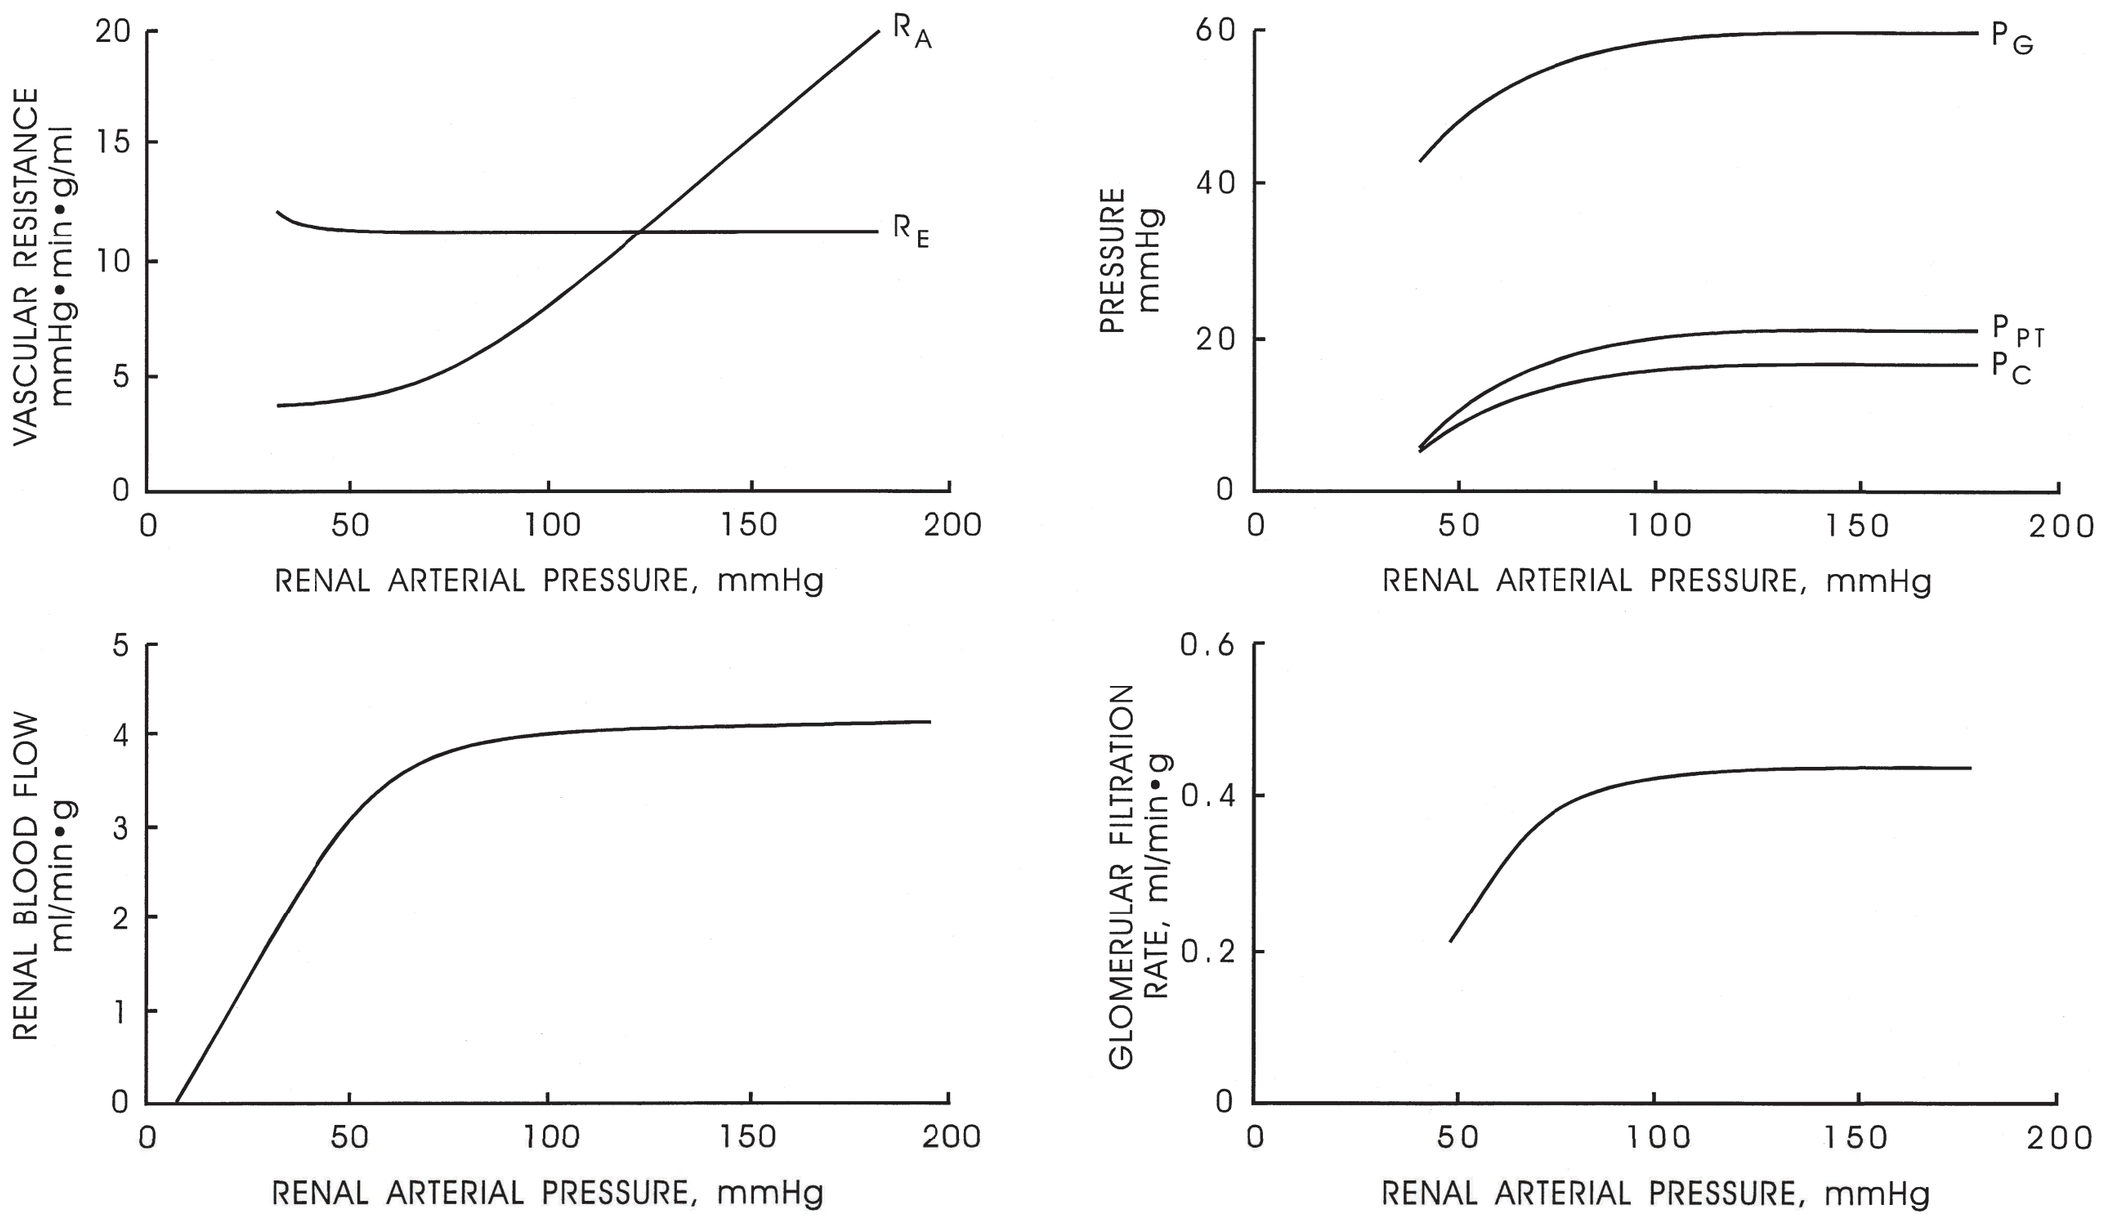

FIGURE 3.15 Representative relationships between renal arterial pressure and renal blood flow (*lower left panel*), glomerular filtration rate (*lower right panel*), and segmental vascular resistance (*upper left panel*) for afferent arteriolar resistance (R_A), efferent arteriolar resistance (R_E), and hydrostatic pressure (*upper right panel*) in glomerular capillary (P_g), proximal tubule (P_{PT}), and peritubular capillary (P_C).

Although a large vessel such as the arcuate artery responds to pressure, its contribution to total resistance is quite small. Thus, the preglomerular arteriolar network has the ability to respond to extrinsic physical or mechanical disturbances by an intrinsic myogenic response of vascular smooth muscle. The initial autoregulatory adjustments in vascular resistance occur rapidly (a few seconds) as a result of a direct local vascular mechanism. Such a fast response is thought to buffer the glomerular capillaries and the tubular network from sudden changes in arterial pressure and protect from high systolic pressures, especially at higher frequencies. Long-standing glomerular hypertension is associated with proteinuria and the development of glomerular sclerosis.[1,93,95–97]

A contraction caused by an increase in intraluminal pressure is elicited by cell membrane depolarization and increased Ca^{2+} entry through voltage-gated L-type Ca^{2+} channels. L-type channel blockers inhibit the myogenic response and the stretch-activated Ca^{2+} channels in the preglomerular microcirculation. T-type Ca^{2+} channels contribute to the myogenic response as a blockade of T-type channels also attenuate autoregulatory responses. In afferent arterioles, the T-type channels may sense relatively small stimuli, which then cause sufficient Ca^{2+} entry and membrane depolarization to activate voltage-gated L-type channels to activate intracellular signaling pathways and to elicit contraction. The increased $[Ca^{2+}]_i$ activates the inositol phosphate cascade to increase IP_3 and DAG and activate PKC. Inhibition of PKC attenuates the autoregulatory constrictor response to a pressure increase. Subconstrictor concentrations of either Ang II or ET-1 potentiate myogenic contraction of afferent arterioles. NO attenuates the rate and strength of the myogenic response. Although endothelial cells play a role in the rate of autoregulation, stretch-induced, steady-state myogenic tone is observed in vessels without a functional endothelium. The actual mechanosensitive transducer on vascular smooth muscle cell membranes has not been completely characterized. Cell surface integrins have been postulated to serve as mechanotransducers by responding to shear, stretch, or tension. Sodium channels have also been shown to respond to mechanical deformation via a degenerin/epithelial sodium channel complex.[2,14,92,93,98–101]

Additional theories to explain the autoregulatory phenomenon evolved because of the recognition that slower acting hemodynamic mechanisms are responsive to the metabolic demands of tubular transport. The existence of structures within the kidney that seem ideally suited to act as communication links between the distal tubular segments and the vasculature provide the morphologic basis for the TGF hypothesis. Indeed, the unique configuration of the juxtaglomerular apparatus (Fig. 3.4) allows the macula densa to sense some aspect of fluid composition at the end of the ascending loop of Henle and transmit a signal(s) to the afferent arteriole of the parent glomerulus. Thus, the juxtaglomerular apparatus provides the anatomic basis for a negative feedback mechanism, operating in each nephron,

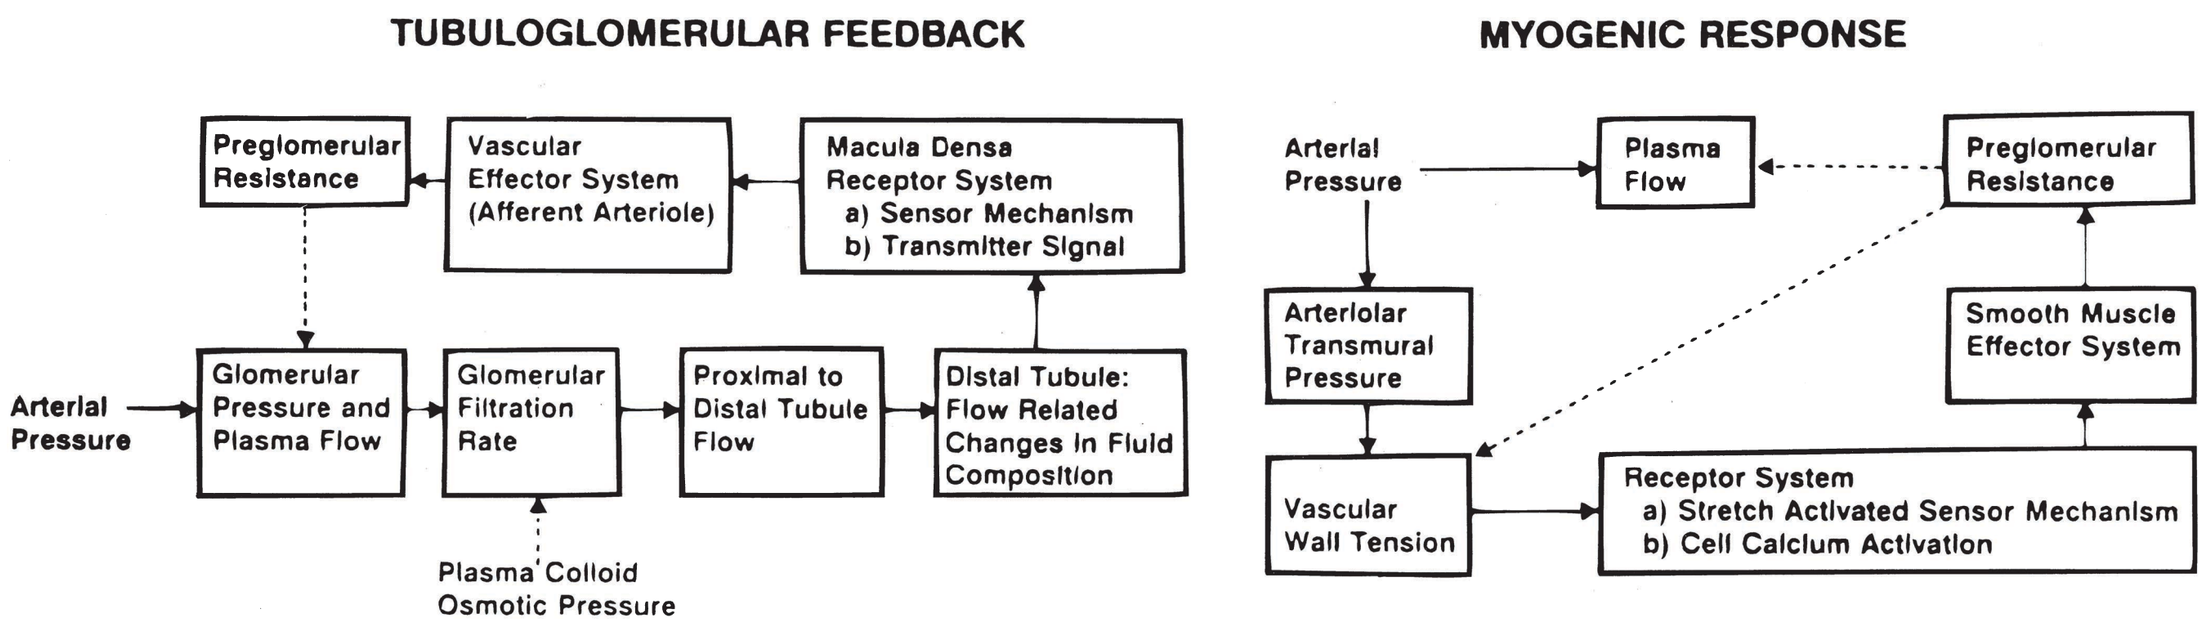

FIGURE 3.16 The macula densa tubuloglomerular feedback hypothesis (*left panel*) and the myogenic response (*right panel*) as mechanisms to explain renal autoregulation. *Solid lines* indicate direct relations; *dashed lines* indicate inverse effects.

that maintains balance between the hemodynamic inputs that control GFR and the filtered load and the metabolically determined reabsorptive function of the tubules.[1,2,102]

Autoregulation mediated by the TGF mechanism is shown in the left panel of Figure 3.16. For example, an increase in arterial pressure initially increases RBF, glomerular pressure, and GFR. The increased filtered load increases fluid and solute delivery from the proximal convoluted tubule into the loop of Henle. Such an effect leads to flow-dependent increases in NaCl concentration and osmolality of the tubular fluid in the ascending loop of Henle. The macula densa cells sense the increased tubular fluid NaCl or total solute concentration and transmit a vasoconstrictor signal(s) to the afferent arteriole and thus restore RBF and GFR to preexisting levels. Conversely, a decrease in arterial pressure causes a reduction in tubular fluid flow that elicits dilation of the afferent arterioles. The presence of primary cilia on the lumen of macula densa cells provides a flow sensing mechanism such that increased flow, per se, activates macula densa signals that elicit afferent arteriolar constriction. The TGF mechanism helps explain vascular responses that occur when the solute load to the distal nephron changes as a consequence of changes in tubular reabsorptive function such as those pharmacologically induced in the proximal reabsorption rate.[2,12,14,103–105]

Studies at the single nephron level indicate that the maintenance of flow to the distal nephron is a requisite for the full manifestation of autoregulation of GFR. As is shown in Figure 3.17, autoregulation of single nephron GFR in

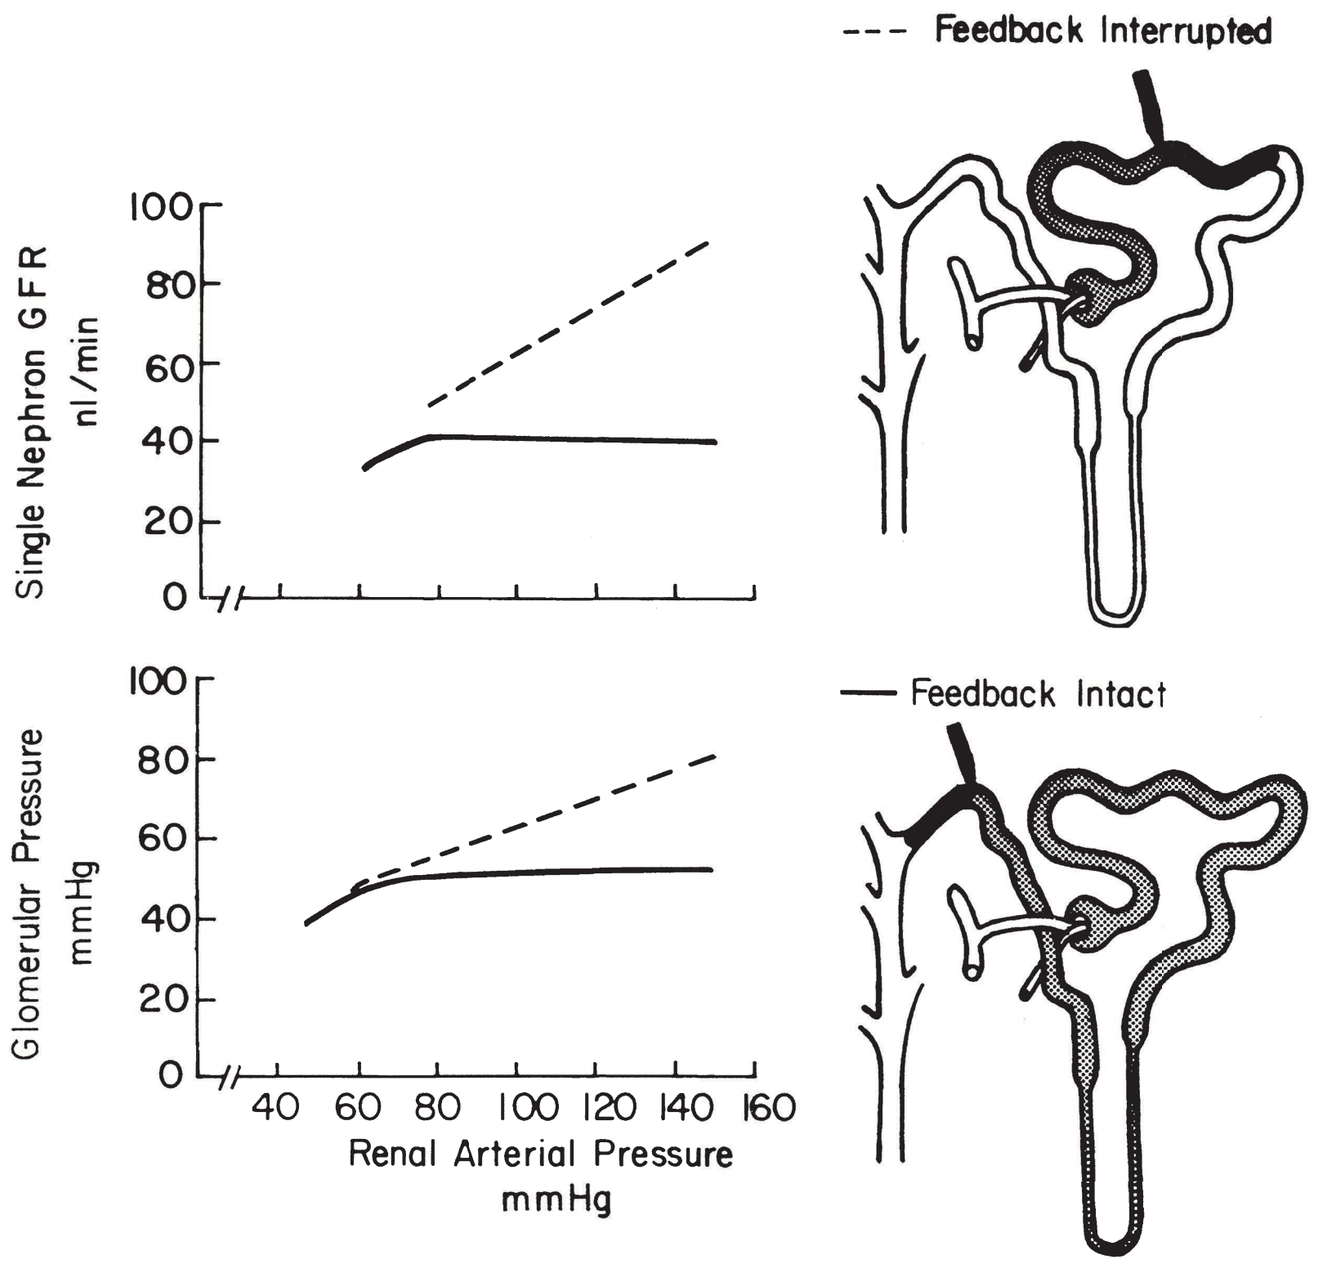

FIGURE 3.17 Responses of single nephron glomerular filtration rate (*GFR*) and glomerular pressure to changes in arterial pressure during conditions of intact flow to the macula densa (*solid lines*) and during interrupted flow conditions (*dashed lines*).

response to acute changes in arterial pressure is highly efficient when tubular fluid flow to the distal nephron is maintained, but it is significantly impaired when flow past macula densa cells is interrupted. Similar responses have been reported for glomerular capillary pressure. Nevertheless, the impairment in GFR autoregulation is not as great as would be predicted for a fully passive mechanism, indicating that the TGF mechanism works in concert with the myogenic mechanism to yield the highly efficient autoregulation characteristic of renal circulation. Recent studies suggest that the interactions are synergistic, in that the presence of active macula densa signals augments the sensitivity of the myogenic response. The afferent arteriole is the effector limb of both mechanisms, and the blockade of Ca^{2+} entry through L-type channels inhibits both the myogenic and TGF responses. The highly localized myogenic component can respond very quickly to a pressure stimulus. The TGF loop is more complex, involving multiple structures and cell types, and its response to a pressure change being transmitted along the tubule is slower, on the order of 15 seconds. The relative importance of these two systems may vary according to experimental conditions. Normally each contributes about 45% to near perfect autoregulation initiated by an acute, single step change in renal perfusion pressure. A putative third component contributes roughly 10% to the final adjustments in RVR that occurs between 25 and 100 seconds.[92,93,96,97,106]

Increases in flow through the loop of Henle elicit the constriction of the parent afferent arteriole with consequent reductions in glomerular pressure and the filtration rate of the same nephron. These responses are represented in Figure 3.18. Note that the response is nonlinear, with the most sensitive region in the physiologic range of tubular flow. Another important feature is that the reactivity or sensitivity of the TGF mechanism can be modified by a variety of paracrine agents, hormones, and pharmacologic agents. Increased sensitivity is generally associated with extracellular fluid volume contraction, and reduced responsiveness has been observed during expansion of extracellular fluid volume.[107]

The macula densa sensing segment is located at the end of the ascending loop of Henle, a nephron segment that is virtually impermeable to water and has a powerful NaCl cotransport mechanism. Such transport characteristics result in the delivery of a hypotonic fluid to the macula densa cells. The nature of the transport processes of the thick ascending limb is discussed in detail in Chapter 4. In essence, increases in fluid delivery from the proximal tubule lead to progressive increases in distal flow, sodium chloride concentration, and osmolality. This coupling between fluid flow through the ascending limb and tubular fluid solute concentration at the macula densa provides the means by which volume delivery out of the proximal tubule is sensed and regulated. The signal sensed by macula densa cells may be a specific constituent of tubular fluid such as sodium or chloride or total solute concentration.[1,107,108]

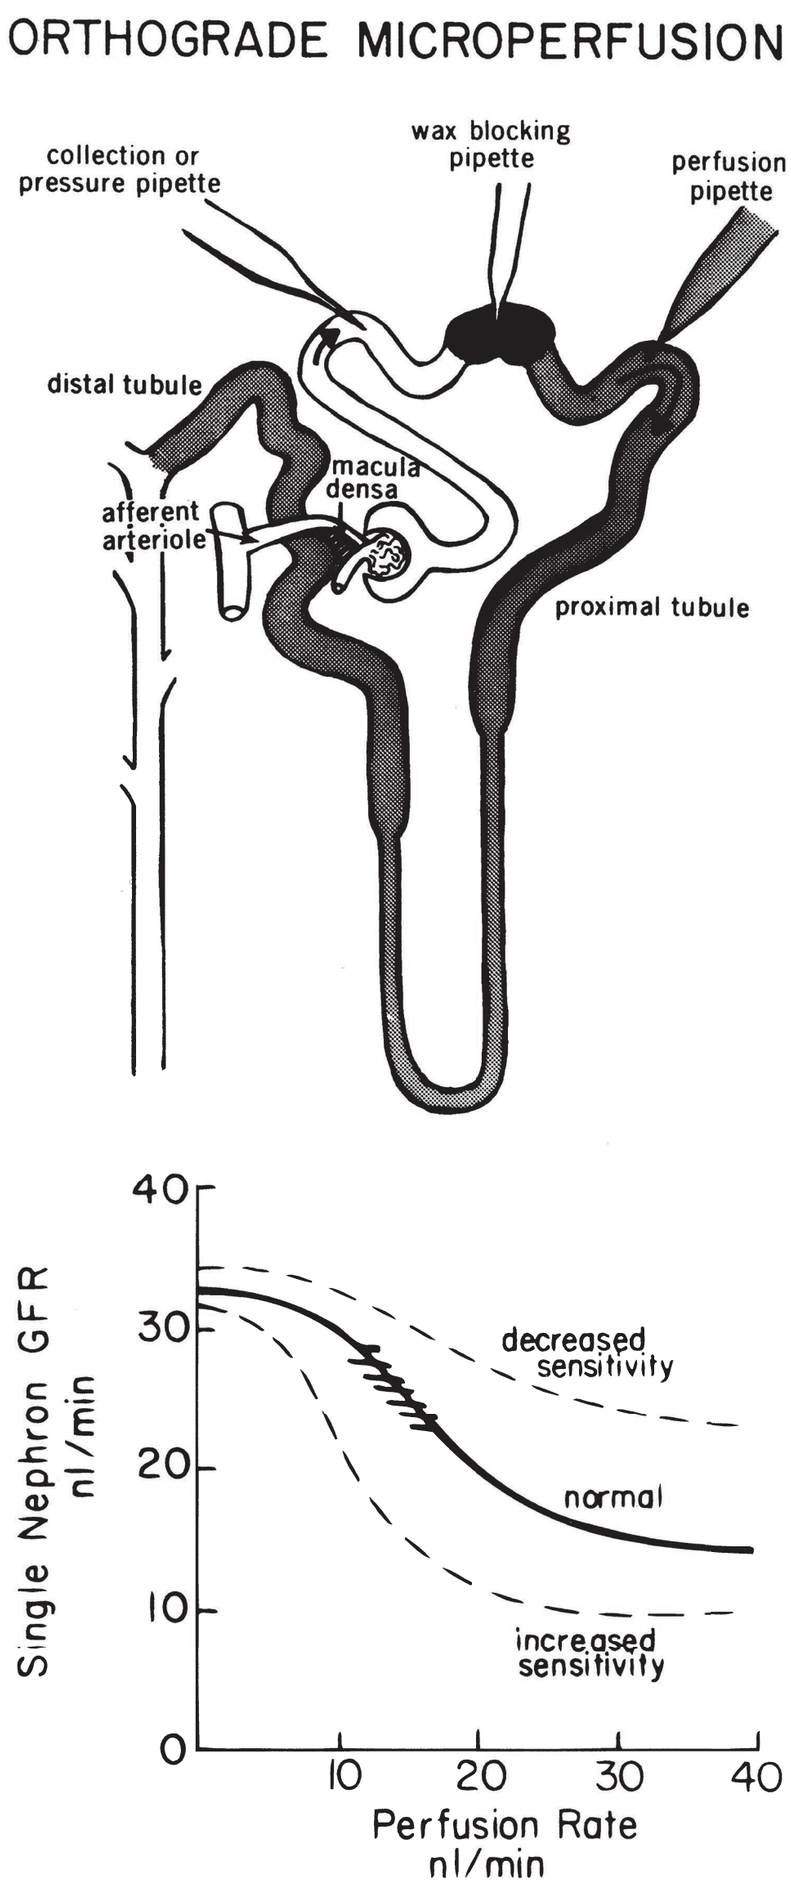

FIGURE 3.18 The relationships between the perfusion rate into a late proximal tubule and a single nephron glomerular filtration rate (GFR). *Dashed lines* show responses during conditions of decreased and increased feedback sensitivity. The *stippled area* shows the physiologic range of single nephron GFR as a function of late proximal flow rate. The technique used to obtain the feedback responses is illustrated in the *top panel*.

The cellular mechanisms responsible for transmitting signals have remained controversial and intriguing. Macula densa cells, like those of the thick ascending limb of Henle, possess a Na-K-2Cl cotransporter, which is sensitive to the diuretic furosemide. This cotransporter must be functional for TGF signals to be transmitted, but it may not be the actual mechanism that activates intracellular signals, which appear to involve increases in Ca^{2+} entry from the basolateral side of the macula densa cells and increased $[Ca^{2+}]_i$ in response to increases in tubular fluid osmolarity or NaCl concentration

of the luminal fluid. The mechanisms by which $[Ca^{2+}]_i$ is related to the formation and release of vasoactive mediators of TGF signals remain unclear. Calcium changes can be counteracted by elevations in cAMP. These intracellular ionic changes signal the macula densa cells to form and secrete constrictor and dilator substances that influence vascular contraction as a function of macula densa transport. The actual final effector messenger between the macula densa cells and the afferent arteriole(s) remain under investigation. Early studies fostered the idea that the effector signal was locally formed Ang II. However, it is now clearly established that the changes in the activity of the renin–angiotensin system modulate the sensitivity of the feedback response but do not directly mediate TGF signaling. The effector agent is thought to operate primarily by activating voltage-dependent Ca^{2+} channels in the afferent arteriole and perhaps the interlobular artery. Attractive candidates that have been considered recently include purinergic agents such as adenosine and ATP or arachidonic acid metabolites. Several recent studies link the secretion of ATP by macula densa cells to afferent arteriolar constriction via the activation of P_2 receptors and associated increases in Ca^{2+} entry via voltage-dependent Ca^{2+} channels. In support of this notion, a defective P_2X receptor function is associated with impaired TGF function of juxtamedullary nephrons.

An alternative view is that the ATP is metabolized to adenosine, which elicits afferent arteriolar vasoconstriction. Consistent with this proposal, mice lacking adenosine A_1 receptors do not exhibit TGF responses in superficial nephrons. Also, mice lacking the nucleotidase involved in degrading ATP to adenosine have impaired TGF. Another possibility is that an arachidonic acid metabolite such as 20-HETE participates in mediating TGF-dependent vasoconstriction. Studies show that increased luminal NaCl concentration leads to NO release, which counteracts the constrictor response. In contrast, PGE_2 release is increased by reduced NaCl concentration.[2,12,103,107,109–112]

The Modulation of Tubuloglomerular Feedback Activity by Vasoactive Agents

Macula densa cells also signal the juxtaglomerular cells to regulate renin synthesis and release. Mechanisms of renin release are discussed in the section on the renin–angiotensin system. In brief, the directional changes in renin release and Ang II formation are opposite to those that are required for Ang II to mediate TGF. For example, high tubular flows and elevated luminal NaCl concentrations are associated with reduced renin release but TGF-mediated afferent arteriolar constriction. Nevertheless, Ang II exerts an important role in modulating TGF activity during changes in salt diet, extracellular fluid volume, and renal perfusion pressure. Tubuloglomerular feedback is absent in mice lacking AT_{1A} receptors, although the renal vasculature is capable of responding to Ang II. Tubuloglomerular feedback is nonresponsive in animals unable to produce Ang II when ACE is mutated.[2,14,104]

The neuronal NO synthase (NOS) isoform localized in macula densa cells produces NO in response to increased tubular flow above the normal range, which modulates TGF activity. A blockade of NO synthesis augments the strength of TGF responses, whereas enhanced NOS levels attenuate the vasoconstrictor response to increased distal nephron flow. Salt uptake across the luminal membrane by a furosemide-sensitive Na-K-2Cl transporter may link increases in cellular cAMP and $[Ca^{2+}]_i$ to NO production. O_2 radicals generated in the vicinity of the juxtaglomerular apparatus can act to scavenge NO, limiting macula densa NO signaling and thereby producing vasoconstriction and enhancing TGF activity. Normal TGF is found in gene knockout animals lacking neuronal NOS.[2,113–115]

Arachidonic acid metabolites also modulate TGF activity and interact with other vasoactive modulators. Cyclooxygenase 2 (COX-2) has been localized to macula densa cells and the surrounding ascending loop of Henle cells; the release of PGE_2 from macula densa cells occurs in response to reduced luminal NaCl. A COX-2 metabolite attenuates the vasoconstrictor autoregulatory and TGF-mediated response of the afferent arteriole to an increase in arterial pressure. Such a dilator agent also appears to contribute to the macula densa production of NO, which inhibits afferent arteriolar responses to pressure. Thromboxane A_2 and a cytochrome P450 metabolite such as 20-HETE are also involved in the constrictor limb of TGF. However, gene targeting rendering the thromboxane receptor nonfunctional has no effect on TGF activity.[104,116–118]

Recent evidence supports the existence of a second TGF loop that links increases in connecting tubule sodium reabsorption via epithelial sodium channels to dilation of the afferent arteriole of the parent glomerulus. It is noteworthy that the response of this positive feedback loop is opposite to the constrictor signal arising from macula densa cells in response to increased salt delivery to the end of the thick ascending limb of Henle. The connecting tubule signal transmitted to the afferent arteriole to increase GFR involves COX-derived prostaglandins and epoxygenase-derived EETs. The magnitude of this feedback response is enhanced by Ang II acting on AT_1 receptors to stimulate epithelial sodium channel activity and sodium reabsorption. The connecting tubule–glomerular feedback circuit may function to dampen the effects of vasoconstrictor stimuli on the afferent arteriole.[119,120]

The Renin–Angiotensin System

The Formation of Ang II

The renin–angiotensin system exerts control of renal hemodynamics via its major vasoactive metabolite Ang II, which acts as both a circulating hormone and a locally generated paracrine agent. Renin is a proteolytic enzyme that cleaves Ang I from renin substrate (angiotensinogen) that is formed primarily by the liver but also in the kidney. Renin is synthesized primarily in epithelioid granular cells of the

juxtaglomerular apparatus and is secreted into the surrounding interstitium; renin is also formed in proximal tubule cells and principal cells of connecting tubule and collecting duct segments. Angiotensinogen availability in the plasma and intrarenal compartments is less than is required to produce maximum reaction velocity, so alterations in substrate levels contribute to the regulation of Ang I production. The inactive decapeptide Ang I is then cleaved by ACE to form the active octapeptide Ang II. There are abundant amounts of endothelium-bound ACE in the lungs and in almost all other tissues. Most of the Ang II in the systemic arterial blood is formed in the lungs. The major sites of ACE localization in the kidney are on the luminal surface of endothelial cells lining arteries and arterioles (in particular, the afferent arterioles), but also the efferent arterioles and the glomerular capillaries, and on the brush border and basolateral membranes of the proximal tubule; extravascular ACE is also present in the interstitial compartment and on the lumen of collecting duct segments.[2,13,121–125]

Several peptidases act on angiotensinogen to form biologically active peptides other than Ang II. Angiotensin with amino acids 1 to 7 is formed by neutral endopeptidase, but appears to have only slight effects on the renal vasculature under physiologic conditions. Elevated levels of Ang 1 to 7 occur during ACE inhibition and may dilate renal and nonrenal vascular beds. Ang III (angiotensin with amino acids 2 to 8) has actions similar to that of Ang II, which can be blocked by Ang II receptor antagonists. Ang IV (angiotensin with amino acids 3 to 8), a hexapeptide, is reported to produce vasodilation by the release of NO or prostanoids from endothelial cells by acting on a specific AT_4 receptor. The recently described enzyme ACE-2 forms Ang (1 to 9) from Ang I and Ang (1 to 7) from Ang II. Thus, ACE-2 can produce more Ang (1 to 7) from Ang II and, in this manner, reduces the available Ang II.[124,126–128]

Ang II is delivered to renal vascular receptors as a circulating hormone or may be formed locally from systemically delivered Ang I by endothelial ACE. About 20% of the circulating Ang I is converted to vasoactive Ang II in the kidney. Ang II is also formed in the interstitial fluid from Ang I, generated as a consequence of enhanced renin release or from Ang I that diffuses from peritubular capillaries into the interstitium. The renal tissue Ang II levels are higher than that of arterial blood, indicating significant amounts of Ang II are generated intrarenally. In addition, Ang I and II may be formed within juxtaglomerular granular cells and coreleased with renin to act on adjacent glomerular arterioles. High concentrations of Ang II also exist in proximal and distal tubular fluid as a result of secretion by proximal tubular cells. Ang II derived from proximal tubular cells also may have vascular effects after traversing the interstitium.[123,129,130]

Renin Production and Release

As Figure 3.19 shows, renin is released in response to several stimuli, including decreases in sodium intake, the contraction of extracellular fluid volume or blood volume, increased sympathetic renal nerve activity, decreased sodium load to the macula densa, and decreased renal arterial perfusion pressure. Ang II, ET-1, NO, vasopressin, prostaglandins, and potassium also influence renin release, acting directly on juxtaglomerular cells. The final effector mechanisms center on changes in the Ca^{2+} and cAMP concentrations

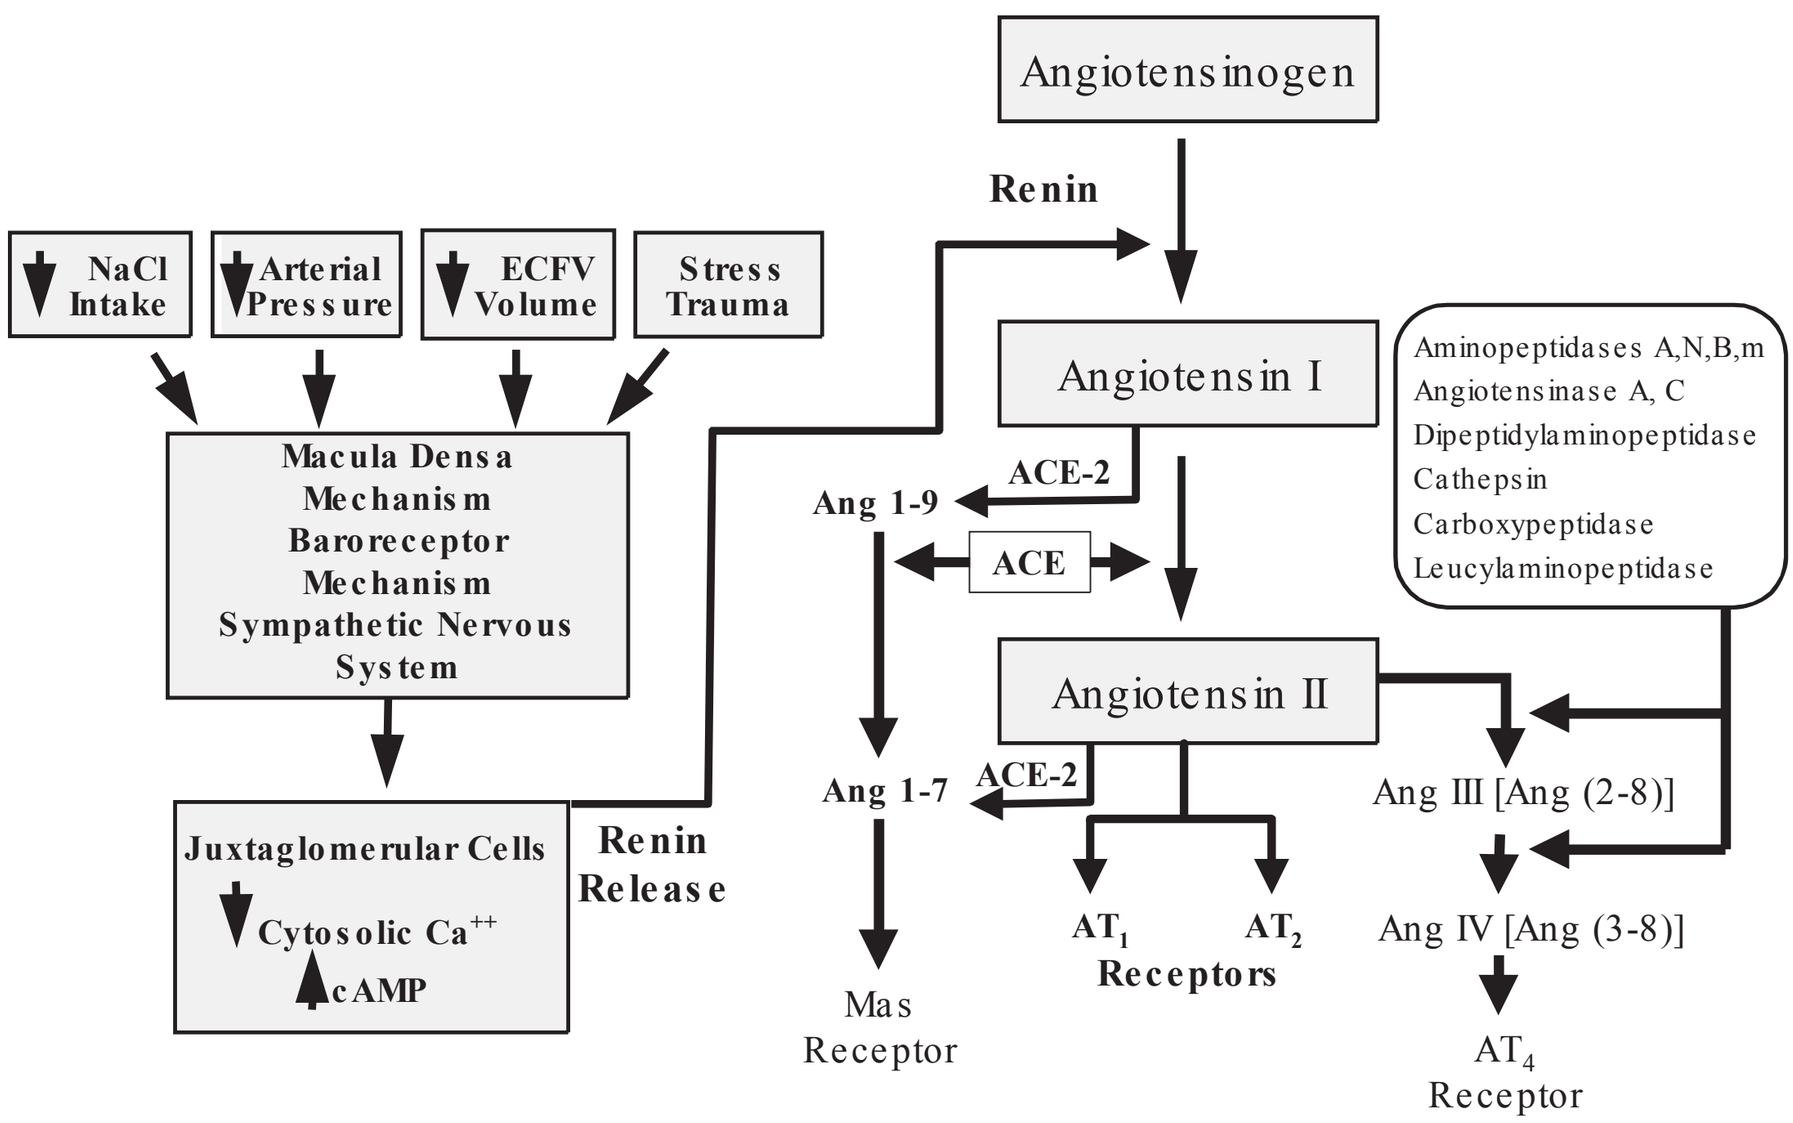

FIGURE 3.19 A schematic representation of the renin–angiotensin system and the mechanisms of renin release.

in juxtaglomerular granular cells. The Ca^{2+} mechanism is unusual for exocytosis of secretory renin granules in that a decrease in $[Ca^{2+}]_i$ functions as a stimulator of renin release, in contrast to the opposite in most other secretory cell types. Renin exocytotic release is elicited by increases in cellular cAMP levels. Cytosolic cAMP concentration is controlled by synthesis via adenylate cyclase and hydrolysis by cyclic nucleotide phosphodiesterases (PDEs). Intracellular Ca^{2+} inhibits PDE to modulate the magnitude of cAMP-mediated renin release. PDE_3 is the major isoform localized to afferent arterioles, and recent evidence indicates that the pharmacologic inhibition of PDE_3 increases cAMP and basal renin secretion and also enhances the renin secretory response to β-adrenergic and PGE_2/EP_4 receptor stimulation.

Exocytosis of secretory granules in the juxtaglomerular cells is also stimulated by cell shrinkage due to high extracellular osmolality. Juxtaglomerular cells have Ca^{2+}-sensitive voltage-gated K channels (BK_{Ca}) that are activated by cAMP to hyperpolarize cells from -32 to -48 mV. Vasoconstrictor G-protein coupled receptor agonists such as Ang II and ET-1 inhibit renin release by activating PLC and mobilizing Ca^{2+} that activates Ca^{2+} entry through store-operated cation channels.[2,13,121,131]

There are several first messenger systems that impact on cAMP or $[Ca^{2+}]_i$ in juxtaglomerular cells to regulate renin release. These are discussed briefly in the following section and in more detail in Chapter 9.

Sympathetic Nervous System and Catecholamines. Juxtaglomerular granular cells are richly innervated and respond to renal sympathetic nerve stimulation and to circulating catecholamines. There are both direct and indirect effects on renin release. Subtle increases in renal nerve traffic or circulating epinephrine activate β_1-adrenoreceptors on juxtaglomerular cells, which activate $G\alpha_s$ proteins to increase cAMP, thereby enhancing renin release. Strong renal nerve activity reduces RBF and GFR through activation of α_1-adrenergic receptors, with subsequent indirect stimulation of renin release secondary to afferent arteriolar vasoconstriction that reduces intrarenal baroreceptor and macula densa stimuli.[13,132]

Renal Vascular Baroreceptor. Decreases in renal afferent arteriolar pressure directly increase renin release independent of the renal nerves and the macula densa mechanism. The juxtaglomerular cells appear to be directly sensitive to intraluminal pressure and stretch such that decreased wall tension decreases cell Ca^{2+} entry and $[Ca^{2+}]_i$, whereas the opposite occurs at elevated arterial pressures. Under some circumstances, the same extrinsic disturbance may influence both the macula densa and the vascular baroreceptor mechanism to increase renin release, but the vascular receptor system can act independently.[2]

Macula Densa. Macula densa cells detect decreases in the NaCl load or concentration emerging from the ascending loop of Henle and send a signal(s) to the juxtaglomerular cells to increase renin secretion. Although the sensing mechanism involving furosemide-sensitive luminal uptake of NaCl is not completely understood, evidence suggests that adenosine can inhibit renin release, and its precursor, ATP, is secreted by macula densa cells in response to increases in tubular NaCl concentration and is converted to adenosine via ectonucleotidases. Circumstances that result in extracellular volume depletion or sodium deprivation stimulate renin release, at least in part, by the macula densa mechanism. Reduced tubular fluid flow to the macula densa leads to increased COX-2 activity and PGE_2 release that directly stimulates renin release via activation of EP_4 receptors and increased cAMP production in juxtaglomerular granular cells.[12,14,116,133]

Other Factors. Renin secretion is inhibited by elevated plasma or local concentrations of Ang II, vasopressin, adenosine, thromboxane A_2, and potassium. The effects of Ang II and other vasoconstrictors appear to be a consequence of an end-product inhibition due to increased $[Ca^{2+}]_i$ in juxtaglomerular cells. PGE_2 and PGI_2 can stimulate renin release through direct effects, which may be related to the stimulation of cellular cAMP levels. The atrial natriuretic peptide increases cellular cGMP production and inhibits renin release. Endothelium-derived factors also modulate renin release, with NO stimulating renin release.[13,116,121,134]

COX-2, nNOS, and renin synthesis often change parallel with changes in salt diet and alterations in tubular fluid NaCl concentration, and their products may mutually determine synthesis and activity of these enzymes. nNOS and COX-2 are coexpressed in macula densa cells and the expression of both enzymes is stimulated in volume contraction and high renin states. Parallel changes are observed during chronic changes in salt in the diet, with low salt stimulating nNOS, COX-2, and renin secretion as compared to the inhibition occurring during a chronic high salt diet. NO derived from nNOS exerts a stimulatory role on COX-2 expression to produce PGE_2 / PGI_2 and to stimulate renin release by acting on EP_4 and IP receptors, respectively. PGE_2 exerts short-loop feedback to inhibit nNOS expression. In some situations, NO appears to play a more indirect permissive role, permitting the macula densa pathway of renin secretion to function normally. NO stimulates renin release by cGMP, inhibiting PDE_3 to increase cell cAMP concentration by reducing cAMP breakdown in juxtaglomerular cells, with the activation of cAMP sensitive PKA.[13,116,121,135]

Although many stimuli increase activity of the renin–angiotensin system, most are related to circumstances that compromise body fluid volume homeostasis. Thus, the stimulation of renin release and the activation of Ang II–dependent mechanisms help to minimize renal fluid and sodium losses and to maintain extracellular fluid volume and arterial blood pressure. The myriad of actions exerted by Ang II all seem to be homeostatically appropriate to achieve this end. Only the renal vascular actions of Ang II will be covered in this chapter, but it should be pointed out

that Ang II is also a potent stimulator of aldosterone release and can directly enhance salt reabsorption by the proximal tubule, the Henle loop, and the distal nephron segments. It also has important effects on the central nervous system such as stimulating thirst, vasopressin release, and sympathetic nerve activity.[2,129]

The macula densa plaque has distinct mechanisms for renin release and the TGF system. The TGF mechanism involves the macula densa by sending a vasoconstrictor signal to the afferent arteriole in response to increases in tubular flow and the accompanying increases in solute and sodium concentration from the Henle loop. Under these conditions, the macula densa signals to decrease renin release and local Ang II activity, which is opposite to that required for Ang II to mediate a TGF-induced contraction of the afferent arteriole. Thus, Ang II clearly does not mediate TGF responses; it does, however, modulate the sensitivity of the TGF mechanism to the macula densa vasoconstrictor signal(s). When tissue Ang II levels are increased, smooth muscle responsiveness is augmented. In contrast, when Ang II levels are suppressed, whether in response to physiologic manipulations or as a consequence of a pharmacologic blockade, the sensitivity of the TGF system is attenuated. Interestingly, sensitivity can be restored by the administration of Ang II but not norepinephrine. In addition to directly affecting the afferent arteriole, Ang II affects TGF activity by altering tubular reabsorption and fluid delivery to the macula densa. The vascular and tubular effects work in concert to reduce GFR when sodium excretion is reduced as observed during volume contraction. As previously mentioned (Fig. 3.18), changes in TGF responsiveness during altered volume states may be largely due to changes in tissue levels of Ang II. The interactions between the renin–angiotensin system and the TGF mechanism are illustrated in Figure 3.20.[1,2]

The precursor of renin, prorenin, is also released by juxtaglomerular granular cells and renin-producing tubular cells. Although prorenin is inactive, it can bind to the prorenin receptor that has been recently discovered and characterized. Binding of prorenin to the prorenin receptor activates prorenin and increases its catalytic efficiency to generate Ang I from angiotensinogen. Thus, increased tissue levels of prorenin or the prorenin receptor may influence the local generation of Ang I, leading to increased Ang II formation. Prorenin also appears to signal via the MAP kinases extracellular signal regulated kinase (ERK) 1/2 to upregulate profibrotic and COX-2 genes independent of Ang II. Prorenin receptors are localized in vascular endothelial and smooth muscle cells, glomerular mesangial cells and podocytes, and collecting duct segments of the nephron.[136,137]

Angiotensin Receptors

There are two major subtypes of receptors for Ang II in the renal circulation. In utero, animals have a larger population of AT_2 than AT_1 receptors, which decreases progressively after birth; in adult life, the major subtype on vascular smooth muscle cells is the AT_1 receptor. The AT_1 receptor is present on preglomerular arteries and arterioles, juxtaglomerular granular cells, glomerular mesangial cells, efferent arterioles, and vasa recta bundles of the inner medullary stripe. Humans have one AT_1 receptor, whereas rodents have two, termed AT_{1A} and AT_{1B}, which are 94% homologous. Currently available pharmacologic antagonists of AT_1 receptors, such as candesartan, losartan, and valsartan, do not distinguish between the two AT_1 subtypes in rodents. Almost all of the vasoconstrictor actions of Ang II on the renal vasculature under physiologic conditions are mediated by AT_1. Both

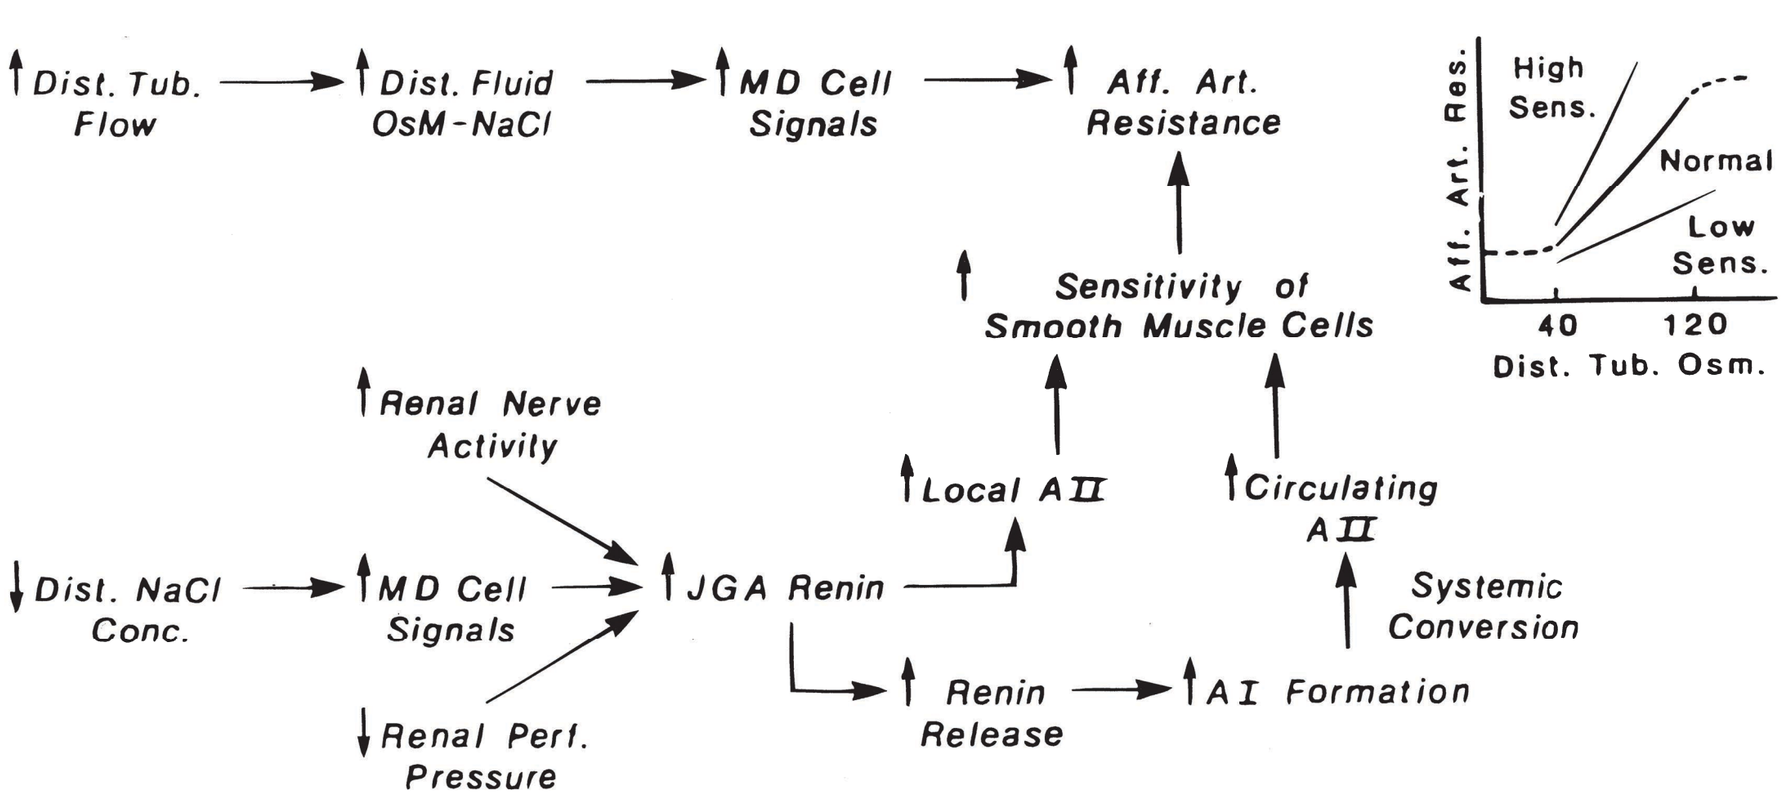

FIGURE 3.20 The modulator hypothesis for postulated interactions between the tubuloglomerular feedback mechanism and the intrarenal renin–angiotensin system. Flow-related changes in the tubular fluid concentration can elicit signals from macula densa (*MD*) cells to vascular contractile cells independent of angiotensin levels. Changes in the angiotensin II (*A II*) concentration influence the sensitivity or responsiveness of macula densa cells or of vascular smooth muscle cells to the signals coming from the macula densa cells. *A I*, angiotensin I; *A II*, angiotensin II; *Aff. Art.*, afferent arteriole; *JGA*, juxtaglomerular apparatus.

the AT_{1A} and AT_{1B} receptor mediate Ang II–induced Ca^{2+} signaling in smooth muscle cells and renal vasoconstriction. Evidence for the role of AT_{1B} receptors derives from mice lacking a functional AT_{1A} receptor.[36,138–141]

The AT_1 receptor is primarily coupled to the GTP-binding protein $G\alpha_{q11/12}$, whose activation leads to the triggering of several signaling pathways, including the stimulation of PLC_β. The receptor activation of protein tyrosine kinases leads to somewhat slower stimulation of phospholipase $C\gamma$. Phospholipases D and A_2 may also be activated, favoring the release of DAG and phosphatidic acid from phosphatidylcholine and arachidonic acid, respectively. The PLCs act on membrane-bound phosphoinositides to yield DAG and IP_3. DAG stimulates protein kinase C, whereas IP_3 diffuses through the cytosol to activate IP_3-sensitive receptors/release channels on membranes of the sarcoplasmic reticulum, triggering Ca^{2+} release to the cytosol. The mobilized Ca^{2+} triggers a complex array of events. Calcium-sensitive chloride channels may be stimulated to promote chloride efflux and depolarization of the plasma membrane. Such a signal will activate voltage-gated L-type calcium channels to allow for influx down a very steep gradient, from 1 to 2 mM in the extracellular fluid to 100 to 200 nM in the cytosol. Calcium release from internal stores also signals store-operated cation channels to open and allow further Ca^{2+} entry. AT_1 receptor activation may also trigger voltage-dependent Ca^{2+} channels independent of Ca^{2+} release from intracellular stores. As discussed earlier, afferent arteriolar contractions induced by Ang II is dependent on Ca^{2+} entry through voltage-gated channels, whereas efferent arterioles are not affected by L-type channel blockers but are influenced by T-type channel blockers. Recent studies indicate that AT_1 receptors rapidly activate NADPH oxidase to produce superoxide anion by the afferent arteriole. This leads to Ca^{2+} mobilization mediated by RyR through a direct action and/or one mediated by ADP ribosyl cyclase and the production of cADP ribose that sensitizes RyR/release channels on the sarcoplasmic reticulum to increase $[Ca^{2+}]_i$.[1,2,36,107,142,143]

The AT_2 receptor is characterized by a high affinity to the nonpeptide antagonists PD123319, CGP 42112, and Compound 21, and has a sequence 33% identical to that of the AT_1 receptor. Its high expression in fetal tissue suggests a role in embryonic development. This receptor has a typical pattern of seven transmembrane domains and is coupled to a G protein. Recent studies suggest that AT_2 receptors exert modulatory actions to partially counteract the effects caused by AT_1 receptor activation. AT_2 receptor activation increases bradykinin and NO levels, leading to increases in cGMP and vasodilation. AT_2 receptor activity may be upregulated during chronic salt deprivation. AT_3 and AT_4 receptors may be selective for angiotensin with amino acids 1 to 7 and Ang IV (angiotensin with amino acids 3 to 8), although they appear to play a minor role in regulating renal hemodynamics.[107,126,138,144]

Ang II receptors are regulated in response to different physiologic conditions. It is noteworthy that glomerular and vascular receptors are regulated differently from proximal tubular receptors. A low salt diet and high levels of Ang II lead to the downregulation of arteriolar and mesangial cell AT_1 receptors and the upregulation of tubular receptors.[140,145,146]

Actions of Ang II on the Renal Microvasculature

Ang II elicits dose-dependent AT_1-mediated decreases in RBF and GFR. The decreases in GFR are often smaller than the decreases in RBF such that filtration fraction increases. The increased vascular resistance is due to both afferent and efferent arteriolar constriction, and glomerular capillary pressure is well maintained. At high concentrations the glomerular filtration coefficient is reduced. Ang II produces more pronounced vasoconstriction when endogenous levels are low, presumably because of receptor upregulation and when vasodilator prostaglandins are blocked by COX inhibitors. Larger Ang II effects are also noted after the endothelial production of NO is blocked. As mentioned earlier, Ang II can potentiate TGF-mediated changes in preglomerular vascular tone. The multiple effects of Ang II are illustrated in Figure 3.21. In addition

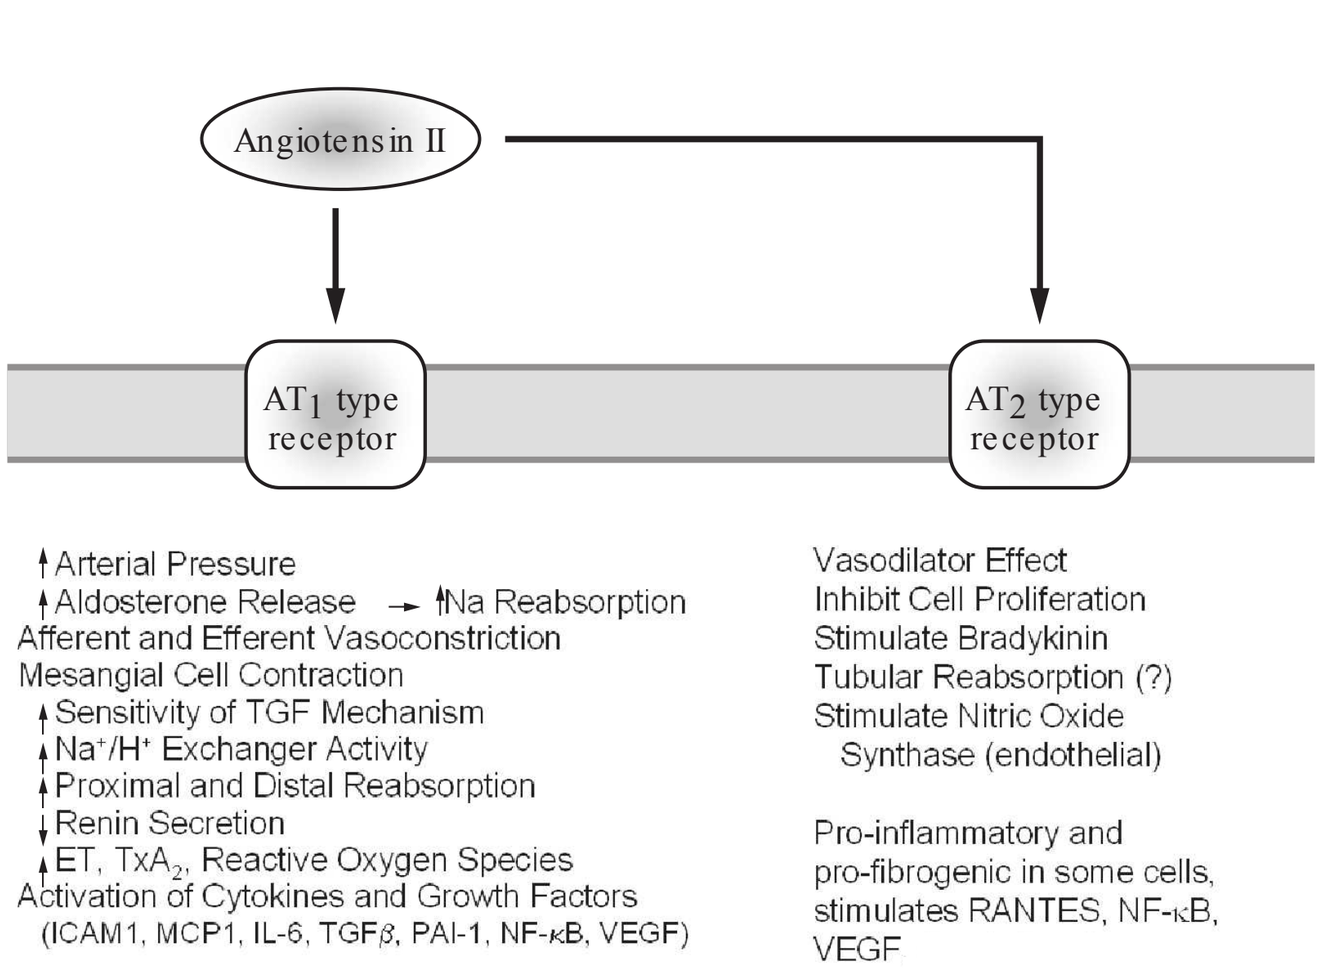

FIGURE 3.21 Multiple actions of angiotensin II on renal function mediated by AT_1 and AT_2 receptors. *ET*, endothelin; T_XA_2, thromboxane; *ICAM1*, intercellular adhesion molecule 1; *MCP1*, monocyte chemotactic protein 1; *IL-6*, interleukin 6; *TGFβ*, transforming growth factor β; *PAI-1*, plasminogen activator inhibitor 1; *NF-κB*, nuclear factor kappa light chain enhancer of activated B cells; *VEGF*, vascular endothelial growth factor.

to these effects, Ang II influences the medullary circulation, notably at concentrations lower than those required to elicit overall vasoconstriction in the cortex. This notion is supported by the finding that the Ang II receptor density is much higher in the medullary vessels and in the interstitial cells than in the postglomerular cortical vasculature.[1,2,36]

The effects of endogenous Ang II are observed using angiotensin receptor antagonists or ACE inhibitors in states when the prevailing Ang II levels are high. During sodium restriction, RBF is increased after the AT_1 receptor blockade, whereas the GFR responses are smaller and more variable; filtration fraction usually declines. Renin inhibition produces similar results, and combined renin and angiotensin inhibition causes decreases in RVR and increases in GFR. Activation of the AT_1 receptor is primarily responsible for the renal vascular effects of the endogenous Ang II on afferent and efferent arterioles and on K_f. Whole-kidney autoregulation is not affected by AT_1 receptor blockade or ACE inhibition, although the contribution of the TGF mechanism may be reduced and the plateau of the autoregulation relationship is elevated.[1,2,36]

Endothelium-Derived Vasoactive Factors

Nitric Oxide

Endothelial cells release NO in response to many stimuli, including mechanical shear stress and hormone, paracrine, and autocrine factors, that increase $[Ca^{2+}]_i$. NO is formed by vascular endothelial cells from the amino acid L-arginine via NOS, which is a soluble $NADPH^-$, and the Ca^{2+}-calmodulin–dependent citrulline-forming enzyme that requires two cosubstrates (O_2 and NADPH) and four cofactors (heme, flavin mononucleotide, flavin adenine dinucleotide, and tetrahydrobiopterin). As shown in Figure 3.7, several agents induce their vascular effects via endothelial cell eNOS activation and the release of NO. Examples include factors that stimulate the M_1-muscarinic receptor (acetylcholine), the B_2-kinin receptor, the α_2-adrenoceptor, the purinergic receptors (ATP, ADP), and the ET_B receptor. The rate of renal NO production is higher in the medulla than in the cortex. NO and nitrosamines have short biologic half-lives of less than 10 seconds, which is especially shortened by hemoglobin scavenging and in oxygenated solutions in the presence of the superoxide anion ($\cdot O_2^-$), by a mechanism involving the production of peroxynitrite (NO_3^-) from NO. In the same manner, NO acts to scavenge $\cdot O_2^-$.[147–149]

The basal release of NO tonically maintains a low RVR at rest, acting to buffer vasoconstriction produced by Ang II, ET-1, catecholamines, and other endogenous factors. Acute inhibition of basal NO production causes renal vasoconstriction, with decreases of 25% to 35% in RBF and reductions in cGMP levels in the interstitium and the urine. GFR responses are smaller and tend to be unchanged or decrease about 10%. Thus, the filtration fraction is increased. Basal NO dilates both the preglomerular vasculature (arcuate and interlobular arteries, afferent arterioles) and the efferent arterioles. NO also appears to contribute to the increased or maintained glomerular filtration coefficient. Endothelial factors mediate or modulate pressure-dependent responses of vascular segments exhibiting autoregulatory behavior. Note however, that NO does not fit a mediator role in this scheme because increased pressure and shear stress cause increased production of NO, a vasodilator, at the same time the responsive vascular elements exhibit vasoconstriction. NO inhibition results in renal vasoconstriction, but the steady-state autoregulatory RBF responses to changes in perfusion pressure are unaffected and remain highly efficient.[2,149,150]

NO-induced renal vasodilation is mediated by cGMP-dependent and perhaps a cGMP-independent system. The latter appears to involve cGMP cross-talk with the cAMP pathway, with cGMP inhibiting cAMP breakdown by PDE_3, more so than the activation of cGMP-protein kinase activity. Part of the dilatory response to NO may be mediated through increased K^+ channel activity and reduced production of 20-HETE.[62,118,151]

Although NO does not affect overall steady-state autoregulatory adjustments in RVR, NO attenuates the strength and rapidity of the myogenic adjustments in resistance. NO also attenuates the strength of TGF responses to increased distal tubular flow. The inhibition of NOS leads to greater relative decreases in medullary blood flow than in cortical blood flow. A NO blockade usually reduces renin release and responsiveness to reductions in perfusion pressure.[92,93,152,153]

Endothelial NO synthase is localized to the endothelial cells all along the renal vasculature (the interlobular arteries, the afferent and efferent arterioles, the glomerular capillaries, and the vasa recta) and the thick ascending limb of the Henle loop. Targeting of eNOS to specialized plasma membrane invaginations termed caveolae is required for maximal eNOS activity. Neuronal NO synthase (nNOS) is present primarily in epithelial cells (thick ascending limb of the Henle loop, the macula densa, the collecting duct). NO inhibits tubular transport along the nephron. An inducible form of NO synthase is normally quiescent but is capable of producing large amounts of NO in vascular smooth cells and mesangial cells during inflammation. An endogenous inhibitor of L-arginine cellular uptake and NOS activity is asymmetric dimethylarginine (ADMA) that is normally inactivated by NG-NG-dimethylarginine dimethylaminohydrolase (DDAH) to form L-citrulline. DDAH expression is found at the same sites as NO synthase. ADMA concentrations are elevated during states of oxidative stress and disease.[154–156]

Endothelin

Endothelin refers to a family of long lasting vasoconstrictor peptides that act locally as paracrine hormones. ET-1, -2, and -3, each a 21 amino-acid peptide, are constitutively released. ET-1 is the major form synthesized and secreted by endothelial cells of the preglomerular vasculature and the vasa recta

and by the medullary collecting ducts. Endothelin-converting enzyme (ECE) is the main enzyme responsible for the genesis of ET-1 from prepro-ET-1 (<200 amino acids); chymase and matrix metalloproteinase II are also involved in the production of ET intermediates. Ang II is a potent stimulus for ET-1 production. Other simulants include bradykinin, ATP, platelet activating factor, thrombin, and shear stress. Neutral endopeptidase 24-11 degrades and inactivates ET-1. Cytokines such as interleukin-1-beta (IL-1β) stimulate ET-1 production. The two known receptor types, ET_A and ET_B, are G-protein coupled and lead to IP_3 and cyclic ADP ribose formation, PKC activation, and Ca^{2+} mobilization, in addition to Ca^{2+} entry. ET_A receptors are predominantly found on vascular smooth muscle cells. ET_B receptors are localized on endothelial and tubular cells as well as vascular smooth muscle cells. The afferent arteriolar constriction produced by ET-1, like that caused by Ang II, is dependent in part on Ca^{2+} entry through voltage-dependent L-type channels. The action of ET-1 on efferent arterioles appears to depend exclusively on the mobilization of intracellular Ca^{2+} and/or entry through voltage-independent cation channels. The highest concentration of ET-1 in the body exists in the renal medulla, where it is synthesized by collecting duct cells and acts in a paracrine/autocrine manner to cause natriuretic and diuretic effects through ET_B receptors via the stimulation of NO. In addition, ET-1 has inotropic, chemotactic, and mitogenic properties. Overall, ET-1 increases blood pressure and vascular tone.[156–158]

The vascular actions of ET-1 reflect a combination of vasoconstrictor ET_A and ET_B receptors on smooth muscle cells and ET_B receptors on endothelial cells, which cause vasodilation mediated by NO. Concurrent ET-1 stimulation of ET_A + ET_B receptors causes net renal vasoconstriction, and the inhibition of ET_B receptor activation leads to more pronounced vasoconstriction. Thus, endothelial ET_B receptors buffer the constriction caused by the stimulation of both ET_A and ET_B receptors on the smooth muscle cells. Nevertheless, selective stimulation of vascular ET_B receptors using a pharmacologic agonist elicits renal vasoconstriction. Thus, there appears to be a complex interaction between receptor signaling. Endothelial ET_B receptors in the kidney and lung also seem to function as nonsignaling clearance receptors, effectively reducing the local concentration of ET-1, and thereby attenuating vasoconstriction.[150,159]

Exogenous ET-1 reduces RBF by stimulating both ET_A and ET_B receptors to cause the constriction of the arcuate and interlobular arteries and the afferent and efferent arterioles. Glomerular capillary pressure is relatively well maintained in the presence of reduced RBF. The decrease in GFR is primarily mediated by reductions in plasma flow and K_f. The reduction in K_f appears to be mediated by a secondary release of Ang II, eicosanoids, or neurotransmitters. The preglomerular vasculature has equal proportions of ET_A and ET_B receptors as compared to a ratio of 2:1 on their smooth muscle cells devoid of endothelial cells. Under basal conditions, ET-1 exerts dual actions on the vasculature that are equal and opposite. The ET_A receptor blockade produces renal vasodilation due to a 5% to 10% increase in RBF, whereas ET_B receptor antagonism leads to constriction of 5% to 10%. Although ET-1 contributes to basal vascular tone, it does not interfere with renal autoregulatory mechanisms.[2,150,160,161]

ET_A and ET_B receptors stimulate $[Ca^{2+}]_i$ in smooth muscle cells of preglomerular arteries/arterioles through a combination of mobilization and entry pathways. Low concentrations of ET-1 activate Ca^{2+} entry channels, with higher concentrations mobilizing intracellular Ca^{2+} via the PLC-IP_3R and NADPH oxidase/cADPR/RyR pathways. Calcium channel blockers reduce the magnitude and duration of ET-1–induced renal vasoconstriction. The afferent arteriolar constriction produced by ET-1, similar to that caused by Ang II, is dependent in part on Ca^{2+} entry through voltage-dependent L-type channels as well as mobilization in intracellular Ca^{2+} stores. The action of ET-1 on efferent arterioles appears to depend exclusively on the mobilization of intracellular Ca^{2+}. ET-1 inhibits renin synthesis and release by ET_A and ET_B receptor stimulation of $[Ca^{2+}]_i$ in juxtaglomerular granular cells.[13,20,162]

ET-1 acts on glomerular mesangial cells to cause the contraction and stimulation of mitogenesis. High concentrations of ET-1 that reduce sodium excretion increase plasma renin activity, presumably via the macula densa mechanism. In addition, ET-1 may affect neurotransmission, eicosanoid synthesis, and ANP synthesis and release. The activation of endothelin receptors causes the release of eicosanoids and NO from endothelial cells and ANP from myocytes.[157,158,163]

Heme Oxygenase and Carbon Monoxide

Heme oxygenases (HO) are microsomal enzymes that catalyze the degradation of heme to form iron, biliverdin, and carbon monoxide (CO). The vascular actions of CO include the direct relaxation of vascular smooth muscle cells and the indirect contraction through the inhibition of NOS. Similar to NO, CO produces vasodilation by stimulating soluble guanylyl cyclase in smooth muscle cells to signal through the cGMP/PKG pathway. CO also may bind directly to Ca^{2+}-activated BK channels to depolarize the plasma membrane. A primary action of CO is to attenuate vasoconstriction produced by agents such as Ang II and catecholamines, with greater buffering effects in the absence rather than in the presence of NO. Nevertheless, CO can dose-dependently increase NADPH oxidase-dependent O_2^- production and constrict interlobar and interlobular arteries via thromboxane thromboxane prostanoid (TP) receptor activation, perhaps involving isoprostanes, effects inhibited by the O_2^- scavenger biliverdin. Thus, the vascular response to CO is mixed in that CO can elicit signaling leading to vasodilation and vasoconstriction, the net effect depending on experimental conditions.[164,165]

HO-2 is constitutively expressed in the kidney, mainly in proximal tubules with relatively weak presence in the renal vasculature. HO-1 is inducible during inflammation

and oxidative stress. The influence of endogenous HO-2 metabolites on renal hemodynamics appears to be minor under physiologic conditions. Pharmacologic inhibition of HO (chromium mesoporphyrin [CrMP]) reduces urinary excretion of sodium and water even under conditions where there are no effects on arterial pressure, RBF, GFR, or plasma renin activity, both in control animals and after NOS inhibition, suggesting a primary tubular effect of endogenous CO. Likewise, HO inhibition with CrMP does not alter afferent arteriolar diameter of juxtamedullary nephrons of normal rats. However, other studies using SnMP to inhibit HO report decreases in RBF with variable responses in GFR. Another study shows that acute inhibition of renal medullary HO activity and CO production reduces medullary blood flow and sodium excretion and blunts pressure natriuresis. Chronic HO inhibition produces hypertension that is salt sensitive. Mice deficient in HO-2 are normotensive with normal RBF during basal conditions or during NOS inhibition, whereas Ang II paradoxically produces less pronounced renal vasoconstriction in the absence of HO-2. Other investigators report that the pressor and renal vasoconstrictor responses to low levels of Ang II are magnified by inhibition of HO activity (tin mesoporphyrin) in normal euvolemic animals.[164,166–169]

Both HO-1 and HO-2 mRNA are expressed in macula densa cells, and HO metabolites inhibit TGF. Increased HO activity attenuates TGF-induced vasoconstriction through macula densa release of CO and biliverdin during increased salt reabsorption. The CO effect on TGF is linked to cGMP pathway and biliverdin to reduce O_2^- levels. Renal HO-1 induction (hemin, $SnCl_2$) dilates afferent arteriolar diameter and attenuates juxtamedullary afferent arteriolar autoregulatory responses to increases in renal perfusion pressure, an effect mimicked by CO acting through cGMP/PKG signaling but not biliverdin. These results are consistent with findings that increasing CO levels directly or with hemin administration increase RBF, urine flow, and sodium excretion. Whether the effects involve myogenic and/or TGF mechanisms await investigation.[164,170,171]

Hypoxia-induced HO upregulation protects renal tissue from acute and chronic injury. Activation of HO has an antioxidant effect by degrading the heme moiety of heme-containing enzymes such as NOS, COX-2, and cytochrome P450 monooxygenase. HO can attenuate the production of reactive oxygen species through its heme degradation and production of CO, biliverdin/bilirubin, and free iron. Excess free heme catalyzes ROS formation, which may lead to endothelial cell dysfunction, vasoconstriction, and tissue damage commonly associated with pathologic cardiovascular–renal conditions. Increased HO-1 activity and the metabolite bilirubin suppress NADPH oxidase activity and O_2^- production in vascular smooth muscle cells.[164,172]

Hydrogen Sulfide

Endogenous hydrogen sulfide (H_2S) is a recently discovered vasoactive gas transmitter (joining NO and CO in this classification). Cystathionine-γ-lyase and -β-synthetase are the main enzymes forming H_2S from L-cysteine or L-homocysteine in endothelial and smooth muscle cells of the vasculature wall and erythrocytes, physiologically activated by Ca^{2+}-calmodulin. H_2S is inactivated by binding to hemoglobin to form sulfhemoglobin, As an endothelial-derived relaxing factor, H_2S produces concentration-dependent dilation of large conduit arteries and small resistance arterioles, primarily acting directly to open K_{ATP} channels to hyperpolarize vascular smooth muscle cells. In contrast to NO and CO, H_2S does not stimulate soluble guanylate cyclase. Being a reducing agent, H_2S appears to alter cellular redox status. Low concentrations of H_2S may cause vasoconstriction reducing NO availability by reacting with NO to form a nitrosothiol compound and inhibit eNOS. H_2S and the H_2S donor NaHS downregulate cAMP production in vascular smooth muscle cells, producing vasoconstriction, and in juxtaglomerular granular cells, inhibiting renin release. Physiologic levels of H_2S are also angiogenic, antiproliferative, and anti-inflammatory. Mice deficient in a synthetic enzyme have reduced H_2S levels, reduced endothelium-mediated vasodilation, and develop hypertension.[173–176]

Little is known about H_2S effects on the renal microcirculation. H_2S is produced in the kidney and the exogenous H_2S donor NaHS exerts diuretic, natriuretic, and kaliuretic effects in association with increases in GFR and RBF. Conversely, acute intrarenal inhibition of H_2S production reduces GFR and sodium excretion without affecting RBF. Chronic inhibition of H_2S synthesis reduces RBF but not GFR because sodium excretion decreases in association with the development of hypertension. The actions of H_2S on afferent and efferent arterioles and TGF activity await investigation.[177,178]

Because H_2S is oxidized in mitochondria in pO_2-dependent manner and ambient pO_2 is lower in the renal medulla than the cortex, H_2S accumulates in medullary regions. High H_2S concentrations in the relatively hypoxic renal medulla function as an oxygen sensor that acts to increase local O_2 by increasing medullary blood flow in combination with the direct inhibition of mitochondrial respiration.[179]

Arachidonic Acid Metabolites

Renal prostaglandins, or eicosanoids, are biologically active fatty acid products of arachidonic acid that contribute to the regulation of renal hemodynamics. They are synthesized intracellularly and immediately released to act locally on the renal vasculature as paracrine/autocrine agents. Free intracellular arachidonic acid can be metabolized on demand via one of three major enzymatic pathways: cyclooxygenase, lipoxygenase, or cytochrome P-450 monooxygenase. Depending on cell types, the net production of the various metabolites may cause vasoconstriction under some conditions and vasodilation during others. The multiple products of this cascade are depicted in Figure 3.22. Phospholipase A_2 (PLA_2) catalyzes the formation of arachidonic

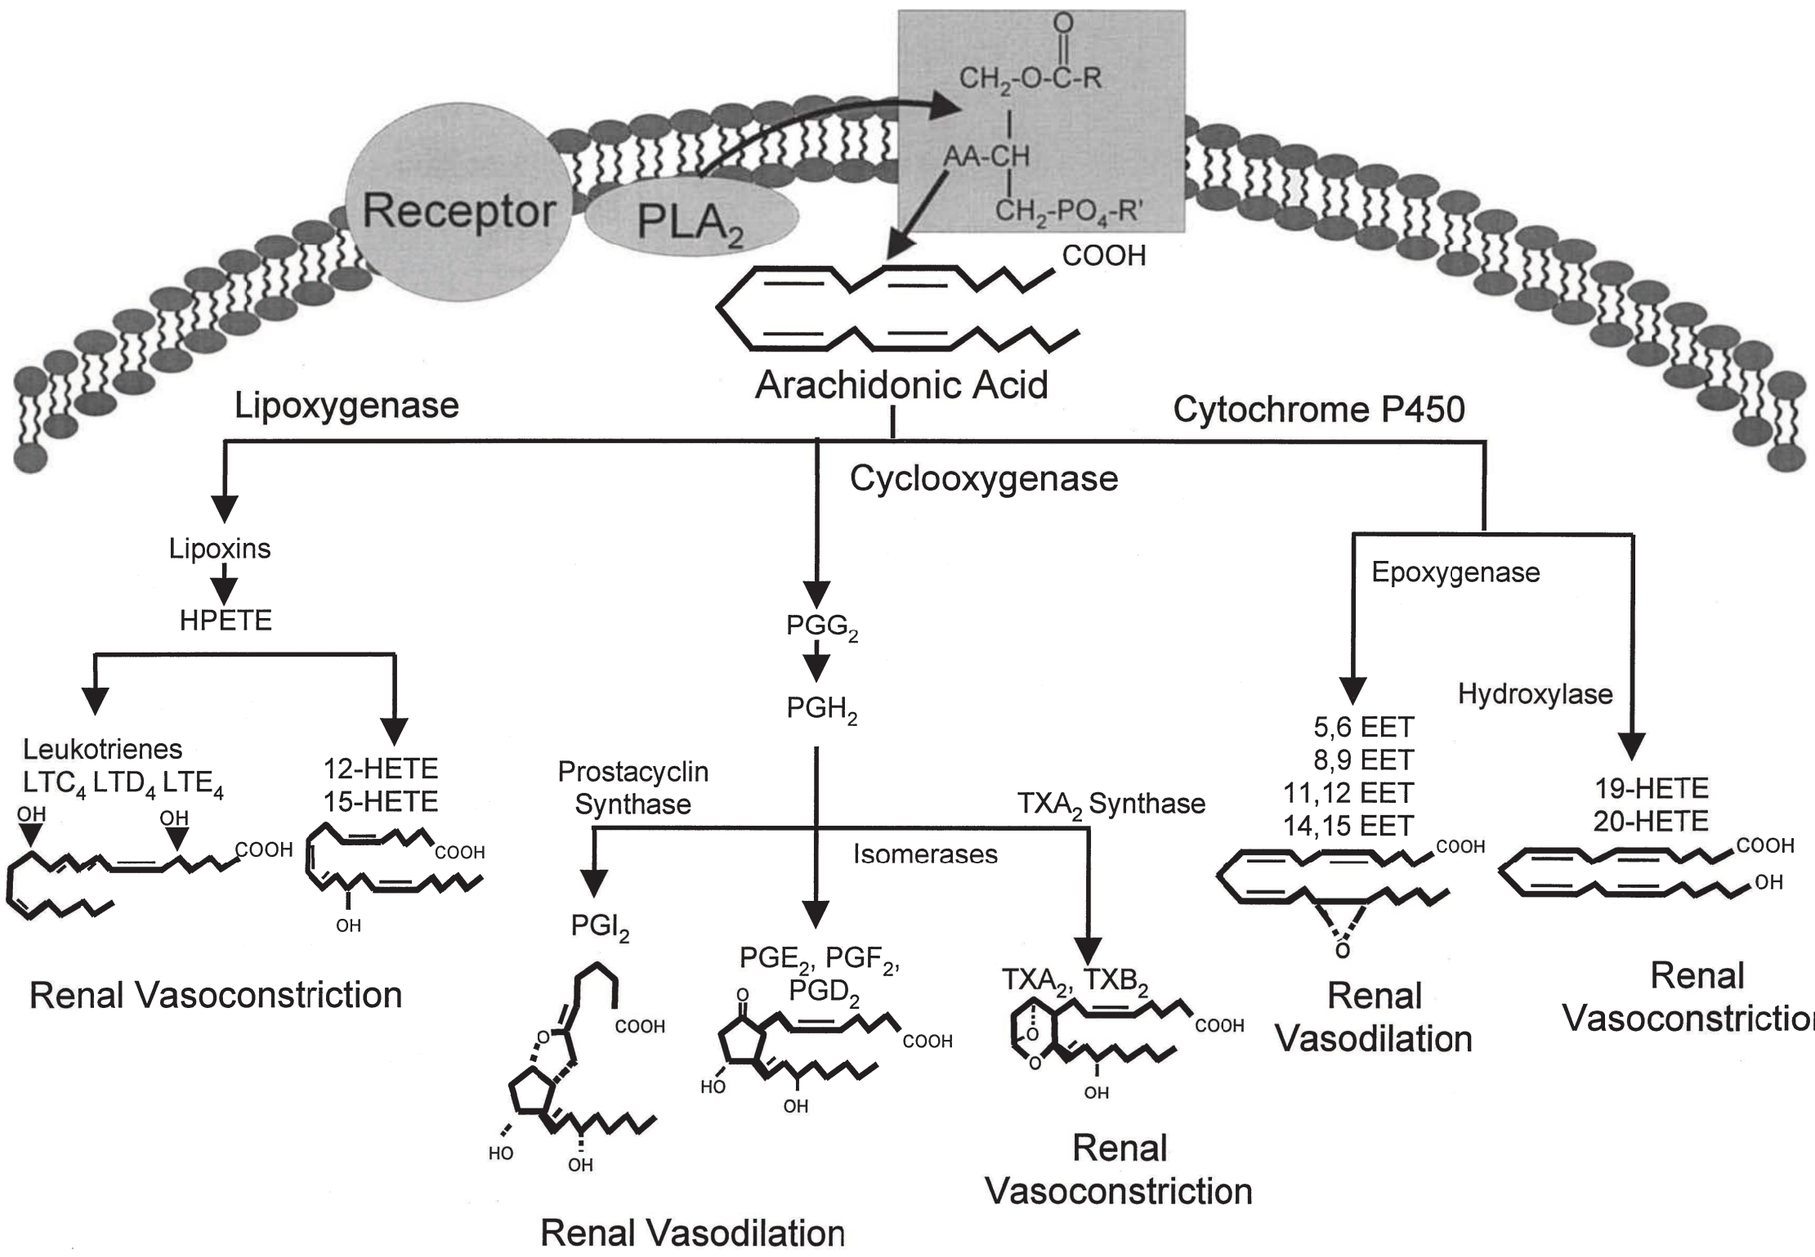

FIGURE 3.22 Three major pathways of eicosanoid synthesis from arachidonic acid involving cyclooxygenase, lipoxygenase, and cytochrome P-450 monooxygenase enzyme systems. acid, an unsaturated 20-carbon fatty acid, from membrane phospholipids.[2]

A key regulatory, rate-limiting step for prostaglandin synthesis is the conversion of arachidonic acid to prostaglandin (PG) G_2/H_2 by COX. There are two major COX enzymes. COX-1, a constitutive enzyme, is found in renal arteries and arterioles, glomeruli, cortical and medullary collecting ducts, and medullary interstitial cells. COX-2 is a regulated constitutive enzyme that is important in development, and in adult animals is commonly activated by growth factors, inflammatory states, glucocorticoids, and low salt diet. Renal COX-2 mRNA is localized primarily to epithelial cells of the cortical thick ascending limb that includes the macula densa region and medullary interstitial cells, with greater amounts in the papilla than the cortex. COX-2 expression is noticeably absent from arterioles, glomeruli, and cortical or medullary collecting ducts, sites of COX-1 expression; COX-2 is also expressed in endothelial cells of medullary vasa recta. COX-2 expression in thick ascending limb cells and macula densa cells varies with salt diet, increasing during chronic sodium restriction and decreasing during sodium loading. COX-2 expression in medullary interstitial cells is induced by water deprivation and high interstitial osmolality, high levels of Ang II and AVP, as well as growth factors and cytokines through MAP kinase pathways. Leukotrienes are synthesized by another major pathway involving the enzyme lipoxygenase. Vasoactive metabolites are also formed via the cytochrome P-450 monooxygenase pathway. Medullary tubular and interstitial cells have a larger synthetic capacity than the vasculature in the cortex. Endothelial cells produce PGE_2 and PGI_2, whereas thromboxane A_2 seems to derive from vascular smooth muscle cells and mesangial cells.[118,180–184]

Prostaglandins

General stimuli for renal prostaglandin synthesis are renal vasoconstriction and states of volume depletion and hypoperfusion. Anesthesia, surgery, and associated stress may exacerbate prostaglandin production. The diuretics ethacrynic acid and furosemide also stimulate renal release of prostaglandins. Many vasoactive receptor agonists stimulate phospholipases that promote the release of arachidonic acid from membrane phospholipids. The stimulation of PGE_2 and PGI_2 production by Ang II is well characterized. In turn, the vasodilatory PGE_2 and PGI_2 usually buffer the vasoconstriction elicited by Ang II and stimulate renin release from juxtaglomerular cells. Other stimulants include ET_A receptor agonists. Vasodilators such as acetylcholine and bradykinin stimulate the production of PGE_2 or PGI_2 as well as NO. In addition, acetylcholine may stimulate the production of thromboxane A_2. The vasoactive peptides Ang II, ET-1, vasopressin, acetylcholine, and bradykinin increase the

availability of the substrate, arachidonic acid, secondary to membrane receptor–mediated Ca^{2+} influx and the activation of phospholipase A_2. Phospholipase A_2 is activated by increased activity of the Ca^{2+}-calmodulin complex, increased production of DAG, or phospholipase C-mediated phosphorylation of lipocortin, a membrane-bound enzyme that normally inhibits phospholipase A_2. Thus, there is a common pathway by which many vasoconstrictor agents can increase the production of COX-derived prostaglandins, primarily vasodilatory PGE_2 and PGI_2, which in turn can counteract vasoconstriction. Vasodilatory prostaglandins produced by the endothelium of glomerular arterioles and mesangial cells exert net effects to stimulate adenylate cyclase and the formation of cAMP and the activation of protein kinase A. α-Adrenergic neurotransmission can be inhibited prejunctionally and postjunctionally by prostaglandins.[71,185,186]

Four forms of PGE_2 receptors (termed EP_1 through EP_4) have been identified and cloned. The EP_4 receptor, coupled via $G\alpha_s$-proteins to generate cAMP and activate protein kinase A, predominates along the preglomerular vasculature and mediates the principal vasodilator actions of PGE_2. Similar actions are exerted by the single IP receptor for PGI_2 (prostacyclin). Low concentrations of the prostaglandins PGE_2 and PGI_2 normally formed by the arterial vasculature exert part of their physiologic effects by attenuating the actions of vasoconstrictors, with larger amounts acting as vasodilators that increase RBF. The buffering action of PGE_2 and PGI_2 in the preglomerular vasculature is primarily mediated by the ability of cAMP and protein kinase A activation to inhibit IP_3-induced release of Ca^{2+} from internal stores. A low density of a vasoconstrictor receptor (EP_1 or EP_3) may counteract some of the net dilation. The EP_1 receptor increases Ca^{2+} mobilization. The EP_3 receptor inhibits the production of cAMP via a pertussis-toxin-sensitive $G\alpha_i$ protein. EP_2 receptors, which act through a $G\alpha_s$ protein to increase cAMP in tubules, appear to be absent from the renal vasculature under normal conditions. Arachidonic acid dilates the isolated interlobular artery and afferent arteriole; a smaller response occurs in efferent arterioles. Intrarenal infusions of arachidonic acid, PGE_2 or PGI_2 increase RBF and reduce renal resistance without affecting GFR. $PGF_2\alpha$ has little or no effect on the renal circulation. Local administration of small amounts of PGE_2 or its stable analog cause renal vasodilation and attenuate the constrictor effects of Ang II, thromboxane A_2, and norepinephrine. PGE_2 and PGI_2 dilate both afferent and efferent arterioles such that glomerular capillary pressure is constant when the stimulatory effects of the prostaglandins on Ang II formation are blocked. However, the application of PGE_2 from the interstitial side causes vasoconstriction of juxtamedullary nephrons, a response due to subsequent metabolism to a vasoconstrictor agent or the activation of EP_1 or EP_3 receptors.[60,185,187,188]

Endogenous prostaglandins regulate RBF and GFR by direct effects on vascular smooth muscle and indirectly by modification of the action of other hormones or neural stimuli. The vasodilator prostaglandins serve an important protective function and homeostatically balance the hemodynamic effects of vasoconstrictor substances. Studies of inhibition of COX activity indicate that the major function of COX-derived prostaglandins is to attenuate the influence of vasoconstrictor substances during the activation of the renin–angiotensin system, the sympathetic nervous systems, or both. These counteracting effects provide a balance between the vascular effects of Ang II and those of prostaglandins during variations in plasma volume and sodium intake. As is shown in Figure 3.23, blockade of the compensatory dilator action of prostaglandins promotes vasoconstriction when the renin–angiotensin and sympathetic nervous systems are

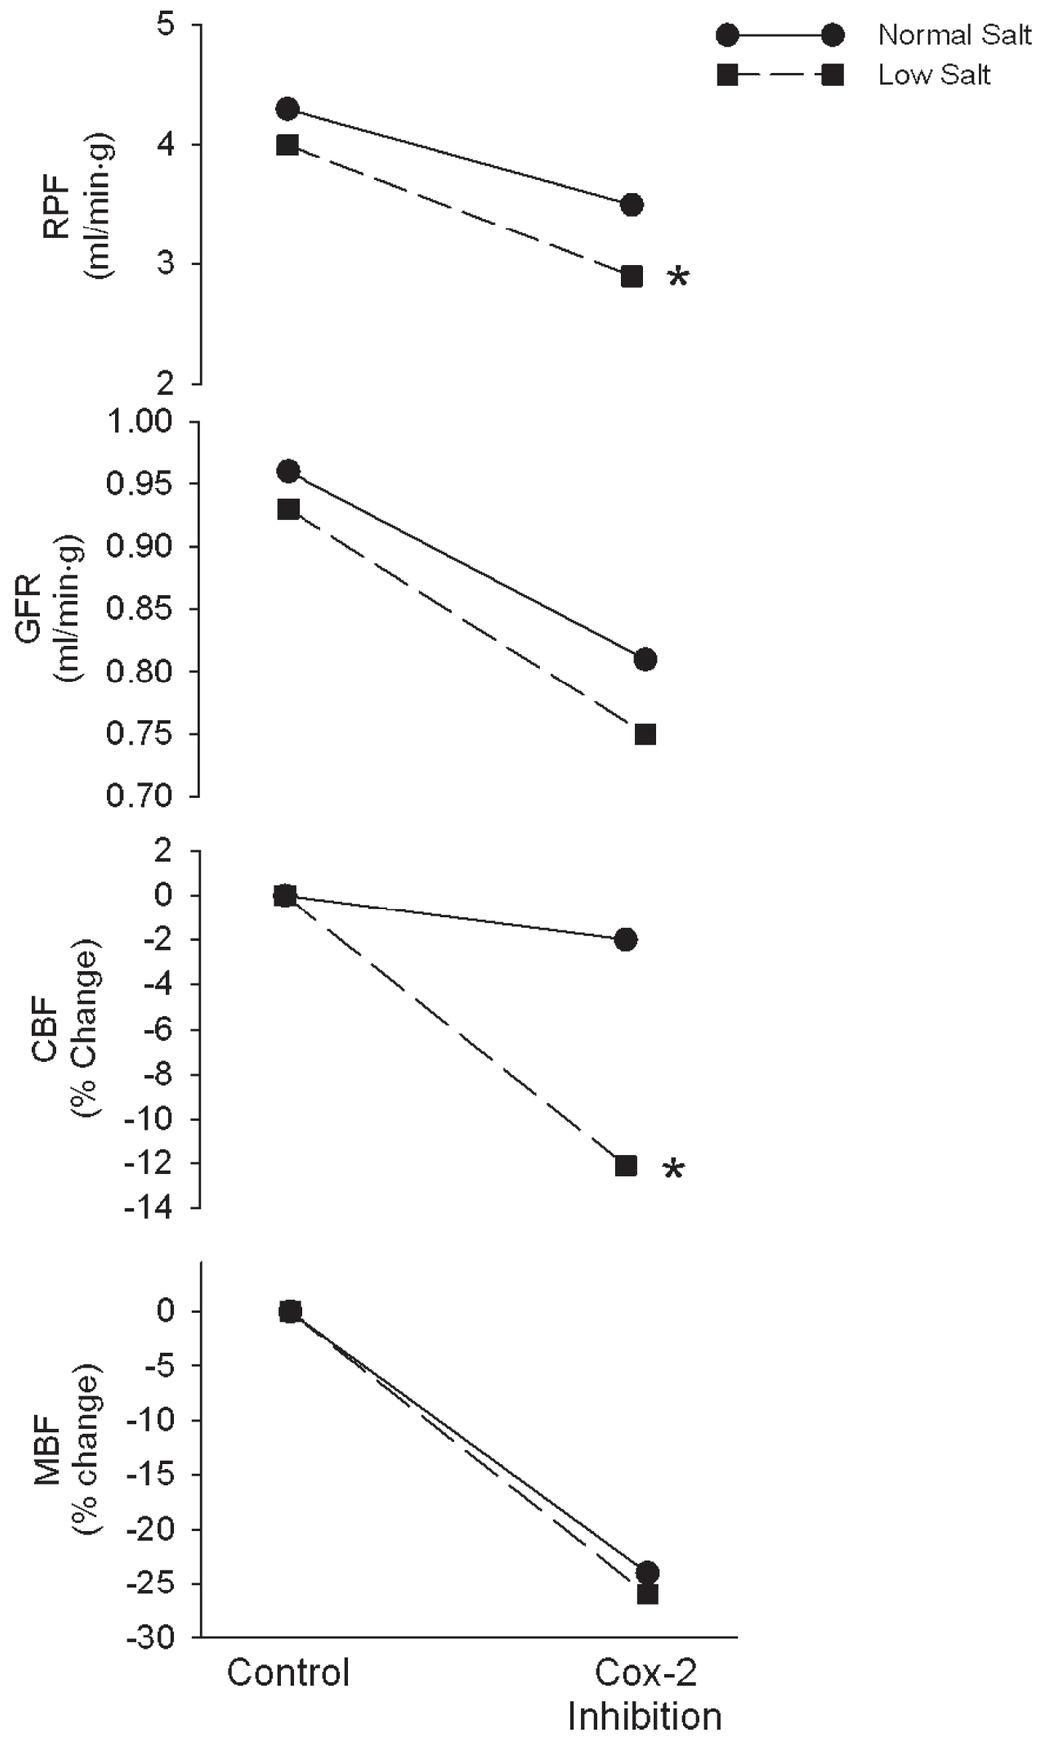

FIGURE 3.23 Renal plasma flow (*RPF*), glomerular filtration rate (*GFR*), cortical blood flow (*CBF*), and medullary blood flow (*MBF*) responses to the inhibition of cyclooxygenase (Cox-2, nimesulide) in anesthetized rats maintained on a normal salt diet (●) or on a low sodium diet (■). * $P < .05$. stimulated, such as during sodium depletion. Prostaglandins also antagonize the tendency for high concentrations of vasopressin to produce renal vasoconstriction. In contrast, in a healthy, unstressed individual with a normal plasma volume, the inhibition of prostaglandin synthesis has little or no effect on RBF and GFR (Fig. 3.23). Basic autoregulatory efficiency of whole-kidney RBF and GFR remains high even during the blockade of renal prostaglandin synthesis via the COX pathway. The inhibition of COX-2 produces renal vasoconstriction that may be greater in the medulla than in the cortex. During afferent arteriolar constriction induced by TGF, COX-2 generates vasodilatory metabolites in response to increased nNOS activity that attenuate the strength of feedback-mediated vasoconstriction.[2,116,182]

Renin release is increased by arachidonic acid, endoperoxides, PGE_2, and PGI_2. PGE_2 and PGI_2 act on their respective EP_4 and IP receptors on juxtaglomerular granular cells to stimulate renin release by stimulating adenylate cyclase activity and producing cAMP. COX inhibitors reduce renin release under basal as well as during stimulated conditions. α-Adrenergic neurotransmission can be inhibited prejunctionally and postjunctionally by prostaglandins.[13,116,121,133]

The COX-2 metabolite PGE_2 plays a key role in linking NaCl control of macula densa signaling to juxtaglomerular cells to regulate renin release and to afferent arterioles to regulate TGF. COX-2 activity in the macula densa increases in response to a salt deficient diet and to a loop diuretic, such as furosemide, with increases in PGE_2 production and renin release. nNOS in the same cells may serve as an upstream intermediate responding to salt transport. High levels of nNOS and COX-2 parallel each other, and the inhibition of nNOS causes a fall in COX-2 expression and an uncoupling to transport. On the other hand, high renin states suppress COX-2 expression in the cortical thick ascending limb and macula densa cells via Ang II and AT_1 receptors; ACE inhibition has the opposite effect. The recruitment of renin-containing cells retrograde along the afferent arteriole during chronic salt restriction or ACE inhibition appears to be COX-2 dependent as renin is restricted to juxtaglomerular cells during these stimuli in COX-2–deficient mice. Plasma renin activity is reduced in COX-2–null mice and also in nNOS-deficient mice. The inhibition of COX-2 produces renal vasoconstriction that may be greater in the medulla than the cortex.[117,182,189]

In disease states, endogenous vasodilator prostaglandins serve a protective role in maintaining renal function by means of their effects on vascular resistance, GFR, and renin release. The administration of nonsteroidal anti-inflammatory drugs to patients with clinical disorders such as advanced hepatic cirrhosis, severe congestive heart failure, and sodium depletion often produces deleterious effects with reductions in renal perfusion and GFR. In other pathophysiologic conditions, there may be enhanced production of the vasoconstrictor thromboxane A_2, which may contribute to the deterioration of renal function. Some of the vasoconstriction produced by Ang II may be mediated by thromboxane A_2 in pathophysiologic settings. Administration of a stable thromboxane-receptor agonist reduces RBF and GFR by causing afferent and efferent arteriolar constriction. K_f appears to be unaffected, although it is noteworthy that thromboxane A_2 causes the contraction of isolated glomeruli and cultured mesangial cells. As mentioned in the section on TGF, although very little thromboxane A_2 is produced under normal conditions, thromboxane plays a modulatory role in the preglomerular vasoconstriction associated with the activation of the TGF mechanism and the vasoconstrictor response to chronic Ang II infusion. The thromboxane A_2-PGH_2 receptor is coupled by the $G\alpha_q$ protein to the activation of phospholipase C, increased $[Ca^{2+}]_i$, and possible inhibition of adenylate cyclase. The renal vasoconstriction produced by thromboxane A_2 is primarily mediated by Ca^{2+} influx. Chronic activation of PKC appears to reduce the number of thromboxane A_2 TP receptors. In Ang II–dependent hypertension, the administration of COX-2 inhibitors decreases RBF and GFR due to increased RVR, reflecting a renal vasodilator action of intrarenal COX-2 metabolites; however, systemic vascular resistance is decreased, reflecting a vasoconstrictor role of COX-2 metabolites on the systemic circulation.[116,184,190]

Leukotrienes

Lipoxygenase enzymes convert arachidonic acid to leukotrienes (LTs), HETEs, and lipoxins (see Fig. 3.22). The major lipoxygenase products are monohydroxyeicosatetraenoic acids—12-HETE and 15-HETE—generated by glomeruli, mesangial cells, renal cortical tubules, and vascular tissues. LTs (LTB_4, LTC_4, LTD_4, and LTE_4) are hydroperoxy fatty acid products of the intermediate 5-hydroperoxyeicosatetraenoic acid (HPETE). Stereoisomers of 12-HETE are produced by different enzymatic pathways. The 12(S)-HETE isomer is predominantly produced in the cortex; however, the 12(R)-HETE is a primary biologically active metabolite of the cytochrome P-450 pathway. The renal vasculature constricts in response to 12(S)-HETE and 15-HETE due to the depolarization of smooth muscle cells, increased Ca^{2+} entry, and the activation of PKC. Vascular generation of 12-HETE is increased in pathologic conditions associated with oxidative stress and inflammation.[2,180,183,191]

Receptors for LTC_4 and LTD_4 have been identified on preglomerular arteries, glomeruli and cultured mesangial cells, and efferent arteriole. The infusion of LTC_4 or LTD_4 causes renal vasoconstriction, reduces GFR and filtration fraction, and activates the renin–angiotensin system. Leukotriene C_4 receptors are linked to ion channels, but specific mechanisms are not known. Some of the LT actions may be mediated by endothelial cells. LTD_4 is known to release NO in addition to activating a pertussis-toxin–sensitive G protein. Lipoxin A_4 increases renal plasma flow and GFR, with a small reduction in K_f. Interestingly, the effects are COX dependent and can be completely reversed by the inhibition of this enzyme. On the other hand, the ability of

lipoxin B_4 to decrease RBF and GFR is independent of COX activity.[180,183]

Cytochrome P-450 Metabolites

Vasoactive metabolites of the cytochrome P-450 pathway are produced by vascular smooth muscle cells, endothelial cells, renal tubular cells, and glomeruli. Arachidonic acid is oxygenated via NADPH-dependent microsomal monooxygenases. As is shown in Figure 3.22, epoxygenase enzymes are responsible for the production of epoxides or epoxyeicosatrienoic acids (EETs) (e.g., 11,12-EET and 14,15-EET). A second cytochrome P-450 pathway involves the ω-hydroxylase formation of 19- and 20-HETEs. The major metabolites of this pathway are EETs in the cortex and HETE in the medulla. Salt diet, Ang II and other hormones, and various pathophysiologic settings alter the renal cytochrome P-450 metabolism.[118,183,192–195]

Cytochrome P-450 ω-hydroxylase metabolites, in particular 20-HETE, participate in regulation of cortical and whole-kidney blood flow. Although rodent studies report effects of 20-HETE, studies in dogs and rabbits have failed to show an effect of cytochrome P-450 inhibition on autoregulation and pressure natriuresis. In isolated rat vessels, transmural pressure stimulates ω-hydroxylase activity to produce 20-HETE, which is thought to participate in myogenic vasoconstriction. Cytochrome P450-4A–derived eicosanoids may also participate in the renal hemodynamic effects of Ang II and endothelin. Products of the cytochrome P-450 pathway potentiate control of preglomerular vasomotor tone by the juxtaglomerular apparatus. Inhibition of P-450 metabolites blunts TGF activity, whereas the luminal perfusion of 20-HETE restores TGF responses. 20-HETE causes vasoconstriction by the inhibition of tonically active K^+ channels, thereby causing depolarization and activation of voltage-gated Ca^{2+} channels and increases intracellular Ca^{2+}.[118,181,183]

Epoxygenase metabolites elicit variable vascular responses. 11,12-EET is an endothelial-derived factor distinct from NO that produces vasodilation in interlobular arteries and afferent arterioles mediated by membrane hyperpolarization following the activation of cAMP/protein kinase A and of K^+ channels, actions independent of the vascular endothelium or COX activity. 5,6-EET or 8,9-EET induces vasoconstriction with a decrease in GFR, mediated in part by thromboxane TP receptor activation. However, COX inhibition changes the renal response to these EETs to vasodilation and an increase in GFR. Inhibition of epoxygenase activity enhances afferent arteriolar autoregulation. Not clear is whether epoxygenase/EET actions blunt the pressure-induced myogenic response, or TGF, or both. EETs, in particular 11,12-EET, have now been identified as being an endothelial-derived hyperpolarizing factor and activate potassium channels, thus increasing the membrane potential, leading to renal vasodilation and attenuated responses to vasoconstrictor influences.[183,196,197]

Isoprostanes such as 8-epi-$PGF_{2\alpha}$ are vasoconstrictor metabolites related to prostaglandins. They are stable products of nonenzymatic lipid peroxidation of arachidonic acid, formed in and released from cell membranes and excreted in urine. Isoprostane production is stimulated by peroxynitrate, a reactive oxygen species resulting from NO scavenging by superoxide anion.[114,198,199]

Kallikrein–Kinin System

Plasma and glandular/tissue kallikreins are distinct serine protease enzymes acting on kininogens (inactive α_2-glycoproteins) to form the biologically active nonapeptide bradykinin and also the decapeptide lysyl-bradykinin (kallidin). It is unlikely that circulating kinins affect the renal microcirculation because they are rapidly inactivated enzymatically by endothelial-bound kininase II (ACE) and neutral endopeptidase. Within the kidney, tissue kallikrein and its substrate, kininogen, are located predominantly in the distal convoluted and cortical collecting tubules. The synthesis and the release of kallikrein into the tubular fluid and interstitium are stimulated by prostaglandins, mineralocorticoids, Ang II, increased renal perfusion pressure, and several diuretic drugs. The renal vasculature and tubules contain the constitutive B_2 receptor and the inducible B_1 receptor. Bradykinin B_2 receptors on vascular endothelial cells cause renal vasodilation as a result of stimulation of NO, EET, and prostanoid production. The B_2 receptor density in glomeruli is reduced by a low sodium diet and water deprivation. B_2 receptors on tubular epithelial cells inhibit sodium reabsorption. The bradykinin B_1 receptor is not normally expressed and is silent under physiologic conditions. Its expression is highly inducible by inflammatory mediators and tissue damage, chronic ACE (kininase II) inhibition, or genetic deletion of B_2 receptors.[200–203]

The infusion of bradykinin elicits renal vasodilation characterized by a larger increase in RBF than GFR, and a natriuresis and diuresis. Exogenous kinins also produce an independent stimulation of prostaglandin formation (PGE_2 and PGI_2) and renin release. Kinin-induced vasodilation, however, may be similar in the presence and absence of COX inhibition of prostaglandin synthesis owing to major actions of NO and EETs. As a result of vasodilatorlike actions, exogenous bradykinin reduces the vasoconstrictor responses to Ang II and norepinephrine. The observed decline in glomerular K_f contrasts with the well-known effect of kinins to increase capillary permeability in other tissues. The mechanisms responsible for the reduction in K_f are not known. Additional effects include the enhanced conversion of inactive to active renin and the presynaptic inhibition of adrenergic neurotransmitter release. Isolated vessels and cultured mesangial cells devoid of endothelium exhibit B_2-receptor–dependent constrictor responses to bradykinin. Signal transduction appears to involve a pertussis-toxin–insensitive G protein, a PKC pathway, increased $[Ca^{2+}]_i$, and arachidonic acid metabolites.[1,2]

B_2 receptors reside on endothelial and vascular smooth muscle cells. Vasodilator effects of bradykinin are observed in isolated preparations of afferent and efferent arterioles. In the isolated perfused afferent arteriole, low concentrations of bradykinin ($<10^{-10}$ M) vasodilate by acting on endothelial B_2 receptors to produce NO and prostaglandins. Epoxygenase-dependent EETs also contribute. Higher concentrations ($>10^{-9}$ M) vasoconstrict by acting on B_2 receptors to produce COX-derived thromboxane. In contrast, the vasodilator effect of bradykinin in efferent arterioles (perfused in retrograde direction) via B_2 receptors is mediated by cytochrome P450 metabolites (probably EETs), but not by NO or COX products. Perfusion of bradykinin through glomeruli releases prostaglandins that dilate the efferent arteriole. Bradykinin relaxes pericytes surrounding the outer medullary descending vasa recta. Endogenous bradykinin dilates afferent and efferent arterioles in vivo to a greater extent in the deep versus superficial cortical glomeruli with primary mediation by NO. EETs also participate in vasodilation of afferent arterioles of juxtamedullary nephrons. Isolated vessels and cultured mesangial cells devoid of endothelium exhibit B_2-receptor–dependent constrictor responses to bradykinin. Signal transduction appears to involve a pertussis-toxin–insensitive G protein, a PKC pathway, increased $[Ca^{2+}]_i$, and arachidonic acid metabolites. Endogenous bradykinin, potentiated during ACE inhibition in animals fed a low sodium diet, dilates the renal vasculature with predominant actions in the medulla. During extracellular fluid volume expansion, bradykinin promotes sodium excretion and reduces regional autoregulatory efficiency to increase medullary blood flow, effects largely mediated by B_2 receptor stimulation of NO.[15,204–209]

Early studies evaluated endogenous kinin activity using an infusion of bradykinin-binding antibodies, the suppression of renal kallikrein activity with the serine protease inhibitor aprotinin, and the pharmacologic inhibition of kininase II. The results suggest that locally formed kinins attenuate renal vasoconstriction. Further understanding has been gained by employing more specific receptor antagonists. Use of a specific B_2 receptor antagonist reveals that basal kinin levels do not contribute appreciably to the regulation of renal function during normal conditions. However, when their levels are elevated as during sodium restriction and volume depletion, kinins act as vasodilators in a manner similar to the prostanoids, which buffer the renal vasoconstriction associated with elevated local levels of Ang II, norepinephrine, and vasopressin. A combined blockade of both degrading enzymes (ACE or kininase II and neutral endopeptidase) leads to increases in RBF and GFR in association with an increased urinary excretion of kinins. Kinins may participate in the autoregulation of GFR and the TGF mechanism, although overall steady-state RBF autoregulation is not affected by kinin receptor blockade. Kinins exert larger vasodilatory effects in the medulla than in the cortex.[208]

Animal studies on the role of the renal kallikrein–kinin system using kininogen-deficient rats and also B_2 receptor knockout mice indicate that this system primarily functions to promote a natriuresis that impacts on the pressure–natriuresis relation when there is excess sodium intake or high plasma aldosterone concentration. Genetic dysfunction of the renal kallikrein–kinin system leads to altered functional maturation of the kidney and the development of salt-sensitive hypertension. Rats with a genetic reduction in urinary kallikrein excretion have an altered pressure–natriuresis relationship, with this defect being corrected by an infusion of purified tissue kallikrein. Knockout mice lacking the B_2-receptor gene have elevated arterial pressure under basal conditions, reduced RBF, increased renin mRNA, and enhanced blood pressure sensitivity to salt.[210]

Purinergic Actions on Renal Microcirculation

Adenosine and ATP

Adenosine nucleosides and nucleotides have received considerable attention as regulators of renal hemodynamics and renin release. It is proposed that GFR and filtered sodium load are coupled to tubular transport capacity and O_2 consumption via the hydrolysis of ATP and the resultant adenosine production. Adenosine and other adenine nucleotides are secreted into the interstitial fluid in the extracellular compartment. ATP is released from cells through membrane channels and coreleased with transmitters from nerve terminals. In this fashion, purine-based substances act as paracrine agents to influence renal microcirculation.[1,2,121]

Purinergic Receptors

Renal purinoceptors display different sensitivities for ATP, ADP, AMP, and adenosine. P_1 purinoceptors respond primarily to adenosine and sometimes to AMP, but are relatively insensitive to ADP and ATP. Extracellular ATP predominantly activates P_2 purinoceptors. There are at least two subtypes of adenosine-responsive P_1 receptors in the renal vasculature. P_1-vasoconstrictor A_1 receptors are coupled to a pertussis-toxin–sensitive $G\alpha_i$ protein that inhibits adenylate cyclase and cAMP production. The stimulation of A_1 receptors decreases GFR and RBF. A local application of an A_1 receptor agonist constricts both preglomerular and postglomerular microvessels. A_2 receptors cause vasodilation of afferent and efferent arterioles, stimulating adenylate cyclase through a $G\alpha_s$ protein, and also increase EETs and NO, which contribute to the vasodilation. There are two subtypes (A_2a and A_2b), with A_2b being prevalent in afferent arterioles.

P_2 receptors, present on endothelial and vascular smooth muscle cells, have a greater affinity for ATP and ADP than for adenosine or AMP. Interstitial fluid ATP concentrations are sufficiently high to play a role in regulating the vascular resistance changes responsible for autoregulation and TGF. The receptor subtype P_{2X} increases $[Ca^{2+}]_i$ by increasing Ca^{2+} influx through voltage-gated and receptor-operated

Ca^{2+}channels. The low frequency stimulation of renal sympathetic nerves causes renal vasoconstriction that is mediated, in part, by a nonadrenergic component involving ATP corelease with the neurotransmitter acting on P_{2X} receptors. P_{2Y} receptor activation increases $[Ca^{2+}]_i$ via the PLC-IP_3 cascade. Endothelial cells have a high concentration of P_{2Y} receptors, and their activation by ATP leads to vasorelaxation mediated by NO, or PGI_2, or both. However, ATP causes a rapid, marked constriction of the afferent arteriole when NO synthesis is inhibited. The P_{2U} purinoceptor is termed a nucleotide or 5′-nucleotide receptor because it responds to all nucleotides with a similar potency of ATP and uridine triphosphate. P_{2U} receptor activation increases $[Ca^{2+}]_i$ by a G-protein stimulating the PLC pathway.[1,2,211,212]

Adenosine

The intrarenal administration of adenosine produces a biphasic renal response. Resistance vessels respond initially with transient vasoconstriction, mediated by P_1-A_1 receptors, followed by gradual vasodilation, mediated in part by P_1-A_2 receptors. In isolated preparations, adenosine A_1 receptor stimulation constricts both afferent and efferent arterioles. Endogenous adenosine serves as an important regulator of renal hemodynamics. The blockade of A_1 receptors decreases afferent arteriolar resistance and K_f in anesthetized animals.

Evidence about the importance of adenosine in intrinsic autoregulatory mechanisms is mixed. One set of results suggests that adenosine is not essential for autoregulation. Interstitial fluid concentrations of adenosine are unchanged over the autoregulatory range of arterial pressure, and the administration of adenosine-receptor antagonists does not impair autoregulatory capability. Other results, however, implicate a role of adenosine in the regulation of afferent arteriolar tone by TGF. Salt transport by the ascending limb of the Henle loop or macula densa cells requires metabolic energy and the use of ATP that is linked to control of preglomerular vascular resistance through macula densa signaling. As transport increases, more adenosine is liberated within cells and is available to diffuse to the afferent arteriole, where it elicits vasoconstriction to reduce RBF and GFR. Luminal perfusion of A_1 adenosine-receptor agonists cause TGF-induced vasoconstrictor changes in glomerular capillary pressure. Attenuated TGF-mediated responses of the afferent arteriole are observed when an adenosine antagonist is added to either the luminal fluid or peritubular capillary blood. The effects are insensitive to the salt transport inhibitor furosemide, indicating P_1-A_1 adenosine-receptor–mediated effects by acting on either the macula densa or vascular smooth muscle cells. Moreover, an adenosine-receptor blockade reduces TGF control of preglomerular resistance, and mice without functional A_1 receptors lack TGF activity. However, unopposed A_2 receptor activation may result in substantial vasodilation. Dynamic RBF studies on gene-targeted mice are consistent with A_1 receptors mediating pressure-induced TGF responses participating in RBF autoregulation but not the myogenic response of the preglomerular vasculature. In addition, mice lacking the enzyme NTPDase/CD39, which reduces the formation of adenosine, have impaired TGF activity.[1,104,213–217]

Although adenosine and Ang II can act independently of each other on glomerular arterioles, they also act synergistically. Adenosine enhances afferent arteriolar reactivity to Ang II by increasing Ca^{2+} sensitivity. On the other hand, Ang II amplifies afferent arteriolar constriction to adenosine by a different mechanism, one due to increased $[Ca^{2+}]_i$. In this manner, adenosine can amplify vasoconstriction during high renin states and increased endogenous Ang II. Adenosine causes larger long-term decreases in GFR and the filtration fraction in sodium-depleted animals with increased renin-angiotensin activity than in animals consuming a normal salt diet.[218,219]

Adenosine participates in the regulation of renin secretion. Adenosine infusion inhibits renin release in vivo. The mechanism involves adenosine receptors on juxtaglomerular cells, with A_1 and A_2 receptors having opposite effects. Renin release is inhibited by A_1 purinergic receptors coupled to a $G\alpha_i$ protein and stimulated by A_2 receptors. A tonic inhibitory effect of adenosine is observed in isolated afferent arterioles with and without macula densa cells attached.[220–222]

ATP

P_2 receptors are also involved in mediating autoregulatory adjustments in RVR involving TGF responses. Extracellular ATP, at high levels that saturate P_2 purinoceptors, causes renal vasoconstriction and impairs the autoregulatory ability of the vasculature to dilate in response to decreases in arterial pressure. The effect on autoregulation appears to be specific to ATP because similar studies show that RBF autoregulation is not impaired when the vasoconstrictor is norepinephrine or Ang II.

The renal arterial infusion of ATP increases RBF. The renal vasodilation is mediated by activation of endothelial receptors to release NO. The ATP effect is converted to vasoconstriction during NO synthesis inhibition. P_2 receptors are present on vascular endothelium, with P_{2Y} receptors being responsible for NO-dependent vasodilation. P_{2X} receptors on vascular smooth muscle cells produce vasoconstriction. In considering a paracrine role for ATP, it seems likely that endogenous ATP reaches vascular smooth muscle cells from the interstitium. The vasoconstriction is mediated by Ca^{2+} mobilization and entry through L-type Ca^{2+} channels.[1,2]

ATP acts on P_2 purinoceptors to selectively constrict afferent arterioles in a sustained manner, whereas ATP does not elicit any response in efferent arterioles. This is consistent with autoradiographic and immunohistochemical evidence of abundant P_{2x} receptors limited to the preglomerular vasculature. Pressure-induced TGF–mediated afferent arteriolar constriction is prevented by P_2 receptor saturation or desensitization by high arterial concentrations of ATP. Tubuloglomerular responses also are markedly

blunted during peritubular capillary perfusion with saturating doses of ATP or slowly metabolizable analogs. $P_{2(x)1}$ receptor blockade prevents TGF-initiated responses of afferent arterioles.

Renal interstitial fluid concentrations of ATP measured by microdialysis are closely associated with autoregulatory and TGF-mediated changes in RVR. A direct relationship is observed when TGF is stimulated by increased distal fluid delivery due to a carbonic anhydrase inhibition of proximal tubular reabsorption and when TGF is inhibited by the transport inhibitor furosemide. Mice lacking functional P_{2x} receptors have partially blunted whole kidney RBF autoregulation and a loss of TGF. Macula densa cells secrete ATP through a basolateral maxi-chloride channel in response to increases in luminal NaCl concentration. Although macula densa cells have abundant mitochondria, they have low levels of Na^+-K^+-ATPase, making them a good candidate for a source of extracellular ATP. The activation of macula densa signals trigger the rapid propagation of Ca^{2+} waves and associated afferent arteriolar constriction, which are prevented by blocking P_2 receptor activation or increasing ATP hydrolysis. Collectively, the data support an important role for the ATP-dependent activation of P_2 receptors in the mediation of autoregulation and TGF.[1,2,12,107,211,223,224]

Sympathetic Nervous System and Catecholamines

The renal vasculature is richly innervated with postganglionic adrenergic fibers originating from sympathetic celiac and aorticorenal plexuses that receive inputs from the sixth thoracic through the second lumbar spinal nerves. All arterial segments of the renal vasculature and the large veins are extensively innervated with neuroeffector junctions containing norepinephrine as the primary neurotransmitter. A heavy concentration appears in subadventitial layers of arcuate arteries, with notable innervation of smooth muscle cells of both the afferent and efferent arterioles as well as the juxtaglomerular granular cells and the outer medullary descending vasa recta. The incoming efferent innervation is predominantly adrenergic, although some nerve endings are reported to contain dopamine and neuropeptide Y (NPY) as well as ATP. Alpha$_1$-adrenoceptors, primarily α_{1A} and α_{1D}, increase $[Ca^{2+}]_i$ and Ca^{2+} sensitivity, and mediate nerve stimulation-induced vasoconstriction of glomerular arterioles in the renal cortex and medullary pericytes, an action opposed in part by concurrent activation of α_2-adrenoceptors. Beta-adrenoceptors stimulate renin release from juxtaglomerular granular cells via cAMP/PKA signaling.[132,225]

Renal nerves are divided into two types. Type I almost exclusively innervate afferent arterioles, whereas type II innervate both afferent and efferent arterioles. Type II nerves contain NPY, whereas type I terminals do not. The electrical stimulation of the greater splanchnic or renal efferent nerves produces frequency-dependent renal vasoconstriction that is abolished by α_1-adrenergic receptor antagonists and attenuated by NPY Y_1 receptor blockade. Very low levels of nerve stimulation affect renin release and tubular sodium reabsorption without causing major changes in renal hemodynamics. Intermediate nerve activity elicits renal vasoconstrictor responses in the medullary as well as the cortical circulation, with more pronounced reductions in cortical blood flow. The increased vascular resistance in the cortex is due to the constriction of preglomerular and efferent arteriolar segments. As is shown in Figure 3.24, low levels of stimulation cause an equivalent constriction of afferent and efferent arterioles such that glomerular pressure is unchanged. Similar results are obtained in isolated afferent and efferent arterioles when α_1-adrenoceptors are stimulated. Higher frequencies of nerve stimulation produce predominant constriction of preglomerular vessels and thus reduce glomerular capillary pressure and GFR. Intense stimulation at 10 Hz produces glomerular ischemia.[226]

The renal medullary circulation is less sensitive than the cortical vasculature to renal nerve stimulation, particularly at low stimulus intensities. This is largely due to more effective blunting of vasoconstriction by NO and eicosanoids. The electrical stimulation of renal nerves causes parallel reductions in RBF and cortical blood flow, whereas the decrease in medullary perfusion is approximately 50% less. Low frequency nerve stimulation ($<$2 Hz) increases NO production, which buffers the vasoconstriction in all regions of the kidney. More severe renal vasoconstriction produced by high frequency nerve stimulation ($>$4 Hz) leads to the activation of AT_1 receptors that magnifies nerve-induced constriction in both the renal cortex and the medulla. NO derived from nNOS is critical to protecting the medullary regions.[227,228]

Infusions of norepinephrine, epinephrine, or α_1-adrenergic agonists produce similar dose-related vasoconstrictor effects on the renal microcirculation. Studies on individual vessels indicate that norepinephrine constricts the interlobular artery and the afferent and efferent arterioles. Total RVR responses to norepinephrine are substantially attenuated by Ca^{2+} channel blockers and by the inhibition of IP_3-mediated release of stored Ca^{2+}. Ca^{2+} responses of the afferent arteriole to α-adrenoceptor stimulation are mediated by the mobilization from internal stores in combination with Ca^{2+} entry through voltage-gated L-type channels and channels insensitive to dihydropyridine Ca^{2+} channel blockers. The latter includes voltage-independent receptor-operated Ca^{2+} channels. Ca^{2+} sensitivity is also increased. Recent evidence implicates superoxide anion generation and downstream signaling involving cyclic ADP ribose, ryanodine receptors on the sarcoplasmic reticulum, and Ca^{2+}-induced Ca^{2+} release. Efferent arteriolar responses to norepinephrine appear to be independent of L-type channels.[20,58,143]

The renal nerves are not essential for efficient steady-state autoregulation of RBF and GFR or for the operation of either the myogenic or the TGF mechanism. These conclusions are

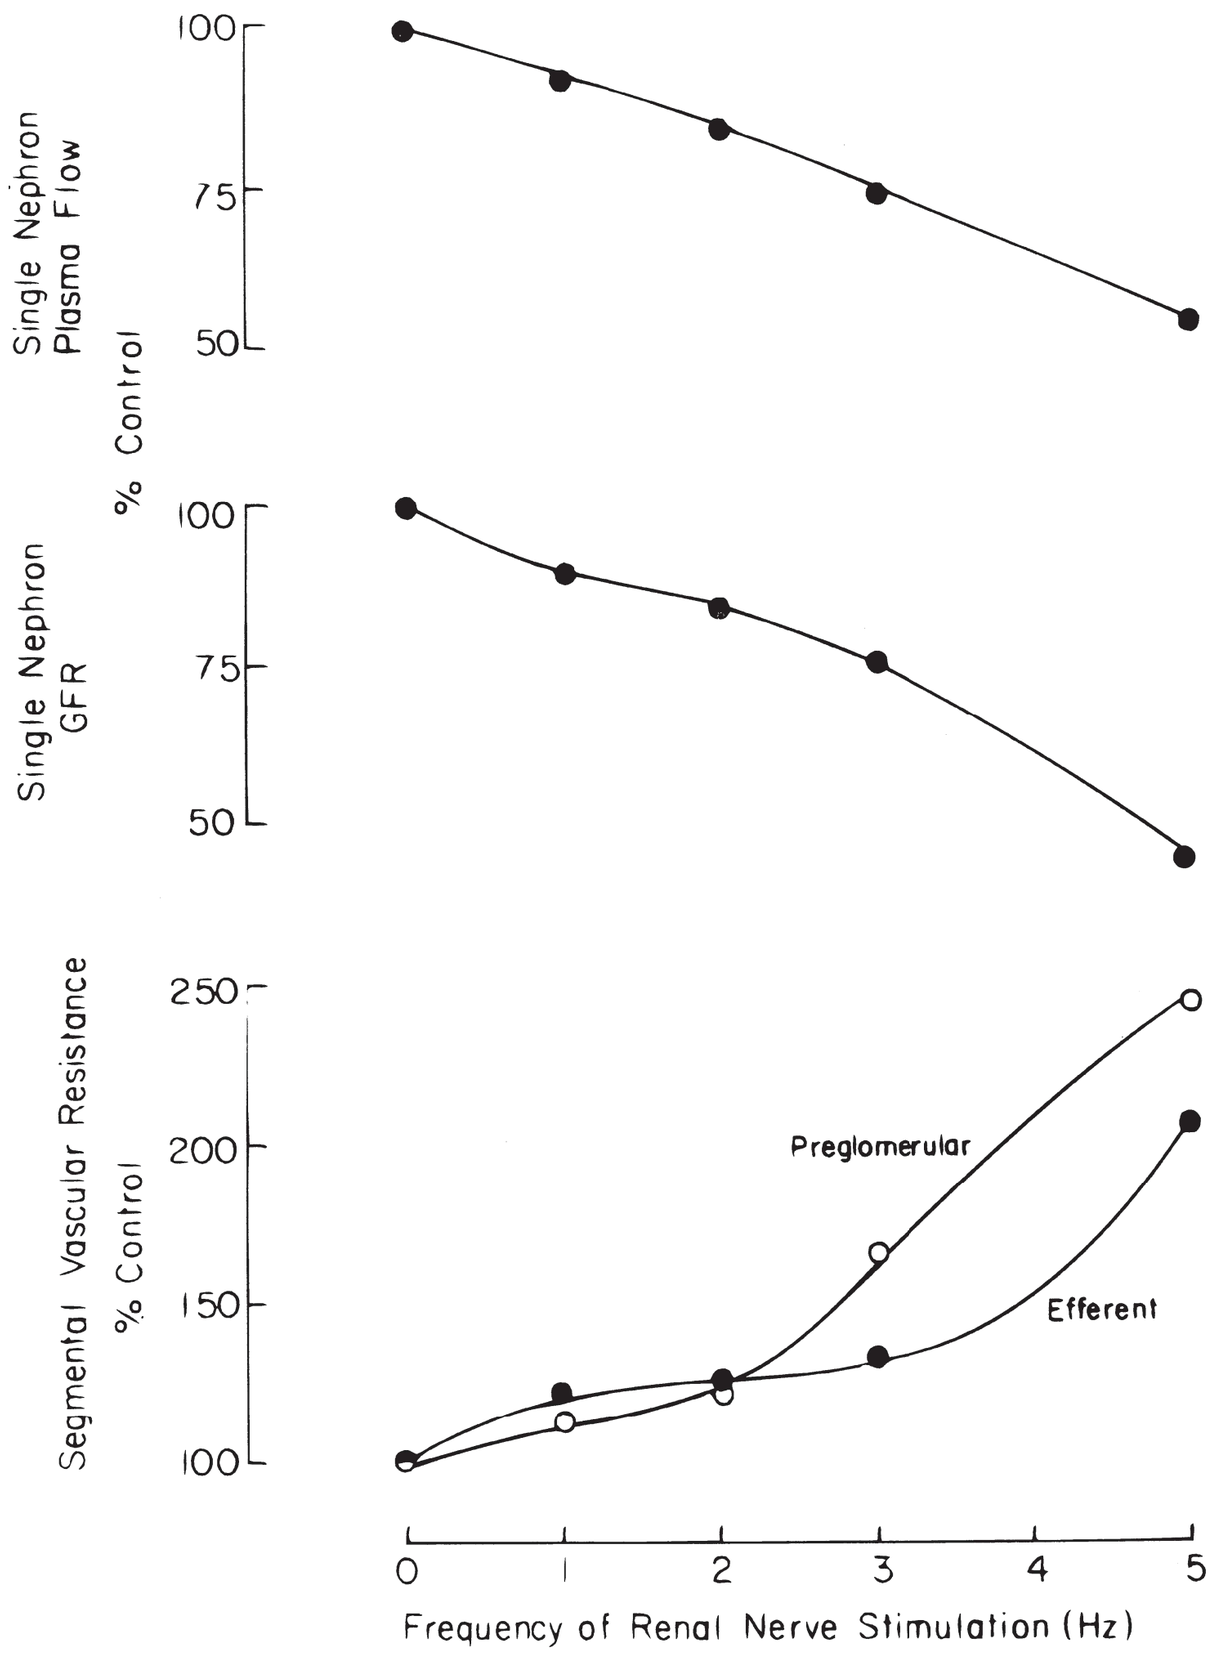

FIGURE 3.24 The effect of electrical stimulation of renal efferent nerves at 1 to 5 Hz on a single nephron glomerular filtration rate (*GFR*), plasma flow, and the resistance of preglomerular vessels and efferent arterioles.

reinforced by a frequency analysis of RBF dynamics indicating that baroreflex-mediated changes in renal sympathetic nerve activity and acute denervation have little impact on intrinsic autoregulatory mechanisms stabilizing renal perfusion in normotensive animals. Under unstressed conditions, while basal efferent sympathetic tone is low, neither acute nor chronic renal denervation affects RBF or GFR. Physiologic changes in renal efferent nerve activity during sleeping, grooming, and movement cause inverse changes in RBF in conscious animals. In anesthetized animals, moderate hypoxia and reflexively induced increases in renal sympathetic nerve activity reduce RBF more than GFR with increases in glomerular capillary pressure as a result of greater constriction of efferent over afferent arterioles. More severe hypoxia reduces RBF and GFR equally as afferent and efferent arteriolar resistances were increased to the same extent. Moderate increases of about 50% in renal nerve activity that are induced reflexively by high- or low-pressure receptors fail to alter renal hemodynamics, although this level of stimulation is capable of affecting tubular sodium reabsorption and renal release of renin and prostaglandins. Hypercapnic acidosis associated with an increase in PCO_2 from 25 to 70 mm Hg activates the renal efferent nerves but the neurally mediated renal vasoconstriction is partially counteracted by enhanced synthesis of vasodilatory prostaglandins. Neurally induced vasoconstriction is more readily demonstrable during more stressful states, such as during dehydration, blood-volume contraction, hemorrhage, and congestive heart failure. The pronounced activation of renal efferent nerve activity (+500%) produced by auditory or emotional stimuli causes intense renal vasoconstriction.[1,132,229]

In addition to a direct effect on vascular smooth muscle, the renal efferent nerves exert secondary hemodynamic effects as a consequence of an intrarenal stimulation of the constrictors Ang II and ET-1 and the formation of dilator prostaglandins and NO. Renal nerve stimulation elicits an increase in renin release from juxtaglomerular cells primarily by the activation of β_1-adrenoceptors signaling through the cAMP/PKA pathway. Prostaglandin synthesis is enhanced by the activation of phospholipase A_2 and the augmented availability of arachidonic acid. Ang II formation accentuates norepinephrine release and renal vasoconstriction

produced by increased renal nerve activity. α_1-Adrenoceptor activation enhances Ang II–mediated afferent arteriolar vasoconstriction by increasing calcium sensitivity. The vasoconstriction caused by moderate renal nerve stimulation is reduced in the presence of the Ang II/AT_1 receptor blockade, suggesting that part of the effect is mediated by increased intrarenal Ang II formation due to the neural stimulation of renin. On the other hand, vasodilatory prostaglandins buffer a significant fraction of the vasoconstriction elicited by nerve stimulation as evidenced by much larger changes in GFR, RBF, and vascular resistance during COX inhibition. Moreover, endothelium-dependent NO release, possibly via the activation of β_3-adrenergic receptors, functions as an inhibitory modulator of vasoconstrictor responses to the sympathetic transmitters norepinephrine and NPY. The effect of renal nerve stimulation on glomerular K_f is controversial. Some investigators report a reduction; others find that K_f is normally unaffected by nerve stimulation but that a reduction of K_f is evident during the inhibition of prostaglandin synthesis.[2]

Afferent renal nerves serve important functions in the neurohumoral control of arterial pressure, vasopressin release, and renal excretion of sodium and water. Afferent nerve endings contain neuropeptides such as calcitonin gene-related peptide, substance P, and vasoactive intestinal peptide. Afferent input from intrarenal sensory receptors in the pelvic wall participates in renorenal reflexes that modulate efferent nerve activity to the contralateral kidney. Baroreceptors or mechanoreceptors are activated by high venous or interstitial pressure. High renal pelvic pressure reduces efferent renal nerve traffic to the opposite kidney, which results in compensatory increases in RBF, GFR, and sodium excretion. Similar functional changes in the opposite kidney are elicited by ischemia-sensitive chemoreceptors responding to increased urinary potassium or very high sodium concentration. Outgoing afferent nerve activity is influenced also by incoming efferent nerve activity such that increased efferent input usually increases afferent nerve activity. The norepinephrine release from efferent nerves activates adrenoceptors on sensory nerves, with α_1-adrenoceptor activation increasing afferent nerve activity and α_2 receptor stimulation reducing afferent firing.[230,231]

Although cholinesterase-containing fibers and β-adrenergic sites have been identified histologically in the renal cortex, there is little functional evidence for neurogenic renal vasodilation mediated by acetylcholine or β-adrenoceptors. The neural release of acetylcholine, however, may exert a small indirect effect at presynaptic sites to inhibit norepinephrine release. Infusions of exogenous acetylcholine increase RBF and reduce RVR, whereas GFR is unaffected. The decline in total resistance is due to parallel reductions in afferent and efferent arteriolar resistance. Acetylcholine relaxes isolated preparations of the interlobular artery and the afferent and efferent arterioles. As pointed out earlier, however, the full vasodilatory effect of acetylcholine requires an intact endothelium and is primarily mediated by a combination of NO as well as prostanoids and EETs.[132]

Dopamine, a sympathomimetic amine precursor of norepinephrine, is a neurotransmitter capable of regulating renal hemodynamics, renin secretion, and sodium excretion. Histofluorescent evidence suggests dopaminergic innervation of the cortical vessels, primarily the glomerular vascular poles. However, dopamine synthesized from L-dopa via L-dopa decarboxylase in proximal tubular cells is clearly the major source of urinary dopamine and its metabolites, with the greatest production during high salt diet and lowest synthesis during sodium restriction. There are two major receptor families: D_1-like (D_1 and D_5 receptors) and D_2-like (D_2, D_3, D_4 receptors). D_1 receptors are postsynaptic receptors located on vascular smooth muscle and tubular cells, but are absent from glomeruli. They cause vasodilation by cAMP/PKA signaling. D_2 receptors are either presynaptic or postsynaptic and are located in glomeruli as well as vessels and tubules in both the cortex and medulla. The presynaptic D_2 receptor indirectly dilates vessels by the inhibition of norepinephrine release. Dopamine is commonly used to evaluate the renal functional reserve—the ability to dilate the renal vasculature—in various pathologic conditions.[232–236]

Although receptor blockers abolish renal effects produced by exogenous dopamine, such antagonists do not consistently affect basal renal hemodynamics, questioning the role of physiologic levels of dopamine. Further, the prejunctional stimulation of dopamine receptors during moderate levels of renal efferent nerve activity has little influence on RVR. Small amounts of exogenous dopamine or a D_1 receptor agonist dilate the renal vasculature. Responses include an increase in RBF and a decrease in filtration fraction; GFR and glomerular capillary pressure are unaffected. Most of the dopamine-induced renal vasodilation is mediated by D_1 receptors, which are coupled to cAMP/PKA signaling. Dopamine and D_1 receptor agonists relax afferent and efferent arterioles and interlobular and arcuate arteries. D_1 receptor stimulation attenuates the constriction of both afferent and efferent arterioles produced by either Ang II or ET-1. The D_1-induced dilation of the preglomerular vasculature does not impair autoregulatory adjustments in vascular resistance to changes in perfusion pressure. D_1-receptor stimulation attenuates tubuloglomerular feedback responsiveness. The vasodilation elicited by dopamine is more pronounced after denervation or pharmacologic blockade of α-adrenoceptors, suggesting that presynaptic D_2-dopamine receptors augment norepinephrine release from nerve terminals. D_2-receptor stimulation is associated with increases in GFR and the attenuation of Ang II–induced contraction of glomerular mesangial cells. D_1 receptors also stimulate a renin release from juxtaglomerular cells. D_1 agonists inhibit fluid and electrolyte transport indirectly via hemodynamic mechanisms and directly by the occupation of D_1 receptors in the proximal tubule, the thick ascending limb of Henle, and the collecting duct. D_1 receptor null mice have elevated proximal tubular salt transport and hypertension.[2,132]

NPY is another neurotransmitter. Nerve endings containing immunoreactive neuropeptides are localized along the interlobular and arcuate arteries extending to glomerular arterioles, innervating both afferent and efferent arterioles. NPY is a cotransmitter of the renal sympathetic nerves that is coreleased with and may potentiate the vascular pressor effects of norepinephrine and ATP. NPY is less potent than norepinephrine. The kidney expresses NPY receptors that can also be activated by peptide YY (PYY), a circulating hormone released from gastrointestinal cells. NPY and PYY produce renal vasoconstriction via the Y_1 receptor. Administered NPY constricts both the afferent and efferent arterioles and inhibits renin release. Nerves innervating the efferent arteriole contain more immunoreactive NPY than those to the afferent arteriole. NPY acts prejunctionally to inhibit norepinephrine release via Y_2 receptors. Despite marked reductions in RBF, systemic NPY infusion elicits a diuresis and natriuresis that is mediated in part by bradykinin. NPY antagonists increase basal RBF but do not alter basal urinary excretion.[226,228,237]

Other Vasoactive Agents

Atrial Natriuretic Peptide

ANP is a 28-amino acid peptide family involved in the physiologic regulation of renal function and sodium excretion. A high molecular weight precursor of ANP is constitutively synthesized in cardiocytes of the atria. ANP is released into the circulation as a function of atrial volume or distention in association with changes in sodium and water balance. In addition to ANP, related peptides include ventricular brain natriuretic peptide (BNP) and renal urodilatin. Studies implicate renal conversion of ANP to urodilatin, which is closely related to sodium excretion under a variety of conditions.[238,239]

ANP receptors are concentrated in glomerular capillaries and the collecting duct; they are also present along the cortical arterioles and the medullary arterioles and the vasa recta; cell types include the collecting duct, the vascular smooth muscle, and the endothelial and mesangial cells. There are three subtypes of natriuretic peptide receptors (NPR), termed NPR-A, NPR-B, and NPR-C. The A- and B-type receptors include a cytoplasmic catalytic domain and the active particulate guanylate cyclase, exerting physiologic effects by increasing cell cGMP. ANP may buffer the action of vasoconstrictors such as Ang II and norepinephrine via an interaction of cGMP with intracellular Ca^{2+}, perhaps secondary to the inhibition of Ca^{2+} mobilization and the stimulation of Ca^{2+} efflux. The renal vasculature also has biologically silent, NPR-C "clearance" receptors, that remove ANP from the circulation with no role in signal transduction or guanylate cyclase activity. [240–242]

ANP is a rapid-acting, potent natriuretic and diuretic peptide that is also capable of lowering arterial pressure by direct vasodilatory effects on the systemic vasculature and reducing cardiac output. Physiologic concentrations of ANP inhibit tubular reabsorption without altering RBF, GFR, or the filtered sodium load. Medullary blood flow is increased during the administration of ANP, but the effect seems to be secondary to the ANP-induced natriuresis. Several tubular sites have been evaluated, including a Na-ATPase of the proximal tubule and an amiloride-sensitive sodium channel in the collecting duct and an angiotensin-sensitive exchanger in the proximal tubule. ANP has a direct inhibitory action on renin release in cultured juxtaglomerular cells that is mediated by cGMP.[243,244]

The renal vascular effects of ANP are mediated by NPR-A and NPR-B receptors. Activation of NPR-A receptors dilates preglomerular resistance vessels, including arcuate and interlobular arteries, afferent arterioles, and efferent arterioles. The NPR-B receptor contributes to the dilation of the preglomerular vasculature. The reported effect of ANP on K_f is variable. Although glomerular capillary pressure is increased, GFR is usually unchanged, presumably because of a decrease in K_f. ANP infusions increase glomerular permeability to macromolecules. The preglomerular vasodilation produced by ANP does not impair autoregulation of either RBF or GFR. ANP exerts both indirect and direct effects on the TGF mechanism. ANP markedly inhibits TGF control of glomerular hemodynamics when feedback activity is evaluated by the perfusion of the Henle loop with artificial fluid. Studies on mice with underexpression and overexpression of the NPR-A receptor highlight the important role ANP has in mediating the renal vascular and tubular changes resulting from blood volume expansion. Overexpression of NPR-A receptors is associated with enhanced renal vasodilatory and natriuretic responses, whereas the responses are markedly attenuated in mice lacking NPR-A receptors. Synthetic ANP (M-ANP), being tested for use in hypertension and congestive heart failure, are potent agents for lowering blood pressure and systemic vascular resistance, while increasing RBF, GFR, and sodium excretion. Transgenic mice with an overexpression of natriuretic peptide receptor A respond to blood volume expansion with marked natriuresis, along with increases in RBF and GFR, whereas mice deficient in the NPR-A fail to show the increases in RBF and GFR or sodium excretion. These data demonstrate the importance of ANP in regulating renal function in response to volume expansion.[78,107,244–247]

Vasopressin

In addition to its antidiuretic properties, AVP is a vasoconstrictor, with predominant actions in the renal medulla. The plasma AVP concentration is directly related to plasma osmolality and inversely with blood volume and pressure. AVP produces effects on renal function by binding to V_{1a} or V_2 membrane receptors. The well-known osmoregulatory function of low plasma AVP concentrations is mediated through a V_2 tubular membrane receptor that signals through cAMP/PKA to alter water permeability and sodium reabsorption. Vasopressin also stimulates the production of medullary NO via the activation of V_2 receptors, which serves a protective

function to prevent excessive vasoconstriction. AVP affects renal hemodynamics by acting on V_1a receptors localized to cortical arteries/arterioles (interlobar, arcuate and interlobular arteries, afferent and efferent arterioles, glomeruli) and outer medullary vasa recta. V_{1a} mRNA and protein in preglomerular resistance arteries/arterioles are upregulated in response to reduced plasma AVP concentration associated with water loading and downregulated as plasma AVP is increased during water deprivation. Desensitization of V_1 receptors and reduced receptor density are related to PKC-mediated phosphorylation. AVP activates vascular V_{1a} receptors to exert pressor effects that contribute to the maintenance of arterial pressure during conditions of chronic water deprivation, graded hemorrhage, and possibly in various forms of hypertension.[107,248,249]

The vascular effects of AVP are due to the activation of V_{1a} receptors on vascular smooth muscle cells, which is coupled to Gα_q protein that leads to increased IP_3 production and PKC activation. In afferent arterioles, $[Ca^{2+}]_i$ is increased by a combination of Ca^{2+} release from the sarcoplasmic reticulum and Ca^{2+} entry through voltage-gated L-type Ca^{2+} channels and voltage-insensitive store-operated cation channels. The contraction of efferent arterioles is more dependent on Ca^{2+} release from sarcoplasmic reticular stores with little Ca^{2+} entry through L-type channels. In addition to increasing $[Ca^{2+}]_i$, AVP increases Ca^{2+} sensitivity via PKC and Rho-kinase signaling. The K_f lowering effect of AVP may be mediated by a direct action on mesangial cells. It was found, however, that K_f could be normalized by a combined blockade of the vascular action of both AVP and Ang II, whereas the selective blockade of either peptide was ineffective. The V_{1A} receptor on endothelial cells mediates AVP-induced NO release. Also, AVP interacts with the renal arachidonic acid and the renin–angiotensin systems. AVP stimulates renal release of PGE_2 in vivo. Prostaglandin production is increased by AVP-receptor interaction with either V_1 or V_2 receptors on medullary interstitial cells or glomerular mesangial cells. Vascular smooth muscle V_{1A} receptor activation stimulates phospholipase A_2 and prostaglandin production. Mice lacking the V_{1A} receptor are hypotensive and have decreased blood volume and sympathetic activity. They also have decreased activity of the renin–angiotensin system and lower aldosterone levels. The V_{1A} receptor is expressed in macula densa cells and colocalizes with COX-2 and nNOS. The reduced RBF and GFR are due, in part, to reduced blood pressure.[1,55,107,142,248,250–252]

The administration of exogenous AVP produces renal vasoconstriction that is buffered more by NO than COX-dependent prostaglandins, effects mediated by V_1 but not V_2 receptors. Vasoconstriction in the renal medulla is more prominent than in the renal cortex. AVP-induced cortical vasoconstriction is effectively buffered by the cytochrome P450 epoxide production of vasodilator EETs such that cortical blood flow is basically unchanged by AVP. In contrast, the medullary vasoconstriction elicited by AVP is unaffected by the inhibition of cytochrome P450 epoxide activity and EET production.[107,253]

In normal, unstressed conscious animals, the antagonism of V_1 receptors has no effect on basal RBF or arterial pressure, indicating minimal pressor activity of AVP when its plasma concentration is low. Physiologic increases in plasma AVP concentration during 48-hour water restriction and maximum urine osmolality reduce blood flow to the inner medulla via V_1 receptors while maintaining a constancy of blood flow to the outer medulla. V_2 receptor antagonism produces a diuresis. Increases in plasma AVP concentrations up to 8 pg per millimeter reduce medullary perfusion selectively and greatly attenuate the arterial pressure–blood flow and pressure–natriuresis relations without affecting total RBF or renal cortical blood flow. AVP-induced vasoconstriction in the renal medulla is normally modulated by AVP-stimulated local release of NO, perhaps mediated by V_2 receptors, reflecting a compensatory response that buffers the magnitude of the vasoconstriction and stabilizes medullary perfusion.[15]

Adrenomedullin

Adrenomedullin, α- and β-calcitonin gene-related peptide (CGRP), calcitonin, and amylin are homologous polypeptides with overlapping biologic actions such as vasodilation, inhibition of bone resorption, and antiproliferative activity. Adrenomedullin is a potent renal vasodilating and natriuretic peptide (52 amino acids with a disulfide ring), which is made in the kidney as well as the adrenal gland. mRNA for adrenomedullin and its receptor are colocalized to renal vessels, glomeruli, and inner medullary collecting ducts. The proximal tubule is abundant in adrenomedullin mRNA, whereas the greatest amounts of receptor mRNA are in the papilla. Changes in the salt diet do not appear to change the expression of the peptide or its receptor in either the cortex or the medulla. This hormone/paracrine agent increases RBF and sodium excretion without affecting GFR. Natriuretic potency increases during the inhibition of neutral endopeptidase, an enzyme that cleaves endogenous peptides with a disulfide ring such as adrenomedullin and ANP.

Adrenomedullin produces vasodilation by cAMP/PKA signaling and by stimulating endothelial NO production, leading to the activation of ATP-sensitive K^+ channels and Ca^{2+}-dependent K channels and the hyperpolarization of vascular smooth muscle cells. Adrenomedullin increases renin release via increasing cAMP in juxtaglomerular granular cells. CGRP exerts NO-dependent as well as cAMP/PKA vasodilation. The administration of adrenomedullin or CGRP increases RBF and to a lesser extent GFR; both are natriuretic and diuretic. However, the renal vasodilator effects of adrenomedullin are not dependent on CGRP. Adrenomedullin and CGRP dilate afferent arterioles and blunt Ang II- and norepinephrine-induced renal vasoconstriction. Increased adrenomedullin levels in diabetic rats are associated with

the early hyperfiltration and may contribute to the afferent arteriolar vasodilation.[107,254–257]

Reactive Oxygen Species

Small amounts of ROS constantly produced by aerobic metabolism have important roles in signal transduction in the vasculature under physiologic conditions. In pathophysiologic states, ROS initiate and amplify deleterious events such as lipid oxidation and tissue/DNA damage associated with glomerular inflammation and proteinuria, and vascular hypertrophy in addition to vasoconstriction. ROS are products of partial reduction of oxygen, generated by enzymatic and nonenzymatic reactions. Common oxidative enzymes include nicotinamide adenine dinucleotide(NADH)/reduced NADPH oxidases (NOX), COX, cytochrome P450, and xanthine and glucose oxidases. The reduction of molecular oxygen ($O_2 + e^-$) produces superoxide anion ($\bullet O_2^-$), which is normally balanced by its degradation. Superoxide dismutases (SOD) catalyze the conversion of $\bullet O_2^-$ to hydrogen peroxide (H_2O_2) that has oxidizing potential. H_2O_2 is subsequently neutralized by glutathione peroxidases and catalase. An alternative pathway for $\bullet O_2^-$ degradation is to rapidly react with NO to form peroxynitrite ($ONOO^-$), which clearly limits the half-life, the diffusion distance, and the biologic activity of NO as well as $\bullet O_2^-$. Vitamins A, E, and C and bilirubin are scavengers of ROS.[199,258–261]

As intracellular signals, ROS may activate or inactivate redox-sensitive protein kinases and phosphatases to modulate GPCR phosphorylation and transcription factors. Reactive nitrogen species such as S-nitrosothiols can modulate GPCR signaling and internalization through S-nitrosylation of β-arrestin and GRK. Normally there is a fine balance between activities of oxidative and antioxidant enzymes, optimizing NO activity and minimizing superoxide anion generation. $\bullet O_2^-$ functions as the counterpart to NO and its antiproliferative and vasodilatory actions. In the kidney, ROS are formed in arteries and arterioles, glomeruli, and juxtaglomerular cells endowed with oxidases such as NOX, NOS, and COX. NOX1, NOX2, and NOX4 are expressed in the kidney. Predominant isoforms in the renal vasculature are NOX1 and NOX2 that primarily produce $\bullet O_2^-$; epithelial NOX4 mainly generates H_2O_2. $\bullet O_2^-$ is degraded by superoxide dismutases, of which the cytosolic or intracellular isoform accounts for ~70% of the enzyme in the kidney, with lesser amounts in extracellular and mitochondrial compartments. In the juxtaglomerular apparatus, endothelial cells produce NO via eNOS and macula densa cells via nNOS. Stimulants of $\bullet O_2^-$ production include vasoconstrictor agents (e.g., Ang II, ET-1, norepinephrine), growth factors, and stretch. Chronic high Ang II and a high salt diet are potent stimulants, increasing the expression of NOX subunits and reducing superoxide dismutase isoforms. Overall renal actions of $\bullet O_2^-$ are vasoconstriction and the enhancement of tubular sodium reabsorption. NOX-derived $\bullet O_2^-$, largely independent of H_2O_2, contributes to GPCR signaling and participates in renal vasoconstriction elicited by Ang II, catecholamines, and ET-1 activation of ET_A and ET_B receptors.[199,262]

$\bullet O_2^-$ exerts tonic renal vasoconstriction in normotensive rats, an action that becomes more pronounced when NO production is inhibited, indicating an interaction between $\bullet O_2^-$ and NO that have opposing actions on vascular resistance. This is evident because the administration of superoxide dismutase and NOX inhibition increases RBF. Moreover, NOX2-deficient mice have an increased basal RBF with normal GFR and arterial pressure, with less renal vasoconstriction in response to NOS inhibition than observed in wild-type mice that are able to produce the vasoconstrictor via NOX2. NOX-derived $\bullet O_2^-$, largely independent of H_2O_2, contributes to GPCR signaling and participates in renal vasoconstriction elicited by Ang II, catecholamines, and ET-1 activation of ET_A and ET_B receptors. Ang II–induced renal vasoconstriction and reduced GFR are magnified during NOS inhibition and weakened during administration of superoxide dismutase to scavenge $\bullet O_2^-$. Increased endogenous $\bullet O_2^-$ activity produced by acute pharmacologic inhibition of superoxide dismutase (diethyldithiocarbamate) reduces total renal, as well as both cortical and medullary blood flow. The vasoconstriction is greater when the buffering afforded by NO is removed by NOS inhibition. This is also the case for renal vasoconstriction produced by norepinephrine, phenylephrine, and ET-1. Other studies show that increased $\bullet O_2^-$ production stimulated by the acute infusion of Ang II produces more pronounced renal vasoconstriction when NADPH oxidase is intact than when NADPH oxidase is rendered nonfunctional in transgenic animals with NOX2 mutated. Ang II elicits less pronounced renal vasoconstriction in the absence of NOX2. Extracellular superoxide dismutase inactivation of the $\bullet O_2^-$ plays an important role in buffering acute Ang II–induced constriction of the afferent arteriole and increased RVR produced by chronic Ang II infusion.[198,263–266]

The mechanism by which $\bullet O_2^-$ causes or modulates renal vasoconstriction in normal kidneys is still unresolved. Ang II stimulates NADPH oxidase activity and $\bullet O_2^-$ production in the renal cortex and medulla. Ang II and ET-1 receptor activation rapidly stimulates NOX2-mediated O_2- release from afferent arterioles that increases cytosolic Ca^{2+} concentration in smooth muscle cells by increasing ADP ribosyl cyclase activity. The metabolite cyclic ADP ribose sensitizes ryanodine receptors on the sarcoplasmic reticulum of smooth muscle to release Ca^{2+}. $\bullet O_2^-$ may also scavenge NO and reduce bioavailability of this vasodilator, a major factor contributing to endothelial dysfunction in disease states. Accordingly, $\bullet O_2^-$ activity is enhanced during NOS inhibition. It should be appreciated that $\bullet O_2^-$-induced acute renal vasoconstriction is observed during NOS inhibition, highlighting a principal direct action on vascular smooth muscle independent of NO.[20,113,160,198,263,264,266–269]

Increased intrarenal $\bullet O_2^-$ produced by infusions of hypoxanthine and xanthine oxidase increases sodium excretion,

while GFR is reduced more than RBF and arterial pressure is unchanged. In these rats, $\bullet O_2^-$ did not affect the efficiency of pressure-induced steady-state RBF autoregulation. However, other evidence convincingly indicates that $\bullet O_2^-$ regulates both myogenic and TGF mechanisms responsible for renal autoregulation. The pressure-induced myogenic constrictor response of isolated afferent arterioles is mediated or enhanced by $\bullet O_2^-$ independent of H_2O_2 and of eNOS production of NO. In addition, $\bullet O_2^-$ produced by NOX2 in macula densa cells plays a role in TGF-induced afferent arteriolar vasoconstriction via direct action on afferent arterioles. This direct action complements quenching NO availability. The effects of $\bullet O_2^-$ are attenuated by increased levels of superoxide dismutase. Thus, ROS are important signaling molecules that participate in intrinsic autoregulatory responses of the preglomerular vasculature to changes in renal perfusion pressure. Local production of NO and ROS modulates reactivity of descending vasa recta pericytes that control medullary perfusion.[114,171,270–274]

eNOS and NADPH oxidase are both expressed in tubular epithelial cells within the renal medulla, particularly the thick ascending limb of the Henle loop, with the production of NO and $\bullet O_2^-$ participating in the regulation of medullary blood flow and influencing the set point of the pressure–natriuresis relation. Sodium retention and hypertension result when the balance of production of these free radicals favors $\bullet O_2^-$ in conditions such as in activation of the renin–angiotensin system, NOS inhibition, and diabetes. For example, during chronic NOS inhibition, renal vascular actions of $\bullet O_2^-$ are largely unopposed. Intrarenal infusion of the superoxide dismutase tempol in hypertensive L-nitro-arginine-methyl-ester (L-NAME) treated rats increases total RBF and blood flow to both the renal cortex and the medulla, and GFR, while urinary excretion of 8-isoprostane is reduced.[275–277]

Peroxynitrite ($ONOO^-$) is formed endogenously by NO reacting with $\bullet O_2^-$, exerting NO-like biologic activity as well as nitrating proteins during oxidative stress. The administration of low $OONO^-$ concentrations causes renal vasodilation as RBF and GFR increase in parallel in a NO-dependent manner, reverting to the constriction during NOS inhibition. High $ONOO^-$ concentrations produce renal vasoconstriction with larger reductions in GFR than in RBF. The reductions in RBF and GFR are magnified during NOS inhibition.[278]

$ONOO^-$ can oxidize arachidonic acid to form the vasoconstrictor 8-iso-$PGF_2\alpha$ (F2-isoprostane), which activates a thromboxane TP receptor to elicit vasoconstriction. Isoprostanes may increase ET-1 release from endothelial cells. Chronic exposure to high levels of Ang II stimulates isoprostane production by the kidney. Oxidative stress and exaggerated isoprostane levels acting on TP receptors enhances the strength of TGF in some models of hypertension. Such signaling may explain the afferent arteriolar vasoconstriction associated with oxidative stress in Ang II–induced hypertension, which appears to be mediated by an endothelial-derived and COX-derived vasoconstrictor that acts on TP receptors on vascular smooth muscle cells.[279]

Endogenous H_2O_2 appears to have little effect on preglomerular resistance vessels in the renal cortex because the combination of catalase with a superoxide dismutase mimetic has no additional effect as compared to superoxide dismutase quenching O_2^- alone. As mentioned in the following, increases in H_2O_2 above basal levels of 100 to 500 nmol per liter cause vasoconstriction in the renal medulla. H_2O_2, at apparent pharmacologic concentrations in micrometer per millimeter range in vitro, is reported to have biphasic effects on nonrenal resistance arterioles, dilating at low concentrations, perhaps due to NO, and constricting at high concentrations (>50 μmol per liter), possibly due to an isoprostane. H_2O_2 inhibits Ang II increases in $[Ca^{2+}]_i$ in afferent arterioles when the concentration is ≥ 1 μm but not less. Electrophysiologic studies of endothelium of freshly isolated porcine renal arteries indicates that a large conductance (300 pS) Ca^{2+}-activated K^+ channel (BK_{Ca}) is inhibited dose dependently by ROS in nanomole per liter range and H_2O_2 in the micromole per liter range. If tonically active, closure of BK_{Ca} channels causes depolarization and leads to vasoconstriction. Consistent with this view, H_2O_2 was found to reduce bradykinin-induced dilation of isolated renal arteries.[272,280,281]

MECHANISMS REGULATING MEDULLARY MICROCIRCULATION

Blood flow to the renal medulla is only about 20% of the total RBF; however, it is of major importance in regulating sodium homeostasis and in the maintenance of the medullary hypertonic environment. Expressed per gram of tissue, medullary blood flow is lower than cortical blood flow. The unique architecture of the renal medullary microcirculation preserves the axial osmotic gradient generated by the countercurrent exchange of water and solutes between the descending and ascending vasa recta while allowing for the removal of the water and solutes reabsorbed from the descending limb of the Henle loop and the medullary collecting ducts. Blood flow to the renal medulla is supplied from efferent arterioles of juxtamedullary nephrons, which give rise to the vascular bundles located in the outer medulla. The descending vasa recta (DVR) gradually transform until the smooth muscle layer, present in the outer medulla, is replaced by the discontinuous rings of pericytes. Thus, the vascular smooth muscle cells of the juxtamedullary nephron arterioles and of the outer medullary DVR are primarily responsible for the differential regulation of the medullary circulation. The outer zone of the inner medulla is partitioned into two distinct compartments with intercluster regions, one consisting of the ascending and the descending vasa recta and another consisting of the ascending vasa recta (AVR) and collecting ducts. Efferent arterioles and the DVR

are the main medullary structures with sympathetic innervation, which terminates when pericytes replace the smooth muscle cells. Extravascular renomedullary interstitial cells also exhibit contractile properties, but their role in regulating medullary blood flow is unclear. It has been more difficult to study the medullary circulation due to its inaccessibility and the fact that it is positioned in series with the glomerular circulation of juxtamedullary nephrons. Although there is considerable discrepancy regarding the absolute values of medullary blood flow obtained using various techniques, most of them provide a reasonable index of relative changes in blood flow.[1,15,18,89,282,283]

Hematocrit

The hematocrit of renal medullary blood is lower than that of systemic blood or blood derived from the renal cortex. Red blood cell (RBC) transit time is shorter than for plasma, and tissue hematocrit varies inversely with the medullary axis. Studies using videomicroscopic techniques and complementary direct measurements of hematocrit with micropuncture have demonstrated low microvessel hematocrit in the renal medulla. Shrinkage of RBCs in the hypertonic medulla also shifts water from the interior of RBCs to plasma and also contribute to the lower medullary microvessel hematocrit.[2,15]

In contrast to the peritubular capillary plexus that arises from efferent arterioles in the cortex to reabsorb massive volumes of tubular fluid, the vasa recta serve different needs specific to the medulla. Through their countercurrent arrangement, the DVR and the AVR trap NaCl and urea deposited to the interstitium by collecting ducts and the loops of Henle and maintain corticomedullary osmotic gradients. However, metabolic substrates, including O_2, that enter the DVR diffuse to the AVR to be shunted back to the cortex, leading to lower O_2 levels in the medulla than in the cortex. Paracrine agents regulate the renal medulla perfusion in a complex manner involving tubular-to-vascular and vascular-to-tubular paracrine signaling cross-talk. Protection of the medulla from hypoxia by these agents involves the local generation of paracrine agents by tubular and vascular structures and trapping by countercurrent exchange to yield axial concentration gradients that exert variable effects on the medullary vessels.[90]

Autoregulation

As already discussed, overall RBF is autoregulated with very high efficiency over a wide range of systemic perfusion pressure. Although cortical blood flow is well autoregulated within the physiologic range, the extent to which medullary blood flow is autoregulated is more controversial, especially in the rat. Some studies suggest that medullary blood flow autoregulation is not as efficient as in the cortex and that changes in medullary blood flow contribute to pressure natriuresis and the regulation of salt and water excretion as perfusion pressure changes. As mentioned previously, however, the renal medulla is largely perfused by the efferent arterioles from juxtamedullary nephrons, which have very high autoregulatory efficiency. Although a small population of shunt vessels bypass glomeruli, and may escape the autoregulatory adjustments, the extent of periglomerular shunting is very small and unlikely to contribute significantly to overall medullary blood flow responses. Both cortical and medullary blood flows are efficiently autoregulated in the dog. This holds for both outer and inner medullary perfusion. The same is true for cortical blood flow in the rat. Inner and outer medullary blood flows are also autoregulated efficiently in hydropenic rats, but not during marked volume expansion. Thus, it appears that loss of medullary blood flow autoregulation occurs primarily during marked volume expansion in rats subjected to increases in perfusion pressure. Recruitment of flow through the previously unperfused vasa recta may also contribute to that process, in particular because individual medullary vessels also exhibit autoregulatory responses. Volume-expanded sodium-replete dogs and rabbits exhibit efficient intact medullary blood flow autoregulation. The in vitro juxtamedullary nephron preparation that evaluates blood flow through nephrons that give rise to the vasa recta clearly exhibits normal autoregulatory behavior of the preglomerular vasculature. Thus, the extent of medullary blood flow autoregulation efficiency as well as the role of medullary perfusion in the generation of pressure natriuresis varies with species and degree of volume expansion. Nevertheless, paracrine factors act within the medulla to exert local control of medullary blood flow. The pressurization of in vitro perfused DVR increases endothelial $[Ca^{2+}]_i$ and the generation of NO. The release of NO by the vasa recta could increase local blood flow as well as inhibit salt reabsorption by adjacent tubules. A role for NO to provide a diffusible signal between the vasculature and nephrons seems likely.[1,2,15,18,107,153,277,284–286]

Vasopressin

Increases in medullary blood flow reduce the efficiency of passive countercurrent exchange, leading to "solute washout" and reductions in the corticomedullary gradients for NaCl and urea. Vasopressin exerts an important role in reducing medullary blood flow which contributes to increased urinary concentrating ability during antidiuresis. Homozygous Brattleboro rats that lack vasopressin have central diabetes insipidus and elevated medullary plasma flow. Vasopressin exerts its actions via subtype specific V_1 (vasoconstrictor) and V_2 (antidiuretic) receptors and reduces vasa recta blood flow through the activation of both V_1 or V_2, indicating roles for both vasoactive and reabsorptive mechanisms. A selective V_1 receptor agonist reduces inner medullary more than outer medullary blood flow. Similarly, elevated circulating vasopressin in water-deprived rats reduces inner medullary blood flow with weaker effects in the cortex and the outer medulla; these effects are blocked

by a V_1 antagonist, supporting V_1-mediated vascular effects of vasopressin to modulate inner medullary blood flow and to promote antidiuresis by maintaining the elevated osmolality in the medullary interstitium. Vasopressin reduces medullary perfusion by constricting juxtamedullary afferent and efferent arterioles. Afferent arteriolar vasopressin–mediated constriction is dependent upon voltage-gated Ca^{2+} entry via voltage-gated L-type and store-operated channels, whereas efferent constriction may be primarily related to Ca^{2+} mobilization from stores. Vasopressin also constricts outer medullary DVR. A vasopressin V_1 agonist reduces medullary blood flow without constricting either afferent or efferent arterioles, suggesting a greater sensitivity of the vasa recta to vasopressin.[15,252,287,288]

In addition to V_1 mediated constrictor effects of vasopressin, vascular V_2 receptors may cause vasodilation via the stimulation of NO release. V_2 agonists dilate preconstricted afferent arterioles and the outer medullary DVR in vitro. The V_2 agonist, dDAVP, stimulates medullary NO release and increases medullary blood flow. AVP-induced V_2 receptor activation in collecting ducts stimulates the phosphoinositide pathway and causes the mobilization of Ca^{2+} to increase NO production in the medulla and to protect the outer medulla from excessive vasoconstriction and ischemia.[1,15,248,286]

Angiotensin

In addition to its actions on the afferent and efferent arterioles, Ang II tonically constricts the medullary microcirculation via effects on the vasa recta. A NOS blockade constricts DVR and intensifies the constriction by Ang II. Similar to NO, PGE_2 and adenosine blunt Ang II constriction of DVR.[15,275,289]

AT_2 receptor activation elicits vasodilation via the generation of NO and the synthesis of vasodilatory cytochrome P450 epoxygenase-derived EETs. AT_2 activation vasodilates DVR where it inhibits reactive oxygen species formation and facilitates endothelium-dependent $[Ca^{2+}]_i$ signaling that leads to the release of vasodilators. There are also mechanisms leading to the Ang II–induced enhancement of medullary perfusion via AT_1 receptors due to the generation of compensatory vasodilators, particularly NO and vasodilator prostaglandins. Interstitial Ang II concentrations in the renal medulla are higher than in the cortex and Ang II receptor density is also higher in this region.[15,129,228,290–292]

Nitric Oxide

NO is particularly important in defending the renal medulla against hypoxia and ischemia. Chronic and acute systemic or intrarenal NOS inhibition reduces medullary blood flow more than cortical blood flow and elicits hypertension. Per volume of tissue, NO production in the renal medulla exceeds that in the cortex. NO production is closely coupled to L-arginine availability and cellular uptake via an amino acid transporter. Accordingly, dietary L-arginine supplementation increases renal medullary interstitial NO and medullary blood flow and reduces blood pressure in hypertensive Dahl rats and spontaneously hypertensive rats (SHR). DVR is dilated by NO donors and endothelium-dependent vasodilators. Similarly, NOS inhibition increases DVR vasomotor tone, producing as much as a 35% decrease in blood flow and blunts the dilation of preconstricted DVR by the endothelium-dependent vasodilators, acetylcholine and bradykinin. NO has a particularly important role to protect against the excessive reduction of medullary perfusion associated with hypoxia and oxidative stress, and NO levels in the medullary interstitium rise in response to Ang II, norepinephrine, and vasopressin. Conversely, medullary inhibition of NOS and NO production increases vascular sensitivity so that infusion of otherwise ineffective doses of vasoconstrictors reduce perfusion and generate tissue hypoxia.[284,293]

NO has both vasodilatory and natriuretic effects and is synthesized by epithelial as well as endothelial cells, suggesting critical tubular–vascular interactions. NO generated by the medullary thick ascending limb influences DVR tone. Conversely, NO generated by the DVR inhibits sodium reabsorption by adjacent nephron segments.[15,284,294]

The bioavailability and actions of NO are modified to a great extent by opposing the generation of ROS. NO levels in the renal medulla are modulated through reactions with oxygen radicals. ROS generation plays a role in the agonist-induced constriction of renal microvessels in the cortex and the medulla and in Na reabsorption by the ascending limb of the loop of Henle. In the DVR, ROS are generated upon stimulation with Ang II and PKC agonists; superoxide anion generation by the medullary thick ascending limb may limit availability of NO delivery and the vasodilation of DVR. The SOD inhibitor, diethyldithiocarbamate, reduces medullary blood flow, indicating a vasoconstrictor action of superoxide anion. Infusion of the SOD mimetic, tempol, increases medullary blood flow and sodium excretion, an effect that is more pronounced when H_2O_2 is simultaneously eliminated with catalase.[228,270,275,294–296]

Arachidonic Acid Metabolites

Prostaglandins, generated from arachidonic acid by COX-1 and COX-2 enzymes, alter intrarenal hemodynamics and increase blood flow toward the juxtamedullary cortex. Medullary blood flow is protected from excessive vasoconstrictors by prostaglandins as well as NO. Nonselective COX blockade decreases vasa recta blood flow by up to 50% and potentiates medullary hypoxia with a relative sparing of cortical perfusion. PGE_2 is generated in large quantities in the renal medulla and blunts Ang II–induced constriction of isolated perfused DVR. Both COX-1 and COX-2 isoforms contribute to renal prostaglandin synthesis and are predominantly expressed in the renal medulla; COX-2 is subject to greater regulation. Renomedullary interstitial cells express receptors and release paracrine substances including PGE_2, EETs, and medullipin, and express both COX-1 and COX-2. Medullary COX-2 expression is

stimulated by tonicity. Genetic deficiency of COX-2, or its chronic inhibition, reduces medullary blood flow and enhances vasoconstrictor responses to Ang II. COX-2–derived prostanoids serve to maintain medullary blood flow under most conditions.[15,180,290,297,298]

Products of arachidonic acid are also generated by cytochrome P450 isoforms to yield EETs, the HETEs, and their products, dihydroxyeicosatetraenoic acids (DHETs). 20-HETE reduces medullary blood flow and the inhibition of 20-HETE with HET0016 enhances medullary blood flow. In contrast, EETs have been linked to endothelial-derived hyperpolarizing factors and cause vasodilation directly and also oppose vasoconstrictor actions of vasopressin.[118,253,299]

Kallikrein–Kinin System

Kallikreins release kinins from kininogens and are expressed by the outer and inner medullary collecting ducts. Kinins exert their actions by activating B_1 and B_2 receptors. B_2 receptors are expressed throughout the outer and inner medulla, and modulate blood flow and sodium reabsorption in the renal medulla. The infusion of a kinin antagonist causes a 20% reduction of papillary blood flow. The enhancement of kinin activity through the infusion of bradykinin or the inhibition of kininases with enalaprilat or phosphoramidon increases both medullary blood flow and sodium excretion. Blocking bradykinin receptors decreases medullary blood flow, an effect that is blocked by NOS inhibition. ACE inhibition in the presence of an AT_1 receptor blockade causes greater increases in MBF than cortical blood flow, and the effects are blocked by the B_2 receptor antagonist, icatibant. Low sodium diets augment the kinin-mediated component elicited by ACE inhibition. In volume-expanded anesthetized rats, a B_2 receptor blockade with icatibant reduces papillary blood flow. Bradykinin, acting through B_2 receptors, generates robust endothelial cytoplasmic calcium $[Ca^{2+}]_i$ responses in isolated DVR leading to marked NO production and EETs leading to vasodilation of Ang II preconstricted vessels.[15,208,300]

Adenosine

As discussed earlier, adenosine exerts its actions on the renal vasculature predominantly through A_1 and A_2 receptor subtypes. Adenosine A_1 receptor activation transiently reduces cortical and medullary blood flow, whereas A_2 receptor stimulation leads to medullary vasodilation and natriuresis. Both A_1 and A_2 receptors are expressed by DVR, and their respective stimulation induces constriction or dilation. Interstitial adenosine concentrations are near the affinity for the A_2 receptor so that changes should modulate vasodilatory and natriuretic effects. A_1-induced constriction is mediated by the pertussis-toxin–sensitive $G\alpha_i$ protein and phospholipase C activation. A_2-mediated dilation is mediated by the stimulation of the $G\alpha_s$ protein and the activation of K_{ATP} channels via enhanced levels of 11,12-EET. During hypoxia, the medullary thick ascending limb of Henle synthesizes adenosine, which serves a paracrine vasodilator function to preserve medullary perfusion and to augment medullary pO_2.[15,61,212,217,301,302]

Endothelin

Medullary ET receptors are present on medullary vascular bundles, medullary interstitial cells, and adjoining collecting duct cells. ET1 concentrations in the renal medulla are regulated by osmolality. ET1 binds to and stimulates both ET_A and ET_B receptors, thus inducing vasoconstriction. Isolated ET_B receptor stimulation, however, mediates vasodilation. Preglomerular smooth muscle cells show $[Ca^{2+}]_i$ responses to ET_A and ET_B agonists. The DVR from the outer medulla constrict in response to ET1, but medullary perfusion is not greatly affected due to the enhanced production of NO from ET_B-receptor stimulation, counteracting the vasoconstriction. ET_B-receptor stimulation of NO production plays a significant role in protecting the medullary circulation from excessive vasoconstriction.[15,150,156,162,303,304]

ET1 treatment selectively reduces cortical blood flow while transiently increasing medullary blood flow. Medullary vasodilation and natriuresis are prevented by blocking ET_B receptors or NO synthesis. Renal hypoxia stimulates ET1 production. The effects of endothelins on medullary blood flow vary with dietary salt intake. Chronic Ang II infusion, combined with salt loading, increases cortical and medullary immunoreactive ET. The administration of ET1 into ET_B-receptor deficient rats or wild-type rats in which the ET_B receptor is blocked fails to increase sodium excretion. Mice with the collecting duct-specific knockout of the ET1 gene have impaired sodium excretion in response to sodium loading and have salt-dependent hypertension.[156,304]

Reactive Oxygen Species

The production of ROS in the kidney is greatest in the outer medulla. eNOS and NADPH oxidase are both expressed in tubular epithelial cells within the renal medulla, particularly the thick ascending limb of the Henle loop, with the production of NO and $\bullet O_2^-$ participating in the regulation of medullary blood flow by acting on pericytes encircling the DVR. $\bullet O_2^-$ and H_2O_2 cause vasoconstriction, effects that are partially offset by the vasodilator NO. The inhibition of superoxide dismutase in the renal medulla increases local $\bullet O_2^-$ levels and reduces medullary perfusion. This is also the case for increased H_2O_2. Chronically increased oxidative stress such as in the activation of the renin–angiotensin system and diabetes, reduces medullary blood flow and sodium excretion, resetting pressure–natriuresis to produce hypertension.[270,275,277,305]

Collectively, the various vasoactive agents selectively regulate medullary blood flow through their actions on the pericytes that surround the vasa recta. Interestingly, the pericytes respond relatively weakly to vasoconstrictors such as Ang II, ET1, norepinephrine, and vasopressin, but

more robustly to the vasodilators including NO, CO, PGE_2, and adenosine. Furthermore, endogenous Ang II enhances, whereas NO reduces, the impact of increased renal sympathetic activity on medullary blood flow. The continuous interactions among these components regulate medullary blood flow and local oxygen supply.[15,18,208,306]

ADAPTATION OF RENAL HEMODYNAMICS TO ALTERED PHYSIOLOGIC CONDITIONS

Changes in Salt Intake

In healthy young adults, chronic changes in salt in the diet cause proportional changes in extracellular fluid volume and sodium excretion while having a subtle or minor influence on renal hemodynamics and arterial pressure. RBF and GFR are usually maintained within normal limits as a result of basically parallel adjustments in vasoconstrictor and dilator systems; this most often is also the case for arterial pressure. Some people, especially the elderly with compromised renal functions, develop salt-sensitive hypertension when consuming a high sodium diet.

As discussed earlier, the sodium diet and the extracellular fluid volume are major regulators of renin synthesis and release from juxtaglomerular granular cells. Renin secretion and Ang II production are stimulated by volume contraction due to macula densa signaling and increased sympathetic activity. A reduced delivery of salt to the macula densa stimulates COX-2 activity and PGE_2 production and, thereby, renin release. Macula densa COX-2 and microsomal PGE synthase mRNA are induced to increase PGE_2 production during a low sodium diet, whereas the EP_4 receptor expression is increased in glomeruli and in renin-secreting juxtaglomerular granular cells. Other important stimuli to renin-containing cells are sympathetic nerve activity and baroreceptor input. High salt intake inhibits renin release and Ang II production by these three major mechanisms of regulating renin. During sodium restriction, the elevated circulating and intrarenal Ang II levels constrict both afferent and efferent arterioles to either maintain or increase glomerular capillary pressure. K_f tends to be reduced. GFR is maintained in the normal range or is slightly reduced, whereas RBF declines to a greater extent, thus increasing the filtration fraction. Single nephron studies indicate that the TGF regulation of the afferent arteriolar tone is augmented during chronic salt restriction and high endogenous Ang II.[13,121,131,182,307]

The adaptive renal vasoconstrictor component is primarily the elevated Ang II acting on vascular AT_1 receptors because the Ang II receptor blockade increases RBF and GFR and reduces arterial pressure, with predominant effects in reducing afferent arteriolar resistance. Intrarenal ACE inhibition increases RBF and GFR in sodium-restricted dogs as a result of equal dilation of afferent and efferent arterioles in the presence of unchanged arterial pressure; K_f increases slightly. It is noteworthy that recent studies of direct renin inhibition with aliskiren in humans on a low salt diet reveal larger increases in RBF and GFR than in inhibition of the renin–angiotensin system using an ACE inhibitor or AT_1 receptor antagonist.[308]

A high salt diet increases the urinary excretion of salt to maintain a steady-state balance. There is a moderate increase in extracellular fluid volume, whereas the arterial pressure and the RBF and GFR usually remain within the normal range in individuals who are not salt sensitive. The stability of renal hemodynamics is achieved by a balance between vasoconstrictor and dilator systems. The vasoconstrictor effects of the renin–angiotensin system are reduced due to multiple mechanisms, including the suppression of renin release and Ang II production. Macula densa nNOS and COX-2 expression and activity are reduced during sodium loading. Reduced PGE_2 production by macula densa cells contributes to a reduced renin release along with reduced β-adrenergic stimulation by sympathetic nerves and increased baroreceptor inhibition in juxtaglomerular granular cells. Accordingly, inhibition of the renin–angiotensin system has little influence on renal hemodynamics and arterial pressure in animals fed a high salt diet. This also is the case for the AT_1-receptor antagonism and for ACE inhibition. Renal efferent sympathetic nerve activity is also suppressed, as is the case for opposing actions of the major vasodilator systems of NO and prostaglandins, which are reduced in parallel. TGF activity is reduced, whereas distal tubular flow is increased during volume expansion. The underlying mechanisms are not known, but low ambient levels of Ang II may contribute to reduced reactivity.[2]

Renal vascular reactivity to exogenous Ang II is enhanced during sodium loading and attenuated during a low salt diet, being related to AT_1-receptor density that is reciprocally associated with endogenous Ang II levels. Thus, Ang II–induced vasoconstriction is less pronounced when Ang II is chronically elevated because of the downregulation of vascular AT_1 receptors. This is not the case for norepinephrine as glomerular hemodynamic responses to renal nerve stimulation are similar whether animals are maintained on a low, normal, or high salt diet.[146] Intrarenal blood flow varies during changes in the sodium diet, with cortical and outer medullary but not inner medullary blood flow paralleling sodium intake. A high salt diet and reductions in the plasma Ang II concentration lead to increased cortical blood flow but not outer or inner medullary perfusion. Medullary blood flow is relatively well maintained during sodium restriction.[111,309]

The renal hemodynamic influence of vasodilator systems such as eNOS/NO, COX/PGE_2-PGI_2, and epoxygenase 11,12-EET are upregulated by a low salt diet, effectively counteracting the exaggerated vasoconstrictor influence of high Ang II and sympathetic nerve activity. In this setting, COX inhibition reduces RBF, renal cortical blood flow, and GFR, along with PGE_2 production as compared to no effect on renal hemodynamics in sodium-replete animals (Fig. 3.25). Whether the prostanoids are produced

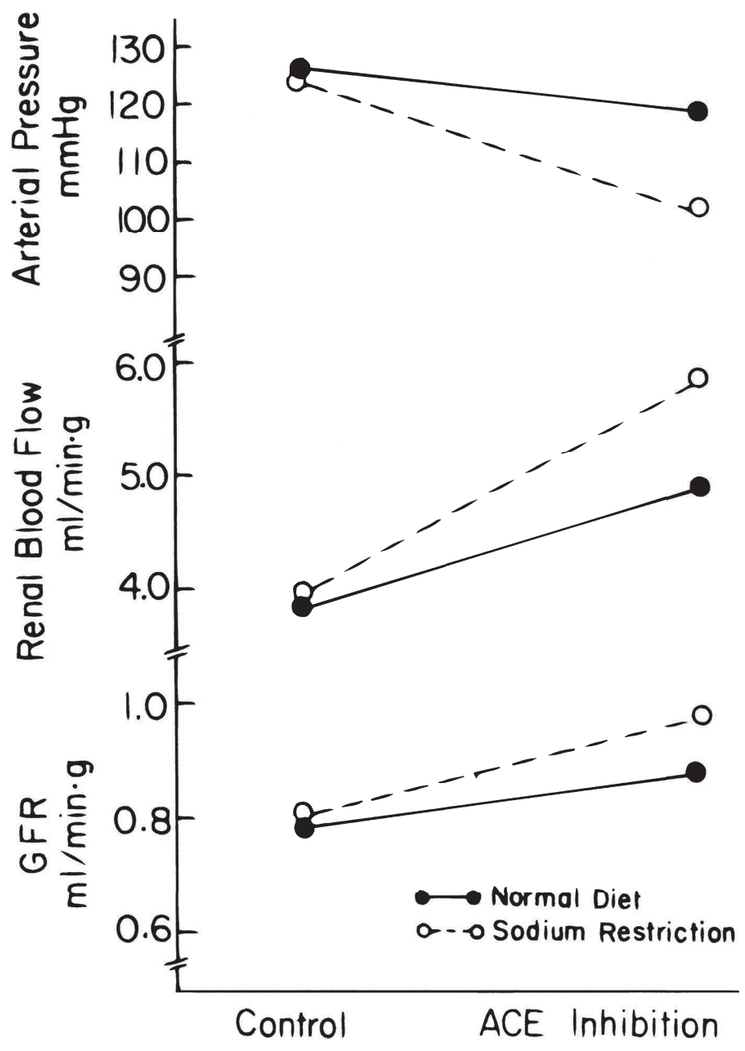

FIGURE 3.25 A comparison of renal hemodynamic and arterial pressure responses to angiotensin converting enzyme (ACE) inhibition in sodium-replete (*solid lines*) and sodium-depleted (*dashed lines*) anesthetized dogs. *GFR*, glomerular filtration rate.

by COX-1 or COX-2 is uncertain. One study finds that the renal hemodynamic changes are dependent on COX-2 activity, whereas another study reports that selective COX-2 inhibition is without effect on whole kidney hemodynamics during sodium depletion. COX-2 inhibition decreases medullary blood flow equally in animals on normal and low salt diets.[71,116,310,311]

COX activity and renal cortical production of vasodilatory prostanoids are low during volume expansion. COX inhibition in high salt animals has essentially no effect on whole kidney RBF or GFR. On the other hand, a high salt diet increases COX-2 expression in the renal medulla. Selective medullary COX-2 inhibition reduces medullary blood flow, which is associated with sodium retention and hypertension in rats consuming a high salt diet.[312–315]

Macula densa nNOS activity and NO productivity are inversely related to the sodium diet. Both endothelial eNOS and macula densa nNOS are upregulated during a low salt diet. NO generation in the kidney from L-arginine participates in adapting renal function to changes in salt intake. Dietary salt loading in animals enhances eNOS expression and activity and NO generation in the renal vasculature. Urinary nitrate + nitrite excretion, an index of NO production, increases during high sodium intake. NOS inhibition produces greater increases in arterial pressure (AP) and RVR and greater reductions in RBF in animals and humans on high versus low salt diets. NOS inhibition reduces medullary more than cortical perfusion during low and normal sodium diets. During sodium loading, NO control is similar for cortical and medullary blood flow. Macula densa nNOS is downregulated during a high salt diet. In contrast, protein expression of eNOS, iNOS, and nNOS is increased in the inner medulla. Afferent arteriolar vasodilatory responses to acetylcholine and sodium nitroprusside were unaffected by chronic high salt diets.[316–318]

Sodium restriction upregulates the kallikrein–kinin as well as the renin–Ang II system. The AT_1-receptor antagonism and ACE inhibition in dogs maintained on a low salt diet increase RBF and cortical blood flow. ACE inhibition causes larger increases in medullary flow than AT_1 receptor antagonism, an effect normalized by the blockade of bradykinin B_2 receptors. The vasodilator kallikrein–kinin system also participates in the renal adaptation to salt loading. Mice lacking vasodilator B_2 receptors respond to a high salt diet by becoming hypertensive with reduced RBF and increased RVR. In contrast, wild-type mice are normotensive with tendencies toward increased RBF and reduced RVR.[206]

Renal vascular reactivity to exogenous ET-1 is reduced by a low salt diet. ET_A receptor blockade has little effect on RBF during volume contraction. Sodium restriction upregulates pre-pro-ET-mRNA in the renal cortex, whereas ET_A and ET_B receptor density is unchanged. Low sodium intake and elevated Ang II acting on AT_1 receptors increase renal medullary ET-1 and ET_A and ET_B receptor mRNA, but not the sensitivity of renal medullary perfusion or sodium excretion to the ET_A or ET_B receptor blockade.[319,320]

Endogenous ET-1 levels are increased in the renal cortex and the medulla of animals fed a high salt diet, and renal vascular reactivity to exogenous ET-1 at the whole kidney level is enhanced. ET-1 reduces renal cortical blood flow and increases medullary perfusion in rats on a high salt diet as compared to cortical vasoconstriction, and has no effect on medullary blood flow in animals on a normal salt diet. Juxtamedullary-afferent arteriolar vasoconstriction produced by ET-1 and the ET_B receptor agonist are reduced. Arteriolar ET_B receptors, but not ET_A receptors, are upregulated presumably on endothelial cells during salt loading, and their vasodilation appears to buffer ET-1–induced vasoconstriction mediated by ET_A receptors. The ET_A-receptor blockade has no effect on whole kidney renal hemodynamics in rats placed on a high salt diet.[158,321]

Sodium loading increases renal ET-1 content and NO production that is in part mediated by ET_B receptors that are responsible for increasing medullary blood flow. A genetic deficiency of ET_B receptors leads to salt-induced hypertension. The more specific deletion of ET-1 or ET_B receptors in the collecting duct also causes salt-sensitive hypertension. In contrast, the specific mutation of ET_B receptors in vascular endothelial cells does not affect the AP sensitivity to salt.[156,322]

Normal kidneys, however, exhibit highly efficient whole kidney steady-state autoregulation of RBF whether animals are fed either a low or high salt diet and thus is independent of endogenous Ang II. Sodium depleted dogs have a normal RBF and GFR, with efficient autoregulation of RBF,

GFR, and single nephron GFR to changes in renal perfusion pressure. RBF is also effectively autoregulated during a low salt diet whether or not ACE is inhibited or AT_1 receptors are antagonized.[2] A high salt diet has little impact on dynamic RBF autoregulation, with either no change or an increased responsiveness of the myogenic mechanism in Sprague-Dawley or Long-Evans rats, respectively. Normal myogenic responses of afferent arterioles to increased luminal pressure is observed in mice fed a high salt diet for 3 months. A slight attenuation of pressure-induced myogenic responses is noted during high salt versus low salt diets for isolated interlobular arteries and afferent arterioles of Dahl salt-resistant rats. In hypertensive states, efficient autoregulatory responses to an increased arterial pressure play an important role in protecting sensitive glomerular capillaries and other renal structures from severe barotrauma. In some individuals, high salt intake may increase RBF and impair autoregulatory mechanisms such that the increased arterial pressure is transmitted to glomeruli, with the eventual development of proteinuria and glomerular sclerosis, along with interstitial inflammation.[93,323–325]

Renal cortical cytochrome P450-2 epoxygenase protein levels in renal microvessels and urinary metabolite EET excretion are increased during the consumption of a high salt diet. Epoxygenase products such as 11,12-EET exert antihypertensive effects as a result of vasodilator and natriuretic actions. Epoxygenase inhibition leads to salt-sensitive hypertension. In contrast, cytochrome P450-4A ω-hydroxylase protein levels are reduced in the renal cortex and in the renal vasculature. Nevertheless, a high salt diet increases overall renal excretion of 20-HETE in an adaptive response that contributes to increased sodium excretion. The pharmacologic inhibition of 20-HETE formation reduces sodium excretion and leads to salt-sensitive hypertension in rats.[183,318,326]

Adenosine produces more pronounced A_1 receptor–mediated renal vasoconstriction in high renin/Ang II states such as during sodium restriction. In contrast, adenosine produces dilation mediated by A_2 receptors in animals on a high salt diet, with increases observed in both the renal cortex and the outer and inner medulla. The reduction in RVR is due in part to enhanced cytochrome P450 activity and EET production during high salt intake. The pharmacologic stimulation of A_1 receptors decreases RBF and perfusion to the cortex and both the outer and inner medulla. In contrast, an A_1 receptor agonist causes reductions in RBF and cortical and outer medullary blood flow, but not inner medullar perfusion in low salt animals.[218,327,328]

Conditions that shift the balance to favor increased vasoconstrictor actions of superoxide and other reactive oxygen species over the vasodilator buffering effects of NO promote salt-sensitive hypertension that is characterized by renal vasoconstriction and enhanced salt retention. A hallmark of endothelial dysfunction is reduced NO production that can result from a reduced expression of eNOS and nNOS and impaired eNOS activation and NO production in the kidney. Salt-sensitive hypertension can be induced by pharmacologic NOS inhibition or genetic deletion of eNOS; the pressor response is reversed by the superoxide dismutase mimetic tempol. Enhanced renal vasoconstriction is associated with stronger than normal actions of Ang II and amplification by oxidative stress and NADPH oxidase–derived ROS as well as isoprostane. A chronic high salt diet leads to oxidative stress and inflammation in the kidney and vascular tissues and, eventually, hypertension, which is independent of Ang II activation of AT_1 receptors. Salt loading increases renal cortical NADPH oxidase subunit expression (NOX2 and $p47^{phox}$) and activity, increases superoxide generation, and increases urinary H_2O_2, 8-isoprostane, malondialdehyde, and thromboxane B_2 excretion, and decreases plasma NO end products. This is accompanied by the reduced expression of antioxidant superoxide dismutase isoforms. Such changes are limited more to the renal cortex than the renal medulla. It is noteworthy that the functional changes associated with oxidative stress and high salt intake are counteracted by oral L-arginine supplementation and improved NO production.[262,329–335]

Sodium restriction increases plasma renin activity and AT_1-receptor dependent oxidative stress in the kidneys as urinary excretion of 8-isoprostane is increased. Chronic activation of the renin–angiotensin system induces oxidative stress in the kidney. The administration of Ang II acting on AT_1 receptors enhances renal cortical NOX1, $p22^{phox}$ expression, superoxide production, and urinary excretion of 8-isoPGF2α (isoprostane). mRNA is decreased for NOX4 and extracellular superoxide dismutase. Although weaker, AT_2 receptors tend to blunt the actions of AT_1 receptors. The administration of the superoxide dismutase tempol increases RBF and arterial pressure, whereas GFR and sodium excretion are unchanged, suggesting predominant actions of superoxide on the renal vasculature.[262,336,337]

Changes in Protein Intake

The Western-style diet is characterized by highly processed and refined foods with a high content of sugars, salt, and fat, and high protein from meat that is chronically associated with dyslipidemia, oxidative stress, and inflammation. It is a major contributor to metabolic disturbances and the development of obesity-related diseases, including type 2 diabetes, hypertension, and cardiovascular and renal disease.

It has long been recognized that variations in the protein diet and plasma amino acid concentrations can have significant effects on the renal circulation. The consumption of protein in excess of 1 g/kg/day is usually associated with renal vasodilation in animals and humans. In dogs, the consumption of a high protein meal leads to increases in RBF and GFR, which are maximal at 3 to 6 hours and then progressively return to normal by 24 hours. The effect of protein feeding on renal function in humans is less marked than that in dogs. A short-term intravenous infusion of casein produces renal vasodilation that is sustained for up to 8 hours even though the blood amino acid concentrations

rapidly return to preexisting levels after the infusion is stopped. Various combinations of amino acids usually produce renal vasodilation and increase GFR; the changes are rapid in onset and reversible. It has been noted that only amino acids that are metabolized dilate the renal vasculature, whereas nonmetabolized amino acids do not affect RBF.[338–341]

The postprandial response to a protein-rich meal or a response to metabolizable amino acid infusion involves renal hyperemia and hyperfiltration because both RBF and GFR increase in both humans and animals. The ability of the kidneys to vasodilate and increase RBF and GFR in response to an acute protein or amino acid load is used clinically as a diagnostic index of vascular adaptability of "renal functional reserve." The greater the response, the more adaptable and thus the healthier the reserve; a weak or absent response is associated with severe nephron loss and aging. The mechanisms responsible for the renal vasodilation are multiple, involving blood-borne vasoactive agents, including pancreatic glucagon and the intrarenal release of COX-derived vasodilator prostanoids, NO, as well as reduced renin–Ang II and reduced TGF activity. Plasma renin activity and Ang II levels are unchanged and ACE inhibition does not impact on the protein-induced renal vasodilation.[154]

In healthy humans and laboratory animals, a high protein diet or the infusion of amino acids exert proportional effects on RBF, GFR, and urinary urea nitrogen excretion. Renal vascular resistance is reciprocally related to protein intake, with larger changes in RBF than in GFR. Arterial pressure remains stable and is independent of protein intake. Some reports, however, find that vegetarians have a reduced GFR relative to omnivores. The high protein diet leads to renal vasodilation and increased RBF and GFR in the face of normal arterial pressure and normal levels of plasma renin activity. Increased RBF and GFR are mediated by COX-dependent prostanoids and are largely prevented by COX inhibition. Glomerular COX and PLA_2 activities are increased, and the glomerular (but not renal papillary) production of PGE_2, $PGF_2\alpha$, and TxA_2 are increased under basal conditions and in response to Ang II. The urinary excretion of PGE_2 and PGF_2 metabolites are increased while plasma renin activity is elevated. Renal vasodilation is little affected by Ang II, as protein-induced changes in renal hemodynamics are unaffected by ACE inhibition. Nevertheless, vascular reactivity to Ang II is reduced during high protein feeding, whereas that of norepinephrine is normal. One mechanism contributing to renal vasodilation and increased GFR on a high protein diet is suppressed TGF control of preglomerular vascular resistance. Nevertheless, glomerular hyperfiltration is observed in adenosine A_1 receptor–deficient mice lacking TGF.[2,111,342,343]

Athletes and exercisers often use high-protein diets to enhance strength and muscle hypertrophy and recovery from intense exercise or injury. High protein diets combined with carbohydrate or fat restriction are also advocated for weight loss. However, it should be appreciated that chronic consumption of large amounts of protein may exacerbate or cause kidney damage. A long-term high protein intake often leads to proteinuria and increased GFR with renal hypertrophy that is accompanied with larger glomeruli and more glomerulosclerosis and tubulointerstitial fibrosis. The glomerular hypertrophy is due in part to increased vascular endothelial growth factor production.[344,345]

During a low protein diet, arterial pressure is normal, whereas plasma renin, Ang II, and aldosterone levels are reduced. Nevertheless, renal renin content is increased and exerts tonic actions on RVR. RBF and GFR are markedly reduced by protein restriction. The reduction in RBF is due to equal increases in both afferent and efferent arteriolar resistance. GFR is reduced due to reductions in plasma flow and the ultrafiltration coefficient. ACE inhibition increases RBF and GFR while reducing RVR, which is consistent with a prominent vasoconstrictor role of intrarenal Ang II. Glomerular AT_1 receptor density in the renal cortex and the medulla is increased during low protein feeding. Dietary protein restriction lowers plasma renin activity as a result of reduced PGE_2 production.[346]

In general, high protein intake aggravates renal injury, whereas restriction of dietary protein (~1 g protein per kilogram of body weight per day) while avoiding malnutrition ameliorates the progressive development of glomerular disease in various models. Based on animal studies, a low protein diet tends to be renoprotective in that it delays damage and proteinuria associated with hypertension, diabetes, obesity, or reduced renal mass and chronic renal disease, thus reducing GFR, glomerular growth, and interstitial infiltrate. A restricted protein diet reduces uremia, the progression of proteinuria, and the decline in GFR in adult patients with moderate-to-severe chronic renal disease. Dietary protein restriction reduces the glomerular permselective defect responsible for proteinuria in human renal disease. Implicated mechanisms include a hemodynamic basis, with reduced blood flow and glomerular capillary pressure, and nonhemodynamic factors related to reduced glomerular growth and less oxidative stress and inflammation. A low protein diet may reduce RBF by increasing TxA_2 production. Local Ang II levels may also participate. A protein restrictive diet lowers plasma renin activity by attenuating renin release, mediated in part by reduced PGE_2 stimulation, and increases AT_1 receptor density in the renal cortex and the medulla.[347–351]

CONCLUSION

As is evident from the previous discussion, there are many exciting issues concerning the area of renal hemodynamics and the multiple control mechanisms that are under active investigation. Modern technologic developments have allowed a more detailed and a more direct evaluation of the characteristics of specific segments of the renal microvasculature and of the various membrane and cellular mechanisms mediating differential responses. The direct assessment of

responses of individual arterioles has allowed for the clarification of long-standing controversies. In addition, developments related to interactions between endothelial cells and vascular smooth muscle cells are now receiving greater attention from investigators studying the renal circulation, as has been the case for interactions between distal tubular macula densa cells and vascular cells of the afferent arteriole and glomerulus. This has led to exciting new concepts with far-reaching implications. Additionally, many of these integrative mechanisms are now being addressed in terms of dynamic as well as steady-state characteristics. This combination of new developments has provided the impetus for renewed interest in the area of renal hemodynamics and the interactions with other intrarenal systems. These new investigations should result in a much better appreciation of the exact mechanisms that regulate renal microvascular contractility and reactivity and how disruptions of these mechanisms can lead to or predispose the kidneys to dysfunction and increased injury.

CHAPTER

4 Regulation of Water Balance: Urine Concentration and Dilution

Yumi Noda • Sei Sakaki

Water is by far the largest component of the body and accounts for approximately 50% to 65% of body weight. Maintenance of body fluid homeostasis, including fluid volume and solute concentration, is essential for cell function and whole-organism survival. The osmolality of body fluid, a concentration of all of the solute in water, is kept within a remarkably narrow range (280 to 295 mOsm per kilogram of water), in spite of large fluctuations of solute and water intakes and losses. Although this constancy is made by a variety of regulatory mechanisms in the body, the most critical regulatory capacities are provided by the kidney's urine concentration and dilution mechanisms.

Body water homeostasis is maintained by the balance between the input and output of water. Each side has regulated and unregulated components. The regulated component of water input is oral intake of fluids in response to a perceived sensation of thirst. The unregulated components of water input are oral intake of liquids and water in foods, and metabolic water of oxidation. Oral intake of water usually varies enormously in excess of homeostatic need because of social, cultural, or psychological influences. Solute-free water excretion by the kidney is the only route of regulated water output. The unregulated component of water excretion occurs via various kinds of insensible water losses including sweat, evaporative loss, gastrointestinal loss, and the obligate amount of water that is required to excrete the solutes in the urine. Sweat volume is determined by the requirements of temperature regulation. Evaporative loss is determined by body temperature and surface area, ventilation, and environmental temperature and humidity. Gastrointestinal water loss is affected by disturbance of its function. Both the input and output of water have very substantial unregulated components, and these can vary tremendously as a result of factors that are unrelated to the maintenance of body water homeostasis. Therefore, the regulated components, which are urine excretion and water intake caused by thirst, must compensate for whatever perturbations result from the unregulated water gains and losses. The daily urine excretion range is as low as 0.5 L to as high as 25 L depending on the requirements for water balance. When the kidney's capacity to conserve water is maximized to the limit due to dehydration, a sensation of thirst is activated, causing oral water intake to be increased.

Because the solute concentrations in water in the body must be kept nearly constant, water loss must be regulated by a mechanism that decouples water and the solutes. The kidney can excrete the appropriate amount of water without marked perturbations in solute excretion. When water intake is too large and dilutes blood plasma, urine diluted more than plasma is excreted to concentrate the plasma. When water intake is too small to concentrate plasma, urine concentrated more than plasma is excreted to dilute the plasma. In both cases, the solute excretion varies little. Renal solute-free water excretion is mainly regulated by the antidiuretic hormone vasopressin. Vasopressin is secreted from the posterior pituitary gland into systemic circulation in response to increases in the tonicity, which is an effective osmotic pressure in the plasma, to decreases in the effective circulating volume or pressure, or to several other stimuli. In response to changing levels of vasopressin in the plasma, the kidney is capable of wide variations in free water excretion. The molecular entity of a major effector of vasopressin in the kidney is aquaporin-2 (AQP2), which is a member of the aquaporin (AQP) water channel family. Molecular identification of the AQP family has revolutionized the understanding of water transport in the body, including urine concentration and dilution.[1,2] AQP2 is abundant in the collecting duct, which is the chief site of regulation of water reabsorption.[3] Acute stimulation of vasopressin promotes AQP2 translocation from an intracellular reservoir to the luminal cell surface, and its chronic stimulation increases the cellular abundance of AQP2, both of which elevate the water permeability of the collecting duct cells, resulting in the promotion of water reabsorption from the urinary tubule. Its impairments result in various water balance disorders including nephrogenic diabetes insipidus (NDI). In addition to AQP2, six other AQP isoforms are expressed in the kidney and play key roles in water transport activities specific for their localization in the nephron segments without

affecting solute transport. In addition to AQPs, the localizations of urea transporters and ion transporters are highly specific through the renal tubule segments. Together with a three-dimensional configuration of the nephron, the specific transport activities of water, urea, and ion all through the renal tubule segments enable the mechanism of urine concentration and dilution.

ANATOMIC CONSIDERATIONS FOR URINE CONCENTRATION AND DILUTION MECHANISMS

General Features of the Nephron Structure

The kidney consists of two populations of nephrons: short-looped nephrons and long-looped nephrons (Fig. 4.1). Both types of loops have a hairpin or a U-shape configuration, and are defined by the length of their Henle loop. Short-looped nephrons originate from superficial glomeruli and have a Henle loop, which turns near the inner-outer medullary border and consists of a proximal straight tubule, a thin descending limb, and a thick ascending limb. Long-looped nephrons originate from the juxtamedullary glomeruli, extend into the inner medulla, bend at various levels of the inner medulla, and contain a thin ascending limb in addition to segments found in short-looped nephrons. Thin ascending limbs are found only in the inner medulla and their transition to thick ascending limbs defines the inner-outer medullary border. Thus, only thick ascending limbs are found in the outer medulla.

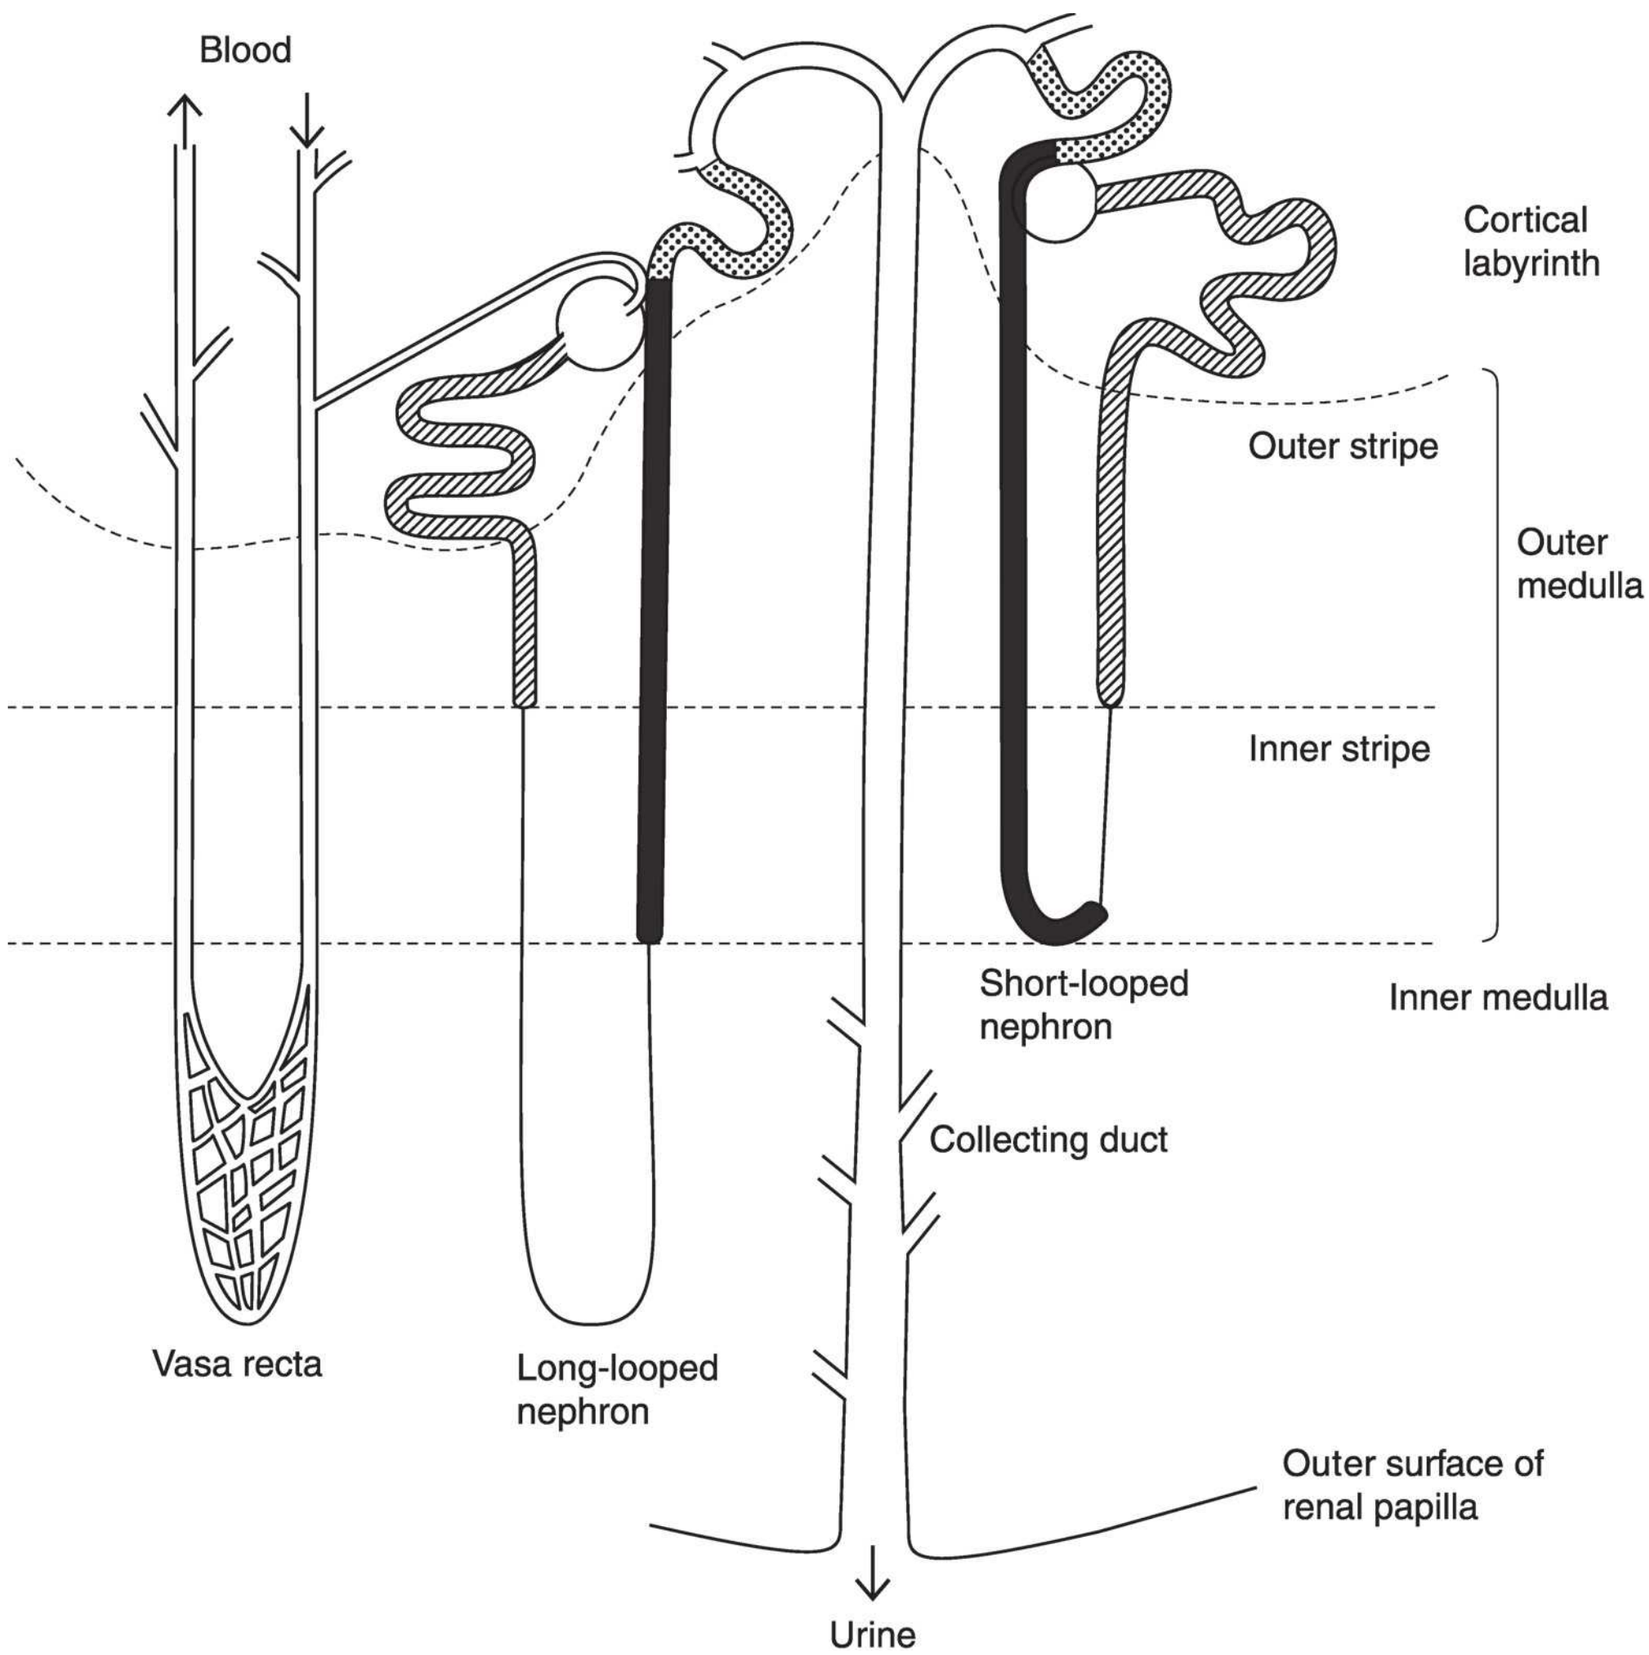

FIGURE 4.1 The kidney structure. The configurations of both a long-looped and a short-looped nephron are shown. The vasa recta is shown in the left. The major portions of the nephron are glomeruli (*circles*), proximal tubules (*hatched*), the thin limbs of the Henle loop (*single lines*), thick ascending limbs of the Henle loop (*solid*), distal convoluted tubules (*stippled*), and the collecting duct system (*open*). (Modified from Knepper MA, Stephenson JL. Urinary concentrating and diluting processes. In: Andreoli TE, Fanestil DD, Hoffman JF, Schultz SG, eds. *Physiology of Membrane Disorders*, 2nd ed. New York: Plenum, 1986:713, with permission.)

The Descending Part of the Henle Loop

The descending part of the Henle loop consists of the S2 proximal straight tubule in the medullary ray, the S3 proximal

straight tubule in the outer stripe of the outer medulla, and the thin descending limbs in the inner stripe of the outer and inner medulla. AQP1 is abundant in both the apical membrane and the basolateral plasma membrane in the S2 and S3 proximal tubules and the descending thin limbs.[4–6] AQP1 is constitutively active and is not regulated by vasopressin. AQP1 is present in sufficient abundance to account for the observed water permeability of these tubule segments.[7] The osmotic water permeability of the thin descending limb is extremely high due to the presence of the AQP1 water channel.[6] However, there is an axial heterogeneity in the expression levels of AQP1 in the thin descending limb; AQP1 is present in entirety through the thin descending limb of the short-looped nephron, whereas it is located in the upper half of the thin descending limb of long-looped nephron.[8–10] A comparison of water permeability and the abundance of AQP1 in these tubule segments indicates that AQP1 is the main route for water movement across the tubules.[8] The high water permeability of these segments is critical for the countercurrent multiplication system that is described in the section Countercurrent Multiplication in the Outer Medulla and Other Mechanisms in the Inner Medulla, which follows. As expected, a severely impaired urine concentrating ability is observed in AQP1 knockout mice.[11]

In addition to AQP1, AQP7 is expressed in the apical membrane of the S3 proximal tubule. AQP7 transports glycerol as well as water, thus AQP7 is an aquaglyceroporin.[12] Studies in AQP7 knockout mice suggest that water absorption mediated by AQP7 is small compared to that of by AQP1 and minimally contributes to urine concentration; whereas glycerol absorption by AQP7 may be important in glycerol metabolism in the body.[13]

A urea transporter UT-A2 is present in the thin limb of the long-looped nephron in the inner medulla and the thin descending limb of the short-looped nephron in the outer medulla. Thus, these segments have a high urea permeability[14] and play an important role for urea-recycling pathways that serve to maintain high urea concentrations within the inner medullary interstitium, which is critical for the urinary concentration that is described in the section Urea Accumulation in the Inner Medulla, which follows.

The Ascending Part of the Henle Loop

The ascending part of the Henle loop consists of the thin ascending limb in the inner medulla, the medullary thick ascending limb in the inner stripe of the outer medulla, and the cortical thick ascending limb in the medullary rays. The thin ascending limb is located exclusively in the inner medulla, is present only in the long-looped nephron, and becomes a thick ascending limb at the inner-outer medullary border. The thin ascending limb has extremely low water permeability and AQPs are not detected. By contrast, the ClC-K1 chloride channel is expressed in the apical and basolateral membrane of the entire length of the thin ascending limb.[9,15,16] Studies with immunohistochemical labeling and computer-assisted reconstruction in rats' inner medullas show that the thin ascending limb marked by ClC-K1 expression occurs about 160 μm before the loop bend.[9]

The thick ascending limb has essentially no water permeability and does not express AQPs. On the other hand, Na-K-2Cl cotransporter (NKCC2) is present in the apical membrane,[17] and Na-K-ATPase, a Na pump, is present in the basolateral membrane in the thick ascending limb. NaCl is actively absorbed by these transporters, resulting in the dilution of the luminal fluid in this segment, which works as the single effect in the countercurrent multiplication (described in the following sections). Urea permeability in the cortical thick ascending limb is higher than in the medullary thick ascending limb.[18] This may also contribute to the dilution of the luminal fluid as it flows up to the cortex by passive urea absorption.

The Distal Convoluted Tubule and Connecting Tubule

After exiting the Henle loop, the luminal fluid enters the distal convoluted tubule that expresses the thiazide-sensitive Na-Cl cotransporter NCC.[17,19] NCC is important for NaCl reabsorption that reduces fluid delivery to the collecting duct, leading to increases in urinary concentrating ability. Water permeability in the distal convoluted tubule is low and the expression of AQP2 or vasopressin V2 receptor is not observed.

Several distal tubules merge to form a connecting tubule arcade. The connecting tubule cells express both AQP2 and vasopressin V2 receptor, suggesting that, like the collecting ducts, the connecting tubules are sites of regulated water absorption. Moreover, vasopressin-regulated water absorption in the connecting tubule can result in a considerable amount of free-water absorption during antidiuresis because the large aggregate epithelial surface area of the connecting arcades is estimated to be roughly equivalent to that of the cortical collecting ducts.[20]

An AQP2 knockin mice model of nephrogenic diabetes insipidus, a rare disease manifested by an inability to respond to vasopressin, shows a severe urinary concentrating defect that results in neonatal death.[21] Meanwhile, AQP2 conditional selective knockout in the collecting duct but not in the connecting tubule rescues mice from the lethal phenotype that is observed in mice lacking AQP2 globally.[22] Although all types of mice show a severe urinary concentrating defect, these findings confirm an important role of the connecting duct for urinary concentration.

The Collecting Duct

The collecting duct is the final structure in the nephron. The luminal fluid from the connecting tubules then enters the collecting tubules in the superficial cortex. The collecting duct spans all the regions of the kidney. From the superficial cortex, the collecting duct descends through the cortex and the outer medulla. In the inner medulla, these collecting ducts

continually merge, finally forming the ducts of Bellini that open into the renal pelvis at the papillary tip. The renal pelvis is continuous with the ureter. The collecting ducts are arrayed parallel to the Henle loop. The collecting ducts have several morphologically discrete tubule segments: the cortical collecting duct, the outer stripe portion of the outer medullary collecting duct, the inner stripe portion of the outer medullary collecting duct, the initial part of the inner medullary collecting duct (IMCD), and the terminal part of the IMCD.

The collecting duct, under the control of vasopressin and other factors, is the nephron segment responsible for the final control of water excretion. The collecting duct expresses the vasopressin V2 receptor and AQP2, which are the primary targets for vasopressin regulation. In the absence of vasopressin, AQP2 resides in the vesicles below the apical cell surface and the entire collecting duct is very water impermeable. When the body is dehydrated, plasma osmolality is increased, which is sensed by the hypothalamic osmoreceptors and results in vasopressin secretion by the posterior pituitary. Vasopressin binds to V2 receptors in the basolateral membrane of the principal cells of the collecting duct, stimulates adenylate cyclase to produce cAMP, activates protein kinase A, phosphorylates AQP2, and inserts this water channel into the apical cell surface, which results in a significant increase in the collecting duct water permeability and water reabsorption.[23–25] This process is described in detail in the section Aquaporin-2, which follows. Not only are AQP2 water channels present, but also are AQP3 and AQP4 water channels in the collecting duct principal cells. There is axial heterogeneity in the abundance of AQP3 and AQP4; AQP3 is abundant in the connecting tubule, the cortical collecting duct, and the outer medullary collecting duct; whereas AQP4 is most abundant in the inner medullary collecting duct.[26] AQP3 and AQP4 are located in the basolateral membrane of these cells and represent a potential exit pathway from the cell to the interstitium for water entering via AQP2.

Water reabsorption mainly occurs in the cortex and the outer medulla. The inner medulla has the highest osmolality and is important for the reabsorption of the remaining water when maximal water reabsorption is required. Rather, water reabsorption by the terminal part of IMCD is greater during diuresis than during antidiuresis[27] because of its large transepithelial osmolality difference and relatively high basal water permeability compared to other portions of the collecting duct.

The connecting tubule and the cortical collecting duct express the amiloride-sensitive sodium channel ENaC.[28,29] Sodium is actively absorbed via ENaC in the apical membrane of the principal cells and exits the cells via Na-K-ATPase in the basolateral membrane. Sodium reabsorption via ENaC is increased by vasopressin or aldosterone and plays an important role for reducing fluid delivery to the medullary collecting duct, thus leading to increases in urinary concentrating ability.[30] On the other hand, the sodium permeability is low in the medullary collecting duct.

The urea permeability is extremely high only in the terminal IMCD and low in other portions of the collecting duct.[31] UT-A1 and UT-A3 urea transporters are present in the terminal IMCD cells.[32] Urea reabsorption in this segment is important for the preservation of high urea concentrations in the inner medullary interstitium, which are essential for its urine concentrating ability and are also important for minimizing the urinary loss of urea that is a major part of the urea recycling pathway. This process is described in detail in the section Urea Accumulation in the Inner Medulla, which follows.

The Vasculature

The blood vessels named the vasa recta carry blood into and out of the renal medulla. Like the Henle loop, there are the descending and ascending parts in the vasa recta, both of which are arranged in parallel and in mutual proximity. Blood from efferent arterioles of juxtamedullary nephrons enters into the descending vasa recta in the medulla, passes through the capillary plexus located at various depths within the medulla, then merges to form the ascending vasa recta. Different from the Henle loop, the descending and ascending vasa recta are separated by the capillary plexus (see Fig. 4.1).

The AQP1 water channel and the UT-B urea transporter are present in the descending vasa recta and enhance the countercurrent exchange of water and urea between the descending and ascending vasa recta in the medulla.[6,33] This countercurrent exchange reduces the effective blood flow, contributing to the conservation of osmolality gradients in the medullary interstitium.

The Medullary Interstitium

The interstitium of the outer medulla and the outer portion of the inner medulla is a narrow space that is important for limiting solute diffusion upward along the medullary axis.[34] To the contrary, the interstitium of the inner half of the inner medulla is much larger. In this region, the interstitial cells are interspersed in a gelatinous matrix of highly polymerized hyaluronic acid,[35] which is largely devoid of capillary plexuses or lymphatics. This structure slows the diffusion of solute and water in the inner medulla.

The Pelvis

The collecting duct finally opens at the papillary surface and urine enters the pelvic space. In the kidney with only one papilla, such as in hamsters and rats, the renal pelvis is an intrarenal urinary space surrounding the papilla. In the kidney with many papillae, such as in humans, each papilla is surrounded by a funnel-shaped calyx. In the human kidney, it is the compartment between the calyces and the ureter that is called the pelvis.[36] This compartment is not present in kidneys with one papilla, where the pelvis is a direct extension of the ureter. The renal pelvic (calyceal) wall contains smooth muscle layers. Contractions of these muscles induce regular peristaltic contractions of the wall that strongly

compress the medullary tissue, resulting in intermittent flow in the collecting ducts and the Henle loop.[37]

URINE CONCENTRATION MECHANISMS

General Features of Urine Concentration

In an adult human, glomerular filtrate is about 180 L per day, most of which is reabsorbed by the high water permeable proximal tubule and descending limb of the Henle loop. However, regulation of water excretion mainly occurs after the luminal fluid reaches the distal tubule. The osmolalities of luminal fluid along the rat nephron are shown in Figure 4.2. The luminal fluid in the proximal tubule is isosmotic to plasma, regardless of antidiuresis or diuresis. This fluid then enters the thin descending limb of Henle and is concentrated as it flows down to the bend of the Henle loop because of water reabsorption. As the fluid flows up the ascending limb of the Henle loop, the luminal fluid becomes diluted because this segment is impermeable to water, and the thick ascending limb actively absorbs NaCl. This diluted fluid finally enters the collecting duct system. In diuresis (low AVP), the fluid remains hypotonic. On the other hand, in antidiuresis (high AVP), the fluid is concentrated to a level far greater than plasma by water reabsorption as it flows down the collecting duct. This is due to a vasopressin-induced significant increase in water permeability of this segment and the existence of an axial osmolality gradient in the medulla. This osmolality gradient with the highest degree of hyperosmolality at the papillary tip is maintained by several mechanisms, including countercurrent multiplication, countercurrent exchange, and urea accumulation in the inner medulla, as described subsequently.

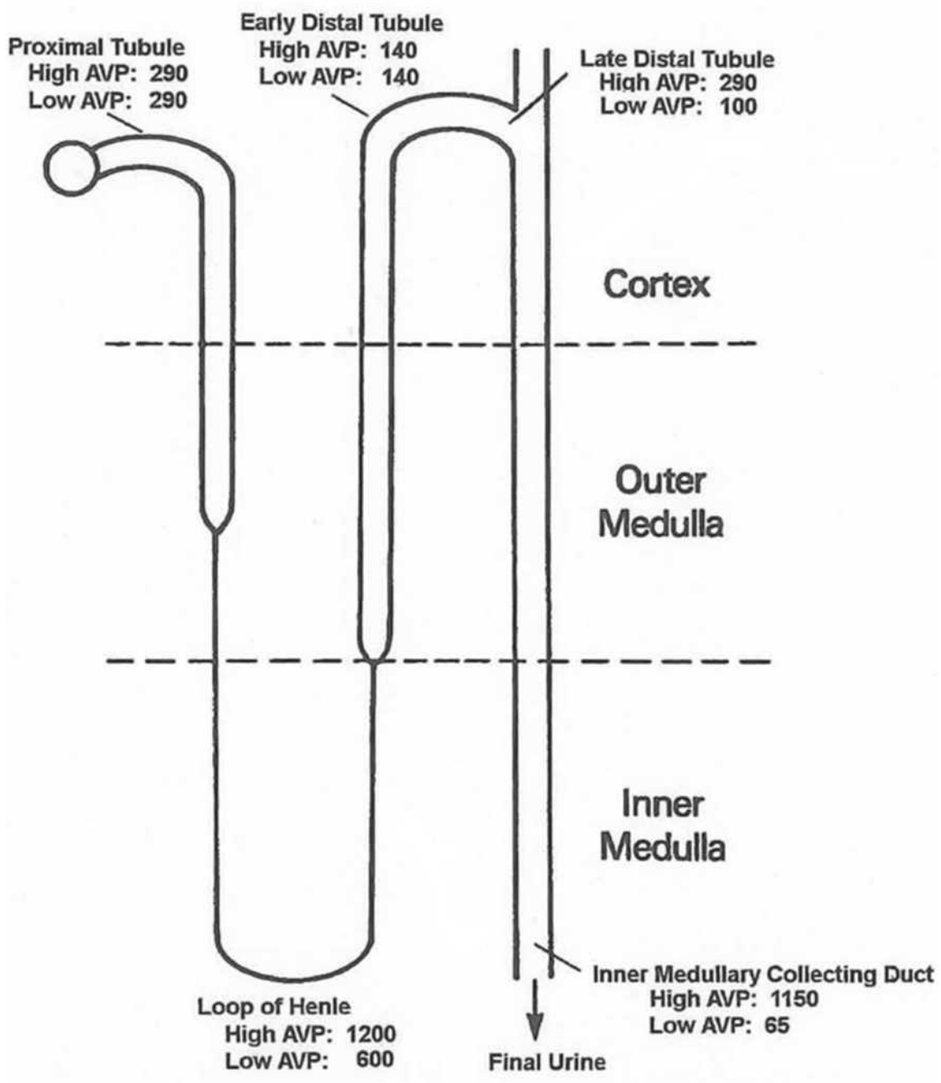

FIGURE 4.2 The typical tubular fluid osmolalities (in milliosmoles per kilogram of water) found along the nephron segments of the rat kidney. Fluid osmolality in the proximal tubule is isotonic, and it increases to 600 to about 1,200 mOsm per kilogram of water at the bend of the loop. Fluid emerging from the thick ascending limb is hypotonic, and final urine osmolalities are determined by urine concentration in the collecting duct depending on circulating vasopressin levels (65 to about 1,150 mOsm per kilogram of water). *AVP*, arginine vasopressin. Countercurrent Multiplication in the Outer Medulla and Other Mechanisms in the Inner Medulla

Countercurrent multiplication is an essential process for generating a medullary osmotic gradient along the corticomedullary axis and occurs in the Henle loop.[38] The counterflow arrangement of this loop makes the osmolality difference between the ascending and descending limbs to be multiplied, resulting in an enormous increase in osmolality toward the bend of this loop. Figure 4.3 illustrates the basic components of this mechanism in the short Henle loop. In the thick ascending limb of Henle, which corresponds to the right limb in Figure 4.3, NaCl is actively reabsorbed at any level of this ascending limb. Because this segment is impermeable to water, the luminal fluid is diluted and NaCl concentrations of the surrounding interstitium become higher than the luminal fluid. On the other hand, the descending limb of the Henle loop, which corresponds to the left channel in Figure 4.3, is highly permeable to water due to the presence of an AQP1 water channel, but is impermeable to NaCl. Water is passively reabsorbed from the descending limb lumen to the interstitium, which has a high osmolality due to NaCl accumulation. The luminal fluid in the descending limb is concentrated by water reabsorption and is continually concentrated downward to the bend of the loop, and then enters to the ascending limb. High NaCl concentrations of this fluid further promote NaCl reabsorption in the ascending limb. This fluid is then diluted by this NaCl absorption while flowing toward the top of the loop. Because the transverse concentration difference between the two limbs is always maintained by active NaCl absorption by the ascending limb (this is called the single effect) and water permeability of the descending limb at each level of the longitudinal axis is high, the bend of the loop achieves a progressively higher osmolality. This results in an enormous increase in osmolality toward the bend of the Henle loop.

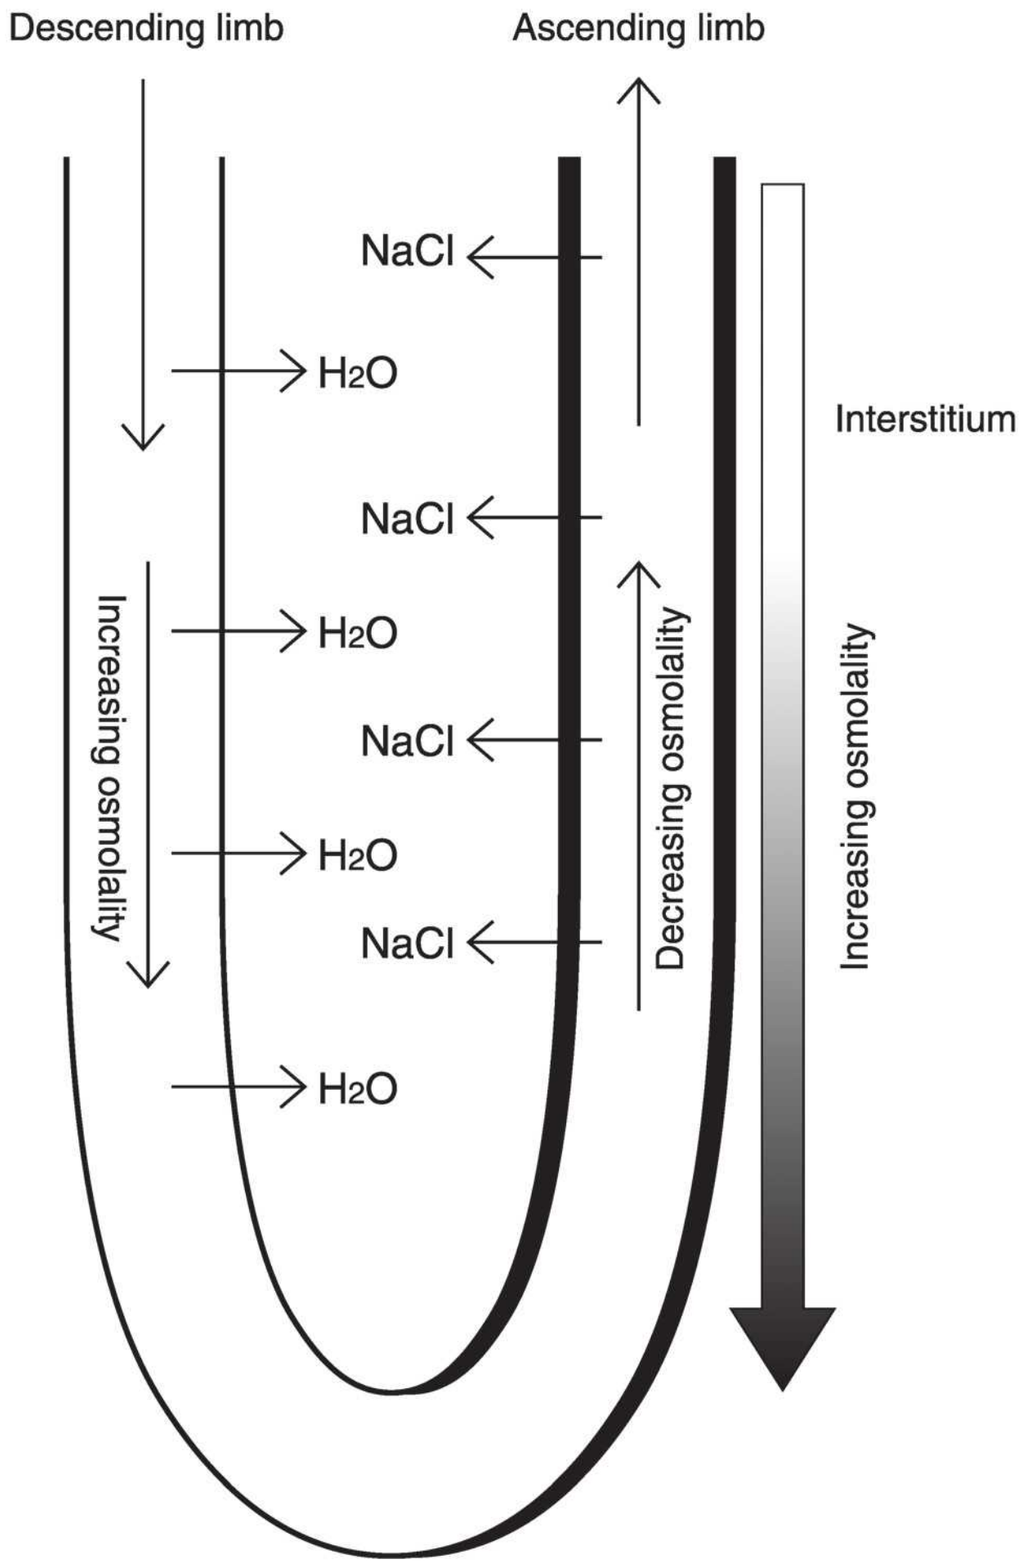

FIGURE 4.3 A countercurrent multiplication in the short Henle loop. In the thick ascending Henle limb, NaCl is actively reabsorbed. Because this segment is impermeable to water (indicated by *bold line*), the luminal fluid is diluted and the interstitium around this segment has high NaCl concentrations. On the other hand, the descending limb of the Henle loop is highly permeable to water, and water reabsorption occurs from the descending limb lumen to the interstitium with high NaCl concentrations. This results in an enormous increase in osmolality toward the bend of the Henle loop.

A countercurrent mechanism is accepted for generating the axial osmolality gradient in the outer medulla, where active NaCl reabsorption occurs in the thick ascending limb. However, in the inner medulla, there is little activity of NaCl transport despite the fact that osmolality continues to increase toward the tip of the papilla. The thin ascending limb of the Henle loop in the inner medulla cannot actively reabsorb NaCl. The high inner medullary interstitial osmolality provides a critical driving force for osmotic water flow across the collecting ducts, where the water permeability is regulated by vasopressin and AQP2 water channel, as described later. For explaining this concentrating effect in the inner medulla, a passive mechanism is widely accepted.[39,40] In this model, urea efflux from the terminal IMCD, which is mentioned previously, results in high urea concentrations in the inner medullary interstitium. This causes osmotic withdrawal of water from the thin descending limb and increases NaCl concentrations of the luminal fluid. This highly concentrated NaCl then exits passively from the thin ascending limb (works as single effect), and the luminal fluid is progressively diluted as it flows up. This passive transport process may produce an axial NaCl concentration gradient in the inner medulla. This model requires that the thin descending limb is highly permeable to water and but not to NaCl or urea, whereas the thin ascending limb is permeable to NaCl but not to water or urea. A microperfusion study of the thin ascending limb shows that the permeability of chloride and sodium are higher than urea, and that luminal dilution takes place when tubule segments are perfused in a condition simulating an in vivo situation.[41] Consistent with these physiologic studies, the ClC-K1 chloride channel is exclusively expressed in the thin ascending limb. ClC-K1 knockout mice show a large urinary concentrating defect with impaired urea as well as NaCl accumulation in the inner medulla.[42,43] This finding confirms the importance of a rapid chloride exit in the thin ascending limb and supports the passive mechanism.

Simulations based on many mathematical models incorporating physiologic parameters have been examined to show the validity of the passive model, but they usually failed to show satisfactory results. However, this does not necessary neglect the passive model because solute permeability and water permeability are sometimes different in species, in nephrons (long looped versus short looped), and within the segment (axial heterogeneity). Moreover, based on extensive studies of the rat inner medulla by immunohistochemical labeling and computer-assisted reconstruction, Pannabecker et al.[10] show that three-dimensional tubular and vascular relationships are more complex than thought before and a more comprehensive understanding of three-dimensional functional architecture is critically important for modeling urine concentration mechanisms of the inner medulla.

Countercurrent Exchange

Although the hypertonic medulla is essential for the ability to concentrate urine, blood flow may decrease the high solute concentrations in the medulla. The osmolality of blood entering to the medulla from the general circulation is far lower than the medullary interstitium and may decrease the osmolality of the interstitium as they come to equilibrium. Meanwhile, blood going out the medulla to the general circulation can carry out the solutes from the interstitium. To minimize this dissipation of the high solute concentrations in the medulla, there is a process called countercurrent exchange. Blood supply to the medulla is done by the vasa recta with the descending and ascending limbs arranged in a counterflow configuration. The vasa recta are permeable to water, sodium, and urea. Therefore, in the descending vasa recta, blood loses water and gains solutes as it flows down because

of the increasing osmolality in the medullary interstitium. After entering the ascending vasa recta, blood gains water and loses solutes as it flows up because of the decreasing osmolality of the surrounding interstitium. This exchange of water and solute between the descending and ascending vasa recta is called countercurrent exchange. This mechanism minimizes the solute washout from the inner medulla to the systemic circulation. Thus, this exchange at each level in the medulla preserves the axial solute concentration gradients in the medullary interstitium. If the blood flow is decreased, for instance in the conditions of volume depletion in the body, the efficiency of countercurrent exchange is further increased by getting enough time for achieving osmotic equilibration, leading to an increase in urinary concentrating ability.

The AQP1 water channel and the UT-B urea transporter are located in the descending vasa recta, which helps the rapid countercurrent exchange of water and urea.[6,33] Indeed, an impaired urine concentration ability is observed in AQP1 and UT-B knockout mice.[11,44]

Urea Accumulation in the Inner Medulla

The major solute responsible for the inner medullary osmolality gradient is urea and NaCl; although, in the outer medulla, it is NaCl.[45] High osmolality in the inner medulla is maintained by urea accumulation in this region in addition to NaCl. There are several mechanisms to maintain the high urea accumulation in the medulla that are called urea recycling (Fig. 4.4).[46,47]

Among the collecting duct, only the terminal IMCD has a high urea permeability due to the presence of UT-A1 and UT-A3 urea transporters in this segment.[31,32] During antidiuresis, water is absorbed in the collecting duct segments in the cortex and the outer medulla, which are impermeable to urea. Thus, the urea concentrations of the luminal fluid are progressively increased as it flows down through the connecting tubule, the cortical collecting duct, and the outer medullary collecting duct. When the luminal fluid reaches the terminal IMCD, which is highly permeable to urea, urea is rapidly absorbed from the lumen to the surrounding interstitium. During antidiuresis, the urea permeability of the inner collecting duct is increased by vasopressin, and this accounts for further rapid reabsorption of urea.[48,49]

Once reabsorbed, urea is not rapidly washed out to the general circulation because of countercurrent exchange and the low effective blood flow of the vasa recta, resulting in the high urea accumulation in the inner medullary interstitium. In addition, during antidiuresis, urea reabsorption by the terminal IMCD has another advantage for decreasing the luminal osmolality and preventing the osmotic diuresis when luminal fluid is very concentrated by enhanced water reabsorption in the upper portions of the collecting duct.

After being reabsorbed by the terminal IMCD, some urea in the inner medullary interstitium enters into the thin limbs of the long Henle loop where urea permeability is high due to the presence of UT-A2.[50] Urea entered in the thin limbs is then carried upward to the cortex through the thick ascending limb, the distal convoluted tubule, the connecting tubule, and the cortical collecting duct, and again enters into the medulla through the outer and inner medullary collecting ducts. Because these segments before the terminal IMCD have low urea permeability, urea can be returned to this region with little loss. Urea is again reabsorbed by the terminal IMCD and recycled to the inner medullary interstitium (Fig. 4.4).

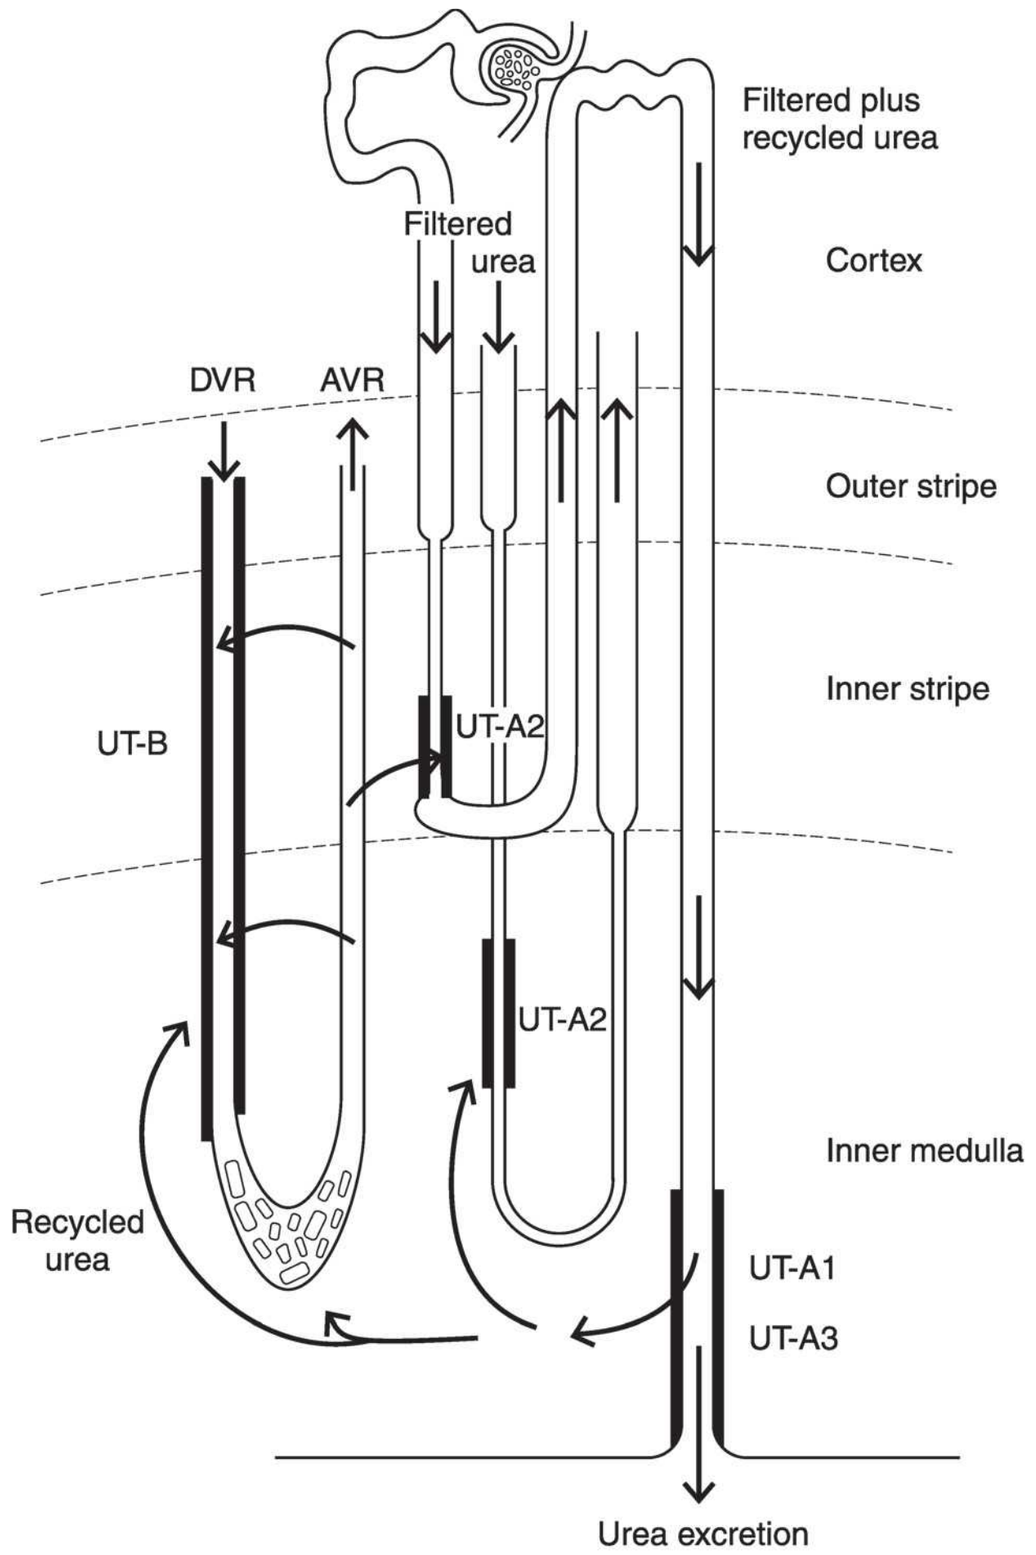

FIGURE 4.4 The urea recycling pathways within the kidney. The terminal portion of the inner medullary collecting duct (IMCD) efficiently reabsorbs urea through urea transporters UT-A1 and UT-A3, and accumulates urea in the inner medullary interstitium. Some of the urea is recycled to the IMCD by being reintroduced to the thin descending limb where UT-A2 is located. A high urea concentration in the medulla is maintained by countercurrent exchange (recycling) of urea between the descending vasa recta (*DVR*) and the ascending vasa recta (*AVR*), which is helped by UT-B in DVR. Some of the urea in the AVR is reintroduced to the thin descending limb and fed again to the IMCD. (Redrawn from Yang B and Bankir L. Urea and concentrating ability: new insights from studies in mice. *Am J Physiol Renal Physiol.* 2005;288:F881, with permission.)

In addition to the recycling pathway via the long loop in the inner medulla, there is another recycling pathway using the short loop in the outer medulla. Some parts of the urea reabsorbed by the terminal IMCD exit the inner medulla via the vasa recta. The vasa recta and the short Henle loop are arranged in parallel and in mutual proximity, and the descending limb of the short loop expresses the UT-A2 urea transporter and has a high urea permeability. Therefore, urea carried by the vasa recta is able to enter the short loop, then is convected through the distal convoluted tubule, the connecting tubule, and the collecting duct. When the luminal fluid finally reaches the terminal IMCD, urea is again reabsorbed to the surrounding inner medullary interstitium (Fig. 4.4).

The reabsorption sites among the collecting duct system are different between water and urea. Water is reabsorbed mainly in the cortex and the outer medulla, where blood flow is so high that water can be rapidly supplied to the systemic circulation. Furthermore, this reabsorption does not dilute the inner medulla. On the other hand, urea is reabsorbed in the inner medulla. Owing to low blood flow in this region and urea recycling pathways, urea can be trapped in the inner medulla, which is required for the passive mechanism, as described previously.

Regulated Water Reabsorption in the Collecting Duct

A countercurrent multiplication in the Henle loop generates a hypertonic medulla. A countercurrent exchange in the vasa recta minimizes the dissipation of this osmotic gradient. However, either of these processes has the ability to regulate water reabsorption in response to the body water balance. This function is performed by the collecting duct. The collecting duct is responsible for the final control of urine concentration, and its water permeability is regulated by vasopressin and other factors. In the absence of vasopressin, the collecting duct has an extremely low water permeability. Because the luminal fluid exiting the Henle loop is diluted, the fluid remains diluted after passing through the collecting duct, yielding a large volume of hypotonic urine. In the presence of vasopressin, the water permeability of the collecting duct is dramatically increased. Based on the hypertonic medullary interstitium generated by countercurrent multiplication and other processes, as described previously, an increase in water permeability of the collecting duct results in significant water reabsorption by the osmotic gradient between the lumen and the surrounding interstitium (Fig. 4.2). The molecular entity of this regulation of water permeability of the collecting duct is vasopressin V2 receptors and the AQP2 water channel expressed in the principal cells of the collecting duct.[26,51–55] V2 receptors and AQP2 are present in the connecting tubule and all segments of the collecting duct. When vasopressin binds to V2 receptors in the basolateral membrane of these cells, it stimulates adenylate cyclase to produce cAMP, activates protein kinase A, phosphorylates AQP2, and inserts this water channel into the apical cell surface, which results in a significant increase in the collecting duct water permeability and water reabsorption. In addition, vasopressin stimulation increases AQP2 protein abundance in the cell (Fig. 4.5). These processes are described in detail in the section Aquaporin-2, which follows. On the basolateral cell surface, AQP3 and AQP4 are located and represent a potential exit pathway from the cell to the interstitium for water entering via AQP2.

Water reabsorption mainly occurs in the connecting tubule, the cortical collecting duct, and the outer medullary collecting duct. In the cortex and the outer medulla, blood flow is sufficiently high so that absorbed water can be carried out to the general circulation without diluting the interstitium. On the other hand, the inner medulla has the highest osmolality and is important for reabsorption of the remaining water when maximal water reabsorption is required.

URINE DILUTION MECHANISMS

Approximately 50 mOsm per kilogram of water is the limit of the urinary diluting ability of humans. The mechanisms responsible for urinary dilution nearly overlap with that for urinary concentration. These two conditions between diuresis and antidiuresis are switched mainly by the collecting duct water permeability, which is regulated by vasopressin stimulation and the AQP2 water channel.

In the thick ascending limb, the luminal fluid is diluted by active NaCl absorption through NKCC2[56] and Na-H exchanger NHE3,[57] regardless of antidiuresis or diuresis. In addition, water impermeability of this segment preserves the luminal low osmolality by preventing water fluxes. The distal convoluted tubule also has the ability to actively absorb NaCl due to the presence of Na-Cl cotransporter NCC[19] and is impermeable to water, resulting in the dilution of the luminal fluid to an osmolality of about 100 mOsm per kilogram of water. In diuresis, this diluted fluid passes through the collecting duct because its water permeability is very low. Active Na reabsorption through Na channel ENaC in the collecting duct[29] can further dilute the luminal fluid. [58]

In addition to diuresis, there is another mechanism that further promotes urinary dilution. The terminal IMCD has a higher basal water permeability than other portions of the collecting duct and is surrounded by a high inner medullary interstitium. Because the osmolality of the luminal fluid reaching the terminal IMCD in diuresis is lower than that in antidiuresis, the transepithelial osmolality gradient in diuresis is larger than that in antidiuresis, resulting in a higher water reabsorption in this segment.[27] This reduces the inner medullary interstitial osmolality, leading to a further decrease in urinary concentrating ability.

VASOPRESSIN

The primary determinant of solute-free water excretion is the regulation of urinary water excretion by circulating levels of vasopressin in plasma. This section describes the regulation of vasopressin secretion from the neurohypophysis.

Structure and Synthesis

Arginine vasopressin is the antidiuretic hormone of most mammals, although members of the pig family have lysine vasopressin, in which a lysine replaces the arginine in position 8 of arginine vasopressin. Vasopressin is produced by the hypothalamic neurohypophyseal tract. This tract is composed of magnocellular neurons that arise bilaterally in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus and project medially to merge in the pituitary stalk and form the posterior pituitary gland in the sella tunica. Vasopressin is synthesized as part of a protein precursor of approximately 21,000 Da of molecular mass that incorporates a signal peptide at its amino terminus and vasopressin, neurophysin, and copeptin at its carboxyl terminus. In the endoplasmic reticulum, the signal peptide is removed. The prohormone then moves through the Golgi apparatus and into the neurosecretory granules that travel down the axon. In the neurosecretory granules, the prohormone is processed to yield amidated vasopressin, neurophysin, and copeptin.[59] Vasopressin and neurophysin form an insoluble complex in the nerve terminal and dissociate from each other after its release into the general circulation.

Regulation of Vasopressin Secretion by the Tonicity of Body Fluid

Under physiologic conditions, the most important determinant of vasopressin secretion is the tonicity of body fluid. Tonicity defines the forces that determine the net flux of water between two solutions separated by a membrane permeable to water but impermeable to certain solutes. On the other hand, osmolality refers to the forces generated by solutes that reduce the random movement of water molecules. The osmolality is a concentration of all of the solute in water, whereas the tonicity is an effective osmotic pressure and a concentration of all of the osmotically effective solutes. There are two types of solutes: osmotically effective and noneffective. Osmotically effective solutes, such as Na and Cl, are characterized by their inability to move across the cell membrane, resulting in a difference in their concentrations between the intracellular and extracellular compartments. On the other hand, osmotically noneffective solutes, such as urea and ethanol, are characterized by their ability to diffuse freely across the cell membrane and their concentrations between these two compartments are similar. Glucose is confined in the extracellular compartment and is osmotically effective in the absence of insulin; whereas in the presence of insulin, glucose is able to enter the cell by insulin-activated transporters, thereby becoming osmotically noneffective. Vasopressin secretion is finely regulated by the tonicity of body fluid.

The changes in the tonicity of body fluid are sensed by a group of cells called osmoreceptor neurons. These neurons are located in several brain areas including the organum vasculosum laminae terminalis (OVLT), the SON, and the PVN nuclei of the hypothalamus.[60] It is postulated that an increase in the tonicity of the extracellular compartment causes water withdrawal and shrinkage of the osmoreceptor neurons. Owing to the presence of mechanosensitive cation channels in these cells, cell shrinkage induces a positive charge influx and depolarizes the cell membrane, resulting in the triggering of neuronal action potentials. Such neurons send axonal projections to the SON, where they release the excitatory transmitter glutamate to synaptically excite the magnocellular neurons that release vasopressin in their distal axons.[60,61]

Recent studies show that the transient receptor potential vanilloid (TRPV) channels are likely to be the major component of the osmoreceptor. The N-terminal truncated TRPV1 channel is selectively expressed in osmosensory neurons in OVLT. The responses of these neurons to hypertonic stimuli, including reactive increases in cation channel conductance, membrane depolarization, and increased frequency of neuronal action potentials, were greatly inhibited in TRPV1 knockout mice. Furthermore, TRPV1 knockout mice showed a higher serum osmolality than wild-type mice, indicating a decreased sensitivity of osmosensation.[62] However, these results were not reproduced by another study.[63] In addition to TRPV1, TRPV2 and TRPV4 are present in osmoreceptor neurons and functional characteristics of these channels show responsiveness to the tonicity. Further studies, such as examining a possible hetero-oligomerization of these TRPV channels, are necessary for a molecular understanding of osomosensation.[60,61]

The functional properties of osmoregulatory mechanisms have a discrete threshold for vasopressin secretion, above which a linear relationship between plasma osmolality and vasopressin levels occurs.[64] When the plasma osmolality is below a threshold level, vasopressin secretion is suppressed to low or undetectable levels (0.5 pg per milliliter). Above this threshold, vasopressin secretion increases linearly in direct proportion to plasma osmolality. Both the threshold level and the slope of the regression line relating vasopressin secretion to plasma osmolality vary between persons due to unknown genetic factors and between the different conditions in the same individual. In general, the threshold is approximately 280 mOsm per kilogram of water, and above this threshold, a rise in plasma osmolality of 1% increases plasma vasopressin by approximately 0.4 to 1.0 pg per milliliter. The renal response to circulating vasopressin is also linear, with urinary concentration that is proportional to vasopressin levels from 0.5 to 5 pg per milliliter, above which urinary osmolality is maximal and cannot increase further. Therefore, changes of as little as 1% in plasma osmolality are sufficient to cause a significant increase in urinary concentration, and maximal antidiuresis is achieved by an increase in plasma osmolality of only about 10 to 15 mOsm per kilogram of water above the threshold. Furthermore, vasopressin secretion occurs within minutes in response to changes in plasma osmolality. After release into the systemic circulation, vasopressin distributes quickly because of its small size, and the equilibration between the vascular and extravascular compartments is almost complete within 10 minutes. The half-life of vasopressin in plasma is within

30 minutes. Therefore, the changes in plasma osmolality are rapidly transferred to changes in urinary concentration.

There are several factors that can alter the threshold and the sensitivity, which is the slope of the regression line relating vasopressin secretion to plasma osmolality. The most important factor is hemodynamic changes, including blood pressure and effective arterial blood volume, which are described in the next section. Aging enhances the sensitivity of vasopressin secretion.[65] In pregnancy, relaxin, an ovarian hormone produced by the corpora, reduces the threshold and increases vasopressin secretion, contributing partly to the increase in blood volume.[66]

Hemodynamic Regulation of Vasopressin Secretion

Vasopressin secretion is also affected by changes in blood volume and pressure.[67] A decrease in blood volume, such as with bleeding, sequestration or redistribution of blood, or fluid loss by sweating, diarrhea, or vomiting, can increase vasopressin secretion. The vasopressin release mechanism is much less sensitive to small changes in blood volume than to comparable changes in osmolality. Small reductions under 8% in blood volume usually have little effect on plasma vasopressin concentration. On the other hand, further acute reduction in blood volume significantly stimulates vasopressin secretion. Usually, 20% to 30% reductions in blood volume increase vasopressin secretion to the levels of 20 to 30 times normal. The stimulus-response relationship follows an exponential pattern. The vasopressin response to an acute reduction in blood pressure is similar to the response to blood volume. Reductions in blood pressure under 10% have little effect on vasopressin secretion, whereas blood pressure decreases of 20% to 30% result in significant increase in plasma vasopressin. The effects of reductions in blood volume and pressure are exerted through shifting the threshold and sensitivity of vasopressin secretion to osmotic stimuli.[68]

These hemodynamic effects on vasopressin secretion are mediated at least in part by neural pathways that originate in stretch-sensitive receptors called baroreceptors in the cardiac atria, the aorta, and the carotid sinus. From these receptors, afferent nerve fibers ascend in the vagus and glossopharyngeal nerves to the nuclei of the tractus solitarus (NTS) in the brainstem.[69] A variety of postsynaptic pathways from the NTS then project, both directly and indirectly, to the SON and the PVN nuclei of the hypothalamus.

Vasopressin secretion through the baroreceptor mechanism is promoted not only by a blood volume decrease but also by the reduction in effective arterial circulating blood volume. For example, upright posture, congestive heart failure, and cirrhosis stimulate vasopressin secretion.[70,71]

Other Influences for Vasopressin Secretion

The sensation of nausea, with or without vomiting, is a powerful stimulus to vasopressin secretion.[72] Nausea increases plasma vasopressin in excess of 200 to 400 pg per milliliter. The pathways responsible for this effect are located in the chemoreceptor zone in the postrema area of the brainstem. Water loading blunts, but does not abolish, the effect of nausea on vasopressin secretion, suggesting that the mechanism of emetic effect has a possible common pathway with that of an osmotic effect.

The renin-angiotensin system also influences the osmotic regulation of vasopressin secretion.[73] Neurons in the subfornical organ (SFO) contain angiotensin II and project axons onto hypothalamic magnocellular neurosecretory cells (MNCs) located in the SON and PVN nuclei. It is suggested that the release of angiotensin II may contribute to the potentiation of osmotically evoked action potential firing and vasopressin release.

Acute hypoglycemia induces a modest increase in plasma vasopressin,[65] although the pathways responsible for this effect are unknown.

The effects of pregnancy on the osmotic regulation of vasopressin secretion are complex. The systemic hemodynamic profile of pregnancy is characterized by a decrease in mean arterial pressure, a rise in cardiac output and plasma volume, and a decrease in body tonicity. This is due to a decrease in the osmotic threshold for vasopressin secretion because of arterial underfilling secondary to systemic arterial vasodilatation.[74,75] In addition, relaxin, an ovarian hormone produced by the corpora, reduces the threshold and increases vasopressin secretion, which contributes partly to the increase in blood volume.[66] On the other hand, the metabolic clearance of vasopressin is increased, owing to circulating cystine aminopeptidase (vasopressinase) produced by the placenta. This mechanism rarely causes transient diabetes insipidus in late pregnancy[76] because of the increased release of vasopressin.

MOLECULAR MECHANISMS OF VASOPRESSIN-REGULATED WATER PERMEABILITY OF THE COLLECTING DUCT

Vasopressin-regulated water permeability of the collecting duct is responsible for the final control of urine concentration. Upon vasopressin stimulation, the water permeability of the collecting duct is dramatically increased. Based on the hypertonic medullary interstitium, the increased water permeability results in significant water reabsorption and urine concentration. The vasopressin V2 receptor and AQP2 in the collecting duct are the primary targets for vasopressin. Vasopressin-regulated AQP2 translocation and abundance change the water permeability of the collecting duct principal cells. The essential roles of the vasopressin V2 receptor and AQP2 in urine concentrations are demonstrated by mouse models. Male mice that were introduced with a nonsense mutation into the AVPR2 gene, which codes the vasopressin V2 receptor and is located in the X chromosome, died within 7 days after birth due to hypernatremic

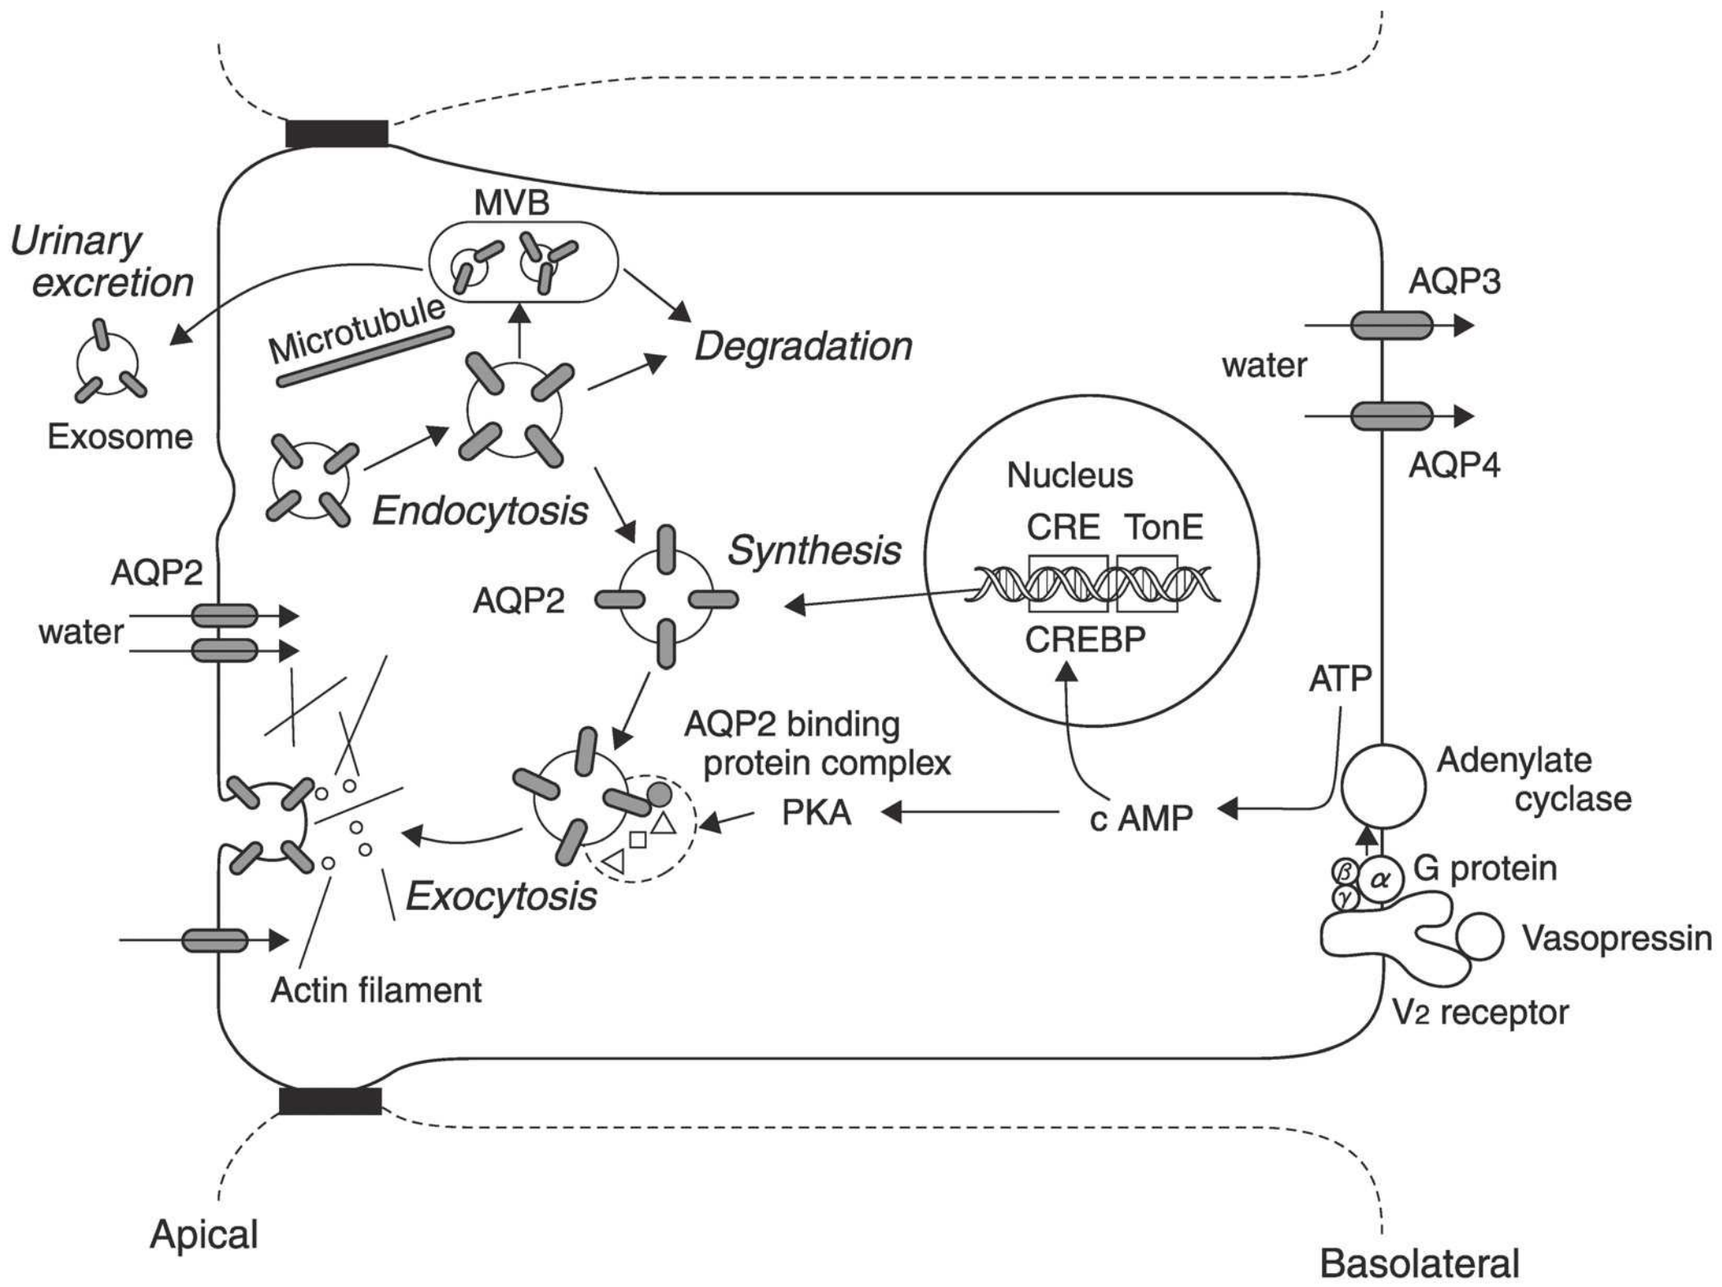

FIGURE 4.5 A schematic representation of the AQP2 protein dynamics within the cell. Vasopressin binds to the V2 receptor and this stimulates adenylate cyclase via G protein, resulting in the production of cAMP. cAMP stimulates the synthesis of the AQP2 protein through the interaction of the cAMP responsive element (*CRE*) of the AQP2 gene and the CRE binding protein (*CREBP*). Synthesized AQP2 are stored in subapical vesicles. Protein kinase A (*PKA*) directly phosphorylates AQP2, and this alters the binding dynamics of AQP2 and its binding proteins (AQP2 binding protein complex), which induces a reorganization of actin and stimulates the exocytosis of AQP2 containing vesicles to the apical membrane. Upon withdrawal of vasopressin stimuli, AQP2 is internalized by endocytosis and degraded. Some of the internalized AQP2 is transferred to the multivesicular body (*MVB*) and is excreted to the urine as an exosome. Thus, water transport—crossing the apical membrane through AQP2 and exiting the basolateral membrane through AQP3 and AQP4—is regulated by vasopressin.

dehydration.[77] Mice models with AQP2 protein deletion in the collecting duct also showed a severe defect in urinary concentration.[22,78] This section describes the molecular mechanisms for the regulation of water permeability of the collecting duct principal cells. Figure 4.5 illustrates several major mechanisms.

Vasopressin V2 Receptor

When circulating vasopressin reaches the kidney, vasopressin binds to the vasopressin V2 receptor expressed on the basolateral plasma membrane of the collecting duct principal cells and initiates the signal transduction in the cell. The V2 receptor is a 371 amino acid protein with 7 membrane-spanning domains and couples to heterotrimeric G-proteins.[79,80] The binding of the V2 receptor to vasopressin promotes the disassembly of the bound heterotrimeric G-protein (Gs) into Gα and Gβγ subunits. GDP-GTP exchange occurs in the Gα subunit and this activated Gsα then stimulates adenylate cyclase, resulting in an increase in intracellular cAMP levels (Fig. 4.5). Increased cAMP activates protein kinase A, which phosphorylates AQP2, and this phosphorylation event is required to increase the water permeability and water reabsorption of renal principal cells, which is described in the next section.

Aquaporin-2

AQP2 is a 271 amino acid protein with 6 membrane-spanning domains and 2 conserved, membrane-embedded asparagine–proline–alanine (NPA) motifs, and selectively permeates water.[3] AQP2 is predominantly expressed in the collecting duct principal cells (Fig. 4.6).[81,82] In response to vasopressin, AQP2 recycles between the luminal cell surface membrane (also called the apical membrane) and the intracellular subapical storage vesicles of the collecting duct principal cells. In the absence of vasopressin, AQP2 predominantly resides in the subapical vesicles. Because water molecules slowly diffuse through the lipid bilayer, the water permeability of the cell membrane without AQPs is low. Therefore, basal water permeability of the principal cells is also low. In the presence of vasopressin, AQP2-containing vesicles fuse with the apical membrane via exocytosis, thus inducing an exceedingly high

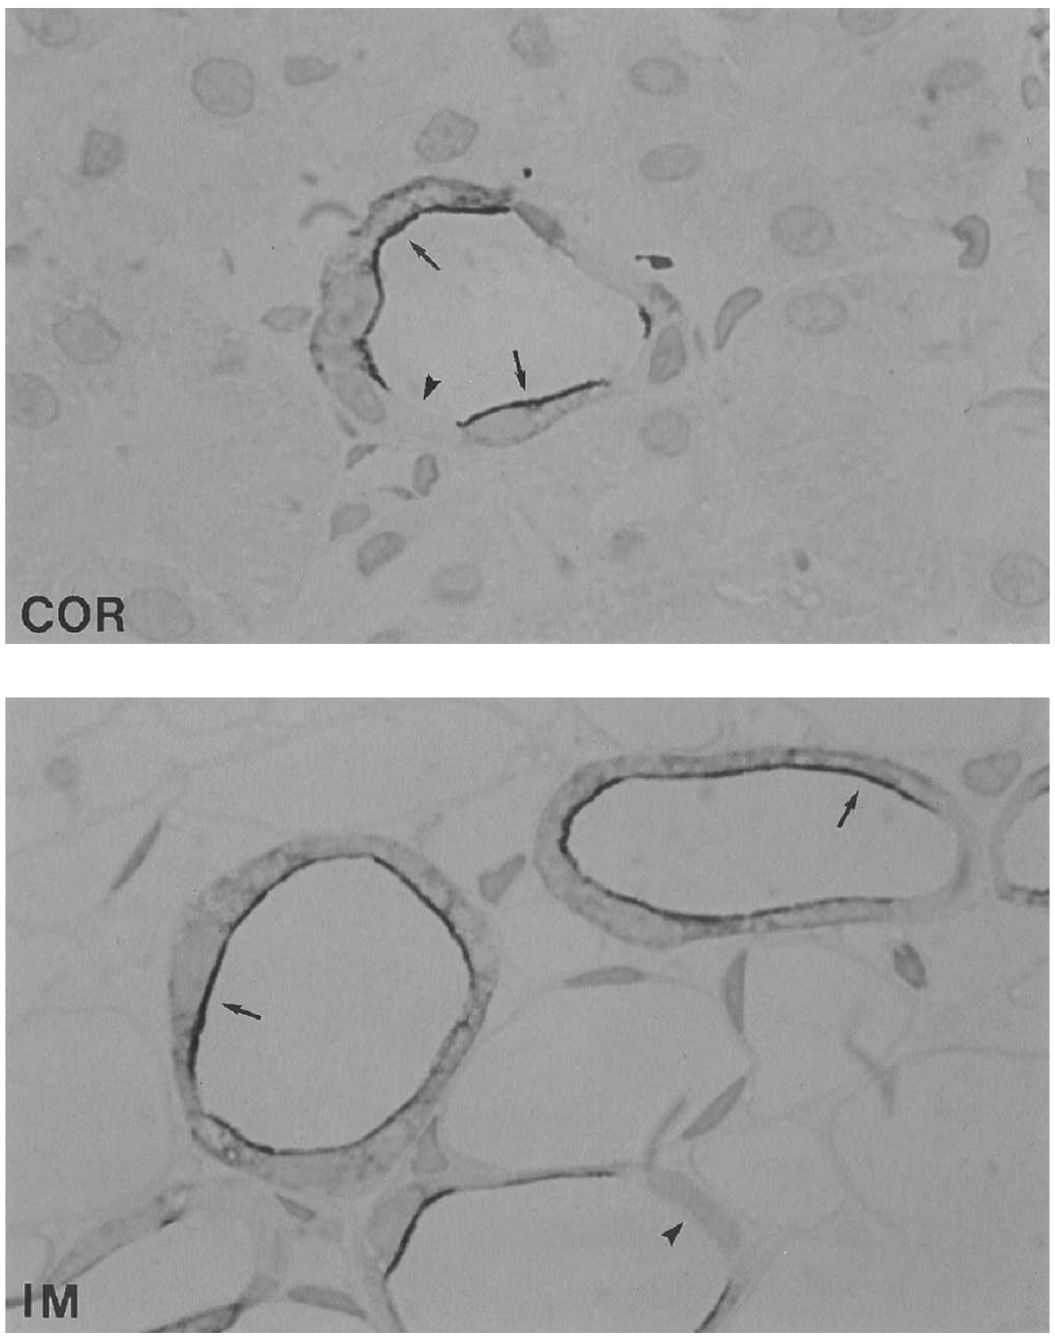

FIGURE 4.6 The immunoperoxidase labeling of AQP2 in the cortical (*COR*), the outer medullary (*OM*), and the inner medullary (*IM*) collecting duct. AQP2 is very abundant in the apical plasma membrane domains, as well as in the subapical domains (*arrows*), whereas intercalated cells are unlabeled (*arrowheads*). In the inner medullary collecting duct, AQP2 is also present in the basolateral part of the cell. (Magnification × 1,100.) (Reprinted from Nielsen S, Knepper MA, Kwon TH, Frøkiaer J. Urinary concentration and dilution. In: Schrier RW, ed. *Diseases of the Kidney & Urinary Tract*, 8th ed. Philadelphia: Lippincott Williams & Wilkins 2005:98, with permission.)

water permeability of this apical membrane (Fig. 4.7).[23–25] Vasopressin increases the water permeability by a factor of 10 to 100 in the cortical collecting duct,[49] 20 to 30 in the outer medullary collecting duct,[83] and 10 to 30 in the initial IMCD.[49] The terminal IMCD has a higher basal water permeability and vasopressin increases the water permeability by a factor of 10 in the terminal IMCD.[49]

The water permeability of the basolateral membrane of the principal cells is always high because of the presence of AQP3 and AQP4, and is not rate limiting for water transport. Thus, water that enters into the cell from the lumen via AQP2 can exit to the hypertonic medullary interstitium by the osmotic gradient. Upon the binding of vasopressin to its receptors, AQP2 is phosphorylated and this phosphorylation event is a requisite for AQP2 translocation to the apical membrane (Fig. 4.5).

Aquaporin-2 Phosphorylation and Trafficking

AQP2 forms homotetramers,[84] and at least three of four monomers in AQP2 tetramers must be phosphorylated for successful apical membrane localization.[85] Phosphorylation of serine 256 is required for the trafficking of AQP2 to the cell surface in cultured cells.[86,87] Protein kinase A and its substrates are present throughout the cell; therefore, localization of protein kinase A in specific sites is necessary for PKA to effectively phosphorylate its target. The phosphorylation process is assisted by protein kinase A anchoring proteins

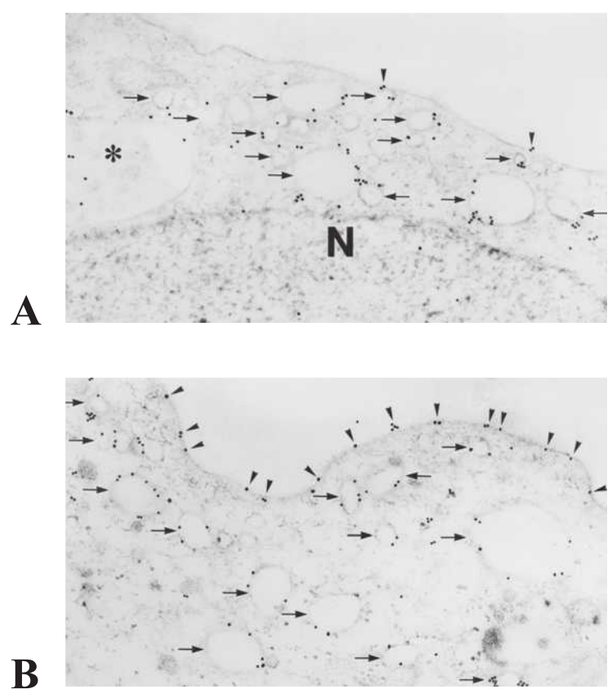

FIGURE 4.7 AQP2 immunogold labeling in the inner medullary collecting duct cells of control **(A)** and vasopressin-treated **(B)** Brattleboro rats. Immunogold labeling is obvious in the subapical cytoplasm in close association with cytoplasmic vesicles (*arrows*) or in the multivesicular body (*) but is sparse on the apical membrane (*arrowheads*). In contrast, heavy AQP2 labeling is observed on the apical membrane after vasopressin treatment (*arrowheads*). *N*, nucleus. (Magnification × 64,000.) (Reprinted from Yamamoto T, Sasaki S, Fushimi K, et al. Vasopressin increases AQP-CD water channel in apical membrane of collecting duct cells in Brattleboro rats. *Am J Physiol.* 1995;268:C1546, with permission.)

(AKAPs). The tethering of PKA to AKAPs is required for AQP2 shuttling to the cell surface.[88] A splice variant of AKAP-18, AKAP-18δ, is specifically involved in AQP2 shuttling[89] and the involvement of AKAP-220 has also been reported.[90]

AQP2 phosphorylation by kinases other than PKA might also be involved in the regulation of AQP2 trafficking. Serine 256 in AQP2 is also a substrate for Golgi casein kinase. AQP2 transition through the Golgi apparatus is associated with a PKA-independent increase in AQP2 phosphorylation at serine 256, suggesting that phosphorylation by Golgi casein kinase may be required for Golgi transition.[91] van Balkom et al.[92] showed that the activation of protein kinase C mediates AQP2 endocytosis, which is independent of the phosphorylation state of serine 256. In addition, a cyclic-GMP-dependent pathway is shown to be involved in AQP2 exocytosis,[93] and an inhibitor of cyclic GMP phosphodiesterase is able to induce AQP2 translocation to the cell surface.[94]

In addition to serine 256, there are three additional phosphorylation sites near the AQP2 C-terminus. These modifiable residues are serine 261, serine 264, and serine 269. Vasopressin induces the phosphorylation of AQP2 also at serine 264, and serine 264-phosphorylated AQP2 is translocated to the plasma membrane similarly to serine 256-phosphorylated AQP2.[95] On the other hand, vasopressin decreases the phosphorylation levels at serine 261, and the localization of serine-261-phosphorylated AQP2 is different from that of serine 256-phosphorylated AQP2, which suggests distinct roles for these residues in AQP2 trafficking.[96] Lu et al.[97] reported that the phosphorylation state of serine 261 does not affect AQP2 trafficking. Serine 269 is shown to be involved in the plasma membrane retention of AQP2.[98] Moeller et al.[99] showed that the phosphorylation of serine 264 and serine 269 depends on the prior phosphorylation of serine 256, and that the phosphorylation of serine 261 partially depends on the phosphorylation of serine 264 and serine 269. In contrast, serine 256 phosphorylation is not dependent on the state of any of the other phosphorylation sites, suggesting that serine 256 is the most important phosphorylation site of AQP2.

Role of Calcium in Aquaporin-2 Regulation

Intracellular Ca^{2+} mobilization is also involved in vasopressin-mediated AQP2 trafficking,[100] although its precise role remains unclear. In addition to increasing cAMP levels in the cytoplasm of the principal cells of the collecting duct, vasopressin binding to V2 receptor triggers a rapid increase of intracellular Ca^{2+}, which is followed by sustained temporal oscillations of the level of this ion. This process seems to be involved in AQP2 exocytosis. Balasubramanian et al.[100] suggest several plausible candidates as downstream effectors of this signaling cascade, such as calmodulin and MLCK. MLCK is a calmodulin-dependent kinase that regulates actin filament organization by phosphorylating the regulatory light chain of myosin II, and thus also activates myosin motor activity. Myosin II and its regulatory light chain are found in the AQP2-binding protein complex,[101] supporting their involvement in AQP2 trafficking. Nevertheless, Lorenz et al.[102] demonstrated that cyclic AMP alone is sufficient to induce AQP2 translocation without the need for an increase in cytosolic Ca^{2+} levels in the inner medullary collecting duct cells.

Involvement of extracellular Ca^{2+} in AQP2 regulation has also been indicated by several findings.[103–106] Urinary AQP2 excretion correlates with the severity of enuresis, a disease characterized by nocturnal polyuria and hypercalciuria.[103] Clinical amelioration demonstrated by a low calcium diet is accompanied by the regulation of urine output through the remodulation of AQP2 expression/trafficking.[104] Drug-induced hypercalcemia/hypercalciuria causes polyuria and reduces AQP2 expression in rats.[105] AQP2 translocation to the apical membrane prompted by forskolin-induced increases in cyclic AMP levels is inhibited by increased levels of extracellular Ca^{2+}.[106] This process is probably mediated by the endogenous calcium-sensing receptor and is associated with an increase in F-actin levels.

Other Influences for Aquaporin-2 Trafficking

Several other factors have recently been reported to affect AQP2 trafficking. Nejsum et al.[107] used Madin–Darby canine kidney epithelial cells transfected with AQP2 and showed that prostaglandin E2 and dopamine induce the internalization of AQP2, regardless of AQP2 dephosphorylation. de Seigneux et al.[108] reported that aldosterone induces a basolateral expression of AQP2, suggesting a role for aldosterone in water metabolism in conditions of increased sodium reabsorption in the collecting ducts.

Role of the Cytoskeleton in Aquaporin-2 Trafficking

The actin cytoskeleton is reported to function as a barrier for AQP2 exocytosis. Actin depolymerization is necessary for the cAMP-dependent translocation of AQP2. [109] In fact, the stimulation of prostaglandin E3 receptors has been shown to inhibit vasopressin-induced inactivation of Rho GTPase, vasopressin-induced F-actin depolymerization, and AQP2 translocation induced by vasopressin, cAMP, or forskolin.[110] Rho GTPase activation by bradykinin stabilizes cortical F-actin and inhibits AQP2 trafficking.[111]

GTPase-activating protein Spa-1 (SPA-1) binds to the C-terminus of AQP2, and this binding is required for AQP2 trafficking.[112] SPA-1 may inhibit Rap1 GTPase activating protein, which triggers F-actin disassembly and may maintain the basal mobility of AQP2.[55,113] SPA-1-deficient mice show impaired AQP2 trafficking and hydronephrosis.[112] In humans, mutations in the C-terminus of AQP2, which is the binding region of SPA-1, causes nephrogenic diabetes insipidus (NDI), a disease characterized by a massive loss of water through the kidney.[114,115] Furthermore, AQP2 binds to a multiprotein complex that includes the actin cytoskeleton, and a pattern of competing interactions between AQP2 and G-actin or tropomyosin directs AQP2 trafficking to the apical membrane (Fig. 4.5).[101,116,117]

F-actin assembly might have both inhibitory and facilitatory effects on an AQP2 transport to the cell surface.[118] Drug-induced actin depolymerization inhibits AQP2 translocation from the early endosomes that express early endosome antigen 1 to the subapical storage vesicles that express Rab-11.[119] Myosin II and its regulatory light chain are found in an AQP2-binding protein complex,[101] and vasopressin induces myosin light chain phosphorylation, which enhances the myosin–actin filament interaction and the formation of actin fibers.[120] Myosin has also been shown to be critical for AQP2 recycling.[121] In addition to acting as a barrier to prevent AQP2 trafficking, actin fibers may function as "cables" that promote and direct AQP2 transport. Dynamic actin reorganization may be responsible for the transformation of the actin barrier into actin cables. Further studies are necessary for understanding these sequential events.

Fusion of Aquaporin-2 Vesicles with the Apical Membrane

The docking and fusion of AQP2-containing vesicles with the apical membrane involves the action of N-ethylmaleimide-sensitive factor activating protein receptor (SNARE) proteins, including VAMP-2, SNAP-23, syntaxin-3, and syntaxin-4.[52] Syntaxin-binding protein 2 (also called Munc18b) is reported to function as a negative regulator of SNARE complex formation and AQP2-vesicle fusion to the apical membrane.[122]

Aquaporin-2 Recycling and Endocytosis

AQP2 is a recycling membrane protein. Upon vasopressin stimulation, AQP2 is transported to the apical membrane, rendering the cell water permeable, as described previously. After vasopressin stimulation is terminated, AQP2 is shuttled back to the cell cytoplasm, a process that restores the water-impermeability of the cell (Fig. 4.5). This internalization process consists of AQP2 retrieval into early endosomes that express early endosome antigen 1, and subsequent transferal of this water channel to storage vesicles that express Rab-11.[123] From Rab-11-positive vesicles, AQP2 is able to go again to the apical membrane. Actually, this recycling process occurs constitutively, and many signaling pathways are involved for the regulation of each part of this recycling itinerary. Vasopressin signaling is the most potent and most important factor that enhances the exocytotic process among the recycling itinerary.

During the endocytotic process of the AQP2 recycling pathway, AQP2 accumulates in clathrin-coated pits and is internalized via a clathrin-mediated process.[124,125] Dynamin is a GTPase that is involved in the formation and pinching off of clathrin-coated pits to form clathrin-coated vesicles, and its dominant-negative mutant K44A renders the protein GTPase deficient and arrests clathrin-mediated endocytosis. This GTPase-deficient dynamin mutant K44A is shown to accumulate AQP2 in the plasma membrane even without vasopressin stimulation.[125] Furthermore, this dynamin mutant K44A or methyl-β-cyclodextrin is able to accumulate the phosphorylation-deficient mutant in the cell surface despite the fact that AQP2-S256A accumulation in the cell surface is not induced by vasopressin. Methyl-β-cyclodextrin depletes membranes of cholesterol and results in a rapid inhibition of endocytosis.[126] These data also support the constitutive recycling of AQP2 and the presence of the processes that are not dependent on phosphorylation of AQP2 at serine 256.

A heat shock protein hsc70, which is important for uncoating clathrin-coated vesicles, binds to the C-terminus of nonphosphorylated AQP2 and is required for AQP2 endocytosis.[127)] Kamsteeg et al.[128] reported that the myelin and lymphocyte protein (also known as MAL), which is involved in the organization of the glycosphingolipid-enriched membrane, interacts with AQP2 and enhances accumulation of AQP2 in the apical membrane by decreasing the level of internalization of the protein. Ubiquitination at lysine 270 of AQP2 is important for AQP2 endocytosis and degradation.[129] Furthermore, LIP5, which is involved in multivesicular body formation, interacts with AQP2 and facilitates its lysosomal degradation.[130]

Regulation of Water Transport Activity of Individual Aquaporin-2s

As described previously, AQP2 phosphorylation induces its apical membrane insertion, rendering the collecting duct cells water permeable. However, whether this phosphorylation regulates the water permeability of individual AQP2 water channels remained unclear until recently. Several groups had examined the role of phosphorylation on osmotic water permeability (P_f) of individual AQP2s. In the Xenopus oocytes expression system, one study showed that PKA phosphorylated AQP2 at serine 256, which increased the P_f of oocytes without a significant increase in the amount of AQP2 on the oocyte surface.[131] However, another study using a similar method showed that the P_f values that corrected for the plasma membrane abundance of AQP proteins were not different between WT-AQP2 and the nonphosphorylation-mimicking mutant S256A-AQP2 expressing oocytes, indicating a lack of an effect of phosphorylation at S256 on the P_f of individual AQP2 proteins.[99] Lande et al.[132] purified endosomes derived from the apical membrane of rat IMCD cells that were highly enriched for AQP2. Then, these endosomes were phosphorylated by an exogenous PKA catalytic subunit or were dephosphorylated by an exogenous alkaline phosphatase. There was no significant difference in P_f between these two samples, suggesting that the P_f of AQP2 is not changed by its phosphorylation. However, involvement of other proteins, such as endogenous phosphatases, cannot be neglected.[132]

To clarify whether the P_f of AQP2 is regulated by its phosphorylation event alone, the experimental system that does not contain any other regulatory proteins is required. Eto et al.[133] performed a large-scale expression of full-length recombinant human AQP2, purification and reconstitution in proteoliposomes, and examined the protein function.

The results showed that the P_f of proteoliposomes was enhanced approximately twofold by phosphorylation at serine 256. This observation indicates that AQP2 water channel activity is directly regulated by its phosphorylation, and the mechanism involved may be the channel gating that is well studied in plant AQPs by X-ray crystal structure analysis.[134] Thus, in addition to AQP2 translocation to the luminal membrane, the water transport activity of individual AQP2 proteins may be involved in the regulation of water reabsorption in kidney collecting ducts.

Actually, vasopressin increases the water permeability of the collecting ducts more than tenfold.[49,83] Thus, vasopressin-induced short-term regulation of P_f of the collecting ducts still seems to be mainly due to AQP2 translocation, and the altered water transport activity of individual AQP2s may have a role of doubling the effect.

Long-Term Regulation of Water Permeability of the Collecting Duct by Altered Aquaporin-2 Abundance

In addition to short-term regulation of collecting duct water permeability described previously, long-term regulation also plays an important role in body water balance. Long-term regulation of collecting duct water permeability is seen when water intake is restricted for 24 hr or more, resulting in an increased maximum concentrating ability. This response is mainly induced by an increase in AQP2 abundance due to increased transcription of the AQP2 gene.[135,136] An increased AQP2 expression level during water restriction is a downstream of vasopressin signaling.[137,138] It is known that the cAMP responsive element (CRE) is present in the 5′-flanking region of the AQP2 gene and regulates the transcription of the gene.[139,140] Hasler et al.[141] examined the AQP2 gene transcription in a cultured cell line, which endogenously expresses AQP2 and showed that the vasopressin-stimulated transcription of AQP2 was mediated through CRE.

Medullary collecting ducts are surrounded by interstitial hypertonicity and the hypertonicity may be another determinant of AQP2 transcription.[142,143] Hypertonicity affects transcription of many genes through the interaction between the tonicity-responsive enhancer (TonE) and its transcription factor TonEBP. TonE is observed in the AQP2 gene, suggesting that TonE/TonEBP contributes to AQP2 transcription. This possibility was examined in TonEBP gene knockout mice, which had mostly embryonic lethality or died within a few weeks after birth. However, the surviving mice showed atrophy of the kidney medulla, and the protein expression of AQP2 but not of AQP3 was clearly downregulated in the knockout mice, confirming the role of TonE/ToneEBP in AQP2 transcription.[144] Taken together, AQP2 protein abundance in long-term regulation is likely to be mediated by stimulated transcription of the AQP2 gene through CRE and TonE motifs. In addition, the presence of AP1 and GATA elements are known in the promoter region of the AQP2 gene, but their roles remain speculative (Fig. 4.5).

CHANNELS AND TRANSPORTERS CONTRIBUTING TO URINE CONCENTRATION AND DILUTION

Urine concentration and dilution are enabled by the specialized organization of the renal tubule and vasculature, and the presence of channels and transporters with their specific localizations. This section describes water channel aquaporin family members other than AQP2 and other channels and transporters involved in urine concentration and dilution. Table 4.1 summarizes the basic characteristics of AQP members in the kidney, and tissue localization and phenotypes of mice and humans caused by gene knockout or mutations. Figure 4.8 shows the localization of these channels and transporters along the nephron. Figure 4.9 shows the maximal urine osmolalities of the knockout mice in which channels and transporters involved in urinary concentration are deleted.

Aquaporin-1

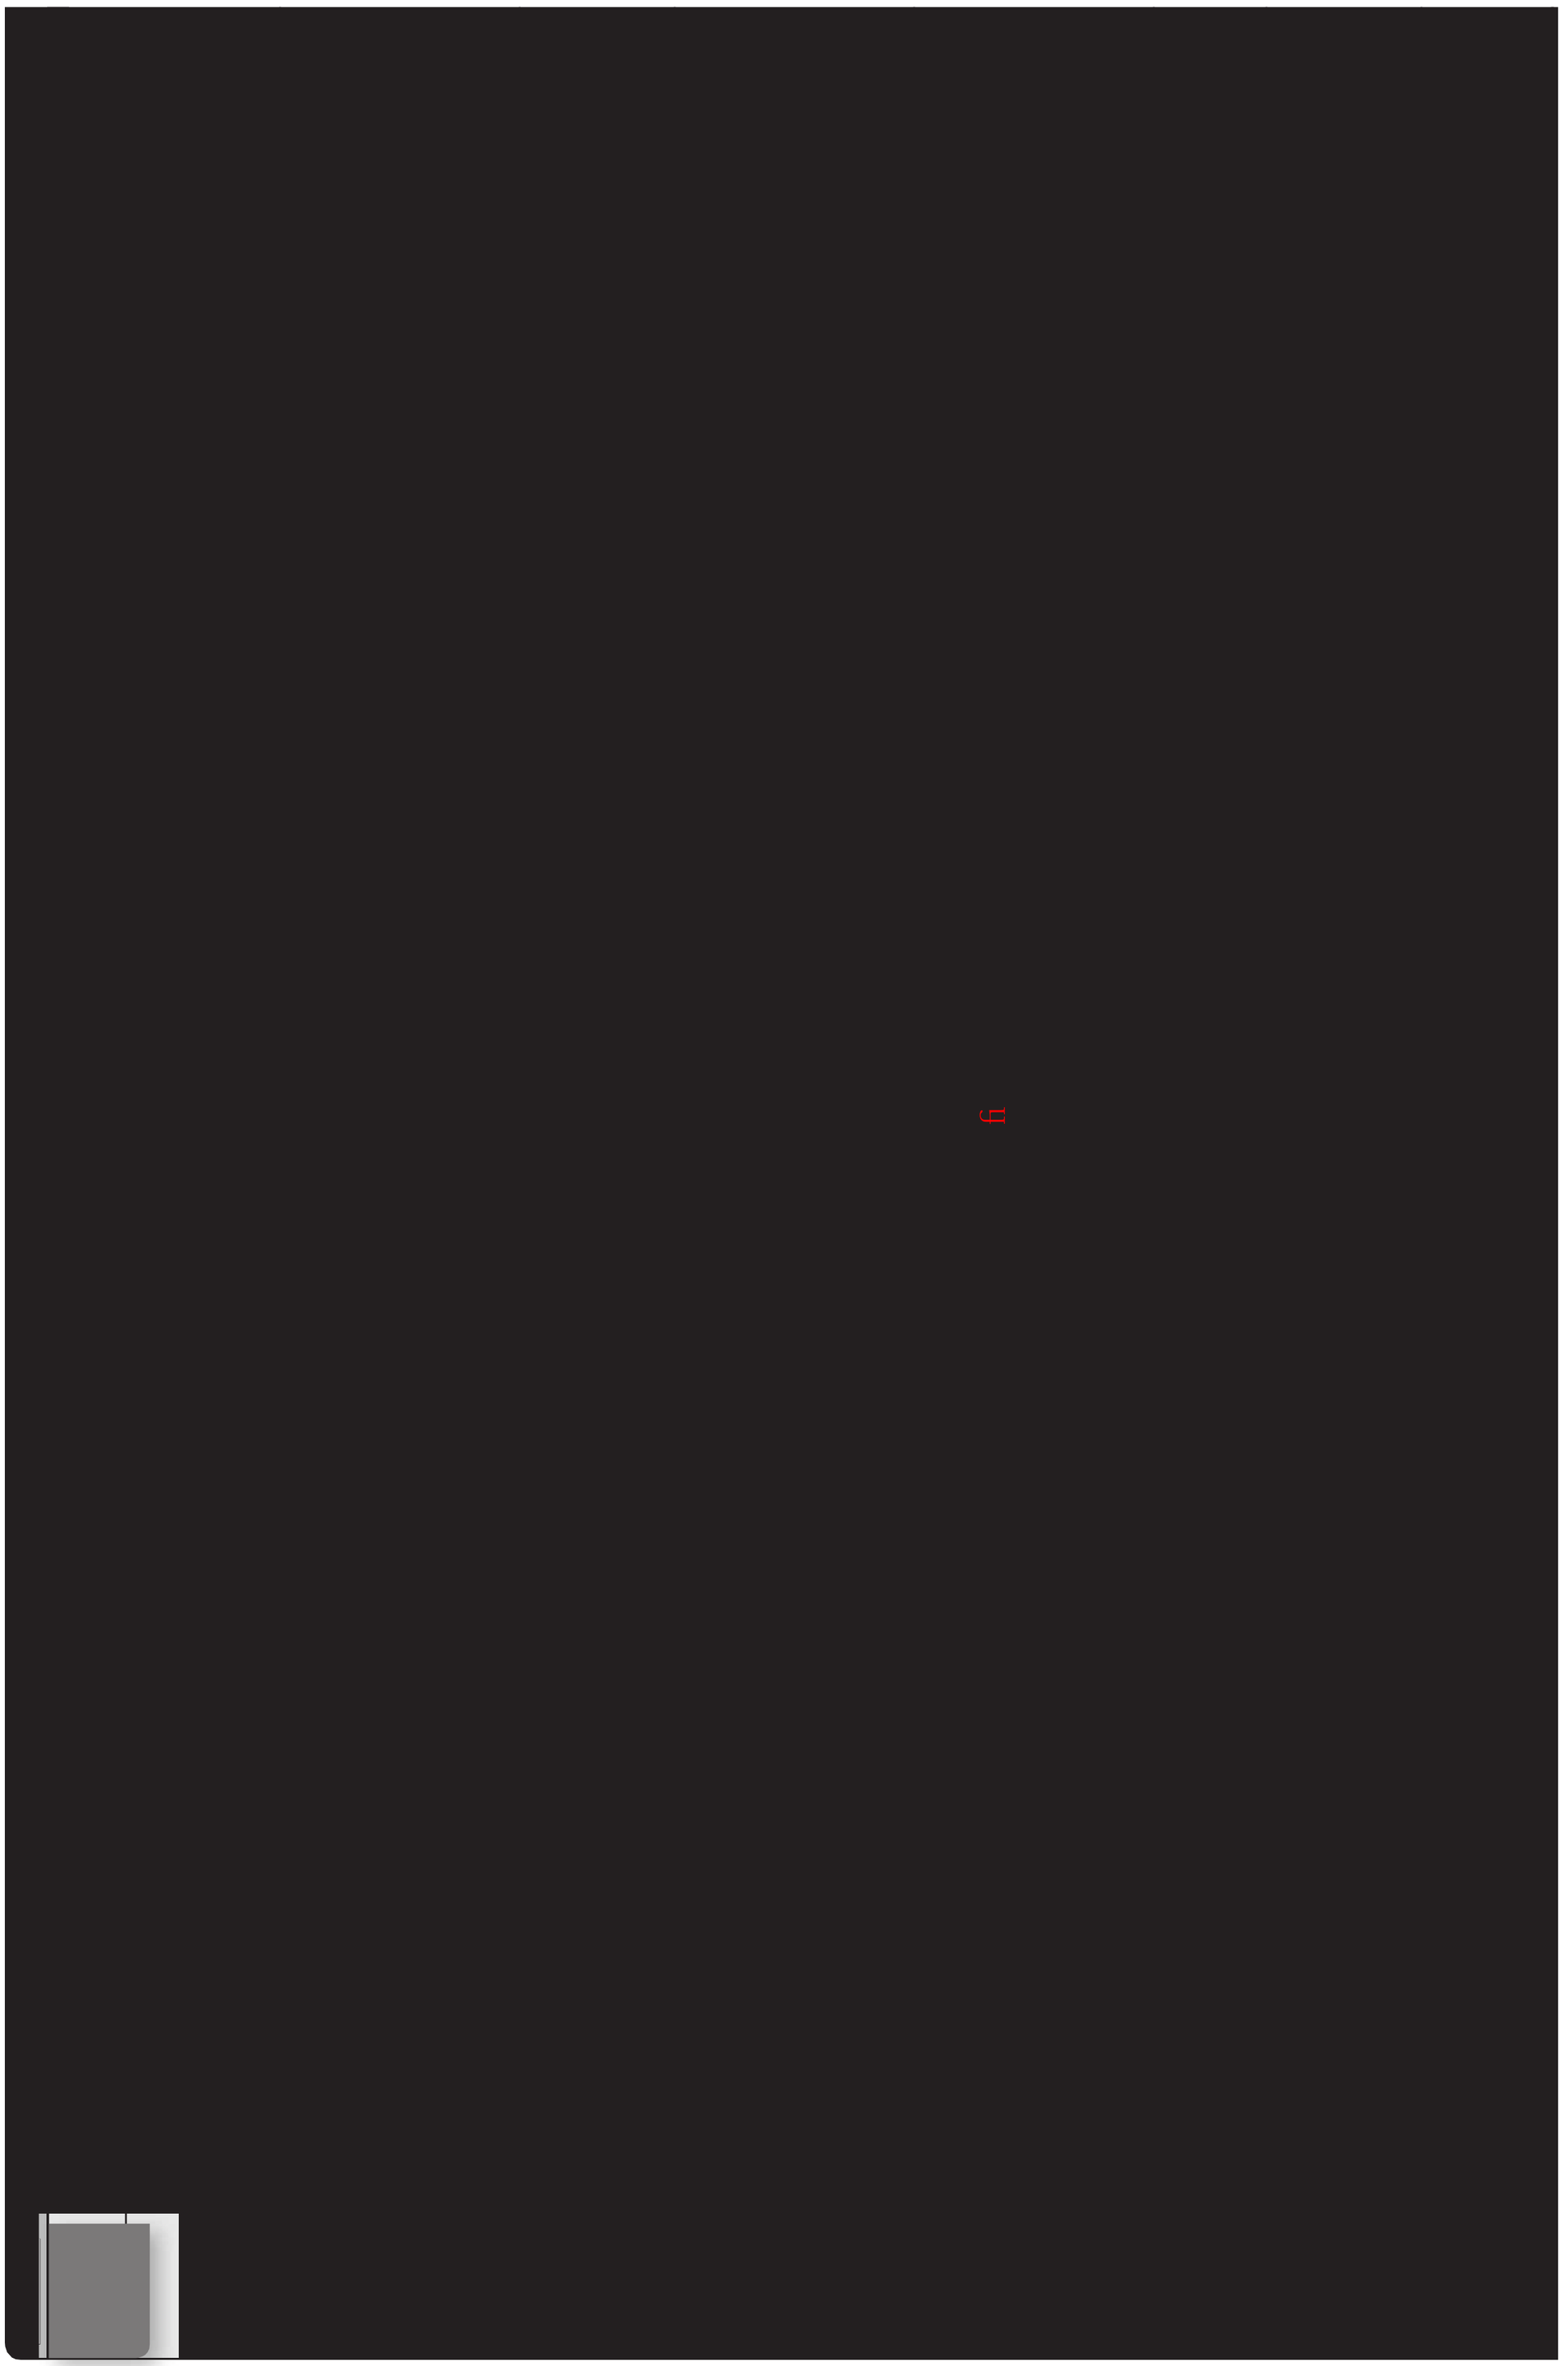
AQP1 is localized on the apical and basolateral membrane of the proximal tubules, the descending thin Henle limbs, and the outer medullary descending vasa recta.

AQP1 is constitutively active as a water-selective pore in these segments.[1,26]

AQP1-null mice show marked polyuria. Urinary osmolality in AQP1-null mice is low and unresponsive to vasopressin secretion or water deprivation.[11,145] As shown in Figure 4.9, maximal urine osmolalities of AQP1 knockout mice is 23% of that of wild-type mice under the same stimulated condition (i.e., 36 hr water deprivation). This phenotype was explained by two distinct mechanisms: impaired near iso-osmolar water reabsorption by the proximal tubule and reduced medullary hypertonicity resulting from impaired countercurrent exchange.[146] Analysis of AQP1-null mice clarified that AQP1 is the principal water channel in the proximal tubules and the descending thin Henle limbs and provides the major route for transepithelial water permeability in these segments.[146] In 2001, two unrelated individuals with a deficiency in AQP1 expression were reported.[147] One of these individuals was homozygous for a deletion of exon 1 of AQP1. The second individual was homozygous for a frame-shift mutation in exon 1 of AQP1. Although both patients seemed asymptomatic under normal conditions, they showed an impaired urinary concentrating ability following 24 hr of water restriction as compared with healthy controls (450 versus 1,000 mOsm per kilogram of water). Such a defect can become clinically meaningful in circumstances that require maximal urinary concentration; for instance, during vomiting and diarrhea.[148]

Aquaporin-3

The AQP3 water channel is present in the principal cells of the connecting tubule and the collecting duct, and enables water entry into the interstitium in these segments.[149] AQP3 is constitutively localized in the basolateral plasma



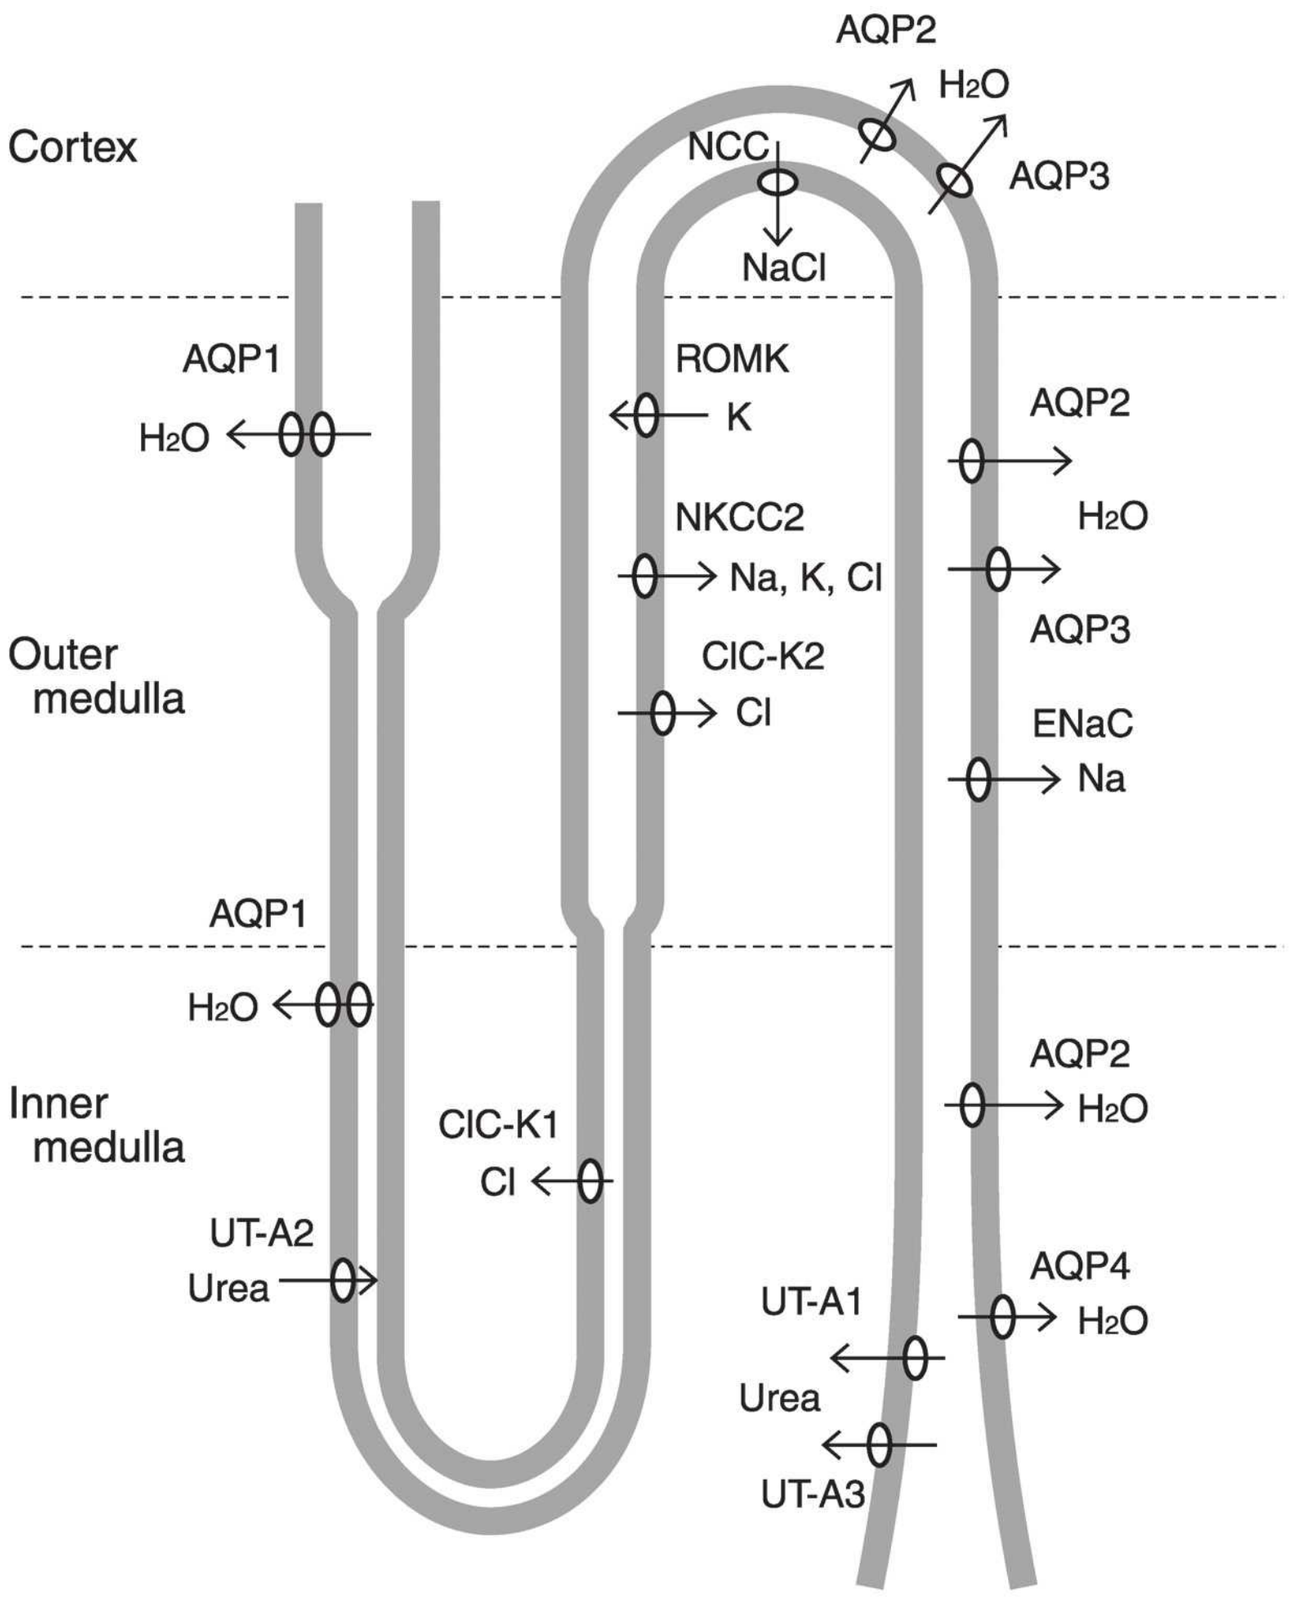


FIGURE 4.8 Transporters and channels involved in urine concentration along the nephron. Water is reabsorbed in the proximal tubule and the thin descending limb by AQP1. Chloride with sodium is passively reabsorbed in the thin ascending limb by the ClC-K1 chloride channel. NaCl is actively reabsorbed across the thick ascending limb by the apical plasma membrane Na-K-2Cl cotransporter (NKCC2). Potassium is recycled through an apical plasma membrane potassium channel, ROMK, and chloride is transported across the basolateral membrane by ClC-K2. Water is reabsorbed across the apical membrane of the collecting duct by AQP2 water channels. Water is reabsorbed across the basolateral membrane by AQP3 in the cortical and outer medullary collecting ducts and by both AQP3 and AQP4 in the inner medullary collecting duct. Urea is reabsorbed in the terminal inner medullary collecting duct by the urea transporters UT-A1 and UT-A3.

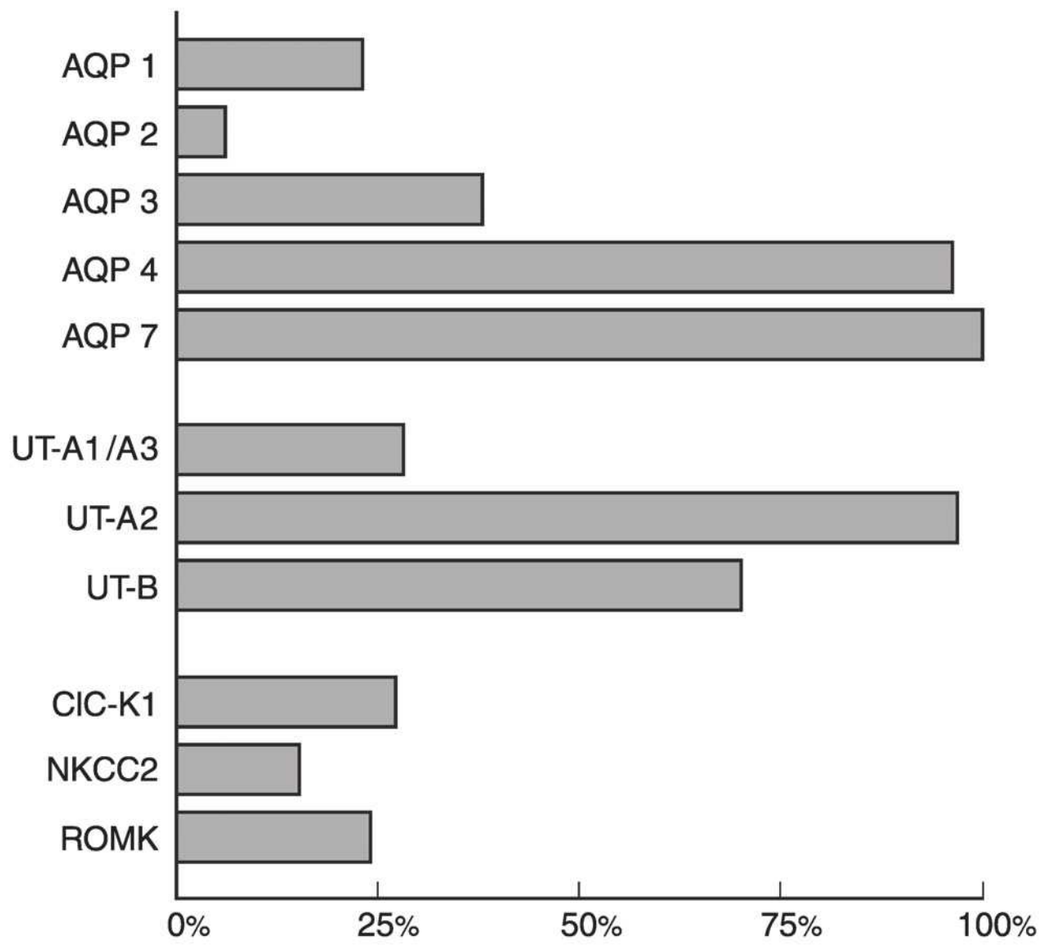

FIGURE 4.9 Maximal urine osmolalities of knockout mice in which transporters or channels involved in urine concentration are deleted. Data are expressed as a percentage of the maximal urine osmolalities of the wild-type mice in the same study. A maximally stimulated urine concentration was induced by water deprivation for 6 to 36 hr or by vasopressin administration. Data are taken from References 11, 13, 32, 42, 44, 78, 152, 158, 172, 180, and 186.

membrane. AQP3, together with AQP4, represents potential exit pathways from these cells for water entering the cell via AQP2. The AQP3 expression is shown to be increased by thirst and by vasopressin or aldosterone secretion.[150,151] AQP3 knockout mice exhibit an NDI-like phenotype, indicating that AQP3 has an important role in urine concentration (Fig. 4.9).[152,153] AQP3 deficiency was reported in humans.[154] This defect is caused by homozygous mutation affecting the 5′ donor splice site of intron 5 of AQP3. This mutation causes the skipping of exon 5 and generates a frameshift change and premature stop codon. However, phenotypes associated with this defect were not reported, possibly because the patients seemed normal.

Aquaporin-4

AQP4 is present in the principal cells of the collecting duct.[155] AQP4 is more abundant in the inner medullary collecting duct cells than is AQP3. The organization of AQP4 into orthogonal arrays of particles might enhance AQP4 water permeability,[156] and this process might be regulated by vasopressin.[157] Similarly to AQP3, AQP4 is constitutively localized in the basolateral plasma membrane. AQP4 knockout mice have a very little urinary concentrating defect (Fig. 4.9).[153,158] In contrast to AQP3, AQP4 expression is not regulated by thirst or by vasopressin secretion. AQP4 water permeability is decreased by high levels of protein kinase C and dopamine. This effect is mediated by phosphorylation at serine 180 of AQP4.[159]

Aquaporin-6

The water channel family member AQP6 is localized in the intracellular vesicles in intercalated cells in the collecting duct.[160–162] AQP6 has low water permeability and acts primarily as an anion transporter.[163] AQP6 is expressed in acid-secreting type-A intercalated cells and colocalizes with V-type H^+-ATPase; therefore, AQP6 is suggested to function to promote urinary acid secretion.

Aquaporin-7

AQP7 is localized in the brush border of proximal straight tubules (S3 segment)[12,164,165] and is able to transport glycerol as well as water.[12] AQP7 knockout mice showed marked glyceroluria,[13] indicating that glycerol can be reabsorbed through AQP7 in the proximal straight tubule, and that there might be no other glycerol reabsorbing system to compensate for this defect in the distal nephron segments.

In AQP7 knockout mice, water permeability of the brush border membrane vesicles was slightly but significantly lower than that in wild-type mice,[13] which suggests that AQP7 makes a small contribution to the water permeability of the proximal straight tubules. This contribution has been estimated to be one-eighth that of AQP1.[166] As expected from the small decrease in water permeability, AQP7 knockout mice did not show a urine concentrating defect (Fig. 4.9).[13]

The case of a man with a point mutation in AQP7 has been reported. However, no renal symptoms were mentioned, although he did have a defective glycerol metabolism.[167]

Aquaporin-11

AQP family members have two widely conserved, membrane-embedded NPA motifs that are essential for forming the water-permeable pore structure. However, AQP11, together with AQP12, have atypical NPA boxes, suggesting that their structure and function are unique.[168] In the kidney, AQP11 is present in the proximal tubular cells. Within the cells, AQP11 is localized in the endoplasmic reticulum (ER) membrane, but not localized in the cell surface plasma membrane. AQP11 knockout mice are born healthy but grow poorly and die before weaning because of uremia caused by enlarged multiple cysts in the kidney.[169] The cysts originate from kidney proximal tubule cells, inside which swollen ER are observed. The role of AQP11 is still unclear, although it seems to have an important role in ER membrane function in proximal tubular cells. Kidney cyst cells in AQP11 knockout mice showed an abnormal gene expression pattern, which is similar to that observed in polycystic kidney disease (PKD) model animals, suggesting that AQP11 knockout mice and PKD animals share common pathogenic mechanisms for cyst formation.[170] Yakata et al.[171] measured the Pf of the vesicles from the membrane fraction of Sf9 cells expressing AQP11 and showed that AQP11 has slow but constant water transport activities. Further studies are required for clarifying the role of AQP11.

Urea Transporters

In the kidney, there are four urea transporters: UT-A1, UT-A2, UT-A3, and UT-B (Figs. 4.4 and 4.8). UT-A1 and UT-A3 are expressed in the terminal IMCD,[32] and UT-A2 is present in the thin descending limb of the long-looped nephron in the inner medulla and the thin descending limb of the short-looped nephron in the outer medulla.[14] Their localization is essential for the urea recycling pathway as described in the section Urea Accumulation in the Inner Medulla, discussed previously. Vasopressin stimulation promotes the phosphorylation of UT-A1 and UT-A3 and the accumulation of UT-A1 and UT-A3 in the plasma membrane of the IMCD cells. This is responsible for the increased urea permeability of the terminal IMCD that results in greater urea reabsorption during antidiuresis.[50] Vasopressin stimulation also increases UT-A2 protein abundance.[14]

UT-A1/UT-A3 knockout mice show a large urinary concentrating defect (Fig. 4.9). This concentrating defect is ameliorated by a low protein diet, indicating that this defect is caused by a urea-dependent osmotic diuresis.[32] Another possibility may be that a low protein diet reduces urea concentrations in the medulla in both UT-A1/UT-A3 knockout mice and wild-type mice, and the difference of urine concentrating abilities of these two groups becomes small. Nevertheless, UT-A1/UT-A3 greatly contributes to urine

concentration by accumulating urea in the medulla when protein intake is normal.

On the other hand, in UT-A2 knockout mice, a small urinary concentrating defect and a reduction in medullary urea content are observed only on a low protein diet, but not on a normal diet (Fig. 4.9; a value on a normal diet is shown).[172] This finding indicates a relative role of recycling urea through the "tubular route"; urea leaves from IMCD to the interstitium, diffuses around, then enters into the tubular lumen at the thin descending limb (mediated by UT-A2), and again comes back the IMCD (Fig. 4.4), is small, and becomes significant when urea delivery to the IMCD is low.

UT-B is localized in the descending vasa recta endothelial cells.[46] UT-B knockout mice show a decrease in urea accumulation in the medulla and a urinary concentrating defect, indicating that the recycling of urea by a countercurrent exchange via the vasa recta is important for urine concentration abilities (Fig. 4.9).[44] Humans genetically lacking UT-B (Kidd blood group antigen) are identified and their maximal urinary concentrating ability is reduced (UOSM, max = 819 mOsm per kilogram of water), which is consistent with the results of the knockout mice.[173]

ClC-K1 and ClC-K2

The chloride channel ClC-K1 is mainly expressed in the thin ascending Henle limb and its expression is upregulated by water deprivation.[10,15,16] ClC-K2 is present from the thick ascending limb through to the collecting duct.[174,175] ClC-K1 knockout mice show a significantly reduced osmolality of the papilla and a severe defect in urinary concentrating ability (Fig. 4.9).[42] This finding indicates that the rapid chloride exit to the medullary interstitium is important for the maintenance of the high inner medullary interstitial osmolality and supports the passive mechanism as described in the section Countercurrent Multiplication in the Outer Medulla and Other Mechanisms in the Inner Medulla, discussed previously. Severities of impaired urine concentrating abilities are comparable in ClC-K1 and UT-A1/UT-A3 knockout mice (Fig. 4.9), implying a functional linkage between the chloride transport by ClC-K1 and the urea transport by UT-A1/UT-A3, which is again consistent with the operation of the passive model in the inner medulla.

The human orthologue of the ClC-K2 gene is one of the genes that, when mutated, causes Bartter syndrome in humans, which is a disease manifested by salt wastage, hypokalemia, metabolic alkalosis, and hyperaldosteronism.[176,177] Polyuria and polydipsia are commonly observed in Bartter syndrome and these symptoms are not relieved by vasopressin, thus showing the presence of NDI.[178] Thus, NaCl reabsorption in the thick ascending limb mediated by a basolateral chloride channel, ClC-K2, importantly contributes to urine concentration through the operation of the countercurrent multiplication system.

NKCC2 and ROMK

NKCC2 is expressed in the thick ascending limb and contributes to NaCl reabsorption in this segment.[56] The gene encoding NKCC2 is another gene, the mutations of which cause Bartter syndrome.[179] Different from NHE3, NKCC2 is also present in the macula densa.[56] NKCC2 knockout mice cannot survive to weaning because of severe dehydration and polyuria. This may be because the compensatory decrease in glomerular filtration does not occur in response to increased distal fluid delivery.[180] This finding indicates that NKCC2 plays an important role in the macula densa in the mediation of tubuloglomerular feedback and is critical for distal fluid delivery. Treatment with indomethacin rescues the knockout mice, and the surviving mice show a large vasopressin-resistant defect in urine concentrating ability (Fig. 4.9).[180] Thus, in the same mechanism as in ClC-K2, NKCC2 contributes to urine concentration.

Another Na-K-Cl cotransporter isoform, NKCC1, is expressed in the collecting duct and contributes to NaCl secretion.[181,182] NKCC1 knockout mice show a reduced capacity to excrete free water.[183] NKCC1 is present also in the juxtaglomerular afferent arteriole and the glomerular and extraglomerular mesangium, where it is thought to participate in the process of tubuloglomerular feedback and the regulation of blood pressure.

The ATP-sensitive, inwardly rectifying potassium channel, ROMK, is expressed in the apical membrane of the thick ascending limb and throughout the distal nephron segments and is involved in NaCl reabsorption in the thick ascending limb.[176,184] Mutations of the gene encoding ROMK are also found in patients with Bartter syndrome.[185] Knockout mice with ROMK have hydronephrosis, are severely dehydrated, and 95% die before 3 weeks of age. The urine concentrating ability of the surviving mice is severely impaired, as expected (Fig. 4.9).[186]

A Na-H exchanger isoform NHE3 is expressed in the thin descending Henle limb and the thick ascending Henle limb and contributes to sodium reabsorption in these segments.[57] NHE3 knockout mice show a marked reduction in proximal tubule fluid absorption. Nevertheless, these mice maintain a relatively normal distal delivery, and its urinary concentrating defect is mild.[187,188] This is due to a compensatory decrease in the glomerular filtration rate owing to an intact tubulo-glomerular feedback.[188] Furthermore, the concentrating defect of NHE3 knockout mice is explained by the decreased expression of NKCC2, a Na-K-Cl cotransporter isoform.[189]

NCC and ENaC

The Na-Cl cotransporter NCC is present in the distal convoluted tubule,[19] and the Na channel ENaC is present in the connecting tubule and the cortical collecting tubule (Fig. 4.8).[28,29] Both the proteins mediate sodium reabsorption beyond the macula densa and contribute to urine concentration by reducing fluid delivery to the medullary

collecting duct. Long-term vasopressin stimulation increases the abundance of NCC and ENaC.[190] Short-term vasopressin stimulation promotes ENaC accumulation in the apical membrane, resulting in increased sodium reabsorption.[191]

URINE CONCENTRATING DEFECTS

Central Diabetes Insipidus

Central diabetes insipidus is caused by inadequate secretion of vasopressin from the posterior pituitary in response to osmotic stimulation. In most cases, this is due to the destruction of the neurohypophysis by a variety of lesions, including granulomas (e.g., histiocytosis, sarcoidosis), neoplasms (e.g., craniopharyngioma, germinoma, lymphoma, leukemia, meningioma, pituitary tumor, metastasis), infections (e.g., meningitis, tuberculosis, encephalitis), trauma, and cerebrovascular diseases (e.g., cerebral hemorrhage, infarction). Several cases with inherited central diabetes insipidus are also reported, although it is a rare disorder.[192–194] Most of these cases show an autosomal dominant mode of inheritance and are caused by mutations in the gene coding for the vasopressin-neurophysin precursor. It is postulated that these mutations cause the production of an abnormal precursor protein that accumulates and damages the neurons.

Osmoreceptor Dysfunction

The osmoreceptors that control vasopressin secretion and thirst are located in the anterior hypothalamus. Osmoreceptor dysfunction is caused by their damage by a variety of brain lesions including granulomas, neoplasms, and cerebrovascular diseases. In contrast to central diabetes insipidus, osmoreceptor dysfunction-causing lesions usually occur more rostrally in the hypothalamus because of the location of the osmoreceptors. One lesion unique to this disorder is an anterior communicating cerebral artery aneurysm. In this disorder, osmoregulation of both vasopressin secretion and thirst is impaired.[195] Patients with osmoreceptor dysfunction typically have osmolalities in the range of 300 to 340 mOsm per kilogram of water, whereas patients with central diabetes insipidus maintain their plasma osmolality within the normal range by polydipsia. This underscores the importance of a normal thirst mechanism. On the other hand, in patients with osmoreceptor dysfunction, the baroreceptor mediated pathway[196] and responses to other nonosmotic stimuli such as nausea are intact. These patients have normal vasopressin and renal concentrating responses to hypovolemia and hypotension.

Nephrogenic Diabetes Insipidus

NDI is caused by the inability of the kidney to respond to vasopressin stimulation. Thus, plasma vasopressin levels in NDI patients are increased or normal depending on their plasma osmolality. Hyperosmolar patients with NDI have elevated vasopressin levels, whereas those with central NDI have an absence of blunted vasopressin responses relative to their plasma osmolality. There are congenital and acquired forms of NDI.

Congenital Nephrogenic Diabetes Insipidus

In more than 90% of cases of congenital NDI, the condition results from a loss of function mutations in the AVPR2 gene encoding the vasopressin V2 receptor, which makes the collecting duct cells insensitive to vasopressin. The AVPR2 gene is located in chromosome region Xq28, and its mutations cause the X-linked inheritable form of NDI. To date, over 200 mutations have been reported in the AVPR2 gene, which are categorized into five classes according to the cellular fate.[197–199] Class I mutations result in premature stop codons or unstable mRNA, and include promoter alterations, exon skipping, aberrant splicing, frameshift, and non-sense mutations that result in truncated proteins. On the other hand, mutations of class II, III, IV, and V result in fully translated proteins. Class II comprises the missense or insertion/deletion mutations that lead to the misfolding of this protein. Misfolded proteins are retained in the ER and, subsequently, are mostly targeted for proteasome degradation. Class II is most prevalent, comprising approximately 45% of all mutations in the AVPR2 gene. Class III and IV mutations do not interrupt the translocation to the plasma membrane. Class III mutations interfere with binding to the stimulatory Gs protein, leading to the reduced activation of adenylate cyclase, whereas Class IV mutations interfere with binding to vasopressin. Class V mutations result in trafficking defects beyond the early secretory pathway and misrouting to different organelles in the cell. Although most female carriers of the X-linked V2 receptor defect have no clinical disease, some females were reported with symptomatic NDI.[200] Rare female patients manifest severe NDI due to the inactivation of the normal X chromosome.[201,202] Furthermore, a significant number of de novo mutations have also been reported.[203]

Congenital NDI can also result from mutations of the autosomal gene that codes for AQP2. AQP2, the gene that encodes AQP2, is located in 12q13 and is comprised of four exons.[139,204,205] To date, over 43 mutations in the AQP2 gene have been reported (Fig. 4.10).[51,206,207] Two inheritance types are possible for the disease: Autosomal-recessive NDI is associated with 35 mutations, and autosomal-dominant NDI is associated with 8 mutations. Almost all of the mutations in recessive NDI are located in the core region of the protein, and they lead to misfolded proteins that become trapped in the ER and then are targeted for rapid degradation by the proteasome. On the other hand, AQP2 homotetramers composed only of wild-type proteins are properly translocated to the apical membrane. This effect explains the healthy phenotype of patients' parents.[206]

All mutations in autosomal-dominant NDI locate in the cytosolic C-terminus of AQP2 (Fig. 4.10). This region is important for AQP2 trafficking and these mutations impair trafficking to the apical membrane, although the water channel function of these mutants is preserved. Arg254Leu and

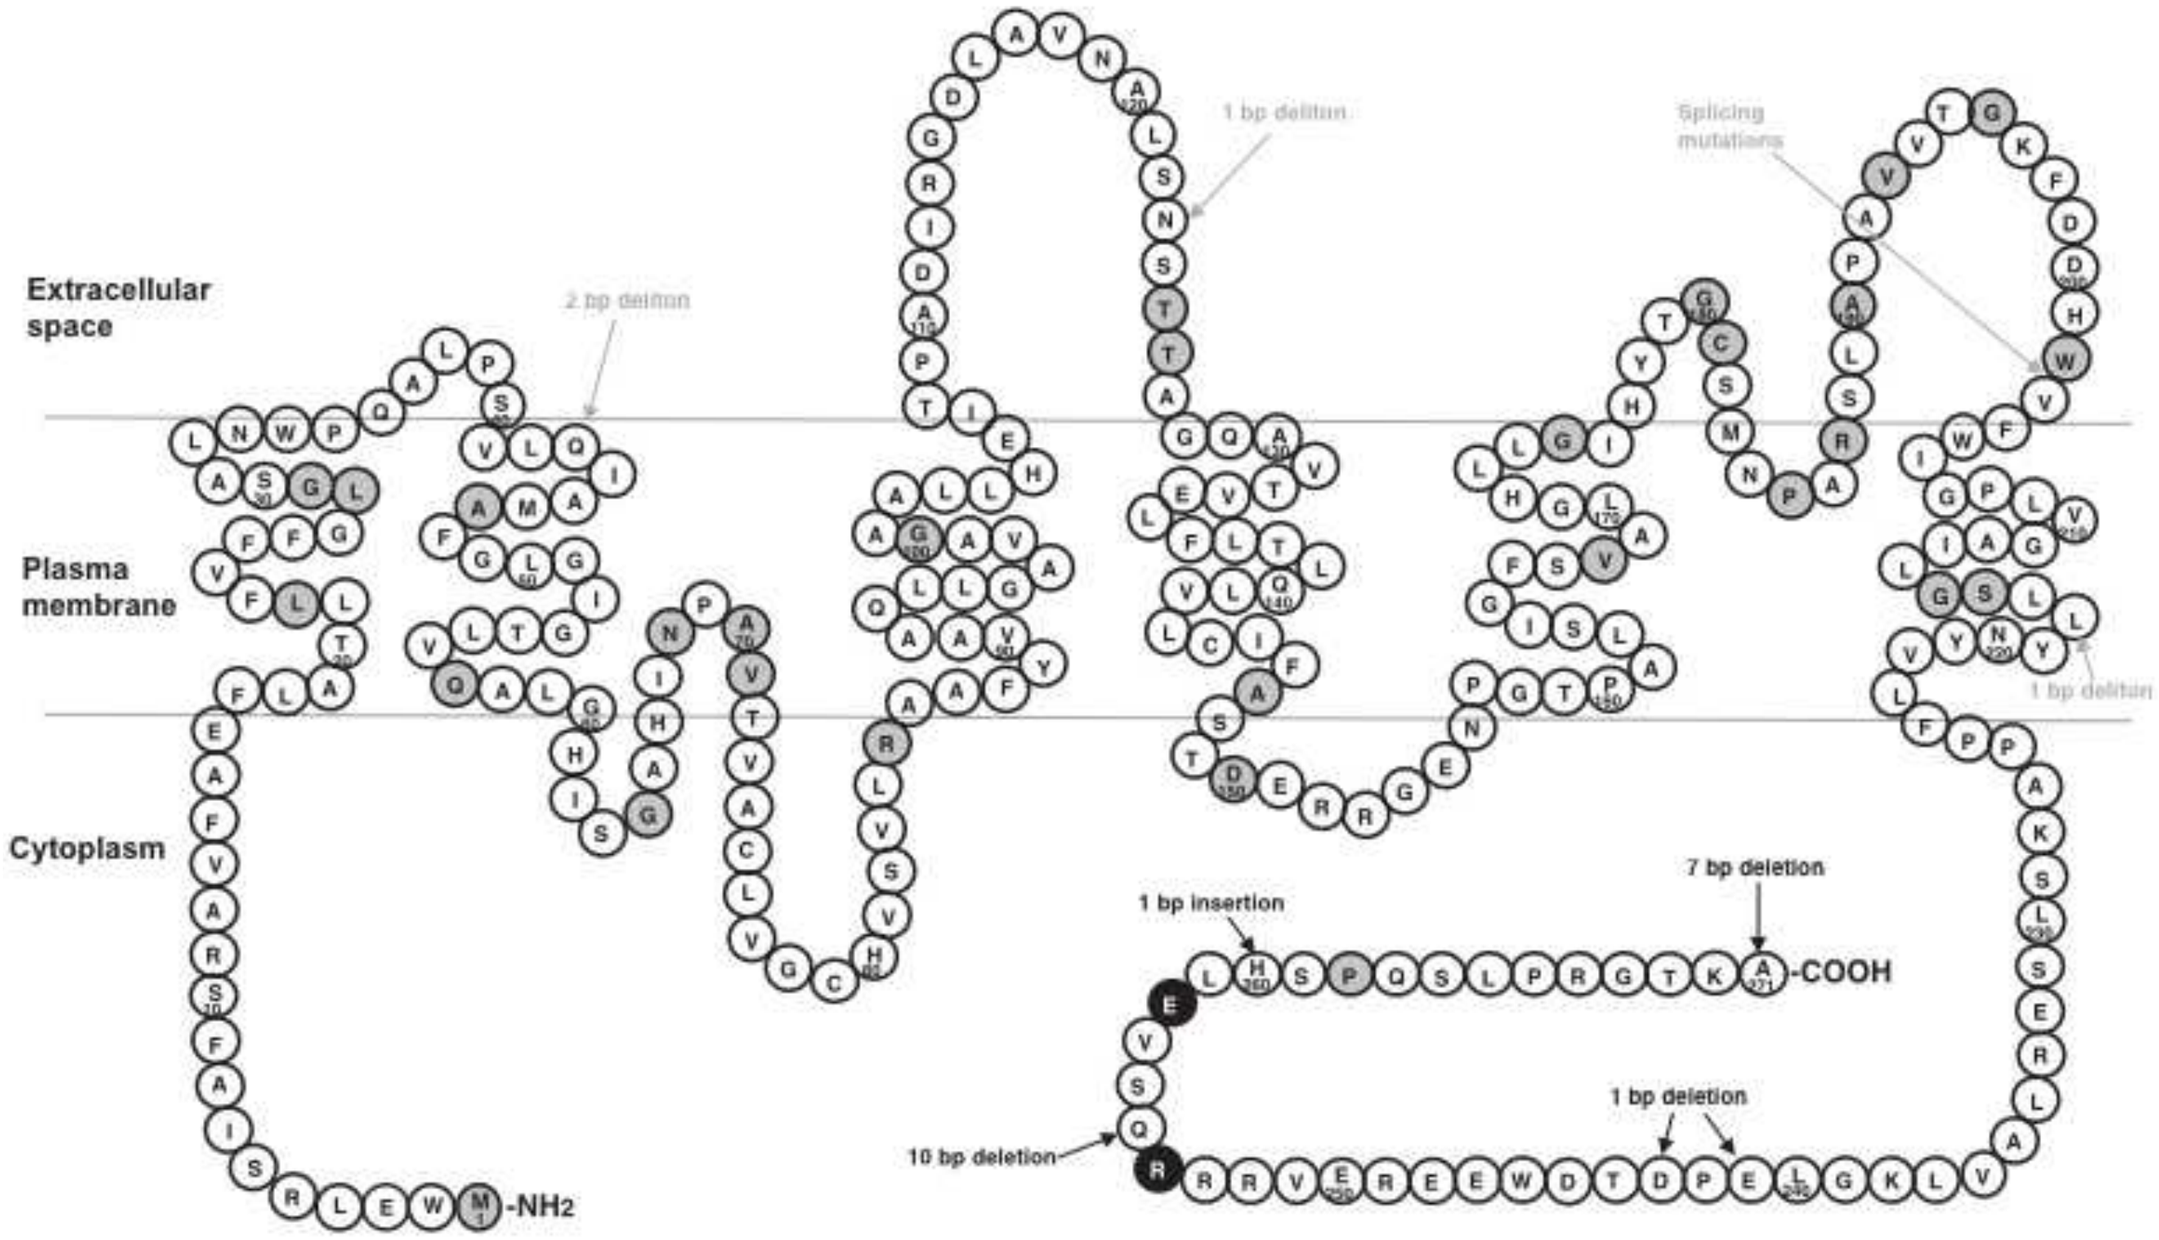

FIGURE 4.10 The AQP2 membrane topology and mutations causing nephrogenic diabetes insipidus. Amino acids that, when mutated, cause the autosomal-recessive form of nephrogenic diabetes insipidus are shown in grey. Also, *grey arrows* show AQP2 deletions and the location of the first amino acid of the protein affected by these nucleotide deletions, which causes the autosomal-recessive form of nephrogenic diabetes insipidus. Amino acids, when mutated, that cause the autosomal-dominant form of nephrogenic diabetes insipidus are shown in *black*. Similarly, in *black* are also reported AQP2 deletions or insertions, and the location of the first amino acid of the protein affected by these nucleotide changes, which cause the autosomal-dominant form of nephrogenic diabetes insipidus. *bp*, base pair.

Arg254Gly mutations destroy the site for PKA phosphorylation, so that forskolin-induced trafficking to the plasma membrane is impaired.[207,208] The Glu258Lys mutant of AQP2 is missorted to multivesicular bodies and/or lysosomes.[209] AQP2 mutants resulting from three gene deletions, 721delG, 763–772del, and 812–818del, have similar extended C-terminal tails, which contain the basolateral-membrane-sorting dileucine (LeuLeu) motif, so these mutated proteins are wrongly translocated to the basolateral membrane.[114,210] In contrast to the AQP2 mutants associated with the recessive form of the disease, AQP2 mutants associated with the dominant form of the disease are not misfolded, so they are able to form heterotetramers with wild-type AQP2. Because of the dominance of the missorting motif in the mutant proteins, tetramers composed of the mutant and wild-type forms are missorted, which leads to severely decreased amounts of AQP2 on the apical membrane. This effect explains the dominant mode of NDI inheritance in patients with these mutations. Sohara et al.[211] generated gene knockin mice with the heterozygous mutant AQP2 resulting from a gene deletion (763–772del) that produces a mouse model of dominant NDI. The mutant AQP2 is wrongly translocated to the basolateral membrane; it forms a heterotetramer with wild-type AQP2 and shows a dominant-negative effect on the normal apical sorting of wild-type AQP2. The urine concentrating ability of these gene knockin mice is severely reduced.

Several other mouse models of NDI caused by AQP2 mutations have also been generated. Yang et al.[21] created mice with a T126M knockin mutation in the AQP2 gene. These homozygous mutant mice died within 6 days after birth, suggesting that the mice may be highly sensitive organisms with regard to water homeostasis, and are unable to survive with polyuria. Lloyd et al.[212] generated mice with a F204V mutation in the AQP2 gene that survived beyond the neonatal period and had a much milder form of NDI.

Acquired Nephrogenic Diabetes Insipidus

Acquired NDI is more common than congenital NDI and is caused by various conditions, including drug treatments, electrolyte disturbances, and urinary tract obstruction. Dysregulation of AQP2 plays a fundamental role in many cases of acquired NDI.

Lithium is widely used for treating bipolar disorder and 20% to 30% of patients treated with lithium develop NDI.[213] In lithium-induced NDI, both AQP2 expression and its trafficking to the apical membrane are inhibited. Lithium enters cells expressing AQP2 via the epithelial sodium channel (ENaC) in the apical membrane and accumulates

intracellularly. This accumulation leads to the inhibition of signaling pathways that involve glycogen synthase kinase-3β (GSK3β). Although the mechanism by which AQP2 is dysregulated in this context is not established, the involvement of GSK3β is speculated. Inhibition of GSK3β by lithium increases the expression of cyclo-oxygenase 2 and the local excretion of prostaglandin E2.[214] Prostaglandin E2 is suggested to counteract vasopressin activity by causing an endocytic retrieval of AQP2 from the plasma membrane, thus impairing the urinary concentrating ability of the cell. Furthermore, lithium increases the intracellular accumulation of β-catenin,[215] which can serve as an activator of T-cell factor-dependent transcription. AQP2 downregulation may be achieved via this transcription mechanism. In addition, AQP3 expression is also decreased. Moreover, lithium treatment caused a marked reduction in the fraction of the principal cells in the collecting duct with a parallel increase in the population of intercalated cells.[216] This restructuring of the collecting duct, together with the downregulation of collecting duct AQPs, may be important in lithium-induced NDI.

Hypokalemia and hypercalcemia cause downregulation of AQP2 expression, which results in a vasopressin-resistant urinary concentrating defect. With regard to hypercalcemia, in addition to AQP2, the expression levels of AQP1 and AQP3 are also decreased.[217] In addition, hypercalcemia reduces the expression of NKCC2 and ROMK,[218] resulting in sodium absorption defects in the thick ascending limb, which would affect the countercurrent multiplication.

Ureteral obstruction decreases AQP2 expression and impairs urine concentrating capacity.[219] In addition to AQP2, AQP1, AQP3, and AQP4 are also decreased by ureteral obstruction.[219]

A urinary concentrating defect is also observed in patients with nephrotic syndrome.[220,221] AQP2 expression is decreased in nephrotic rats.[220,222] However, changes in AQP2 expression levels have not yet been confirmed in patients with nephrotic syndrome.

Mouri et al.[223] reported that AQP2 translocation to the apical membrane is inhibited by metabolic acidosis, a mechanism that might be responsible for the diuresis in patients with chronic renal failure.

Water Retention by Urine Diluting Defects

AQP2 has a critical role in the pathophysiology of many diseases associated with water balance disorders. The best known example is congestive heart failure (CHF). Water retention and hyponatremia are common and clinically important complications of CHF. Plasma vasopressin levels are suppressed by hyponatremia in healthy individuals; however, these levels are not suppressed in patients with hyponatremia who have CHF.[224,225] In CHF, effective blood volume and arterial filling are decreased, which is sensed by aortic and carotid baroreceptors, thus resulting in stimulation of vasopressin secretion. Upregulation of AQP2 expression and increased AQP2 trafficking to the apical membrane of principal cells of the collecting duct have been shown in rat models of cardiac failure.[226,227] Furthermore, water retention and hyponatremia in these rats are reversed by a V2 receptor antagonist.[227] These findings indicate that hyponatremia is caused by nonosmotic stimulation of vasopressin, which promotes the expression and trafficking of AQP2. In patients with heart failure, V2 receptor antagonists promote electrolyte-free water excretion and elevate serum sodium concentration.[228–230] In these patients, vasopressin antagonists also have been shown to improve several symptoms of heart failure, such as dyspnea.[231]

Water retention and hyponatremia are observed in patients with hepatic cirrhosis. In these patients, the nonosmotic secretion of vasopressin occurs secondary to splanchnic arterial vasodilatation and relative arterial underfilling.[225] In cirrhotic rats, AQP2 expression was increased and correlated with the volume of ascites.[232] In patients with hyponatremic cirrhosis, V2 receptor antagonists are effective at inducing free water diuresis and raising plasma sodium levels.[229,233]

During pregnancy, arterial underfilling secondary to systemic arterial vasodilatation with nonosmotic vasopressin secretion and upregulation of AQP2 is observed.[75,234] The administration of a V2 receptor antagonist increases electrolyte-free water excretion in pregnant rats.[234]

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a condition in which plasma vasopressin levels are not appropriately suppressed despite hypoosmolality. SIADH is the predominant cause of euvolemic hyponatremia and is a commonly encountered disorder.[235] SIADH occurs frequently in association with vascular, infectious, or neoplastic abnormalities in the lung or central nervous system. In patients with SIADH, a V2 receptor antagonist is shown to be effective in increasing urine volume and plasma sodium levels.[236] However, the long-term effects of its administration are limited in rats with SIADH.[237] Although the AQP2 protein expression is reduced shortly after the administration of the V2 receptor antagonist to rats with SIADH, it increases again in parallel with the decline of the therapeutic effects.

The nephrogenic syndrome of inappropriate antidiuresis (NSIAD) is a rare hereditary disease caused by gain of function mutations of the V2 receptor gene. Two causative mutations at the arginine residue at the position 137, Arg137Cys and Arg137Leu, have been reported.[238] In patients with this disease, endogenous vasopressin is completely suppressed, whereas antidiuresis persists due to the constitutive activation of the receptor, showing the same clinical pictures as SIADH.[238] The clinical presentation of the disease starts from childhood, but the same mutations seem to explain some sporadic episodes of euvolemic hyponatremia in adults. To differentiate NSIAD from SIADH, it may be helpful to observe the responses to V2 receptor antagonists; the former does not respond to the antagonist, whereas the latter does.[239]

The urinary AQP2 excretion level is associated with vasopressin activity in the kidney and is, therefore, a clinically useful biomarker.[240] AQP2 is excreted into the urine through the secretion of exosomes originating from the internal vesicles of

multivesicular bodies (Fig. 4.5).[241] During this process, the outer membrane of multivesicular bodies fuses with the apical plasma membrane. Urinary AQP2 excretion is increased by dehydration or vasopressin and is decreased by hydration. Urinary AQP2 excretion is also increased in patients with CHF and hepatic cirrhosis and in pregnant women.[242–244] In patients with CHF, the administration of a V2 receptor antagonist produced a significant increase in urine flow and solute-free water excretion, and was accompanied with a dramatic decrease in urinary AQP2 excretion.[242] An increased urinary excretion of AQP2 is also found in SIADH and NSIAD.[245,246] Thus, the urinary excretion of AQP2 is a useful marker of the antidiuretic activity of the collecting duct.

CHAPTER

5 Tubular Sodium Transport

Arohan R. Subramanya • Núria M. Pastor-Solar • W. Brian Reeves • Kenneth R. Hallows

Na^+, the primary extracellular cation, is of critical importance to the maintenance of extracellular fluid volume. The kidneys play the dominant role in regulating Na^+ excretion. Each day, the glomeruli filter roughly 25,000 mEq of Na^+. From this quantity, almost 10 times the total exchangeable Na^+ in the body, the kidneys typically absorb over 99%. A remarkable feature of the Na^+ absorptive process is the precision with which it is regulated. An individual consuming a typical diet containing 6 g of Na^+ will excrete 260 mEq of Na^+ per day. The same individual placed on a 2-g Na^+-restricted diet will promptly reduce Na^+ excretion to 87 mEq per day. Although the fraction of filtered Na^+ absorbed by the kidney changes from 99.0% on a standard diet to 99.6% on a Na^+-restricted diet, this small change represents the addition or removal of over 1 L per day to extracellular fluid volume. Thus, the kidneys absorb large amounts of filtered Na^+ with remarkably precise control.

The exquisitely sensitive regulation of Na^+ absorption by the kidneys relies on sequential actions of the various nephron segments, each with highly specialized transport capabilities. Figure 5.1 provides an overview of Na^+ transport along the nephron. In general, the absolute rates of Na^+ reabsorption are greatest in the proximal tubule and fall as the tubular fluid proceeds from proximal to distal segments. Conversely, the ability to transport Na^+ against steep tubular fluid to blood gradients and its physiologic control increase along the nephron. For example, the proximal tubule reabsorbs the bulk (60% to 70%) of the filtered Na^+ load, but as will be detailed later, does so against at most small electrochemical gradients. Moreover, the ability to alter Na^+ transport in the proximal tubule, in relative terms, is rather limited, usually varying by less than 25%. The collecting duct, in contrast, reabsorbs only a minor fraction ($\sim$2% to 4%) of the filtered Na^+ load. However, the collecting duct can transport Na^+ against a large electrochemical gradient to produce urine, which is almost Na^+ free ($<$10 mEq/L). In addition, the rate of Na^+ transport in the collecting duct can vary over a wide range (tenfold) in response to physiologic stimuli. The different nephron segments thus permit both high rates of Na^+ transport (proximal segments) and highly regulated Na^+ transport (distal segments).

Substantial progress has been made recently in identifying the proteins that mediate Na^+ transport in each nephron segment and in defining their interactions and regulation within each segment. Many Na^+ transport proteins have been linked to specific genetic disorders (Table 5.1). Given the primacy of renal Na^+ transport to the control of extracellular fluid volume, it is not surprising that the majority of these genetic disorders are characterized by either hypotension or hypertension. An updated and curated database of these genetic disorders is maintained at the Online Mendelian Inheritance in Man website (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM).

This chapter considers the transepithelial transport of Na^+ by the various nephron segments. The discussion of each nephron segment begins with a description of the general features of Na^+ transport in that segment along with pertinent structure–function relations. The mechanism of Na^+ transport is then considered on a cellular or subcellular level, with emphasis on recent electrophysiologic, biochemical, and molecular findings. Finally, each section includes a consideration of the factors that regulate Na^+ transport in the individual segments.

PRINCIPLES OF MEMBRANE TRANSPORT

This section describes physical principles that underlie the movement of ions across individual membranes and epithelia. However, it is not intended to be an extended treatment of the thermodynamic aspects of membrane transport processes.

Diffusion Processes

Solute transport across membranes may occur by diffusion or convection, or by a mediated process. Diffusion is the random Brownian motion of a molecule with respect to adjacent molecules and occurs as the consequence of thermal energy.[1] Because the diffusional movement of an

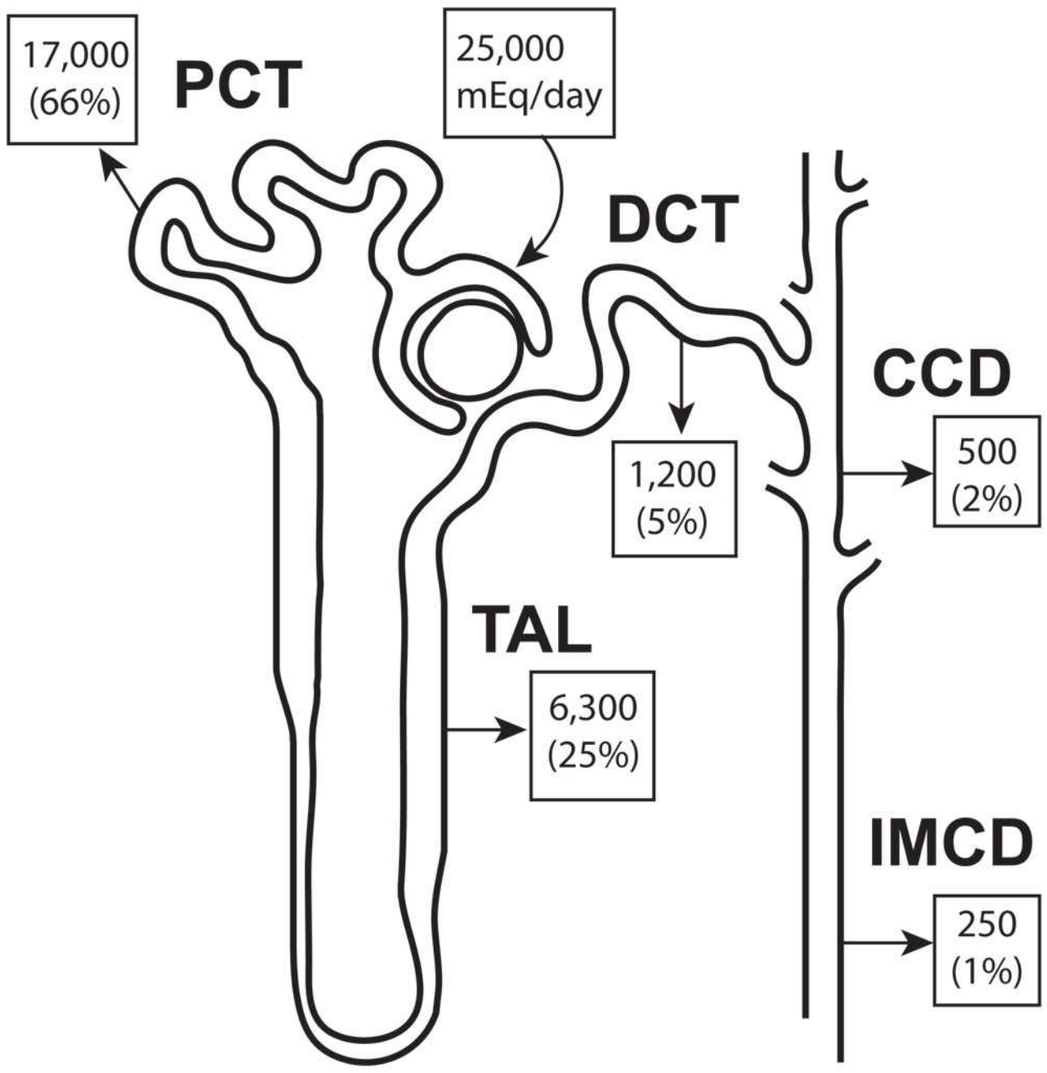

FIGURE 5.1 The contribution of various nephron segments to Na^+ transport. *PCT*, proximal convoluted tubule; *DCT*, distal convoluted tubule; *CCD*, cortical collecting duct; *TAL*, thick ascending limb; *IMCD*, inner medullary collecting duct.

individual molecule is random, a concentration gradient is required for any net transfer of molecules to occur across a membrane. Thus, the concentration gradient represents the driving force for net transport.

For charged solutes, the driving force for transport is the sum of the chemical and electrical potential gradients. The Nernst equation describes the equilibrium condition for a membrane permeable only to a single ionic species:

$$V_m = V_2 - V_1 = -(RT/ZF) \ln (C_2/C_1) \quad (1)$$

where R is the gas constant, T is the absolute temperature, Z is the valence of the solute, F is the Faraday constant, and C and V are concentration and electrical potential terms, respectively. At equilibrium, then, the voltage (V_m) across an ideally selective membrane is defined by the concentrations of the permeant ion on both sides of the membrane, C_2 and C_1, respectively. For systems containing more than one permeant ion, the equilibrium voltage can be described by the Goldman–Hodgkin–Katz (GHK) equation[2,3]:

$$V_m = -RT/F \ln [(P_{Na}C_{2Na} + P_KC_{2K} + P_{Cl}C_{1Cl})/(P_{Na}C_{1Na} + P_K C_{1K} + P_{Cl} C_{2Cl})] \quad (2)$$

where P_x is the permeability of the respective solutes, in this case, Na^+, K^+, and Cl^-. Thus, in a system containing multiple charged solutes, the transmembrane voltage is a function of the relative concentrations and permeabilities of each solute on the two sides of the membrane.

Convective Processes

Convection is the vectorial movement of an ensemble of molecules and is driven by an externally imposed force (e.g., hydrostatic pressure). Examples of convective transport include glomerular filtration and solvent drag, a process in which solute movement is coupled to water movement.

Bulk water flow may be driven by hydrostatic pressure and/or osmotic pressure. The familiar Starling equation:

$$J_v = K(\Delta P - \Delta\pi) \quad (3)$$

describes net volume flow (J_v) in response to hydrostatic (ΔP) and osmotic ($\Delta\pi$) pressure differences. The equivalence of osmotic and hydrostatic pressure is explicit in the Starling equation. The degree to which a solute exerts an osmotic pressure depends on the degree to which it permeates membranes. The ratio of the observed osmotic pressure to that predicted if a solute were excluded absolutely from a membrane is termed the reflection coefficient, σ:

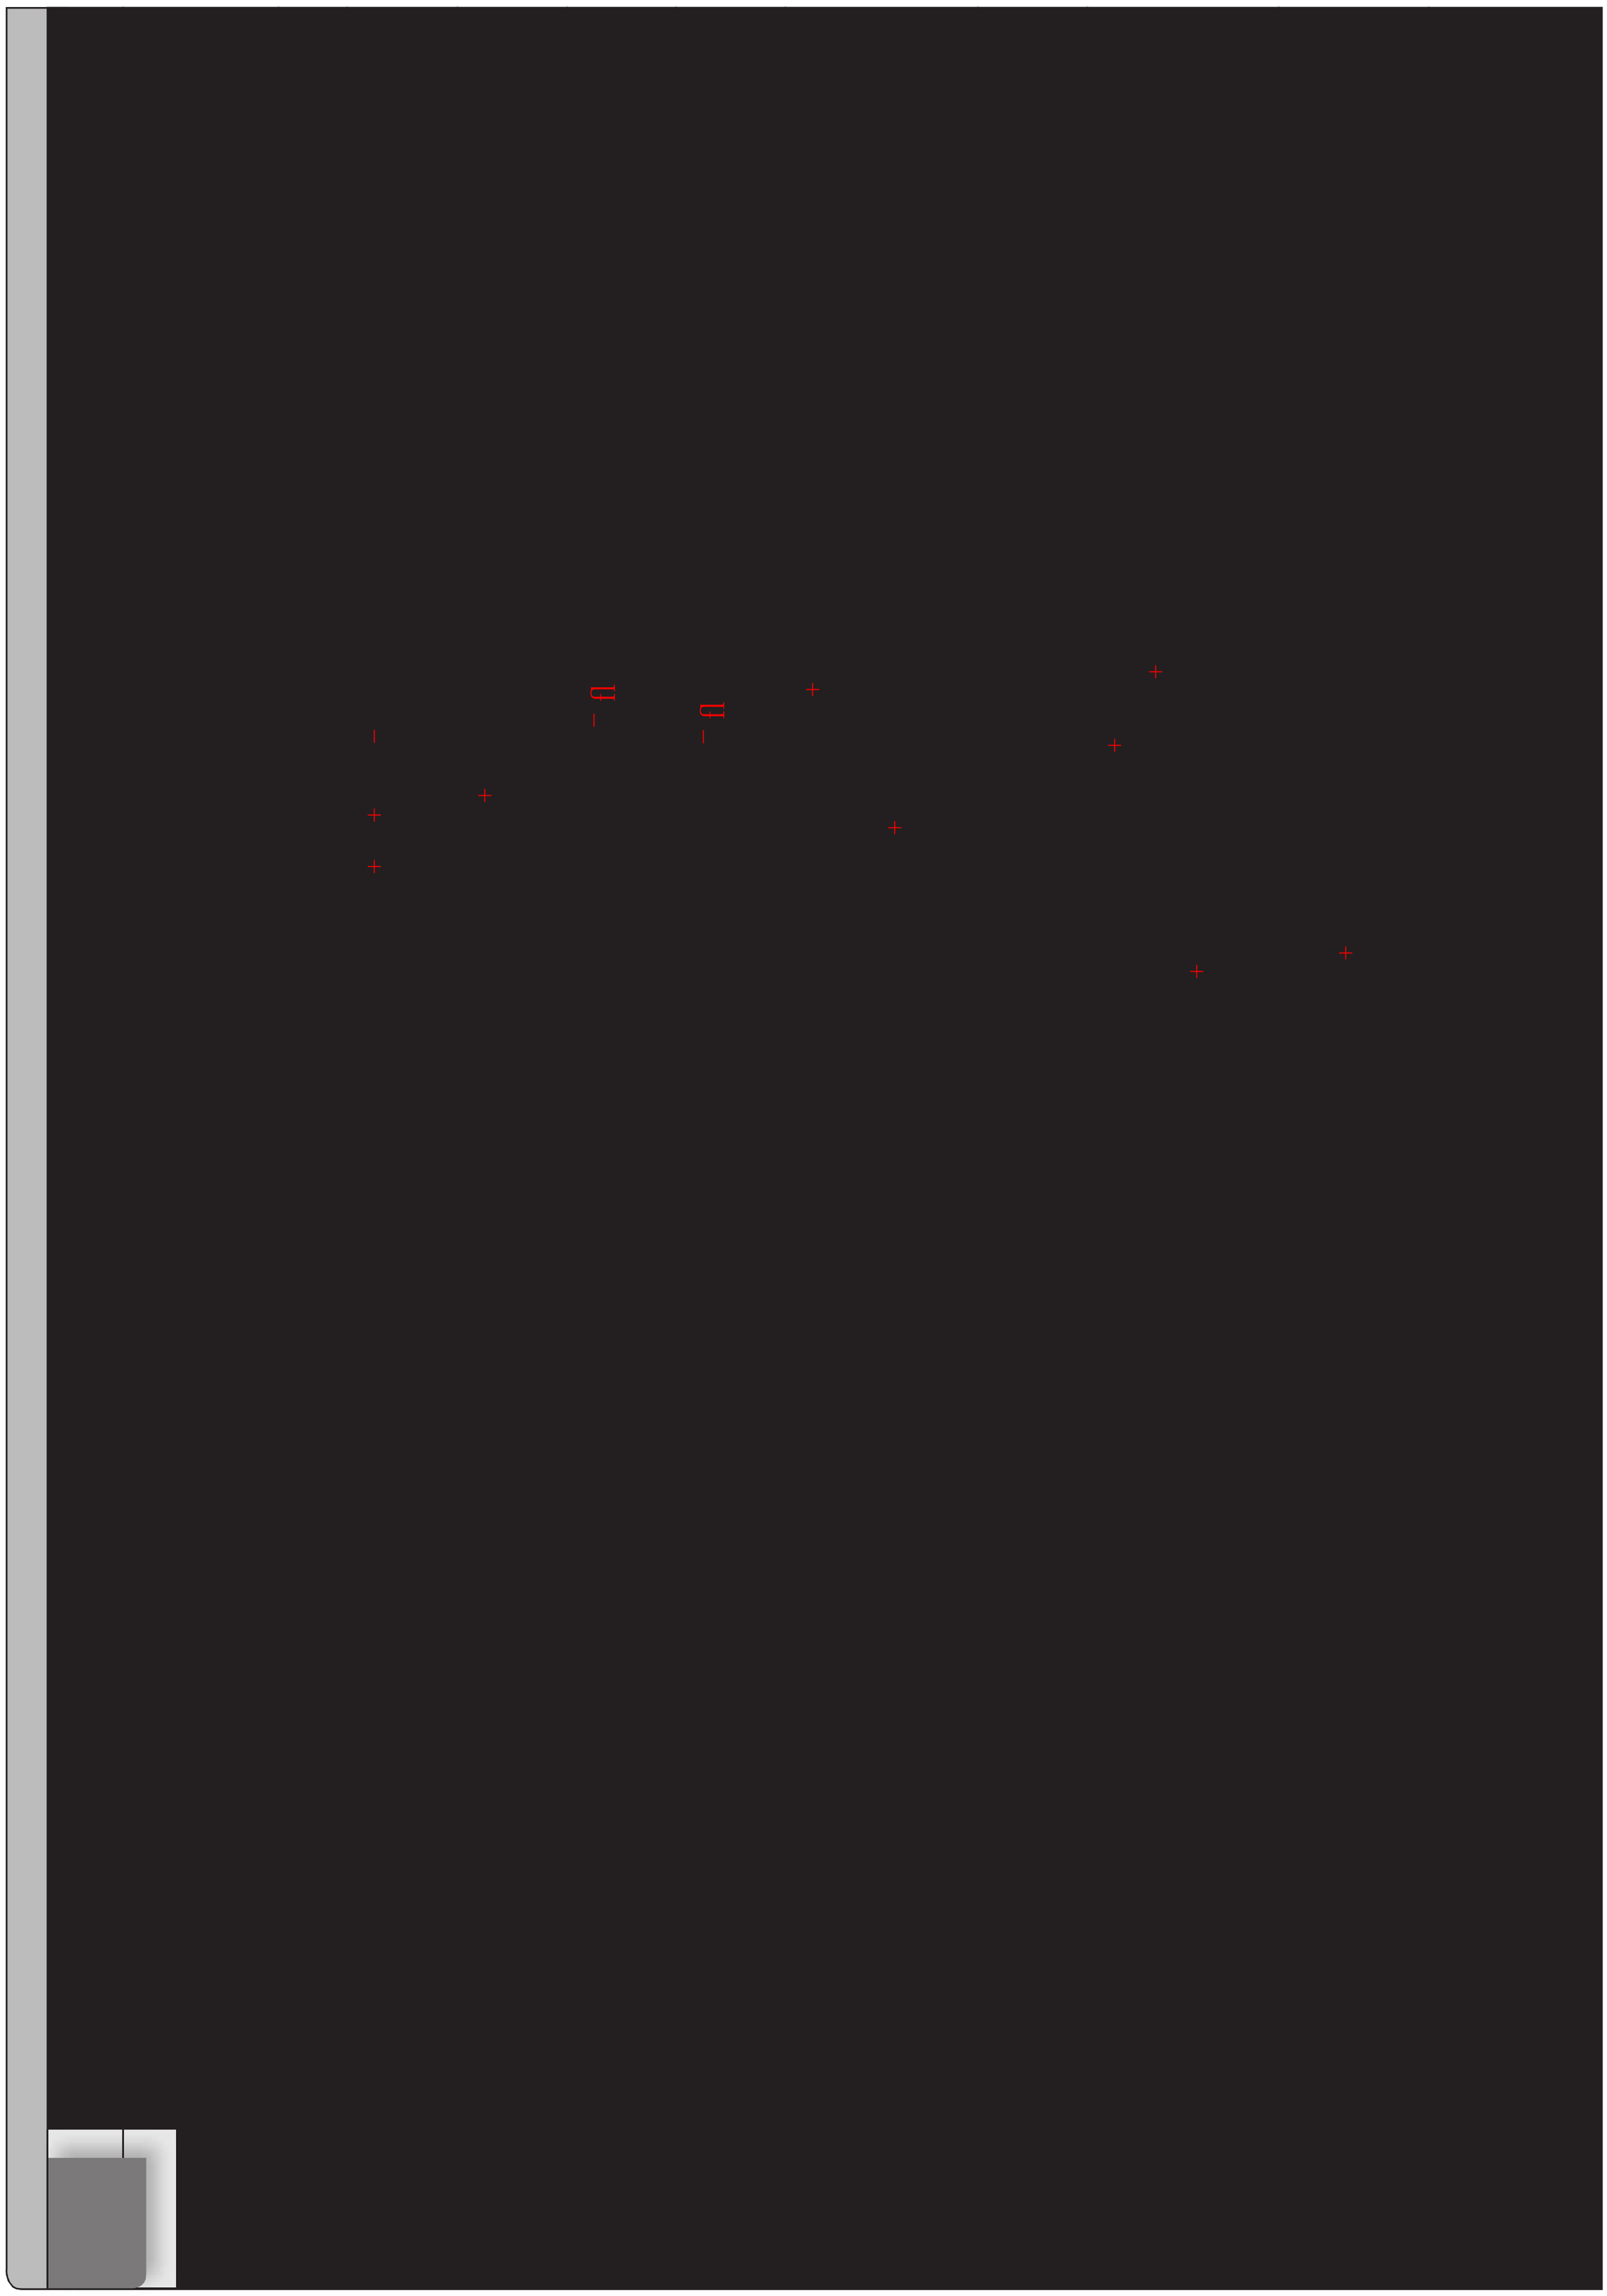
$$\sigma = \Delta\pi_{obs}/\Delta\pi_{theoretical} \quad (4)$$

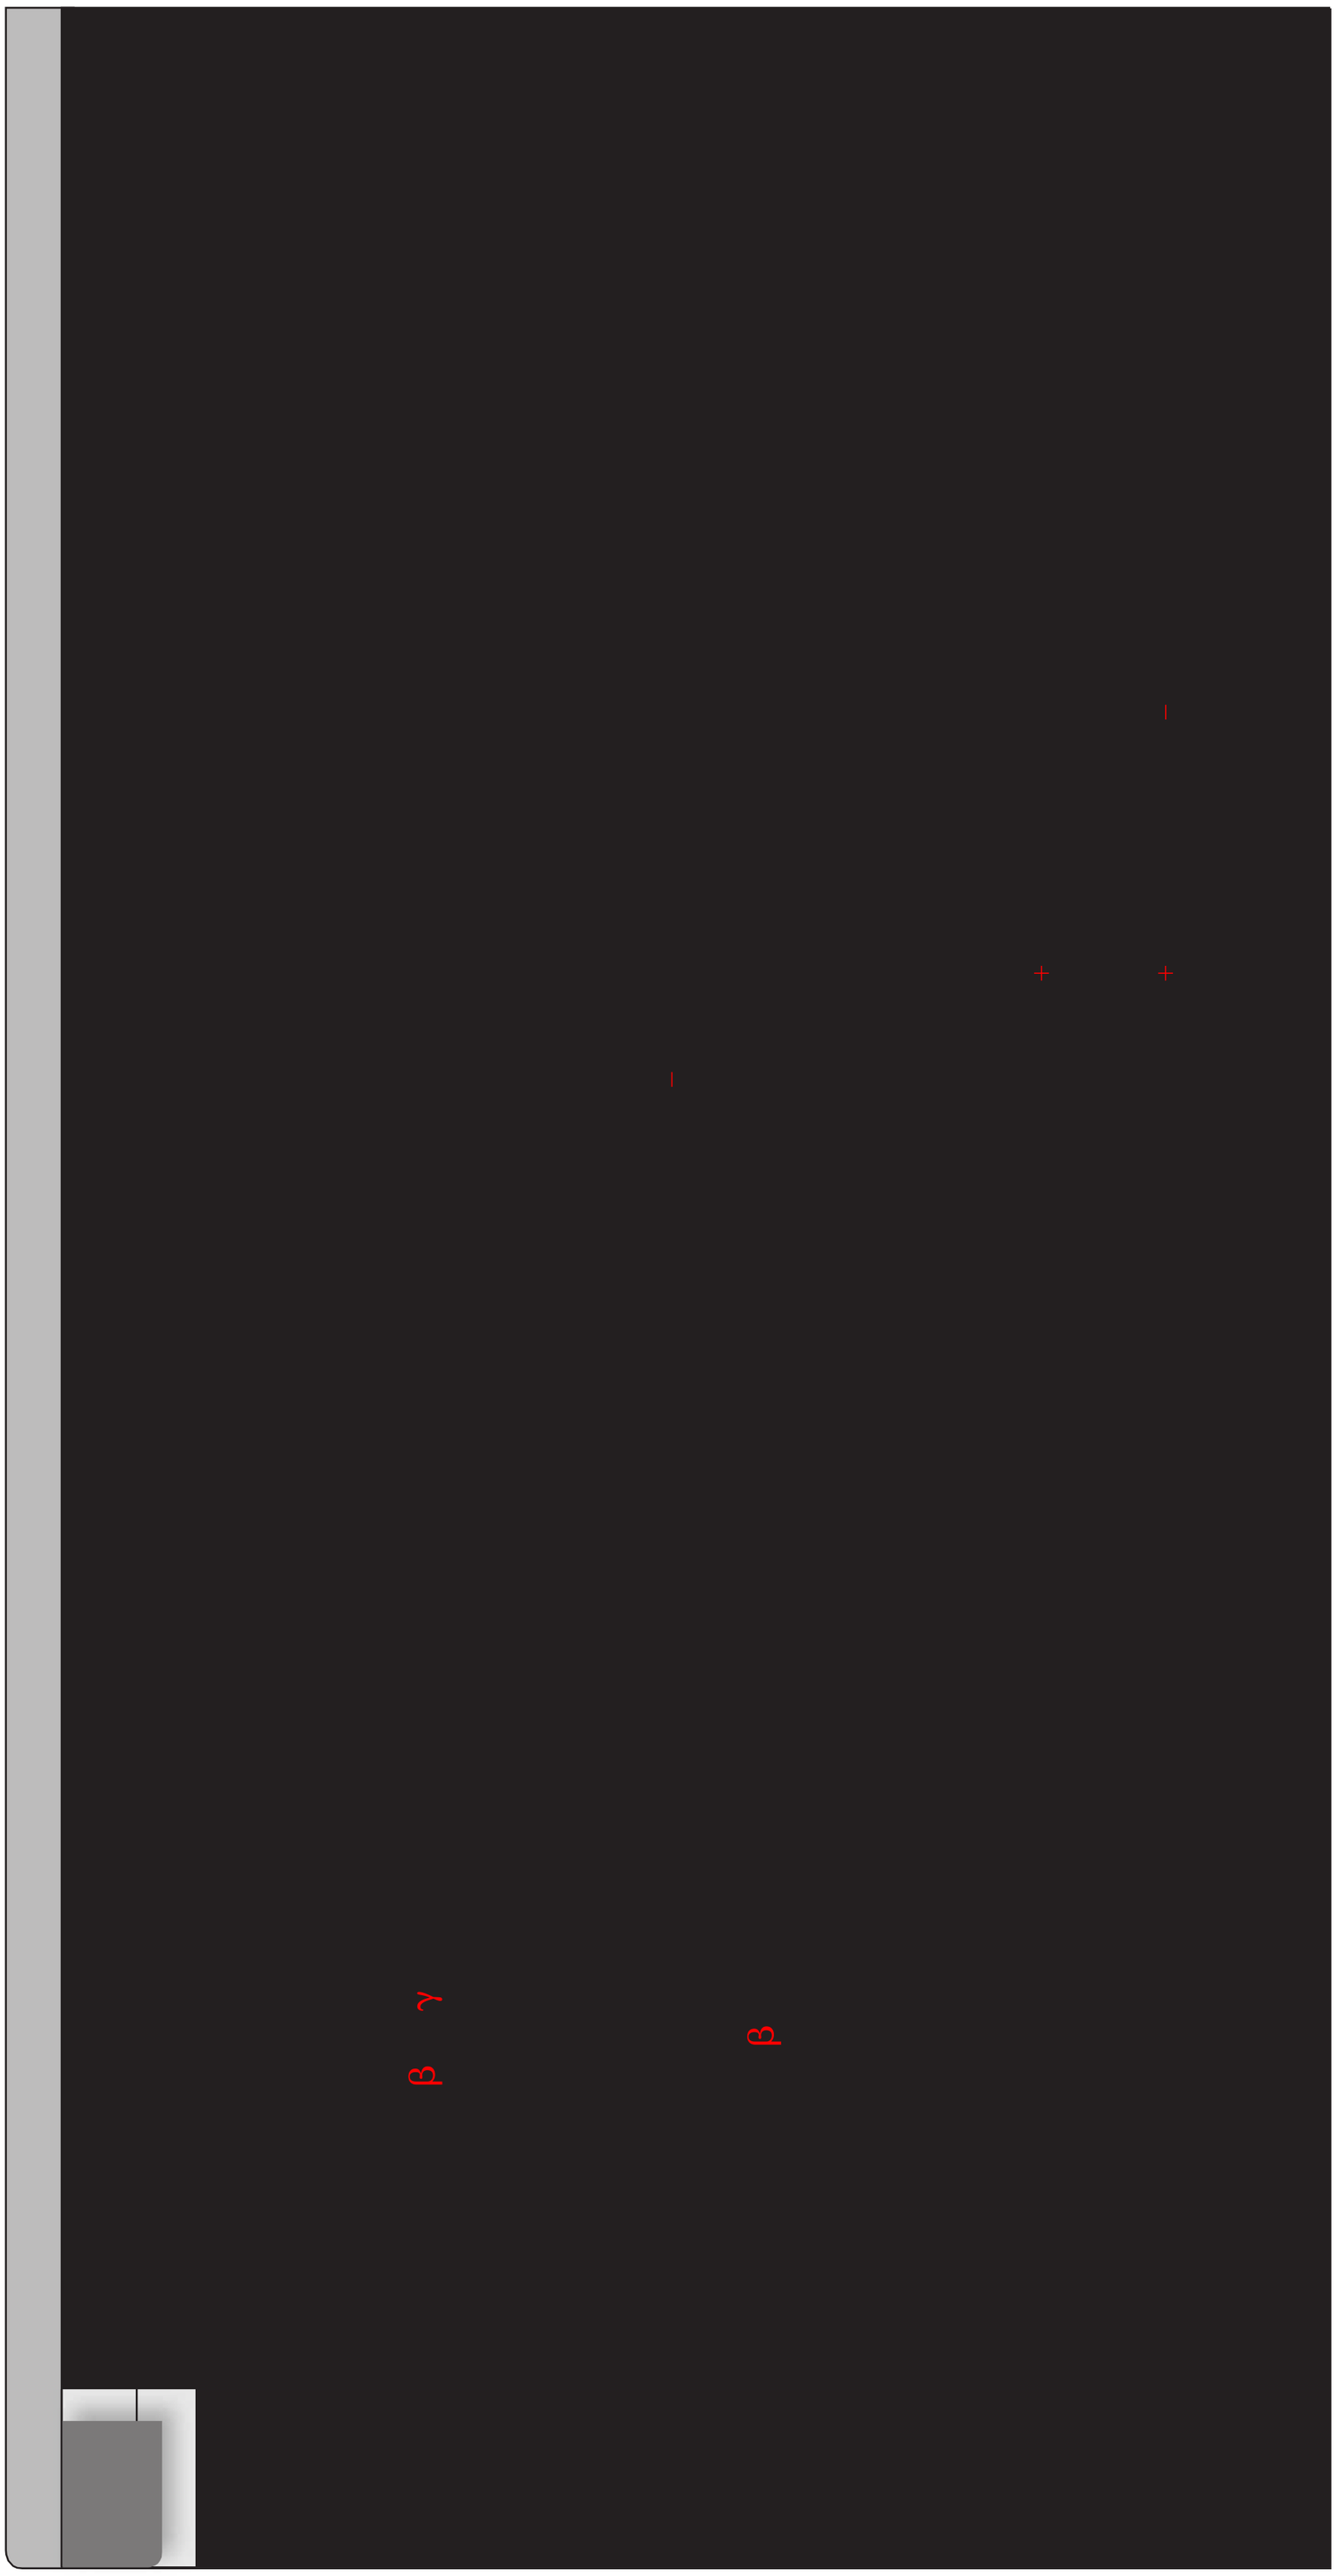
For impermeant solutes, $\sigma = 1$; for highly permeable solutes, σ approaches 0.

For solutes with $\sigma < 1$, transmembrane solute flux will be accelerated in the direction of volume flow. This acceleration is known as solvent drag.[4] Thus, the net passive flux of a permeable solute across a membrane may be driven by both diffusion and entrainment with solvent flow (i.e., solvent drag).

Facilitated Diffusion

Biologic membranes are composed primarily of lipid bilayers. Because the permeability of many hydrophilic solutes through lipid membranes is low, membranes contain proteins that facilitate the transport of certain solutes. Transport proteins, often termed carriers or transporters, have a high degree of specificity for the transported solute. Flux through the limited number of transporters saturates as the solute concentration is increased. An example of carrier-mediated facilitated diffusion is the entry of glucose into renal tubular cells mediated by the hexose transporter, GLUT-1.[5] The movement of ions through ion channels represents another form of facilitated diffusion. In this case, integral membrane proteins containing several membrane-spanning domains form pores in cell membranes through which ions permeate. Ion channels generally have a high degree of specificity for the ions being transported and very high transport rates. Facilitated diffusion mechanisms, like enzymes, serve only to accelerate the rate of transport, but do not affect the equilibrium distribution of solutes. In other words, facilitated diffusion, like simple diffusion and convection, is a passive process that tends to dissipate transmembrane gradients.





β γ
β

Active Transport Processes

Active transport is a special case of facilitated transport in which chemical bond energy is supplied to the transport process so that the final distribution of the solute is remote from equilibrium. The coupling of solute transport to the energy source can take two forms. In primary active transport, solute transport is coupled directly to an energy-yielding reaction.

The most widely recognized example of primary active transport is the transport of Na^+ and K^+ by the Na^+,K^+-ATPase. This enzyme, often referred to as the sodium pump, couples the extrusion of cellular Na^+ to cellular K^+ uptake.[6] In renal tubules, this enzyme is localized to the basolateral membrane. In general, segments with high rates of active Na^+ transport have high Na^+,K^+–ATPase activity.[7] The hydrolysis of each ATP molecule ordinarily pumps three sodium ions out of the cell coupled to two potassium ions moving inward.[8] Therefore, the pump is electrogenic. The Na^+,K^+–ATPase is responsible for maintaining the cell Na^+ activity at a low level, which provides the energy for the Na^+-coupled transport of many other solutes. Thus, the inhibition of Na^+,K^+–ATPase (e.g., by peritubular ouabain addition) causes a significant rise in the cell Na^+ activity.[9] The affinity constant (K_m) of the pump for intracellular sodium, about 15 to 30 mM,[10] is similar to the intracellular sodium activity measured in proximal tubule cells.[9] Therefore, the pump is unsaturated with respect to sodium, and pump activity is very sensitive to changes in the intracellular sodium concentration activity.

In secondary active transport, solute movement against its electrochemical gradient is energized by the movement of another solute down its own gradient.[11] Na^+, because of its steep inward electrochemical gradient maintained by the sodium pump, often participates in the transport of other solutes, either in the same (cotransport or symport) or opposite (exchange or antiport) direction. Thus, by coupling solute transport with sodium movement into cells, cellular metabolic energy generated by the Na^+,K^+–ATPase is stored in the form of a Na^+ concentration gradient, analogous to a battery, and then dissipated in the transport of a variety of different solutes. Some examples of symport processes include Na^+-glucose and Na^+-amino acid cotransport; Na^+-proton and Na^+-calcium exchange are two examples of antiport processes.

PROXIMAL TUBULE

General Features

The proximal tubule is the major site for Na^+ absorption within the kidney and serves two major purposes. First, the proximal tubule protects the extracellular fluid volume by reclaiming the bulk, approximately 60% to 80%, of the glomerular filtrate.[12,13] The proximal tubule with its well-developed brush border membrane is optimally designed to perform the reabsorption of such a large fraction of the filtrate.[14] Second, the absorption of sodium in the proximal tubule provides, by way of coupled processes, the driving force for the absorption of other solutes, such as bicarbonate, glucose, phosphate, and amino acids.

Under most circumstances, fluid at any given point along the proximal tubule has virtually the same Na^+ concentration and osmolality as plasma.[13] The isosmotic nature of proximal tubule fluid absorption derives from the high water permeability of this segment,[15] which effectively clamps the osmolality of the tubular fluid at that of plasma. Although Na^+ transport in the proximal tubule occurs in the absence of large electrical or chemical gradients, the bulk of Na^+ absorption in the proximal tubule involves active transport. For example, Na^+ can be reabsorbed against both concentration[13,16] and electrical[17] gradients. In addition, fluid absorption and sodium transport cease when Na^+,K^+–ATPase activity is inhibited or when cell metabolism is slowed.[18,19]

A significant amount of proximal Na^+ transport also occurs passively.[20] For example, in the late convoluted and straight tubules (S2 and S3 segments), Na^+ diffuses passively out of the tubule driven by the lumen-positive electrical potential difference in those segments. This potential difference derives from a Cl^- concentration gradient across the tubule wall. Even in this case, however, it is the active transport of Na^+ in upstream portions of the proximal nephron that ultimately accounts for these gradients and potentials.

Nephron Heterogeneity

Analyses of proximal tubular Na^+ transport are complicated by two factors: a nonhomogeneous nephron population and axial changes in fluid composition. There is considerable heterogeneity of both morphologic and functional characteristics along the proximal tubule. The S1 segment cells have extensive basal interdigitations, numerous mitochondria, and a well-developed luminal brush border.[21] S3 segment cells, in contrast, are flatter and have fewer mitochondria, lower brush borders, and much less extensive basolateral membranes than S1 cells.[21] The Na^+,K^+–ATPase activity of the S3 segment is only 25% of that for the S1 segments.[22] As might be expected on the basis of these observations, the net rates of the Na^+ and fluid transport in the S3 straight segment are, in general, lower than in the S1 convoluted tubule.[23]

Juxtamedullary proximal convoluted tubules have higher rates of volume and bicarbonate absorption than their superficial counterparts,[23,24] although this disparity has not been noted between juxtamedullary and superficial straight segments.[25]

Glomerular ultrafiltrate in the early proximal tubule undergoes axial composition changes. Figure 5.2 illustrates that the chloride concentration rises as a consequence of the preferential absorption of $NaHCO_3^-$ over NaCl in this segment.[26] Glucose, amino acids, and other organic compounds are also absorbed avidly in association with Na^+ so that their luminal concentrations in this

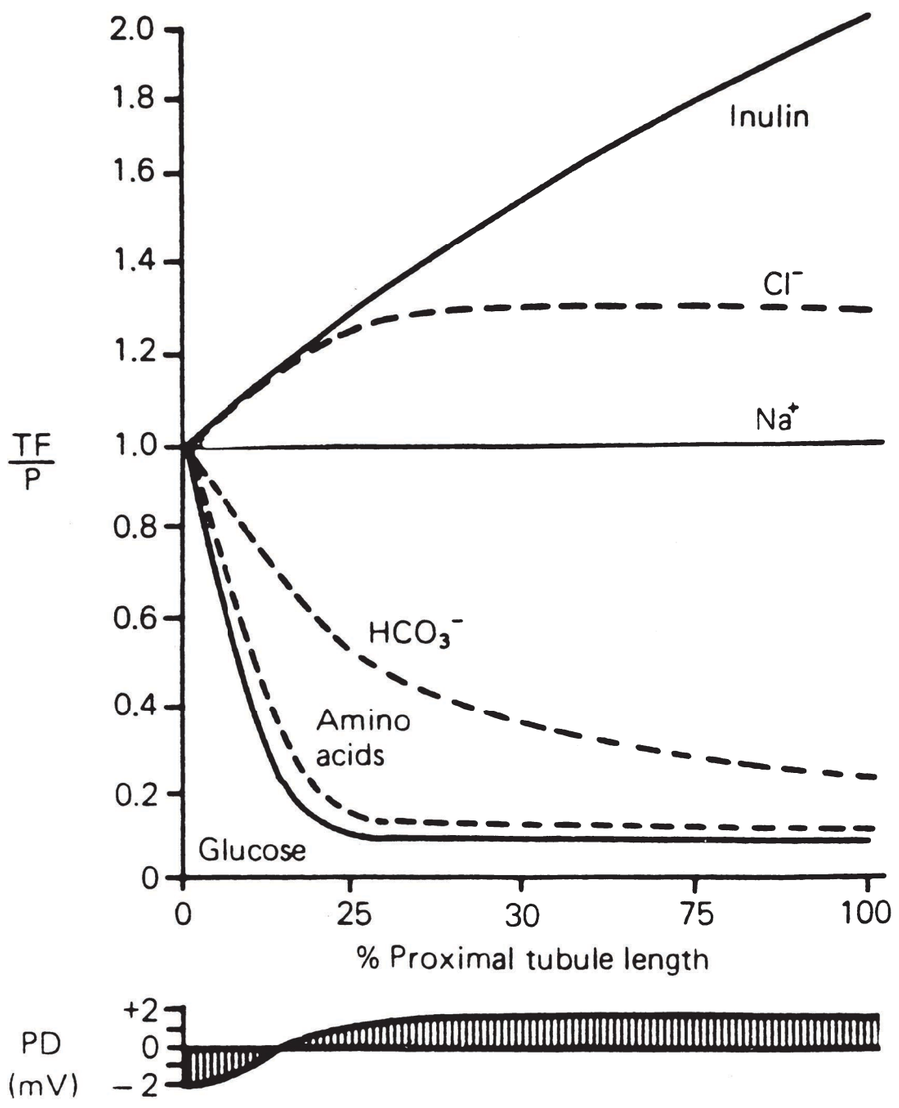


FIGURE 5.2 The profile of transepithelial voltage and solute concentrations along the mammalian proximal tubule. *TF/P*, tubular fluid/plasma concentration ratio; *PD*, potential difference. (From: Rector FC Jr. Sodium, bicarbonate, and chloride absorption by the proximal tubule. *Am J Physiol.* 1983;244:F461, with permission.)

segment approach zero.[26,27] The omission of glucose and amino acids from luminal fluids reduces both the potential difference and the volume absorptive rate.[24,28] In the S3 segment, on the other hand, the omission of glucose and alanine has no effect either on the potential difference or on the fluid absorptive rate,[25,29] although the deletion of all organic solutes does reduce volume absorption by 50%.[30] The rates of transport of glucose, amino acids, phosphate, and Na^+ in the early proximal convoluted tubule exceed those in the proximal straight tubule.[31–33] These rates correlate well with the relative basolateral membrane areas of the respective segments.[34]

Electrophysiology of the Proximal Tubule

Transepithelial Potential Difference

The electrogenic nature of the transport of Na^+ coupled to glucose and amino acids creates a lumen-negative transepithelial electrical potential difference in the early proximal convoluted tubule. The deletion of glucose and alanine from the luminal fluid reduces the potential difference from about −5.0 mV, lumen-negative, nearly to zero.[24,28] This transepithelial potential difference becomes lumen-positive (+2 to 4 mV) when the tubular fluid to plasma chloride concentration ratio is approximately 1.3.[35] This lumen-positive voltage is probably a diffusion potential arising from the Cl^- concentration gradient.

Electrical Resistance

The electrical resistance of the mammalian proximal tubule is remarkably low, making this tubule a classic example of a leaky epithelium, with resistances of 5 to 10 Ω-cm^2.[36,37] In the proximal tubule, the total cellular resistance (i.e., the sum of the apical and basolateral resistance) is 20- to 70-fold greater than the transepithelial resistance. This indicates that the paracellular resistance is low and that the predominant route for passive ion flows in the proximal tubule involves the paracellular pathway.

Ionic Selectivity

The initial convolution of the superficial proximal tubule is Na^+ selective; thereafter, the superficial convoluted and straight tubules are Cl^- selective.[29,38] In contrast, juxtamedullary proximal tubules are Na^+ selective throughout their course.[38] Because the Cl^- concentration rises as fluid flows along the convoluted tubule (Fig. 5.2), oppositely directed gradients for Cl^- and HCO_3^- in late convoluted and straight segments give rise to a lumen-positive transepithelial potential difference.[26] The latter indicates a higher permeability for Cl^- than HCO_3^-, both in superficial and juxtamedullary proximal tubules.[23,39]

MECHANISMS OF SODIUM REABSORPTION

Apical Membrane Sodium Entry

In the proximal tubule, Na^+ entry into the cell may be coupled to the movement of other solutes, such as glucose, chloride, or protons; or Na^+ may enter independently. In either case, the driving force for Na^+ entry is the steep electrochemical gradient favoring Na^+ influx.

The intracellular Na^+ activity ranges from 15 to 35 mM.[10,40] The entry of Na^+ into cells appears to be rate limiting for transepithelial Na^+ transport. Amphotericin B, a polyene antifungal, increases the permeability of the luminal membrane to Na^+ and causes a large rise in net sodium absorption.[41]

Na^+/H^+ Exchange

Directly coupled Na^+/H^+ exchange in the proximal tubular brush border is responsible for most proton secretion and for a large fraction of Na^+ reabsorption in the proximal tubule.[42] The mechanism whereby Na^+/H^+ exchange effects Na^+ reabsorption is presented in Figure 5.3. Briefly, entry of Na^+ is coupled to extrusion of a proton into the lumen. The proton titrates a filtered HCO_3^- molecule to form carbonic acid. Carbonic acid subsequently is dehydrated to CO_2 in a reaction catalyzed by carbonic anhydrase IV in the brush border membrane.[43] Within the cell, the reverse process occurs: carbonic acid formed by the hydration of CO_2 dissociates into H^+ and HCO_3^-. The H^+ is extruded into the lumen by Na^+/H^+ exchange or by the vacuolar H^+–ATPase to repeat another cycle while the HCO_3^- is transported into the blood via a $1Na^+$:$3HCO_3^-$ cotransport process (vide infra).

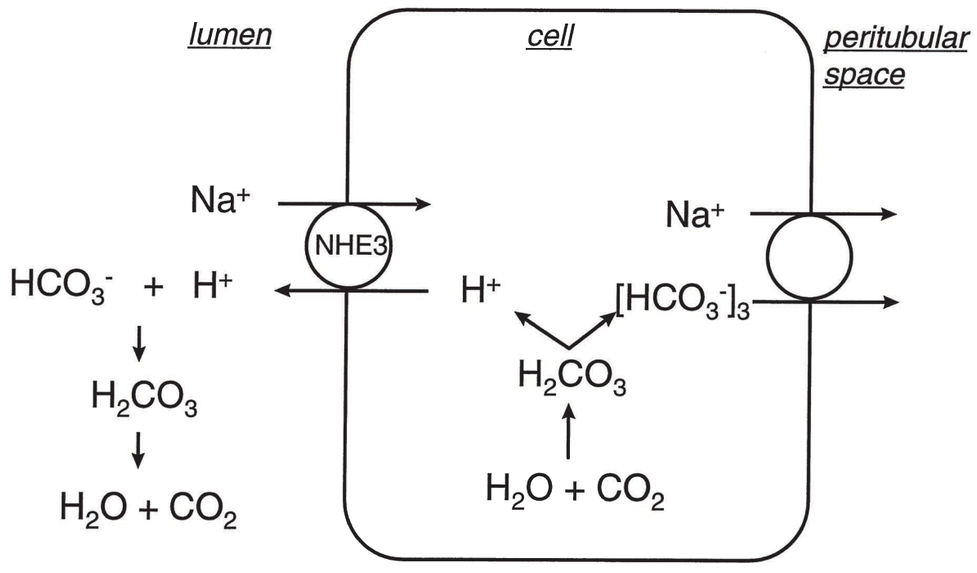

FIGURE 5.3 The scheme of $NaHCO_3$ transport mediated by Na^+/H^+ exchange. See text for explanation.

The mammalian Na^+/H^+ exchanger (NHE) is electroneutral with a stoichiometry of one proton for one sodium.[44] The exchanger is reversibly inhibited by high concentrations of amiloride.[45] Intracellular protons, via an internal activator site,[46] increase Na^+/H^+ exchange in response to intracellular acidosis.[47]

The apical and basolateral membranes of kidney cells contain different forms of NHEs with different affinities for amiloride.[48] The apical Na^+/H^+ exchanger is involved in urinary acidification and has a low amiloride affinity, whereas the basolateral exchanger has a high affinity for amiloride. The sensitivity of NHE1 to amiloride[49] and its basolateral localization[50] suggest that it represents the "housekeeping" NHE. In contrast, NHE3 is in the brush border membrane of proximal tubule cells.[51] NHE3 knockout mice have significantly reduced rates of Na^+ and HCO_3^- transport in proximal tubules.[52] In addition, pharmacologic inhibitors of NHE3 reduce proximal tubule Na^+ reabsorption by about one third.[53] However, a significant rate of amiloride-sensitive HCO_3^- transport still persists in the proximal tubules of NHE3 knockout mice,[54] indicating that the NHE3 is responsible for much, but not all, proximal tubular Na^+-coupled luminal acidification (vide infra). NHE8 is also expressed in the apical membranes of cortical tubules and may contribute to these processes.[55]

Sodium–Glucose Cotransport

Electrophysiologic studies in kidney proximal tubules show that apical membranes depolarize with addition of glucose to luminal fluids.[56] The depolarization occurs because the Na^+-glucose transporter is electrogenic. The Na^+-glucose transporter is specific for the D-stereoisomers of glucose, galactose, and α-methyl-D-glucoside.[57] The Na^+-glucose cotransporter has little affinity for cations other than Na^+.[58] Phlorizin inhibits Na^+-glucose cotransport by competing with glucose for its binding site.[59]

The rate of glucose transport by the early proximal tubule is greater than in late proximal segments.[60] In the proximal straight tubule, the K_m for D-glucose is 5 to 20 times lower than in the proximal convoluted tubule. Moreover, the transporter in the early cortical proximal tubule has a 1:1 Na^+ to glucose stoichiometry,[61] whereas the transporter in the straight medullary segment has a 2:1 stoichiometry.[62] By coupling the energy from two Na^+ ions moving down their electrochemical gradient to the transport of each glucose molecule, the medullary transporter is able to establish a much greater cellular to extracellular glucose concentration ratio than a 1:1 Na^+:glucose transporter.[27] The 2 Na^+:1 glucose transporter is, therefore, well suited to the straight segment, where tubular fluid glucose concentrations have already been reduced by glucose absorption in the more proximal segments.

A Na^+-glucose cotransporter (SGLT-1), which belongs to the SLC5 gene family,[63] mediates high affinity Na^+-glucose cotransport with a sodium-to-glucose coupling ratio of 2:1, whereas SGLT-2[64] shares 59% homology to SGLT-1 and mediates low-affinity Na^+-glucose cotransport with a sodium-to-glucose coupling ratio of 1:1.[65] In situ hybridization revealed high levels of a SGLT-2 message in the S1 segment of the proximal tubule.[66] Recently, better antibodies have confirmed that, in rat kidney, SGLT-1 immunolocalizes to the brush border membrane of all three segments of the proximal tubule.[5] By immunohistochemistry, SGLT-2 was detected at the brush border of the early proximal tubule in mice, which was absent in SGLT-2 knockout animals.[67] Thus, it appears that SGLT-2 may represent the low-affinity, high-capacity sodium–glucose cotransporter in the early proximal tubule, whereas SGLT-1 may represent the high-affinity, low-capacity transporter of the proximal straight tubule.[65]

Mutations in SGLT-2 form the basis for renal glycosuria (Table 5.1), an inherited condition characterized by a lowered threshold for tubular reabsorption of glucose.[68] In contrast, the dominant clinical manifestations of inactivating mutations of SGLT-1[69] relate to the failure to absorb sugars in the intestinal tract (glucose–galactose malabsorption). These findings suggest that SGLT-2 plays a much more significant role, quantitatively, than SGLT-1 in proximal tubule glucose reabsorption. SGLT-2 inhibitors are currently under investigation as potential therapeutic agents for the treatment of diabetes.[70]

Sodium–Amino Acid Cotransport

The proximal tubule reabsorbs amino acids from the tubular fluid via an active transport step at the luminal membrane.[31] Samarzija and Frömter,[71] using double-perfusion micropuncture techniques, observed a depolarization of the luminal membrane during amino acid transport, and they were able to identify five classes of amino acid transporters in the luminal membrane. Over the last decade, many of the transport proteins that mediate the different amino acid transport systems have been identified in kidney and intestine. This topic has been recently reviewed.[72]

Both Na^+-dependent and Na^+-independent amino acid uptake pathways have been characterized in the kidney.[72] Neutral amino acid transport appears to involve at least

three separate transport systems,[73] one that transports all neutral amino acids, one specific for imino acids, and one for the β-amino acids. Glycine may also have a specific transporter.[74] In the kidney, neutral amino acid transport is driven by a Na^+ gradient, as supported by experiments in slices, perfused tubules, and brush border membranes. The neutral amino acid transporter B^0AT1 (SLC6A19) cotransports one Na^+ per amino acid.[75] The K_m of the substrate decreases with an increasing cosubstrate concentration and vice versa. The initial step for transport involves the binding of the amino acid to B^0AT1, and this binding affinity increases under hyperpolarizing conditions.[76]

The acidic and basic amino acid groups each have their own transport systems.[77,78] At least one amino acid transporter, a Na^+-independent transporter for neutral and dibasic amino acids, has been cloned from the kidney.[79,80]

NaCl Transport

Two basic mechanisms account for NaCl reabsorption in the proximal tubule. In simple electrogenic Na^+ entry, sodium is transported actively through the cell, thereby creating a lumen-negative potential difference. Cl^- reabsorption then proceeds through the paracellular pathway driven by the lumen-negative potential difference. In electrically neutral NaCl transport, both Na^+ and Cl^- move through the cell at equal rates, such that no transepithelial potential and, hence, no driving force for paracellular Cl^- movement is generated.

Neutral NaCl Transport

Several lines of evidence indicate that a sizable fraction of proximal NaCl transport is transcellular and electroneutral.[81] First, by virtue of the coupling of Cl^- entry to apical Na^+ entry, the intracellular Cl^- activity of proximal tubule cells is greater than predicted from an equilibrium distribution.[82] Second, Cl^- absorption persists even when the driving force for passive, paracellular movement is abolished.[83] Conversely, Cl^- reabsorption is inhibited by cyanide in the absence of any change in the passive driving forces for Cl^- movement.[83] Finally, the luminal application of SITS,[84] an anion-exchange inhibitor, or removal of chloride from the tubule perfusate,[85] reduces net Na^+ reabsorption.

In principle, electroneutral NaCl transport across the apical membrane of proximal tubule cells could occur as directly coupled NaCl cotransport or as parallel Na^+/H^+ and Cl^-/base exchangers. There is no good evidence for the former process in the mammalian proximal tubule.[81] However, considerable evidence supports the view that electroneutral NaCl transport in the proximal tubule involves parallel exchangers. The coupling of Na^+ absorption to Cl^- absorption in this case occurs because of the relation between cell pH and concentration of base within the cell. With reference to Figure 5.4, the extrusion of H^+ in exchange for Na^+ results in the liberation of the base for participation in Cl^-/base exchange. The uphill entry of Cl^-, then, is indirectly coupled to the downhill entry of Na^+, because both are coupled to the transport of an acid–base pair. The model illustrated in Figure 5.4 uses formate/Cl^- exchange as the anionic component of electroneutral NaCl transport.

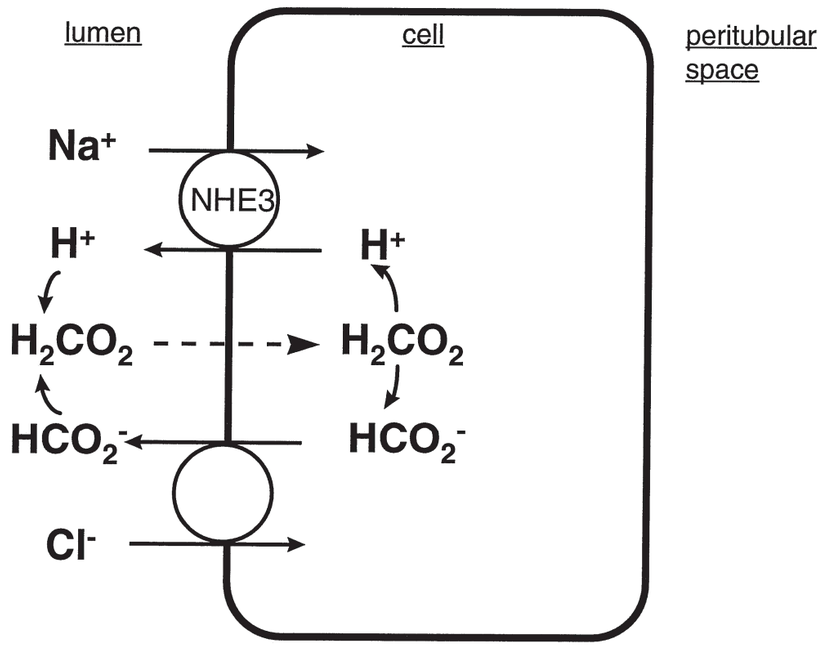

FIGURE 5.4 The scheme of neutral NaCl transport mediated by the parallel action of $Na^+ - H^+$ exchange and formate/Cl^- exchange. Formate (HCO_2^-) combines with H^+ in the tubular lumen to form formic acid (H_2CO_2), which reenters the cell by nonionic diffusion. A similar scheme applies for oxalate–Cl^- exchange.

As indicated previously, there is abundant evidence for a Na^+/H^+ exchanger in proximal tubule brush border membranes. With respect to NaCl transport, the inhibition of Na^+/H^+ exchange by high concentrations of amiloride[86] or more specific inhibitors of NHE3[53] results in a dramatic fall in transcellular NaCl transport. Likewise, knockout of NHE3 also reduces NaCl and fluid reabsorption in the proximal tubule.[52] Several Cl^-/base exchangers have been implicated in NaCl transport. Recent interest has focused on the role of Cl^-/formate (HCO_2^-) and Cl^-/oxalate ($C_2O_4^{2-}$) exchange in NaCl transport.

A Cl^-/formate exchanger is present in brush border membrane vesicles.[87] A role for Cl^-/formate exchange in neutral NaCl transport is suggested by the finding that the addition of formate to the luminal perfusate increases the rate of NaCl reabsorption in rabbit proximal tubules.[88] As depicted in Figure 5.4, formate is presumed to leave the cell in exchange for Cl^-. The secreted formate then combines with a proton, which was transported by the Na^+/H^+ exchanger to form formic acid. The formic acid then reenters the cell by nonionic diffusion and dissociates to supply substrate for the continuation of both exchange processes. CFEX (SLC26A6), a homolog of pendrin, is a protein capable of mediating Cl^-/formate exchange and is present in apical membranes of the proximal tubule.[89]

Cl^-/oxalate ($C_2O_4^{2-}$) exchange has also been demonstrated in brush border membrane vesicles.[90] It has been suggested that Cl^-/oxalate exchange may mediate neutral NaCl transport in a manner analogous to that described for Cl^-/formate exchange. It has also been suggested that NaCl absorption proceeds via the operation of three parallel transporters: the Na^+-sulfate cotransport, the sulfate/oxalate exchange, and the Cl^-/oxalate exchange.[91] Indeed, the CFEX protein, in addition to Cl^-/formate exchange, is also able to mediate Cl^-/oxalate, oxalate/formate, oxalate/oxalate, and oxalate/sulfate exchange.[92]

Other Na^+-dependent transport processes have been described in the apical membrane of the proximal tubule. However, they do not contribute significantly to Na^+ reabsorption because of the low concentrations of substrate present.

Simple Electrogenic Na^+ Entry

The classic Ussing model for salt reabsorption involves passive entry of Na^+ across apical membranes and extrusion across the basolateral membrane by Na^+,K^+–ATPase. A problem in assessing the contributions of electrogenic processes to Na^+ transport in the proximal tubule is the presence of other mechanisms of Na^+ entry. However, when the contributions of Na^+/H^+ exchange and Na^+ cotransport to net Na^+ absorption are minimized by deleting glucose, amino acids, and bicarbonate from the perfusate, a fraction of fluid absorption in isolated perfused straight segments persists and the transepithelial potential is −1.0 mV.[30] These results indicate that in the proximal straight tubule simple electrogenic Na^+ transport constitutes a mechanism for Na^+ absorption. A conductive Na^+ pathway has been demonstrated in brush border membrane vesicles.[93] Unlike the Na^+ channel found in the distal nephron segments, the Na^+ channel in the proximal tubule is not blocked by amiloride.[93]

In the proximal convoluted tubule, however, the deletion of glucose, bicarbonate, and amino acids completely abolishes fluid absorption.[23] Consequently, simple electrogenic proximal Na^+ transport may be limited to straight segments.

Passive NaCl Absorption

The rise in tubular fluid Cl^- concentration, and the attendant lumen-positive voltage (Fig. 5.2), provides a mechanism for passive NaCl absorption in late regions of the proximal nephron. In the Cl-selective superficial pars recta, approximately one-third of net NaCl absorption can be accounted for by this mechanism.[20]

Basolateral Membrane

The proximal tubule, particularly the S1 segment, possesses high Na^+,K^+–ATPase activity in the basolateral membrane. The Na^+,K^+–ATPase pumps Na^+, which entered cells apically, across basolateral membranes. In other words, the pump keeps the cell Na^+ activity low and maintains the electrochemical gradient for Na^+ entry across the apical membrane. Consequently, the inhibition of Na^+,K^+–ATPase activity with ouabain decreases transepithelial Na^+ reabsorption and increases the intracellular Na^+ activity in the proximal tubule.[94]

Na^+ also exits across the basolateral membrane in concert with HCO_3^-. Studies in intact tubules and in membrane vesicles have demonstrated an electrogenic, stilbene-sensitive Na^+-HCO_3^- cotransporter in the basolateral membrane of rat and rabbit proximal tubules.[95,96] The cotransporter transfers two net negative charges across the basolateral membrane. The stoichiometry of this process is 1 Na^+: 1 HCO_3^-: 1 CO_3^{2-} (or SO_3^{2-}).[97] Thus, this transport moiety for Na^+ extrusion, $[Na^+(HCO_3^-)_3]^{2-}$ is electronegative, with the lumen-negative cell interior providing a major driving for Na^+ extrusion. A number of Na^+-HCO_3^- cotransporters have been cloned, along with different splice variants.[98] One of these, NBC1 (encoded by SLC4A4 and subsequently renamed NBCe1-A) is localized to the basolateral membrane of the S1 and S2 segments of the proximal tubule.[99] As illustrated in Figure 5.3, the net result of these steps is the reabsorption of Na^+ and HCO_3^-, accounting for the bulk of HCO_3^- reabsorption and about 20% of Na^+ reabsorption in the proximal tubule. It is believed that this cotransport process accounts for the basolateral transport of most of the bicarbonate reclaimed from the luminal fluid.[97] Mutations in NBCe1-A cause proximal (type II) renal tubular acidosis and other defects in the eye, teeth, and mental development (Table 5.1). The regulation and role of NBC in acid–base transport in the proximal tubule is an area of active research that has been reviewed recently.[100]

The pathways for Cl^- exit across the basolateral membrane are less well defined. Several pathways for Cl^- exit across the basolateral membrane have been proposed: conductive Cl^- channels, KCl cotransport, and $Na^+(HCO_3^-)_2/Cl^-$ exchange (Fig. 5.5). Studies of rat proximal convoluted tubules[101] and rabbit convoluted and straight proximal tubule segments[102,103] using intracellular microelectrodes have indicated that the proximal tubule cell has a very low Cl^- conductance. Thus, in normal proximal convoluted tubule and proximal straight tubule segments, conductive Cl^- efflux across basolateral membranes appears to play a minor role in NaCl absorption. Under hypotonic conditions, however, cell swelling dramatically increases the basolateral membrane Cl^- conductance.[104]

Because the chemical gradient for K^+ to leave cells exceeds that for Cl^- entry, KCl cotransport can mediate basolateral Cl^- exit from proximal tubule cells. Ion-selective microelectrode studies have demonstrated KCl cotransport in basolateral membranes of rabbit proximal tubule cells.[103,105]

Stilbene-sensitive, Na^+-dependent Cl^-/HCO_3^- exchange has been demonstrated in rat[106] and rabbit[107,108] proximal tubules. In this case, the entry of 1 Na^+ and 2 HCO_3^- across the basolateral membrane is coupled to the efflux of Cl^-. The Na^+

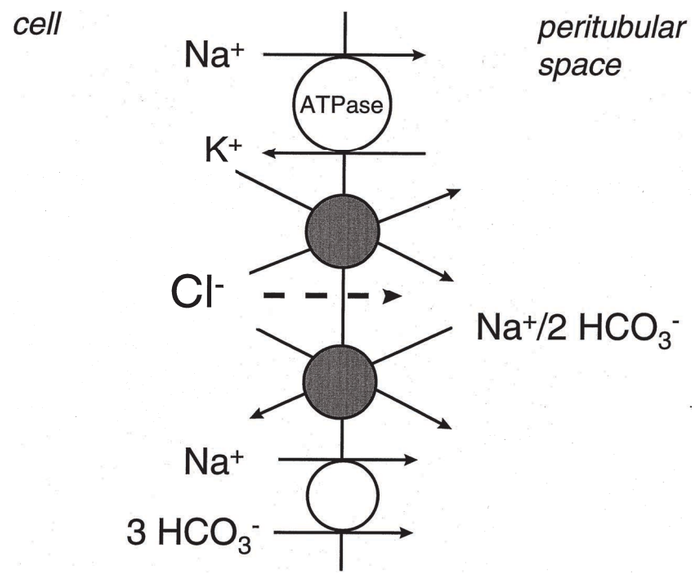

FIGURE 5.5 The transport pathways for Na^+ and Cl^- absorption across the basolateral membrane of proximal tubular cells. Cl^- can leave the cell via KCl cotransport, Na^+–$2HCO_3^-/Cl^-$ exchange, and Cl^- channels (minor). Na^+ exits via the Na^+,K^+–ATPase and Na^+–$3(HCO_3^-)$ cotransport.

and HCO_3^- that enter the cell are thought to be recycled through the $[Na^+(HCO^-_3)_3]^{2-}$ cotransporter (see previous). Indeed, $Na^+(HCO^-_3)_2/Cl^-$ exchange may account for much more Cl^- movement than KCl transport.[108] Na^+-independent Cl^-/HCO_3^- exchange is also present in the basement membrane of proximal tubules.[106–108] However, under physiologic conditions, this process mediates net Cl^- influx and does not contribute to net NaCl absorption.

CONTROL OF PROXIMAL TUBULAR SODIUM REABSORPTION

Glomerulotubular Balance (GTB)

The proximal tubule responds to an increase in glomerular filtration with an increase in the absolute rate of fluid absorption (APR) to minimize variations in the fractional proximal fluid absorption. This phenomenon is termed glomerulotubular balance (GTB). The efficiency of GTB—that is, the extent to which APR/GFR remains constant—is subject to physiologic and pathologic control. The prime factor modulating GTB in vivo is the effective circulating volume. Thus, at a constant or near constant GFR, volume expansion and volume contraction decrease and increase, respectively, the absolute rate of proximal Na^+ absorption. In other words, volume expansion and volume contraction reset GTB upward and downward, respectively.[109,110] This section considers some of the factors that modulate proximal Na^+ absorption.

Peritubular capillary oncotic pressure is one of the factors regulating the rate of salt and water absorption from the proximal tubule.[111] The oncotic pressure of the peritubular proteins favors the movement of fluid across the basement membrane, whereas capillary hydrostatic pressure retards this movement. Thus, at a given renal blood flow, an increase in the glomerular filtration rate and, hence, the filtration fraction, will cause an increase in the oncotic pressure in the postglomerular peritubular capillaries. At constant single nephron glomerular filtration rates (SNGFR), the perfusion of efferent capillaries with hypo-oncotic fluids decreases the absolute rate of proximal fluid absorption, whereas perfusion of the capillaries with hyperoncotic fluids increases proximal absorption.[112] The effects of the peritubular protein concentration can also be demonstrated in isolated perfused tubules.[113]

It is not precisely clear how the peritubular protein concentration modulates proximal fluid absorption. The effect is not simply because of the oncotic pressure exerted by the proteins, because changes in absorption do not occur when active transport is inhibited or from comparable changes in the transtubular hydrostatic pressure.[114] The prevailing views are that the peritubular protein may directly affect transcellular Na^+ transport[115] or the back leak of Na^+ through the paracellular pathway.[113,116]

Luminal factors also contribute to glomerulotubular balance. The flow dependence of proximal absorption has been investigated in the convoluted[15] and straight segments[30] of isolated, perfused rabbit nephrons. The key observations are (1) the volume absorptive rate is clearly dependent on the perfusion rate, (2) the flow dependence persists in the absence of active transport when anion gradients are present, and (3) the flow dependence is abolished in the absence of active transport and anion gradients.

An explanation for these results lies in a consideration of axial versus radial changes in fluid composition along the tubule.[117] The rate of passive Na^+ absorption in the late proximal tubule is dependent on the magnitude of the chloride gradient between the lumen and the bath. At low axial perfusion rates, the radial Cl^- gradient tends to dissipate as a function of distance along the tubule, but this dissipation is minimized at higher axial perfusion rates. Hence, the integrated driving force for passive NaCl absorption increases with the rate of tubule perfusion. In addition, the availability of solutes, such as glucose, amino acids, and bicarbonate, is also partly responsible for the flow dependence of proximal fluid absorption.[118]

The flow dependence of reabsorption in the proximal tubule has also been tested in the mouse proximal tubule. In this experimental model, which included the use of the NHE3 knockout mouse, the data supported the hypothesis that the "brush border" microvilli act as mechanosensors that transmit fluid dynamic torque to the actin cytoskeleton and thus modulate Na^+ absorption.[119]

Catecholamines

Renal denervation reduces proximal tubule Na^+ and fluid absorption.[120] Both α- and β-adrenergic receptors exist in the proximal tubule.[121,122] The rate of salt and water reabsorption in the proximal tubule is stimulated by α- and β-adrenergic agonists.[123] α-Adrenergic agonists increase apical Na^+ entry via the stimulation of Na^+/H^+ exchange[122] and also increase basolateral Na^+ efflux via Na^+,K^+–ATPase activity in rat proximal tubules by a pathway that involves the activation of calcineurin.[124] The effects of β-adrenergic agonists on Na^+,K^+–ATPase activity are less clear, with one study showing that they increase Na^+,K^+–ATPase activity via protein kinase C (PKC).[125] However, others have found that β-adrenergic agonists inhibit Na^+,K^+–ATPase activity via PKA.[126]

Dopamine, which is produced by proximal tubular cells,[127] inhibits Na^+ reabsorption. Dopamine inhibits Na^+,K^+–ATPase activity via its receptors DA-1 and DA-2.[128]

Parathyroid Hormone

Parathyroid hormone (PTH) causes a 30% to 50% reduction in proximal tubular Na^+ and phosphate absorption.[129] PTH stimulates adenylyl cyclase, cAMP production, and PKA, which in turn inhibits Na^+/H^+ exchange in several proximal tubule systems.[130] Weinman et al.[131] demonstrated that phosphorylation by PKA inhibits Na^+/H^+ exchange activity via a PDZ domain-dependent interaction with the NHE regulatory factor (NHERF). In the absence of NHERF, cAMP

does not inhibit the exchange activity of NHE3.[132] The current model for this inhibition is that NHE3 associates with PKA indirectly via NHERF and the cytoskeletal protein ezrin. PKA, when active, phosphorylates NHE3 at serines 552 and 605, which mediates the inhibition of the exchanger.[133] NHE3 is directly phosphorylated by other protein kinases, including calmodulin-dependent protein kinase II, which inhibits Na^+/H^+ exchange activity and PKC, which stimulates the exchanger.[134]

Angiotensin II

The systemic administration of low doses of angiotensin II (Ang II) inhibits the excretion of Na^+,[135] whereas inhibitors of Ang II increase Na^+ excretion.[136] Systemic Ang II causes changes in renal blood flow, aldosterone secretion, filtration fraction, and catecholamine release from renal sympathetic nerve endings.[137] Low concentrations of Ang II ($<10^{-9}$ M) cause an increase in proximal tubule fluid and bicarbonate reabsorption, effects that are mediated by the AT1 subtype of Ang II receptors present in both the brush border and basolateral membranes of the proximal tubule.[138] Higher concentrations ($>10^{-8}$ M) depress fluid and bicarbonate absorption, presumably via counterbalancing effects mediated by the lower affinity AT2 receptor.[138] Studies have demonstrated that the stimulatory effect of Ang II on fluid and bicarbonate reabsorption occurs via enhanced apical Na^+/H^+ exchange via NHE3 and basolateral Na^+-$(HCO_3^-)_3$ cotransport via NBC-1 in the proximal tubule.[139] The physiologic effects of Ang II may involve the coupling of these receptors to both phospholipase A_2 and inhibitory G proteins.[140,141]

Thyroid Hormone

On a clinical level, hypothyroidism is associated with a decreased cardiac output, renal blood flow, and glomerular filtration rate (GFR). Clearance studies in hypothyroid rats have documented decreases in GFR, renal Na^+ reabsorption, and renal Na^+,K^+–ATPase activity.[142] These changes are reversible after thyroid hormone replacement.[143] The thyroid hormone may exert direct effects to stimulate proximal tubular salt and fluid reabsorption via increased basolateral K^+ permeability[144] and/or direct stimulation of Na^+/H^+ exchange through an increase in NHE3 transcription.[145]

Corticosteroids

Although mineralocorticoids do not have an effect on proximal tubular sodium reabsorption,[146] there is evidence for glucocorticoid receptors in the proximal tubule.[147] Dexamethasone inhibits apical membrane Na^+-phosphate cotransport in cultured proximal tubular cells via PKC activation.[148] Dexamethasone also enhances the activity of apical NHE3 and the mRNA expression and functional activity of basolateral NBC-1.[149] The resulting increase in proximal tubule HCO_3^- reabsorption could contribute to the maintenance of the metabolic alkalosis that is associated with increased glucocorticoid production in vivo.

Nitric Oxide

Various forms of nitric oxide synthase (NOS) are expressed in the proximal tubule.[150] Low basal production of nitric oxide (NO) by the proximal tubule is boosted dramatically by lipopolysaccharide (LPS) and cytokines. Even under basal conditions, the proximal tubule may be affected by NO produced by adjacent cells, such as endothelium or other nephron segments. The overall effect of NO on proximal tubule Na^+ transport is controversial and may be biphasic, with acute inhibition and chronic stimulation of Na^+ reabsorption as assessed by pharmacologic agents and genetic knockouts of NOS, respectively.[151] In vitro, NO decreased Na^+/H^+ exchange and Na^+,K^+–ATPase activity in cultured proximal tubule cells.[152]

MECHANISM OF ISOTONIC FLUID ABSORPTION

Proximal tubule water absorption is coupled tightly to solute absorption, because the measured osmolality of the tubular fluid is generally identical to plasma. Three general mechanisms of solute–solvent coupling have been suggested to account for this isotonic absorption: lateral interspace hypertonicity, effective osmotic gradients because of different reflection coefficients for solutes in the tubular and peritubular fluids, and luminal fluid hypotonicity.

The standing gradient theory argues that active transport of salt into the lateral intercellular space raises the osmolality of the space, thus providing an osmotic gradient for fluid transport from the lumen to the interspace.[153] The tight junctions in this model are presumed to be impermeable to water, so that the osmotic flow of water from the cell into the hypertonic interspace raises the hydrostatic pressure in this compartment and forces fluid across the basement membrane.

An alternative explanation[117] proposes that an effective osmotic driving force for fluid absorption can exist between solutions of identical osmolalities if the reflection coefficients of the membrane for the solutes in the solutions differ. Specifically, the elevated tubular fluid-to-plasma Cl^- concentration found in the late proximal convolution and in the pars recta provides an effective osmotic driving force for fluid absorption because σHCO_3^- exceeds σCl^-. That is, the bicarbonate in the peritubular fluid is a more "effective" osmotic agent than is the chloride in the tubular fluid, and, thus, net water flows out of the tubule. Although this mechanism may be applicable to the proximal straight tubule, the reflection coefficients for NaCl and $NaHCO_3$ measured across the rabbit proximal convoluted tubule are virtually identical,[154] so oppositely directed Cl^- and HCO_3^- gradients may make only a negligible contribution to fluid absorption in convoluted segments.

Finally, because of the high osmotic water permeability of the proximal tubule, only small degrees of absolute luminal hypotonicity are needed to provide a sufficient driving

force to account for the observed rates of fluid reabsorption.[20] Experimental evidence supports the view that absolute luminal hypotonicity is a significant driving force for fluid reabsorption in the proximal tubule. Thus, when proximal tubules are perfused and bathed by symmetric NaCl solutions, the luminal fluid becomes slightly hypotonic.[155] The development of luminal hypotonicity can be amplified by maneuvers that decrease the water permeability of the proximal tubule. The aquaporin 1 (AQP1) water channel is abundantly expressed in the proximal tubule. In AQP1 knockout mice, the osmolality of tubular fluid at the end of the proximal tubule is significantly lower than in normal mice.[156] As the luminal fluid becomes more hypotonic, the resorbate becomes more hypertonic, and the degree of resorbate hypertonicity correlates with the rate of volume reabsorption by the tubules.[157]

THE LOOP OF HENLE

The dissociation of salt and water absorption by the loop of Henle is ultimately responsible for the capacity of the kidney, either to concentrate or to dilute the urine. The active absorption of NaCl in the water-impermeable thick ascending limb of Henle (TALH) serves both to dilute the urine and to supply the energy for the "single effect" of countercurrent multiplication. A functionally similar segment, known as the diluting segment, is found in amphibians and teleosts.[158]

The mammalian loop of Henle contains the descending thin limb (DTL), the ascending thin limb (ATL), and the thick ascending limb (TAL). The loop of Henle absorbs about 25% to 40% of the filtered Na^+ load.[159] Furthermore, the fluid leaving the loop is dilute, indicating that more NaCl is absorbed in the loop than water.

SALT TRANSPORT BY THE THIN DESCENDING AND THIN ASCENDING SEGMENTS

As the tubular fluid enters the descending thin limb and flows toward the tip of the renal papilla, it becomes more concentrated.[160] Passive models for urinary concentration indicate that this increase in osmotic pressure is attributable to water extraction rather than solute entry.[161] Current observations indicate that the aquaporin water channel AQP1 mediates water movement across the luminal surface of the DTL.[162] According to some reports, however, AQP1 expression is significantly lower in short loop nephrons than long loop nephrons,[163] suggesting that (1) not all DTLs in the kidney extract water to the same degree, and/or (2) water movement in short loop DTLs is facilitated by alternative water channels or via the paracellular route. In contrast to the DTL, in vitro microperfusion studies demonstrate that the ATL is relatively impermeable to water.[164]

The study of NaCl transport by the DTL and ATL has been complicated by the fact that the transport characteristics of these two nephron segments exhibit significant interspecies heterogeneity.[165] Although the Na^+ and Cl^- permeabilities appear to vary widely among rabbits, hamsters, and rats, one consistent finding was that the DTL is relatively less permeable to NaCl than the ATL. Coupled with the DTL's high permeability to water, the relative lack of solute permeability ensures that the osmotic pressure of fluid entering the renal papilla is greater than that of the fluid leaving it.[166] Thus, the formation of dilute urine by the loop of Henle begins in the ATL.

The decrease in osmolality in the ATL is due primarily to a fall in the NaCl content of the luminal fluid. The electroneutral transport of NaCl appears to occur through two key mechanisms. The transepithelial movement of sodium from the ATL lumen occurs via the paracellular pathway,[167] whereas Cl^- diffusion occurs through a transcellular route. Yoshitomi et al.[168] detected conductive pathways for Cl^- in both the apical and basolateral membranes of ATL cells. The transcellular movement of Cl^- in the ATL is regulated, because the basolateral Cl^- conductance is inhibited at low pH[168] and by low intracellular Ca^{2+} concentrations.[169] Uchida et al.[170] cloned a Cl^- channel in 1993 from the rat renal medulla, ClC-K1 (termed ClC-Ka in humans), which represents the major mediator of transcellular Cl^- movement in the thin ascending limb. This channel, which belongs to the ClC family of Cl^- channels, is expressed exclusively within the kidney and has been localized by immunohistochemistry to both the apical and basolateral membranes of the thin ascending limb of Henle.[171] Its activity is dependent on the coexpression of barttin, an accessory protein that forms a complex with ClC-K1, increases its abundance at plasma membranes, and modifies channel gating.[172–175] The expression of ClC-K1 is increased by dehydration.[170] Genetic knockout of the ClC-K1 gene in mice produced a urinary-concentrating defect, confirming the role of passive NaCl transport in the thin ascending limb in the urinary concentrating mechanism.[176]

NaCl ABSORPTION IN THE THICK ASCENDING LIMB

General Features

The studies of Rocha and Kokko[177] and Burg and Green[178] were the first to investigate salt absorption in the thick ascending limb, and their work defined several key features of this unique epithelium. First, salt absorption in the medullary and cortical TAL generates a lumen-positive transepithelial voltage, which is sensitive to furosemide. Second, the transport of Cl^- occurs against both electrical and chemical gradients and involves an active transport process that is dependent on intact basolateral Na^+,K^+–ATPase activity.[179] A final important feature of the TAL is that this segment consists of a tight epithelium, which despite its high ionic conductance, possesses a very low permeability to water. The apical membrane of the TAL constitutes the major barrier to transcellular and paracellular water flow.[180] The high

ionic conductance and low water permeability effectively further dilutes fluid entering the TAL from the ascending thin limb.

Figure 5.6 integrates the results of several electrophysiologic and biochemical studies to provide a model of salt reabsorption in the thick ascending limb. According to this model, net Cl^- absorption by the TAL is a secondary active transport process. Luminal Cl^- entry into the cell is mediated by an electroneutral Na^+-K^+-$2Cl^-$ cotransport process driven predominantly by the favorable electrochemical gradient for Na^+ entry.[181] Because the Na^+ gradient is maintained by the continuous operation of the basolateral membrane Na^+,K^+–ATPase pump, the apical entry of Cl^- via the cotransporter ultimately depends on the operation of the basolateral Na^+,K^+–ATPase.

In contrast to the electroneutral entry of Cl^- across the apical membrane, the majority of Cl^- efflux across the basolateral membrane proceeds through conductive pathways.[182,183] A favorable electrochemical gradient for Cl^- efflux through dissipative pathways has been demonstrated by Greger et al.[184] in the rabbit cTAL. Intracellular Cl^- is maintained at concentrations above electrochemical equilibrium by the continued entry of Cl^- via the apical Na^+-K^+-$2Cl^-$ cotransporter.[185]

According to the model in Figure 5.6, K^+ that enters TAL cells via the Na^+-K^+-$2Cl^-$ cotransporter recycles, to a large extent, across the apical membrane via a K^+-conductive pathway. This apical K^+ recycling serves several purposes. First, it ensures a continued supply of luminal K^+ to sustain Na^+-K^+-$2Cl^-$ cotransport. Without recycling, the luminal K^+ concentration would fall rapidly as a consequence of K^+ entry via Na^+-K^+-$2Cl^-$ cotransport and would limit net NaCl absorption. Second, the apical membrane K^+ current provides a pathway for net K^+ secretion by the TAL. In mouse TAL, for example, the rate of K^+ secretion amounts to about 10% of the rate of net Cl^- absorption.[182] K^+ secretion in this segment is an active process, ultimately driven by the Na^+,K^+–ATPase, proceeding in the face of a lumen-positive transepithelial potential. Third, under open circuit conditions, the transcellular and paracellular pathways form a current loop in which the currents traversing the two pathways are of equal size, but which traverse in the opposite direction. The potassium current from cell to lumen polarizes the lumen and causes an equivalent current to flow from the lumen to the bath through the paracellular pathway.[186] Because the paracellular pathway is cation selective ($P_{Na}/P_{Cl} = 2$ to 6), the majority of the current through the paracellular pathway is carried by Na^+ moving from the lumen to the interstitium. This paracellular absorption of Na^+ increases the efficiency of Na^+ transport by the TAL.[187] With reference to Figure 5.6, for each Na^+ transported through the cell and requiring the use of ATP, one Na^+ is transported through the paracellular pathway without any additional energy expenditure. Finally, the apical K^+ current satisfies the continuity requirement imposed by a high degree of conductive Cl^- efflux across basolateral membranes.[182]

A small component of Na^+ transport by the TAL is accounted for by $NaHCO_3$ absorption.[188] In the rat TAL, the rate of $NaHCO_3$ absorption is roughly 5% to 10% of that for NaCl absorption. $NaHCO_3$ absorption appears to be mediated by an apical membrane amiloride-sensitive Na^+/H^+ exchanger and a basolateral membrane electrogenic Na^+-$3(HCO_3^-)$ cotransporter.[188]

The following sections will describe the individual components of the mechanism for TAL salt transport (Fig. 5.6) in greater detail.

Apical Na^+-K^+-$2Cl^-$ Cotransport

Studies of Cl^- transport across apical membranes of intact TAL segments[189] and in isolated membrane vesicle preparations[190] established that the predominant mode for Cl^- entry into the TAL cell is via a Na^+-K^+-$2Cl^-$ cotransporter. A characteristic feature of this transporter is its sensitivity to inhibition by furosemide, bumetanide, and other 5-sulfamoylbenzoic acid derivatives.[191] The measurement of isotope flux into TAL cells or membrane vesicles prepared from the inner stripe of the outer medulla yielded a stoichiometry of 1 Na^+:1 K^+:2 Cl^- cotransport.[190] K^+-independent NaCl cotransport has also been described under certain conditions.[192]

The proteins that mediate the Na^+-K^+-$2Cl^-$ cotransport have been cloned. An absorptive form of the Na^+-K^+-$2Cl^-$ cotransporter, referred to as NKCC2 or BSC1, was initially cloned by Gamba et al.[193] based on sequence homology to the thiazide-sensitive Na^+-Cl^- cotransporter (see the following). A second Na^+-K^+-$2Cl^-$ cotransporter, NKCC1, was cloned by Payne et al.[194] NKCC2 (BSC1) is the primary mediator of apical salt entry in the thick ascending limb. In situ hybridization and single-nephron reverse transcriptase polymerase

chain reaction (RT-PCR) studies demonstrated the expression of NKCC2 in the MTAL and CTAL,[195] and immunohistochemical studies indicate that NKCC2 is localized to the apical membrane of these nephron segments.[196] The importance of NKCC2 in mediating salt reabsorption in the TAL is illustrated by the fact that loss-of-function mutations of NKCC2 cause Bartter syndrome (Table 5.1),[197] a Mendelian salt-wasting disorder characterized by hypokalemia, metabolic alkalosis, hyperaldosteronism, and normal-to-low blood pressure, results from a defect in salt absorption by the thick ascending limb.

The NKCC2 cDNA encodes a glycoprotein containing ~1100 amino acids and having a predicted molecular weight of 115 to 120 kDa.[193] The full-length protein contains 12 transmembrane domains containing a sizable extracellular loop with N-glycosylation sites positioned between transmembrane segments 7 and 8, and large intracellular amino and carboxy termini flank the transmembrane regions. NKCC2 belongs to the SLC12A family of cation chloride cotransporters, which is part of the amino acid polyamine organocation cotransporter (APC) superfamily.[198] Based on the homology to other crystallized APC family members, the cotransporter structure probably consists of two clustered groups of five transmembrane helices that are positioned in a symmetric, inverted orientation.[199] The details regarding how this fold facilitates the three-ion cotransport remain obscure but surely will provide an initial framework for more detailed structure-function studies in the coming years.

The two cytoplasmic domains of NKCC2 mediate specific regulatory functions. The amino terminus is believed to be unstructured and contains several cytosol-exposed serines and threonines, which are phosphoacceptor sites. These residues are phosphorylated by at least three protein kinases that stimulate NKCC2 activity and/or plasma membrane expression (discussed in detail below).[200] The carboxy terminus is large and comprises ~40% of the total NKCC2 sequence. It may also contain phosphorylation sites, although to date this has not been explored in detail. It is clear, however, that the NKCC2 C-terminus serves as a hub for interactions with proteins that regulate its trafficking, including the glycolytic enzyme aldolase[201] and secretory membrane carrier protein 2 (SCAMP2).[202] It also serves as the interface for the formation of NKCC2 homodimers,[203] which was confirmed recently when the crystal structure of the C-terminus of the related prokaryotic cation chloride cotransporter MaCCC was solved.[199]

At least six isoforms of NKCC2 have been identified.[200] These isoforms are the result of alternative splicing of two regions of the NKCC2 gene: the first region is a 96 base pair region that encodes part of the second transmembrane domain, whereas the second region encompasses the extreme C-terminus. Three variants of the 96 base pair region are encoded by different versions of exon 4 of the NKCC2 gene. These exons are differentially spliced into NKCC2 pre-mRNAs to generate three distinct isoforms (A, B, and F), which alter the amino acid composition of the second transmembrane domain. Each of the A, B, and F isoforms can have either a long C-terminus, or a truncated C-terminus; although to date, the short isoforms have only been described in the murine TAL.[204] In addition, several "tandem" transcripts have been described in the human kidney; these contain combinations of exons 4A, 4B, and 4F spliced alongside one another into the NKCC2 pre-mRNA.[205] Transcripts containing exons 4A/4F, 4B/4A, and 4B/4A/4F have been reported. Because these tandem transcripts contain redundant sequences encoding for the second transmembrane domain, they probably cause the misfolding of NKCC2, resulting in the formation of nonfunctional isoforms. Because these isoforms may still form oligomers with NKCC2, they likely exert a dominant-negative effect on NKCC2 function and inhibit its activity.[206]

The A, B, and F isoforms show differential expression within the thick ascending limb. In the rat nephron, the A isoform was found in both the cortical and medullary TAL, the B isoform is restricted to the cortical TAL, whereas the F isoform is present in the medullary, but not the cortical, the TAL, and to a lesser extent, in the outer medullary collecting duct. Although some interspecies discrepancies have been noted, similar findings have generally been observed in the embryonic mouse and human kidney.[205,207,208]

When the 4A, 4B, and 4F exons are spliced into transcripts containing a long C-terminus, all three products are capable of mediating Na^+-K^+-$2Cl^-$ cotransport. However, the A, B, and F isoforms have different transport properties that may have physiologic relevance. Isoforms A and B have higher affinities for Na^+, K^+, and Cl^- than the F isoform. The A isoform possesses the highest transport capacity of all three isoforms. Based on the known distribution of the A, B, and F isoforms in the TAL, it is currently thought that the A isoform accounts for the high transport capacity of the medullary TAL, whereas the presence of the more active A and B isoforms in the cortical TAL allows for the continued reabsorption of salt to take place, even though the tubular fluid in this segment is more dilute than plasma. Supporting this is experimental evidence demonstrating that the NKCC2 A and B isoforms can both be strongly activated by Na^+, K^+, and Cl^- at concentrations that are much more dilute than the composition of tubular fluid in the cortical TAL.[208]

Apical K^+ Conductance

An important feature of the luminal membrane of the TAL is a barium-inhibitable potassium conductance.[185] This apical membrane K^+ conductance allows K^+ to be recycled from the cell back into the luminal fluid to support further NaCl absorption via the NaCl cotransporter. Using measured values of intracellular K^+ activity (rabbit cTAL),[209] apical membrane conductance, and intracellular voltage, it can be shown that the measured apical membrane conductance is sufficient to provide for the recycling of all of the potassium uptake via the Na^+-K^+-$2Cl^-$ cotransporter.

Three types of K^+ conductances have been characterized in the apical membrane of the thick ascending limb: a high-conductance (150 pS) calcium-activated K^+ channel, which

does not contribute to net K^+ transport,[210] an intermediate-conductance (70 pS) K^+ channel,[211] and a low-conductance (30 to 35 pS) K^+ channel.[211,212] The latter two conductances account for the majority of the apical K^+ secretion in the TAL.[213] Both the intermediate- and the low-conductance channels are inhibited by intracellular ATP and are increased by high dietary potassium.[214]

A major breakthrough in elucidating the molecular mechanism of K^+ secretion in the TAL was made when Ho et al.[215] cloned the ATP-dependent K^+ channel ROMK from rat kidney. This channel is the prototype for a large family of inward-rectifying K channels (Kir channels), and hence, is also called Kir 1.1. Based on its biophysical properties and regulation, investigators had long suspected that ROMK was the sole mediator of the 30-pS K^+ conductance in the TAL. This hypothesis was confirmed when studies of the thick ascending limb in the ROMK knockout mouse revealed the absence of a 30-pS channel.[216] Subsequent studies of the ROMK knockout mouse demonstrated that these mice also lack a 70pS conductance.[214] Thus, it is likely that ROMK also comprises at least a portion of the intermediate K^+ secretory conductance in this nephron segment. It has been proposed that the intermediate-conductance channel may be a heteromeric protein containing ROMK and other, as yet, unidentified subunits.

The notion that ROMK is the predominant channel responsible for apical K^+ recycling in the thick ascending limb is also supported by the finding of mutations in the ROMK gene in families with type II Bartter syndrome.[217,218] These mutations have generally been confirmed to result in defective K^+-channel function.[219] As noted, Bartter syndrome results from a defect in thick ascending limb salt transport. Thus, the presence of ROMK mutations as a cause of Bartter syndrome indicates the important role of ROMK in net salt absorption by the thick ascending limb (Table 5.1).

Basolateral Membrane Cl^- Transport

Cl^- exit across the basolateral membrane of TAL cells is largely conductive, proceeding down its electrochemical gradient through Cl^--selective channels in the basolateral membrane.[220] The primary mediator of basolateral chloride transport in the TAL in humans is thought to be the chloride channel ClC-Kb, the sequence of which is closely related to the aforementioned human ClC-Ka channel expressed in the ATL (see previously). The name for the corresponding rodent ortholog of ClC-Kb is ClC-K2. In contrast to the relatively narrow expression of ClC-K1, ClC-K2 is expressed broadly throughout the basolateral membranes of multiple segments in the rodent nephron, including the TAL, the distal convoluted tubule, the connecting tubule, and the collecting duct.[171,221,222] Inherited mutations of the ClC-Kb cause type III Bartter syndrome, which can manifest as a mixed Bartter/Gitelman phenotype, possibly owing to the expression of ClC-K2/ClC-Kb in the distal convoluted tubule (DCT) and TAL.[223]

Similar to ClC-K1/ClC-Ka channels in the ATL, ClC-K2/ClC-Kb channels require barttin accessory subunits to be fully functional. Barttin was originally identified by positional cloning of the BSND gene, which is responsible for type IV Bartter syndrome (Table 5.1), a severe form of hereditary salt wasting that is accompanied by sensorineural deafness.[224] Barttin is located in the basolateral membranes of the thin and thick ascending limb, distal nephron, and also in the stria vascularis of the inner ear, where it is believed to play a role in K^+ secretion into the endolymph. The regulation of ClC-K channels by barttin appears to be multifaceted, because the accessory subunit influences channel protein stability, subcellular localization, and gating.[172,173,175] The mutations of barttin identified in Bartter syndrome patients generally impair the ability of barttin to produce a Cl^- conductance when expressed with ClC-Kb.[172,173]

Although less completely studied, there do appear to be additional transport pathways that mediate basolateral Cl^- flux in the TAL. For example, a barium-sensitive transcellular K^+-Cl^- cotransport mechanism has been proposed (Fig. 5.6).[225] The expression of two KCl cotransporters that belong to the same family of SLC12 electroneutral cotransporters as NKCC2, KCC1,[226] and KCC4[227] have been observed. Thus, both of these cotransporters may participate in the extrusion of K^+ and Cl^- from cells in the cortical and medullary TAL. Studies in knockout animals, however, indicate that KCC4 is not the primary mediator of basolateral Cl^- flux in the TAL, because these mice do not develop a salt-wasting phenotype. Rather, the KCC4 knockout mouse develops metabolic acidosis and sensorineural deafness, suggesting that KCC4 plays important physiologic functions in the acid-secreting intercalated cells of the collecting duct and in the cells of the inner ear.[228]

Synchronous Na^+/H^+:Cl^-/HCO_3^- Exchange

Friedman and Andreoli[229] found that net Cl^- absorption and the transepithelial voltage were doubled when CO_2 and HCO_3^- were added to the external solutions bathing cortical TAL segments. Because the (CO_2 + HCO_3^-)-stimulated rate of NaCl absorption did not result in net CO_2 transport and could be abolished by the lipophilic carbonic anhydrase inhibitor ethoxyzolamide or by the luminal addition of the anion-exchange inhibitor SITS or DIDS, it was proposed that the apical membrane of the mouse cortical TAL contains parallel, near synchronous Na^+/H^+:Cl^-/HCO_3^- exchangers in addition to a Na^+-K^+-$2Cl^-$ cotransporter. The addition of CO_2 and HCO_3^- to the bathing solutions had no effect on net NaCl transport in either the rabbit cTAL or the mouse mTAL. Both the rat and mouse medullary TAL do contain Na^+/H^+ exchangers in their apical membranes. However, in these segments, Na^+/H^+ exchange plays a role in net HCO_3^- transport and cell pH regulation rather than transcellular NaCl absorption.[230] The NHE3 isoform of the Na^+/H^+ exchanger is the major isoform expressed in the apical membrane of the thick ascending limb.[231,232]

REGULATION OF SALT ABSORPTION IN THE TAL

Vasopressin

The peptide hormone arginine vasopressin (AVP, also known as antidiuretic hormone, ADH) remains the most extensively characterized stimulatory hormone for NaCl reabsorption in the TAL. The reabsorption of NaCl in the TAL is crucial for efficient urinary concentration, because it is this process that plays a key role in maintaining a hypertonic medullary interstitial solute gradient for water reabsorption in more distal portions of the nephron.[233] Thus, from a teleologic perspective, vasopressin ought to be an important regulator of this process. The cognate receptor for vasopressin, the V2 receptor (V2R), is expressed in both the cortical and medullary TAL, where it participates in signaling cascades that stimulate NKCC2 activity.[234]

Binding of AVP to V2R results in increased intracellular levels of cAMP in the TAL. The increase in cAMP levels ultimately drives the translocation of NKCC2 from intracellular subapical vesicles to the luminal plasma membrane. In addition, cAMP serves as a signal that increases the phosphorylation of residues in the NKCC2 amino terminus that stimulate cotransporter activity in vitro.[235,236] Although this process may be mediated upstream by the cAMP-dependent protein kinase A (PKA), it is unclear whether PKA directly phosphorylates the N-terminal residues that stimulate its activity. Rather, it appears that two other kinases in particular are important downstream mediators of this process. These kinases, the Ste20 SPS1-related proline alanine-rich kinase (SPAK) and oxidative stress responsive kinase 1 (OSR1), are structurally homologous, activated by vasopressin, bind to a defined docking site harbored within the NKCC2 N-terminus, and directly phosphorylate these previously identified stimulatory residues (Fig. 5.7).[237–239]

The importance of SPAK and OSR1 in NKCC2 function has recently been established in transgenic and knockout models.[237,240,241] A complete knockout of SPAK mRNA and protein expression yields a mild salt-wasting phenotype that approaches Gitelman syndrome, likely owing to the elimination of its activity in the DCT (see the following). However, the absence of a Bartter-like phenotype in these animals does not refute the importance of SPAK and OSR1 in the TAL. Rather, the Gitelman-like salt-wasting phenotype in these animals appears to be due to two factors. First, knockout of the SPAK gene not only ablates full-length kinase-active SPAK, but also eliminates the expression of a truncated kidney-specific kinase-defective SPAK isoform (KS-SPAK) that suppresses baseline SPAK and OSR1 activity in the TAL.[237] Second, in the SPAK knockout mouse, TAL-expressed OSR1 appears to compensate for the absence of SPAK activity. Both of these effects ultimately result in increased rather than decreased NKCC2 abundance and phosphorylation, which probably compensates for the lack of DCT salt reabsorption and gives rise to a relatively mild salt-wasting phenotype. The dominance of OSR1 over SPAK in the TAL was recently verified in studies of the OSR1 knockout mouse, which, in contrast to the SPAK knockout animal, exhibits a Bartter-like phenotype.[241] On the other hand, knock-in mice bearing a mutation that ablates a key catalytic activation site in SPAK do exhibit decreased NKCC2 phosphorylation; presumably, this inactivating mutation exerts a dominant-negative effect on NKCC2 phosphorylation by preventing the binding of stimulatory kinases such as OSR1 to the NKCC2 N-terminal docking site.[242] Although it is clear that SPAK and OSR1 are important kinases that are linked to tubular salt reabsorption in the TAL, it is unclear how they directly connect to the well-established upstream cAMP-dependent signaling cascades, which are mediated by vasopressin. Nevertheless, given the fact that vasopressin activates SPAK and OSR1 and stimulates NKCC2 phosphorylation at key SPAK/OSR1 phosphorylation sites, it would appear that these kinases are important downstream intermediaries of the vasopressin signaling pathway.

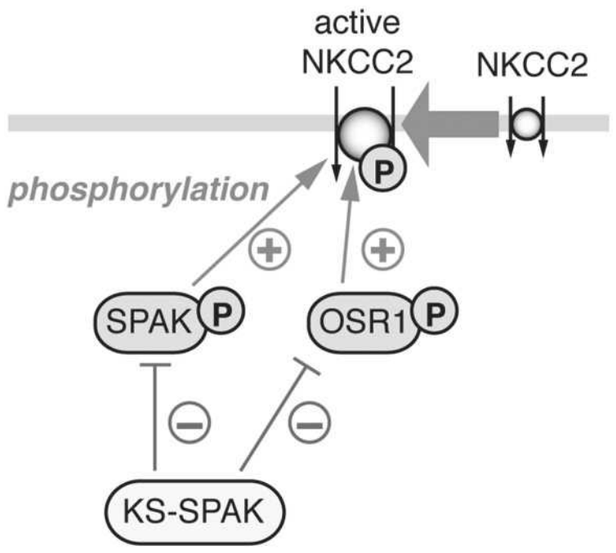

FIGURE 5.7 The current model for SPS1-related proline alanine-rich kinase /oxidative stress responsive kinase 1 (SPAK/OSR1) and kidney-specific (KS)-SPAK regulation of NKCC2 via phosphorylation in the thick ascending limb of the loop of Henle.

In addition to its effects on apical Na^+-K^+-$2Cl^-$ cotransport, vasopressin increases the transcellular electrical conductance of the mouse medullary TAL, and this conductance increase is a major element in the mechanism for the hormone-dependent increase in the rate of net salt absorption.[243,244] The available evidence suggests that both the apical and basolateral membrane conductances are increased by vasopressin. In apical membranes, AVP increases conductance by increasing the functional number of K^+ channels[182]; this increase occurs even when net salt absorption is abolished by furosemide. Ecelbarger at al.[245] showed that this increase in apical K^+ conductance was at least in part due to a dramatic upregulation in ROMK abundance and apical localization. Thus, the machinery for apical recycling of K^+ is increased in the TAL, which would aid in augmenting NKCC2-mediated NaCl reabsorption.

The predominant portion of the ADH-induced increase in cellular conductance is accounted for by an increase in the basolateral membrane Cl^- conductance.[182] Two mechanisms have been suggested for the hormone-

dependent increase in basolateral Cl^- conductance. Schlatter and Greger[183] have proposed that the ADH-induced increase in intracellular cAMP results in a direct increase in Cl^- channel activity. Such a mechanism has been amply demonstrated in Cl^--secreting epithelia, such as the trachea and intestine. Alternatively, ADH might enhance Cl^- conductance indirectly by increasing apical membrane Cl^- entry.[182] According to this proposal, an ADH-dependent activation of apical membrane NKCC2 and ROMK leads to an increase in intracellular Cl^- concentration. Because the activity of basolateral Cl^- channels is exquisitely sensitive to changes in intracellular Cl^- concentration,[246] this increase will translate into an increase in the basolateral membrane Cl^- conductance.

Prostaglandins

Prostaglandin 1 (PGE_2), the major product of prostaglandin synthesis in the renal medulla, participates in a local negative-feedback system that modulates the rate of NaCl absorption by the TAL. PGE_2 resulted in a 50% reduction in ADH-stimulated net Cl^- absorption in isolated perfused mammalian mTAL segments, but had no effect in the absence of ADH.[247] It is likely that PGE_2 inhibits ADH-stimulated generation of cAMP in the mTAL by activating an inhibitory G protein, G_i.[247] Although interstitial cells are a major source of PGE_2 production in the renal medulla, thick ascending limb cells can metabolize arachidonic acid through at least two pathways. Escalante et al.[248] demonstrated that purified medullary thick ascending limb cells produce 20-hydroxyeicosatetraenoic acid (20-HETE) via the cytochrome P450 enzyme, ω-hydroxylase. 20-HETE was subsequently shown to inhibit NaCl transport in the thick ascending limb at steps, which include the apical K^+ channel[249] and the Na^+-K^+-$2Cl^-$ cotransporter.[248] Thick ascending limb cells, particularly in the macula densa (MD), also express COX-2.[250] COX-2 expression in these cells may be coupled to renin secretion. Thus, COX-2 expression is increased by salt restriction, diuretics, and, in Bartter syndrome, all conditions characterized by hyperreninemia.[251] Moreover, COX-2 inhibitors reduce renin secretion in these settings.[252]

Osmolality

Peritubular osmolality is a third factor regulating mTAL salt absorption. In isolated mouse and rabbit TAL segments, increases in peritubular osmolality rapidly and reversibly inhibit the ADH-stimulated rate of net Cl^- absorption.[243] Molony and Andreoli[253] determined that hypertonicity inhibits the basolateral membrane Cl^- conductance. This inhibition of transcellular salt absorption occurs at a locus beyond the generation of cAMP, because supramaximal concentrations of either ADH or cAMP are unable to reverse the hypertonicity-mediated effect.[254] Thus, increasing the absolute magnitude of interstitial osmolality provides a negative feedback signal, which can reduce ADH-dependent salt absorption by the medullary TAL.

Hypercalcemia

Hypercalcemia often results in an ADH-resistant urinary concentrating defect, that is, nephrogenic diabetes insipidus.[255] At least part of this concentrating defect results from the inhibition of ADH-stimulated cAMP production in the TAL by calcium.[256] Preincubation of tubule segments with pertussis toxin abolishes the effect of hypercalcemia on cAMP generation, indicating that the inhibition of cAMP generation is mediated through the activation of G_i.[257] The effects of hypercalcemia are mediated by a G protein–coupled calcium-sensing receptor (CaSR) present on the basolateral membrane of TAL cells.[258] Activation of this receptor also inhibits the activity of the 70-pS apical K channel (ROMK, see previous) via the production of 20-HETE, a P450 metabolite of arachidonic acid.[259,260] Even changes in serum calcium within the physiologic range can alter NaCl absorption via the CaSR.[261] This may help to explain the hypotensive effect of high calcium intake in salt-sensitive hypertensive individuals.[262]

Modulation of NaCl Absorption by Other Peptide Hormones

In addition to ADH, a number of other peptide hormones stimulate adenylate cyclase activity in the TAL. In the mouse and rat, glucagon stimulates NaCl reabsorption and increases the transepithelial potential in isolated microperfused mTAL segments. Calcitonin and PTH stimulate sodium transport in the cortical, but not the medullary, portions of the TAL.[263]

Ang II receptors are present in the thick ascending limb.[264] Ang II has been reported to both stimulate and inhibit sodium transport in the thick ascending limb.[265,266] Chronic infusion of Ang II increased the abundance of NKCC2 in the rat outer medulla by 87%.[267] In a model of heart failure, in which Ang II levels are elevated, NKCC2 expression was also increased and this increase could be prevented by treatment with an angiotensin receptor antagonist.[268]

Adrenergic Agents

β-Agonist-sensitive adenylate cyclase activity is present in the rat, but not the rabbit TAL.[269] Likewise, β-adrenoceptors have been detected along the rat TAL by autoradiographic localization.[270] The physiologic effects of adrenergic agents have been tested in micropuncture and in in vitro microperfusion studies. DiBona and Sawin[271] demonstrated an enhancement of loop NaCl absorption during low-frequency renal nerve stimulation. Acute renal denervation, on the other hand, depressed NaCl absorption by the loop of Henle.[272]

Micromolar concentrations of isoproterenol stimulate net Cl^- absorption by in vitro perfused mouse medullary and cortical TAL.[273] The effects of isoproterenol on NaCl absorption in these segments can be blocked by propranolol.

Nitric Oxide

Acute administration of nitric oxide donor or L-arginine, the substrate for NOS, decreases NaCl absorption in isolated perfused thick ascending limb segments.[274] The effect of

L-arginine on NaCl transport can be blocked by L-NAME, an inhibitor of NOS, indicating that endogenous production of NO mediates the effect of L-arginine. The inhibitory effect of NO on net NaCl absorption appears to involve, at least in part, the inhibition of NKCC2 activity.[275] The thick ascending limb expresses all three isoforms of NOS.[276] Plato et al.[277] used mice deficient in the various NOS isoforms to determine that the effect of L-arginine is mediated by eNOS rather than iNOS or nNOS. In contrast to its effect on NaCl absorption, NO stimulates $NaHCO_3^-$ absorption in the thick ascending limb.[266] Finally, although short-term exposure to NO inhibits NaCl absorption, chronic exposure increases NKCC2 expression,[278] which could translate into increased NaCl absorption.

Sodium Balance

Dietary Na^+ restriction in rats results in a transient decrease in NKCC2 expression,[279] whereas high Na^+ intake has no major effect on NKCC2 expression.[280] Chronic treatment with furosemide in conjunction with a high sodium diet increases NKCC2 expression.[281] The latter phenomenon may account for the development of diuretic resistance and the interdose rebound in sodium absorption in patients chronically treated with loop diuretics.

THE DISTAL NEPHRON

Anatomic Considerations

The distal nephron may be divided into three segments: the DCT, the connecting tubule (CNT), and the collecting duct. Perhaps owing to the nature of the original micropuncture studies characterizing the distal nephron, the DCT was initially thought to be a segment consisting of a homogeneous population of epithelial cells. However, more recent work clearly indicates that the DCT can be further divided into two functionally distinct subsegments, referred to as the "early" and "late" DCT (DCT1 and DCT2, respectively).[282] One of the primary features that distinguishes between the early and late portions of the DCT is the differential sensitivity of these segments to the mineralocorticoid hormone aldosterone. More specifically, the late DCT expresses the enzyme 11beta-hydroxysteroid dehydrogenase 2 (11β-HSD2), which metabolizes cortisol, thereby rendering mineralocorticoid receptors sensitive to aldosterone.[283] For this reason, the late DCT, CNT, and the cortical collecting duct (CCD) are collectively termed the aldosterone-sensitive distal nephron (ASDN).

Na^+ Transport in the Distal Convoluted Tubule and the Connecting Segment

General Characteristics

The DCT absorbs roughly 5% to 10% of the filtered Na^+ load.[284] Fluid enters the DCT with a Na^+ concentration of 25 to 30 mM, but salt is added along the initial 20% of the DCT, so that the Na^+ concentration averages 50 mM at a point 200 to 300 μm from the macula densa.[285] From there, tubular Na^+ concentration decreases along the DCT to a value of approximately 30 mM at the end.[286] Tubular fluid to plasma Na^+ ratios as low as 0.10 have been observed during stationary microperfusion.[287] This finding, together with the presence of the lumen-negative potential difference (see the following), clearly establishes the active nature of Na^+ absorption in this segment.

Na^+ absorption by the DCT is load dependent. That is, over a wide range of delivery rates, the proportion of Na^+ absorbed by the DCT remains constant at 80%.[286] At high tubular fluid flow rates, the fall in luminal Na^+ concentration along the tubule is attenuated; thus, more Na^+ is available to distal Na^+ absorptive sites at high rather than at low flow rates.

Electrophysiologic Considerations

Depending on the type of electrodes that were used, measurements of the transepithelial voltage in the earliest loops of the DCT vary from slightly lumen negative to slightly lumen positive.[288–291] Consistent among all measurements, however, is the observation that the transepithelial voltage becomes progressively more lumen negative as tubular fluid passes to the end of the DCT and into the CNT and CCD.

The progressively lumen-negative transepithelial electrical potential is primarily due to a change in Na^+ transport pathways from the early DCT to more downstream nephron segments. As shown previously by Ellison et al.,[292] Na^+ reabsorption in the early DCT is largely mediated by an electroneutral, thiazide-sensitive NaCl cotransporter, whereas Na^+ absorption in the late DCT also involves an amiloride-sensitive electrogenic pathway.[282] These and other mechanisms of Na^+ absorption are discussed in detail in the following sections.

The Mechanism of Na^+ Absorption

A general model for these mechanism by which Na^+ is reabsorbed in the early and late DCT is presented in Figure 5.8.

The Apical NaCl Cotransport. The absorption of Na^+ and Cl^- in the early DCT are coupled.[293] The coupling of Cl^- to Na^+ entry provides a mechanism to maintain the intracellular Cl^- activity above its electrochemical equilibrium.[294] The early distal tubule is the site of action of thiazide diuretics.[295] Autoradiographic studies[296] and immunocytochemical studies[297] have demonstrated thiazide-binding sites in the apical membranes of DCT and connecting tubule cells.

The thiazide-sensitive NaCl cotransporter (NCC, TSC, SLC12A3) mediates electroneutral NaCl reabsorption in the early and late DCT (Fig. 5.8).[298] The cotransporter shares considerable sequence homology to the bumetanide-sensitive Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) present in the TAL,[193] yet exhibits markedly different inhibitor sensitivity and ionic requirements. NCC transports NaCl with a

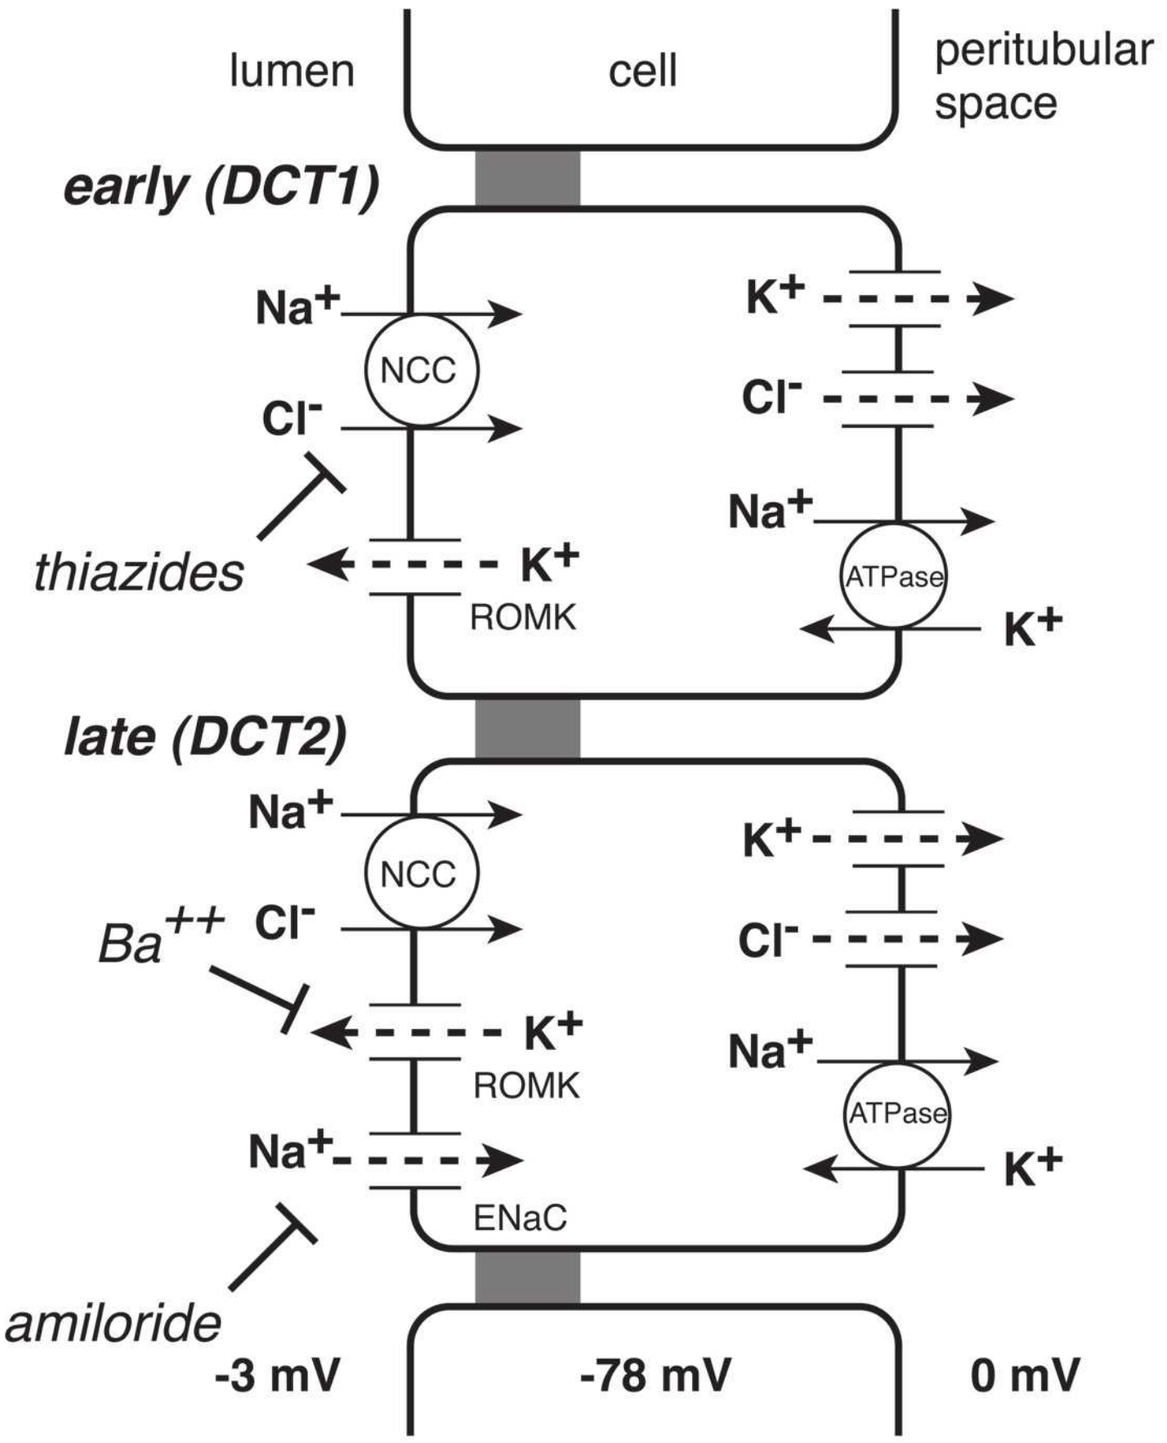

FIGURE 5.8 A model of NaCl absorption by cells of the early and late distal convoluted tubule (DCT). The early and late DCT express NCC, a thiazide-sensitive, electroneutral NaCl cotransporter. The late DCT also expresses the amiloride-sensitive Na^+ channel ENaC. Basolateral K^+ channels include Kir4.1, mutated in EAST/SeSAME (epilepsy, ataxia, sensorineural deafness, and tubulopathy/seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance) syndrome, a hereditary salt-wasting disorder. *ROMK*, renal outer medullary K channel; *NCC*, thiazide-sensitive NaCl cotransporter.

1:1 stoichiometry, is K^+-independent, and is inhibited by thiazide diuretics.[299] NCC is expressed in the apical membrane of DCT cells and extends, in most species, into the connecting segment.[300]

Gitelman Syndrome. Loss-of-function mutations in the NCC gene have been linked to the pathogenesis of Gitelman syndrome.[218] This syndrome resembles Bartter syndrome (hypokalemia, alkalosis, sodium wasting), except that urinary calcium excretion is reduced in Gitelman syndrome and is elevated in most cases of Bartter syndrome. Thus, physiologically, Gitelman syndrome mimics the effects of thiazide diuretics. Several studies have evaluated the consequences of mutations causing Gitelman syndrome on NCC function, and in most cases, these mutations alter the NCC coding sequence in such a way that they reduce NCC expression and trafficking to the apical plasma membrane of the DCT.[301,302] In this regard, most of these disease-causing mutations result in the conformational misfolding of NCC, resulting in the recognition of mutant NCC by chaperone-dependent endoplasmic reticulum (ER) quality control machinery that targets the cotransporter for proteasomal degradation.[301,303]

Familial Hyperkalemic Hypertension. Studies of another inherited disorder of distal Na^+ transport, familial hyperkalemic hypertension ([FHHt] type 2 pseudohypoaldosteronism, Gordon syndrome), have yielded additional insights into the regulation of NCC function. FHHt is the phenotypic opposite of Gitelman syndrome and is characterized by hypertension, hyperkalemia, and metabolic acidosis (Table 5.1). The disorder is largely corrected by the infusion of sodium with poorly reabsorbable anions, or by treatment with thiazide diuretics.[304] These features suggested that the hypertension in FHHt is chloride dependent, and that an increase in NCC activity may be involved in the pathogenesis of PHA II. Positional cloning demonstrated that FHHt is caused by mutations in either of two with-no-lysine (WNK) serine-threonine kinases, WNK1 or WNK4.[305] These kinases have been intensely studied since their linkage to FHHt in 2001, and are well-established regulators of NCC, but the mechanisms by which they affect NCC function are complex. Both WNK1 and WNK4 have been shown to regulate NCC plasma membrane trafficking and activity (Fig. 5.9). In the current model it is believed that WNK4 acts as an inhibitor of NCC trafficking at the baseline state because it prevents the cotransporter from trafficking from the biosynthetic pathway to the cell surface.[306–308] In contrast to this inhibitory effect on NCC traffic, it has been hypothesized that under certain physiologic states that favor NaCl reabsorption, WNK4 stimulates NCC phosphorylation. Because NCC is structurally similar to NKCC2, it is activated by the serine–threonine kinases SPAK and OSR1 (see previous section). WNK4 and WNK1 activate SPAK and OSR1, which then can

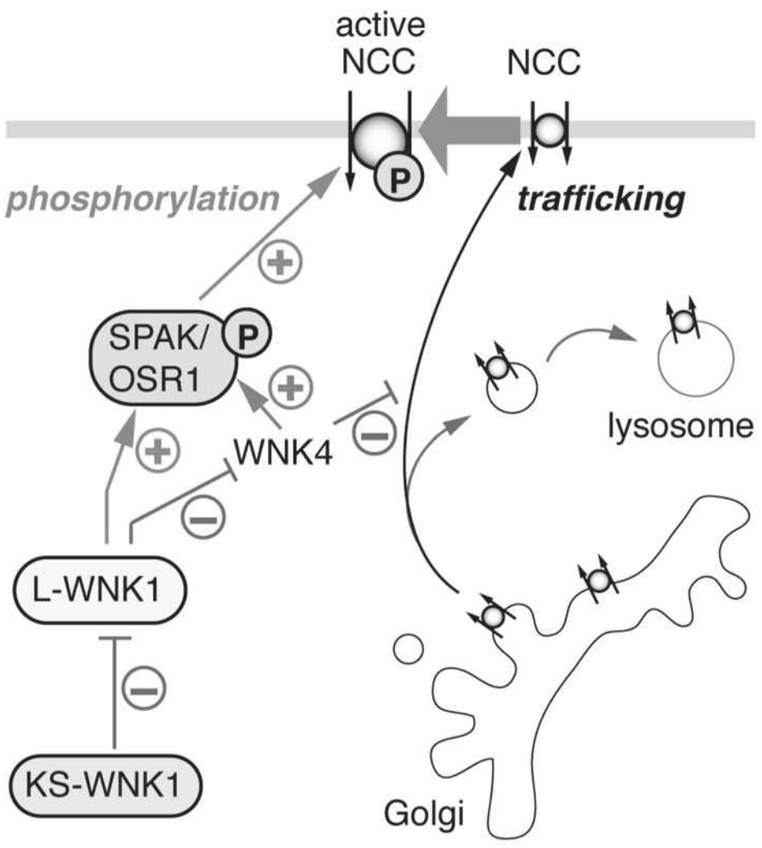

FIGURE 5.9 A model of thiazide-sensitive cotransporter (NCC) regulation by the with-no-lysine SPS1-related proline alanine-rich kinase/oxidative stress responsive kinase 1 (WNK-SPAK/OSR1) signaling pathway. With-No-Lysine (WNK) kinases regulate NCC trafficking and phosphorylation. *L-WNK1*, full-length kinase-active ("long") WNK1; *KS-WNK1*, short kinase-defective "kidney-specific" WNK1.

bind to NCC and stimulate its activity by phosphorylating a cluster of serines and threonines in its NH_2-terminus.[307] In contrast to the TAL, only the full-length kinase active SPAK is expressed in the DCT (i.e., no inhibitory KS-SPAK isoforms are expressed).[237] Due to the observations that WNK4 inhibits NCC under some experimental conditions and stimulates it under others, several have proposed that the WNK signaling pathway acts as a "switch" that converts the DCT from a salt-wasting to a salt-reabsorptive segment, although more work is needed to confirm this hypothesis.[309–311] In FHHt, missense mutations of WNK4 stimulate NCC activity through two mechanisms. First, mutant WNK4 is incapable of reversing the inhibitory effect on NCC at the baseline; this results in increased NCC surface expression.[308,312] Second, the FHHt-associated mutant increases NCC phosphorylation, presumably through enhanced SPAK/OSR1 activity. Thus, through incompletely defined mechanisms, mutant WNK4 appears to "lock" the DCT into a high Na^+ reabsorptive state by increasing the total number of active NCC molecules at the cell surface, resulting in thiazide-sensitive hypertension.[313]

In contrast, WNK1 appears to influence NCC traffic indirectly by suppressing the inhibitory effect of WNK4 (Fig. 5.9). This effect requires intact WNK1 kinase activity and releases NCC from intracellular retention, thereby facilitating NCC delivery to the cell surface.[307,308] Unlike WNK4, WNK1 mutations that cause FHHt do not alter the kinase's coding sequence. Rather, WNK1 mutations are large intronic deletions that increase the mRNA abundance of WNK1 isoforms.[305] Kinase-active WNK1 is capable of phosphorylating and activating SPAK and OSR1.[314] Thus, the WNK1 gene mutations that cause FHHt presumably do so by reversing the inhibitory effect of WNK4 on NCC traffic and by stimulating NCC phosphorylation.[315] As with SPAK gene expression in the TAL (see previous), long and short WNK1 isoforms are expressed in the DCT. The long form of WNK1 (L-WNK1) is kinase active and stimulates NCC activity and trafficking through the mechanisms described previously. A short kidney-specific kinase-defective product (KS-WNK1), in contrast, suppresses L-WNK1 activity (Fig. 5.9).[316] The balance of these two isoforms has been postulated to act as a "switch" that controls overall L-WNK1 kinase activity in the DCT, which should in turn regulate NCC activity.[310] Consistent with this idea, selective knockout of KS-WNK1 expression increases NCC activity, whereas overexpression of the kidney-specific isoform in KS-WNK1 transgenic mice causes salt-wasting through NCC inhibition.[317]

The Basolateral Electrogenic Na^+ Pump. In both subsegments, the basolateral extrusion of Na^+ from the cytosol into the peritubular space (and eventually, the plasma) occurs via the electrogenic Na^+,K^+–ATPase. The activity of this pump results in the generation of a constant transepithelial voltage across the basolateral membrane of −60 to −90 mV.[318,319] A reduction in the luminal sodium concentration causes V_{bl} to depolarize, whereas increases in the sodium concentration hyperpolarizes V_{bl}. In addition, V_{bl} depolarizes after ouabain treatment.[320] These observations are consistent with the notion that apical Na^+ entry stimulates the electrogenic Na^+,K^+–ATPase system in the basolateral membrane.

Basolateral K^+ Efflux. Recent insights from rare Mendelian diseases highlight the importance of basolateral K^+ transport in tubular sodium transport in the distal nephron. In 2008, two groups identified that patients with mutations in the K^+ channel gene KCNJ10 (Kir4.1) develop hereditary salt wasting.[321,322] Patients with these mutations develop a complex constellation of neurologic defects in addition to the renal salt wasting. The disease has been named EAST syndrome (epilepsy, ataxia, sensorineural deafness, and tubulopathy) by some investigators and SeSAME syndrome (seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance) by others (Table 5.1). The salt-wasting phenotype in these patients is reminiscent of Gitelman syndrome, suggesting that the disorder results in an impairment of salt transport in the DCT. Indeed, Kir4.1 is expressed on the basolateral membrane of DCT cells, and patients with EAST/SeSAME syndrome mutations develop markedly reduced infoldings of the DCT basolateral membrane. This deficiency in total basolateral membrane content results in a decrease in the number of surface Na^+,K^+–ATPase molecules, resulting in decreased sodium pump activity and impaired salt reabsorptive capacity.[323] Additionally, it is thought that loss-of-function mutations of Kir4.1 impair K^+ recycling across the basolateral membrane, which reduces the efficacy of Na^+,K^+–ATPase (Fig. 5.8).[321]

Basolateral Cl^- Transport. As mentioned previously, ClC-Kb channels and barttin are both expressed in the DCT, where they mediate basolateral Cl^- reabsorption.[172] Because the apical transport mechanism in the DCT via NCC occurs through the coupled reabsorption of Na^+ and Cl^-, basolateral Cl^- transport is essential to the development of a gradient for Na^+ entry and to reduce the intracellular Cl^- concentration, which stimulates SPAK/OSR1–mediated NCC phosphorylation.[324] Mutations in either ClC-Kb or the accessory subunit result in impaired distal salt reabsorption. Because barttin is required for adequate basolateral Cl^- reabsorption in the loop of Henle and DCT (see previous), patients with barttin mutations develop a more severe form of Bartter syndrome.[172]

Apical Conductive Na^+ Channels. The entry of sodium into the Amphiuma distal tubular cell[325] and late rat DCT cell[326] is inhibited by amiloride, a Na^+ channel blocker. A Na^+ channel in the apical membrane would serve to depolarize the membrane and create the observed lumen-negative transepithelial potential. This transepithelial voltage, in turn, is a driving force for passive Cl^- reabsorption. Na^+ channel subunits have been found by immunolocalization in the late DCT in mouse and rat kidney,[327,328] but not the human kidney.[329]

The Regulation of NaCl transport in the Distal Convoluted Tubule

Na^+ Delivery. NaCl reabsorption in the DCT is dependent on the delivered load of NaCl.[286] The DCT responds to chronic increases in the delivery of NaCl with an increase in the capacity for NaCl transport,[330] as well as marked ultrastructural changes in the DCT cell. These morphologic changes include an increase in the size of the DCT cell, an increase in the basolateral membrane surface area, and an increase in the size of mitochondria.[330] Accompanying the functional and morphologic changes are an increase in Na^+,K^+–ATPase activity and an increase in thiazide-binding sites.[331] These effects appear to result from an increase in Na^+ entry into the DCT cell rather than the increase in distal NaCl delivery or changes in plasma aldosterone or ADH levels that occur with chronic furosemide treatment. Inhibition of NaCl entry into DCT cells with chronic thiazide treatment resulted in a loss of cell height, loss of normal polarity, and apoptosis of the DCT cells.[332] The cellular mechanisms whereby NaCl entry affects transport function and morphology are not known.

Dietary Na^+. Studies in rats and rabbits have yielded conflicting results regarding the effects of increased dietary Na^+ on DCT morphology and Na^+ transport. In rats, no consistent effect of a high Na^+ diet on either cell morphology, transport rates, or thiazide-receptor density could be demonstrated.[330,331,333] Rats fed a low Na^+ diet[279] or treated with thiazide diuretics,[281] however, demonstrated a significant increase in NCC expression, which may have been because of the stimulation of mineralocorticoid secretion.[334] In contrast, rabbits fed a high Na^+ diet developed an increased rate of DCT Na^+ reabsorption and an increase in Na^+,K^+–ATPase activity.[335]

Steroid Hormones. Currently available evidence suggests that adrenal steroid hormones regulate Na^+ transport in the DCT. The presence of both mineralocorticoid and glucocorticoid receptors in the DCT has been demonstrated by immunohistochemistry and by hormone binding.[283,336,337] In addition, an adrenalectomy resulted in a decrease in Na^+,K^+–ATPase activity in the DCT.[338] The Na^+,K^+–ATPase activity could be restored by replacement doses of glucocorticoids, but not by mineralocorticoids.[338,339] Microperfusion studies of superficial distal tubules (containing both DCT and CNT), however, demonstrated an increase in Na^+ transport in animals receiving aldosterone infusions.[340,341] Both the thiazide-sensitive and the thiazide-insensitive components of Na^+ transport were increased by aldosterone.[341] The former may reflect neutral NaCl cotransport in the DCT, whereas the latter reflects electrogenic Na^+ absorption in the late DCT or CNT. Aldosterone infusion also resulted in an increase in thiazide-binding sites in the renal cortex, as determined by [^{3}H]metolazone binding, an increase in the natriuretic response to thiazide diuretics, and a large increase in NCC protein.[341–343] These findings establish NCC as an aldosterone-regulated transporter. By combining immunohistochemical and in situ hybridization techniques, Bostanjoglo et al.[283] determined that DCT cells coexpress NCC, mineralocorticoid receptors, and 11beta-hydroxysteroid dehydrogenase type 2, an enzyme typically found in mineralocorticoid target sites. Thus, DCT cells, particularly those in the late portions of the DCT, express the key elements required for selective mineralocorticoid actions.

In 1998, Kim et al.[343] showed that aldosterone increases the total protein abundance of NCC. This effect did not correlate with changes in NCC mRNA abundance, suggesting that aldosterone regulates NCC abundance by posttranslational mechanisms. Recent work indicates that at least two molecular mechanisms account for this effect. Aldosterone rapidly induces and activates the serine–threonine kinase serum and glucocorticoid-regulated kinase 1 (SGK1), which directly phosphorylates and inactivates two inhibitors of NCC trafficking, WNK4 (described previously), and neural precursor cell-derived, developmentally downregulated 4-2 (Nedd4-2), an E3 ubiquitin ligase.[344,345] SGK1-mediated phosphorylation of two residues located at the C-terminus of WNK4 releases NCC from inhibition. This results in WNK4 inactivation and diverts the cotransporter away from intracellular degradation pathways, allowing NCC to traffic directly to the plasma membrane from the biosynthetic pathway.[344] By phosphorylating Nedd4-2, SGK1 suppresses the ability of the E3 ligase to attach ubiquitin molecules to NCC; this

reduces NCC degradation and increases its plasma membrane expression.[345] Both of these effects provide an explanation for the aldosterone-induced increase in NCC total protein abundance that was initially seen by Kim et al[343] Aldosterone also appears to stimulate NCC transport activity by promoting NCC phosphorylation, an effect that occurs independently of the effects of mineralocorticoids on NCC traffic.[346,347] The mechanism by which this effect occurs remains unclear but appears to correlate directly with increased SPAK/OSR1 activity, suggesting that additional connections between aldosterone and the WNK/SPAK/OSR1 signaling pathway may exist.

As mentioned previously, glucocorticoids increase Na^+,K^+–ATPase activity following an adrenalectomy in the DCT.[338,339] This effect was not blocked by spironolactone, a mineralocorticoid receptor antagonist, suggesting that glucocorticoids were acting via glucocorticoid receptors rather than mineralocorticoid receptors.[339] In addition, dexamethasone infusions increased thiazide-sensitive NaCl transport and [^{3}H]metolazone binding sites in adrenalectomized rats.[341,342] Nevertheless, the role of glucocorticoids in the physiologic regulation of Na^+ transport in the DCT remains unclear.

Gonadal steroid hormones may also influence NaCl transport in the DCT. Chen et al.[348] reported gender differences in the density of thiazide receptors and in the natriuretic response to thiazides in rats. Female rats had higher levels of thiazide-binding sites in the renal cortex than males. The levels in females fell following ovariectomy, whereas levels rose in males following orchiectomy. Moreover, the increase in urinary Na^+ excretion caused by thiazides was greater in females than in males, suggesting that the differences in thiazide-binding sites were reflective of differences in thiazide-sensitive salt transport in vivo. Likewise, using antibodies against NCC, Verlander et al.[349] found that estrogen treatment increased NCC expression in the DCT. These results are consistent with the view that male sex hormones (e.g., testosterone) may downregulate NCC expression and salt transport, whereas estrogens increase NCC expression and salt transport in the DCT. The authors are not aware of gender differences in the response of humans to thiazide diuretics.

Vasopressin. Recent work indicates that vasopressin is a potent activator of the thiazide-sensitive cotransporter.[350,351] Two groups have shown that the vasopressin analog deamino-Cys-1, d-Arg-8 vasopressin (dDAVP) stimulates increases in NCC abundance, trafficking to the plasma membrane, and activation through SPAK/OSR1-mediated phosphorylation of its amino terminus. This effect is probably dependent on cyclic AMP and protein kinase A (PKA), well-established intermediaries of vasopressin-dependent signaling.[352] The effect on NCC abundance may be a Nedd4-2-dependent process, because PKA can phosphorylate and inactivate Nedd4-2 through mechanisms similar to SGK1[353]; however, this hypothesis is yet to be tested.

Na^+ TRANSPORT IN THE CORTICAL COLLECTING DUCT

General Considerations

The transport processes in the collecting duct mediate final adjustments in urinary composition. The collecting duct is a major locus of action of mineralocorticoid hormones and plays a major role in K^+ homeostasis and acid–base balance. Quantitatively, it is a minor site of Na^+ absorption, reclaiming only about 2% to 4% of the filtered Na^+ load.[354]

Electrophysiologic Aspects

The transepithelial voltage in the CCD varies widely from +10 to −100 mV,[295,355,356] which largely results from differences in mineralocorticoid levels at the time of measurement in the animals. The reported values for transepithelial resistance also vary widely depending on apical Na^+ and K^+ channel activities, as shown by the effects of luminal amiloride and barium, respectively, on transepithelial resistance.[356,357] The basolateral membrane is conductive to K^+ and, at least in rabbits, Cl^-.[357]

Mechanisms of Salt Absorption in Collecting Ducts

A proposed model for Na^+ absorption and K^+ secretion in the CCD is presented in Figure 5.10. As indicated previously, apical membranes of CCD principal cells possess conductive pathways for Na^+ and K^+.[358,359] Na^+ enters principal cells through Na^+ channels in the apical membrane down its electrochemical gradient. Na^+ is then pumped across the basolateral membrane by the Na^+,K^+–ATPase in exchange for K^+. The Na^+ current across the apical membrane depolarizes

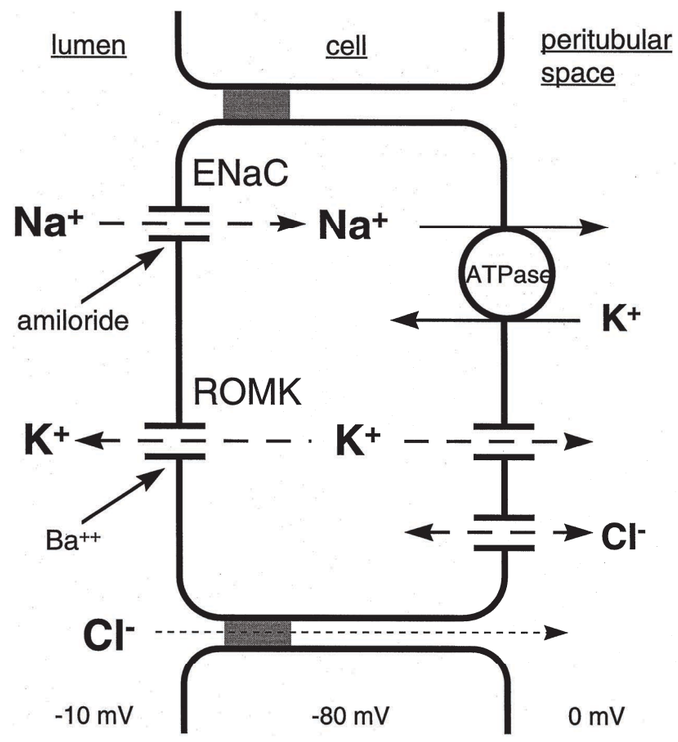

FIGURE 5.10 A model of salt transport by the principal cell of the cortical collecting duct. Apical Na^+ entry proceeds via amiloride-sensitive Na^+ channels (ENaC). Apical K^+ channels (ROMK) mediate K^+ secretion by this segment. Cl^- absorption is driven by the lumen-negative voltage through the paracellular pathway.

the cell, so that the cellular K^+ is above its equilibrium concentration, and thus leaves the cell through conductive pathways in the apical or basolateral membrane.[360]

Apical Na^+ Channels

Apical Na^+ entry depolarizes the apical membrane relative to the basolateral membrane, causing a lumen-negative transepithelial voltage, which in turn provides the driving force for Cl^- reabsorption through the paracellular pathway. Patch-clamp studies of collecting duct cells and urinary bladder cells provided some details regarding the electrophysiologic properties and regulation of apical membrane Na^+ channels.[361] The amiloride-sensitive epithelial Na^+ channel (ENaC) has been cloned,[362,363] has a single-channel conductance to Na^+ of 4 to 5 pS, and is highly selective for Na^+ over K^+ ($P_{Na}/P_K > 20$). ENaC exhibits slow gating, with openings and closings lasting several seconds. Amiloride blocks ENaC at submicromolar concentrations.[364]

ENaC consists of three homologous subunits (α, β, and γ).[363] The subunits share a common structure consisting of two transmembrane domains, intracellular N- and C-termini, and a large extracellular loop.[365,366] Although the α subunit of ENaC can form Na^+ channels on its own,[362] coexpression of all three subunits dramatically increases the membrane Na^+ conductance.[363] Based on homology to the related acid-sensing ion channel (ASIC1), the crystal structure of which was recently solved,[367] native ENaC likely exists as an α, β, and γ heterotrimer. The single channel properties of the expressed channel closely resemble those of the 4 to 5 pS highly selective channel studied in native tissues.[363] The large extracellular domains of the α and γ subunits can get proteolytically cleaved by furin in the biosynthetic pathway.[368,369] Other proteases like prostasin and plasmin may cleave the γ subunit.[370] These cleavage events release small inhibitory fragments of the α and γ subunits, causing an increase in the open probability of ENaC.[370] ENaC activity is also enhanced by increasing luminal flow rates, as the extracellular domain of ENaC subunits respond to laminar shear stress.[371,372] Thus, collecting duct Na^+ absorption is enhanced with increased distal fluid delivery via ENaC, a mechanosensitive channel.[373]

The key importance of ENaC for Na^+ reabsorption in the collecting duct is highlighted by naturally occurring mutations in ENaC that are responsible for Liddle syndrome, an autosomal dominant form of hypertension, and pseudohypoaldosteronism type 1, an autosomal recessive form of salt wasting (see Table 5.1).[374] In Liddle syndrome, mutations in the ENaC subunits result in an increase in amiloride-sensitive Na^+ channel activity with a consequent increase in sodium reabsorption and volume-mediated hypertension.[375–377] Most Liddle mutations occur in the cytoplasmic C-termini of the γ (SCNN1G) and β (SCNN1B) subunits.[375] These mutations affect a conserved PY motif in the C-terminus, which is necessary for interaction with the ubiquitin ligase Nedd4-2 and subsequent internalization and degradation of ENaC.[378] Liddle syndrome mutations cause excessive ENaC accumulation at the apical plasma membrane, increasing Na^+ absorption. Pseudohypoaldosteronism type 1 (PHA-1), the clinical opposite of Liddle syndrome, is caused by homozygous inactivating mutations in the ENaC channel, resulting in a syndrome of Na^+-wasting, hypotension, and hyperkalemia.[379] The majority of mutations causing PHA-1 are frameshift or nonsense mutations that result in truncated, nonfunctional ENaC proteins.[374]

Apical Electroneutral Na^+ Transport

It was first observed in rats that a portion of Na^+ entry across the apical membrane in perfused CCD segments was sensitive to luminal hydrochlorothiazide, which inhibited Na^+ and Cl^- absorption without changing the transepithelial voltage.[380] In addition, amiloride inhibited Na^+ transport in this segment by only 50%, and the effects of amiloride and hydrochlorothiazide were additive. It was thus concluded that the CCD may possess two parallel transport pathways for Na^+: an electrogenic pathway involving amiloride-sensitive Na^+ channels and a thiazide-sensitive neutral NaCl cotransport pathway.[380] More recently, a Na^+-dependent Cl^-/HCO_3^- exchanger (NDCBE/SLC4A8) was identified in intercalated cells and found to mediate the amiloride-resistant, thiazide-sensitive electroneutral Na^+ reabsorption in the CCDs of mice.[381] That NCC knockout mice also exhibited significant natriuresis following treatment with thiazide diuretics suggests the importance of this pathway. The mechanism for net NaCl reabsorption in this setting involves the parallel activity of the NDCBE and Na^+-independent Cl^-/HCO_3^- exchange via pendrin/SLC26A4 at the apical membrane of type B intercalated cells. The basolateral reabsorption pathways for the Na^+ and Cl^- that enter at the apical membrane in this model are the Na^+,K^+–ATPase and ClC-K Cl^- channels. Thus, a novel target of thiazide diuretics distinct from NCC has been identified in the collecting duct with the implication that Cl^- transport by intercalated cells plays an important role in blood pressure regulation.[382] Because pendrin is a key mediator of bicarbonate secretion, and thus acid–base regulation, these findings also suggest a strong link between acid–base and volume/blood pressure regulation.

Control of Na^+ Absorption in the Cortical Collecting Duct

Aldosterone

Aldosterone is one of the key regulators of Na^+ transport in the collecting duct, where it increases the rates of Na^+ absorption and K^+ secretion.[383,384] The major target site for mineralocorticoid effects is the principal cell of the CCD, although actions in the DCT have also been documented (see previous). Mineralocorticoid effects are produced by the binding of either mineralocorticoids or glucocorticoids[385] to mineralocorticoid receptors found predominantly in the CCD.[336,337] In addition, the binding of glucocorticoids to glucocorticoid receptors can also produce mineralocorticoid responses.[385] This lack of specificity results from two

factors: first, mineralocorticoid receptors do not discriminate between aldosterone and glucocorticoids,[386] so that either class of steroids can bind to and activate the receptor. Second, the DNA binding domains of mineralocorticoid and glucocorticoid receptors are highly conserved such that both receptors can activate many of the same genes.[387] The specificity for mineralocorticoids in vivo is provided by the selective degradation of glucocorticoids, but not mineralocorticoids, by the enzyme 11 β-hydroxysteroid dehydrogenase.[386] 11β-Hydroxysteroid dehydrogenase activity is high in CCD segments.[388,389] Illustrating the important role of this enzyme in regulating access of hormones to the mineralocorticoid receptor, genetic deficiency of this enzyme produces a syndrome, apparent mineralocorticoid excess, resembling hyperaldosteronism (hypertension, hypokalemia, metabolic alkalosis), except that aldosterone levels are low.[390] The clinical manifestations result from the stimulation of mineralocorticoid receptors by circulating glucocorticoids.

In isolated perfused CCDs from mineralocorticoid-treated rabbits, there is an increase in both the Na^+ and K^+ conductance of the apical membrane and an increase in basolateral Na^+,K^+–ATPase activity.[356] The functional changes after aldosterone treatment are accompanied by morphologic changes in principal cells. The basolateral membrane length of principal cells falls by 35% after an adrenalectomy, and the administration of aldosterone, but not dexamethasone, restores the membrane length to control levels.[391]

An early effect of aldosterone, occurring within a few hours of exposure, is an increase in the sodium permeability of the apical membrane of the CCD principal cell. Results from electrophysiologic and immunologic studies support the view that the early aldosterone-induced increase in apical sodium permeability is because of the activation of quiescent Na^+ channels rather than the synthesis and/or the insertion of new Na^+ channels into the membrane.[392–394] Several pathways have been implicated in the aldosterone-mediated increase in Na^+ channel activity. An important downstream mediator of aldosterone is the serum and glucocorticoid-regulated kinase SGK1.[395] SGK1 is expressed in the thick ascending limb, DCT, connecting segment, and cortical collecting tubules.[396] Aldosterone increases the transcription of SGK1 in vitro,[395] although the effects of aldosterone on SGK1 protein expression in vivo appear to be minor.[396] Coexpression of SGK1 with ENaC results in markedly greater sodium currents than seen with ENaC alone.[395,397] SGK1 is required for the stimulation of sodium transport by aldosterone both in vitro[397] and in vivo.[398] SGK1 increases sodium currents by increasing cell surface expression of ENaC[399] and also increasing the open probability of individual ENaC channels.[400] The effect of SGK1 on cell surface expression of ENaC is largely mediated by Nedd4-2. Specifically, Nedd4-2 is a substrate for SGK1. Upon phosphorylation by SGK1, the affinity of Nedd4-2 for the PY domains of ENaC is diminished,[401] whereas Nedd4-2 binding to 14-3-3 scaffolding proteins is increased.[402,403] Thus, 14-3-3 proteins act to sequester Nedd4-2 and prevent it from binding to ENaC. As discussed earlier, the binding of Nedd4-2 to ENaC induces internalization and degradation of the channel.

Recently, additional aldosterone-induced proteins have been discovered, including the glucocorticoid-induced leucine zipper protein (GILZ1), the transcription of which is rapidly induced by aldosterone in collecting duct principal cells. GILZ1 stimulates ENaC-mediated Na^+ transport and ENaC surface expression by inhibiting Raf-1 in the extracellular signal-regulated kinase (ERK) signaling pathway.[404,405] Soundararajan and colleagues[406] have also identified another aldosterone-induced protein, CNK3 (connector enhancer of kinase suppressor of Ras 3), which also stimulates ENaC and appears to be a scaffolding protein. The emerging story is that a multiprotein complex exists in CCD cells that promotes context-specific aldosterone signal transduction to induce ENaC activity and apical Na^+ conductance. Specifically, aldosterone stimulates ENaC activity through synergistic aldosterone-dependent activation by SGK1 via Nedd4-2 and by GILZ1 via Raf-1 and CNK3.

Nongenomic effects of aldosterone (rapid effects that are mineralocorticoid receptor-independent) have also been described in many tissues, including the kidney.[407] Elucidating the mechanisms of such effects is an area of active investigation and appears to include the mitogen-activated protein kinase (MAPK) pathway and the methylation of proteins and lipids. Aldosterone also increases the activity of a number of cellular methyltransferase enzymes.[408] Moreover, the β subunit of ENaC itself is a substrate for methylation, and, when methylated, exhibits increased Na^+ transport activity.[409] The effects of aldosterone on Na^+ channel activity may also involve small GTP-binding proteins, for example, Ras,[410] and phosphatidylinositol 3-kinase.[411] SGK1 is a downstream mediator of phosphoinositide-3-kinase.[412]

Sometime after the increase in apical membrane Na^+ conductance occurs, the basolateral membrane Na^+,K^+–ATPase activity and pump current increase.[413] This increase is due initially to the effect of increased cell sodium activity on existing pump units.[414] Later, aldosterone induces the synthesis of additional Na^+,K^+–ATPase pump subunits.[415] Increased apical membrane Na^+ entry may promote the late synthesis of Na^+,K^+–ATPase, because the inhibition of sodium entry by amiloride markedly reduced the aldosterone-induced increase in Na^+,K^+–ATPase activity.[416]

Aldosterone also exerts an additional, late effect on the amiloride-sensitive Na^+ conductance. Patch-clamp studies in rats exposed to high levels of aldosterone for several days demonstrated a large increase in the amiloride-sensitive whole cell Na^+ conductance,[417] which correlated with an increase in the number of active Na^+ channels in the apical membrane.[418] Increases in ENaC mRNA[419] and protein[334] levels in aldosterone-treated tissues suggest that the synthesis of new ENaC channels may contribute to the late aldosterone-induced increase in Na^+ conductance. SGK1, in addition to increasing the cell surface expression of ENaC, also regulates the transcription of ENaC subunits, principally α.[420]

Antidiuretic Hormone (ADH)

Exposure of rat CCD segments in vitro to ADH results in a sustained stimulation of Na^+ absorption.[421] ADH increases the transepithelial potential, depolarizes the apical membrane, and increases the conductance of the apical membrane of principal cells.[422] These changes are entirely reversed by luminal amiloride, indicating that ADH increases the apical membrane sodium conductance of the principal cell. These effects of ADH are mediated intracellularly by cAMP.[423] Moreover, the effects of ADH on Na^+ transport in the rat CCD are enhanced by prior treatment of the animals with mineralocorticoids.[421]

ADH and aldosterone increase apical membrane ENaC activity through both overlapping and distinct mechanisms of action. Like aldosterone via SGK1, ADH induces enhanced PKA-dependent phosphorylation of Nedd4-2 at phosphorylation sites that overlap those of SGK1.[353] As described previously, these phosphorylation events promote sequestration of Nedd4-2 through enhanced binding to 14-3-3 proteins. In contrast to aldosterone, which can activate quiescent channels, ADH, via cAMP, promotes the insertion of additional Na^+ channels into the apical membrane.[424] In addition, PKA-mediated phosphorylation may also directly stimulate the activity of ENaC channels already present in the apical membrane, potentially both directly[425] and indirectly via Nedd4-2 inhibition, causing enhanced channel residency time at the membrane and thus proteolytic cleavage.[370] Long-term exposure to ADH may also increase the capacity of the collecting duct for Na^+ transport by increasing the expression of both Na^+,K^+–ATPase and ENaC.[426]

Other Agents

Bradykinin is produced in the connecting duct[427] and binds to specific receptors in the CCD.[428] An intrarenal infusion of bradykinin produces a diuresis. Bradykinin has been reported to reduce Na^+ absorption in rat CCD segments.[429] More recently, bradykinin was shown to acutely and reversibly decrease the open probability of ENaC in patch-clamp studies performed ex vivo on split open CCDs isolated from rats. This effect appears to be mediated specifically through the bradykinin B_2 receptor.[430]

As will be discussed in the following section, the major site of action of atrial natriuretic peptide (ANP) is the inner medullary collecting duct. ANP stimulates cGMP production in the CCD,[431] and inhibits the hydro-osmotic actions of ADH in the CCD.[432] Biphasic effects of ANP on conscious, sedated rats have been observed with acute water and sodium excretion within minutes, followed by retention after 90 minutes, which was associated with increased apical membrane expression of α- and γ-ENaC. These delayed effects may represent a compensatory response to increase sodium and water reabsorption and prevent volume depletion in response to prolonged ANP infusion.[433]

α2-Adrenergic agonists inhibit sodium reabsorption in the rat CCD.[434] This inhibition is associated with an increase in the apical membrane resistance, reflecting decreased Na^+ entry through Na^+ channels. These changes appear to result from an inhibition of adenylate cyclase and antagonism of ADH by α2 agonists.[435]

Prostaglandin E_2 exerts diuretic and natriuretic effects on the kidney. Part of this action is mediated by an inhibition of Na^+ absorption in the CCD.[436] The application of PGE_2 to the basolateral surface of perfused rabbit CCD segments reversibly inhibits the negative transepithelial voltage and net sodium absorption.[436] The effect of PGE_2 on sodium transport is coupled to a rise in intracellular [Ca^{2+}] and is dependent on the activation of PKC.[437] Four PGE_2 receptor subtypes, designated EP1, EP2, EP3, and EP4, have been characterized. Studies using receptor subtype–specific agonists and antagonists suggest that the EP1 receptor mediates PGE_2-dependent inhibition of Na^+ transport in the CCD.[438] This inhibition of Na^+ transport is associated with depolarization of the apical membrane voltage, consistent with inhibition of the basolateral Na^+,K^+-ATPase.[439] In contrast to the inhibitory effect of basolateral PGE_2 on Na^+ transport, luminal PGE_2 increases transepithelial voltage and presumably Na^+ absorption via the EP4 receptor.[440]

Epidermal growth factor (EGF) reduces Na^+ absorption in rabbit CCD by about 50% via the inhibition of apical electrogenic Na^+ entry via ENaC.[441,442] More recent studies performed on cultured mouse CCD cells suggest that the effects are mediated by the ErbB2 EGF receptor and that there is actually a biphasic effect of EGF on ENaC activity.[443] Acutely (<4 h), EGF treatment increases the ENaC current, an effect that appears to be mediated via the PI-3-kinase pathway. Chronically (>8 h), the ENaC current was inhibited via effects through the MEK/ERK pathway.[443]

Endothelin-1 (ET-1) is heavily secreted from the basolateral aspect of CD epithelial cells where it binds to basolateral ET_B receptors and may thus act in an autocrine fashion to inhibit both Na^+ and water reabsorption in this segment, as shown in vitro.[444] The physiologic relevance of these findings has been confirmed in vivo, because mice with CD-specific knockout of ET-1 or ET receptors are hypertensive on a normal Na^+ diet and have exacerbated Na^+ retention and hypertension when placed on a high-Na^+ diet. ET-1 inhibits ENaC activity through Src- and MAPK-dependent pathways.[444]

Nitric oxide is also a downstream mediator of ET-1,[444] where it decreases Na^+ transport in rat CCD segments by 40% to 80%.[445] The addition of nitric oxide to tubules decreased the intracellular [Na^+], but did not affect the activity of basolateral Na^+,K^+–ATPase, suggesting that the primary effect of nitric oxide is to inhibit apical Na^+ entry via ENaC. The inhibitory mechanism involving NO remains to be determined.[444]

Dopamine inhibits ADH-dependent Na^+ transport and transepithelial voltage in rat and rabbit CCD segments, although the particular basolateral dopamine receptor subtype may be species specific.[446,447]

Ang II stimulates sodium channel activity in rabbit and mouse CCDs.[448] Chronic Ang II infusion also increases the abundance of the α subunit of ENaC, the rate-limiting subunit for ENaC assembly.[449] Both the acute effects of Ang II on ENaC activity and the chronic effects on ENaC abundance are mediated by the AT1 receptor.[448,449] A more recent study performed on rats suggests that the Ang II-induced ENaC stimulation downstream of the AT1 receptor involves a Ca^{2+}-independent PKC pathway that induces superoxide generation. The blocking of arachidonic acid–induced inhibition of ENaC may also play a role.[450]

Bicarbonate (HCO_3^-) changes in the CCD lumen, which may reflect changes in total-body acid–base status or local HCO_3^- secretion from neighboring intercalated cells via the apical Na^+-independent Cl^-/HCO_3^- exchanger, pendrin, have been shown recently to modulate Na^+ reabsorption in the CCD.[451,452] Specifically, the bicarbonate-stimulated soluble adenylyl cyclase (sAC) appears to stimulate both basal and agonist-stimulated Na^+ reabsorption in the kidney collecting duct, acting to enhance Na^+,K^+–ATPase catalytic activity.[451] Another study suggests that pendrin increases ENaC abundance and activity, at least in part by increasing luminal [HCO_3^-].[452]

The elucidation of other cellular signaling pathways and kinases that are important in the regulation of ENaC, and Na^+ transport in the CCD is a very active area of research and involves signaling pathways downstream of diverse stimuli, including inflammation (IkappaB kinase/NF-kappaB/NF-κB pathway)[453] and metabolic stress (AMP-activated protein kinase).[454] A full treatment of these signaling pathways is beyond the scope of this chapter, but the interested reader is referred to a recent review.[455]

NA^+ TRANSPORT IN THE OUTER MEDULLARY COLLECTING DUCT

The transport properties of the outer medullary collecting duct (OMCD) have been studied by in vitro perfusion of isolated tubule segments. The functional properties of the OMCD differ depending on the location of the segment within the outer medulla. Segments within the outer stripe of the outer medulla ($OMCD_o$) exhibit electrophysiologic properties resembling the cortical collecting duct; that is, a lumen negative transepithelial voltage and electrogenic apical Na^+ entry.[456] Compared to the CCD, the $OMCD_o$ displays a less negative transepithelial voltage, much lower ionic permeabilities, and a lower rate of active reabsorption of Na^+.[457] As the collecting duct descends into the medulla, principal cells, which mediate Na^+ and K^+ transport in the CCD (see previous), are replaced by cells the electrical properties of which are similar to intercalated cells of the CCD (i.e., the apical membrane lacks a demonstrable Na^+ or K^+ conductance).[458] Within the inner stripe of outer medulla ($OMCD_i$), principal cells are virtually absent and no net Na^+ absorption occurs.[457]

NA^+ TRANSPORT IN THE INNER MEDULLARY COLLECTING DUCT

Mechanism of Na^+ Transport

The analysis of salt transport by the inner medullary collecting duct (IMCD) has been confounded by problems of axial tubule heterogeneity, species variability, and differences in experimental approach. Based on morphologic factors, the IMCD has been divided into three subsegments: $IMCD_1$, $IMCD_2$, and $IMCD_3$.[459] This morphologic heterogeneity is paralleled, to some extent, by functional heterogeneity. For example, the urea permeability and its responsiveness to ADH increases from $IMCD_1$ to $IMCD_3$ with increasing medullary depth.[460] Further complicating the analysis is the observation that similar subsegments from different species exhibit different properties relating to salt transport.[461,462] Finally, for unclear reasons, studies examining IMCD function in vivo (e.g., by microcatheterization)[463] have yielded markedly different results than have in vitro studies of isolated perfused tubules.[461,464]

Microelectrode impalement studies of IMCD segments from rats demonstrated that the apical membrane constituted the major cellular resistance, and the luminal application of amiloride increased the apical membrane voltage and resistance and decreased the transepithelial voltage.[461] These results, and others,[465] are consistent with the presence of an amiloride-sensitive sodium conductance in the apical membrane of IMCD cells. Patch-clamp studies of cultured rat IMCD cells indicate that Na^+ entry is mediated by a 20 to 30 pS amiloride-sensitive, nonselective, cGMP-gated cation channel in the apical membrane.[465,466] The basolateral membrane of IMCD cells contains the Na^+,K^+–ATPase, a K^+ conductance and a HCO_3^- conductance.[461]

The results discussed previously can be combined into a model for sodium transport in the IMCD (Fig. 5.11). Na^+

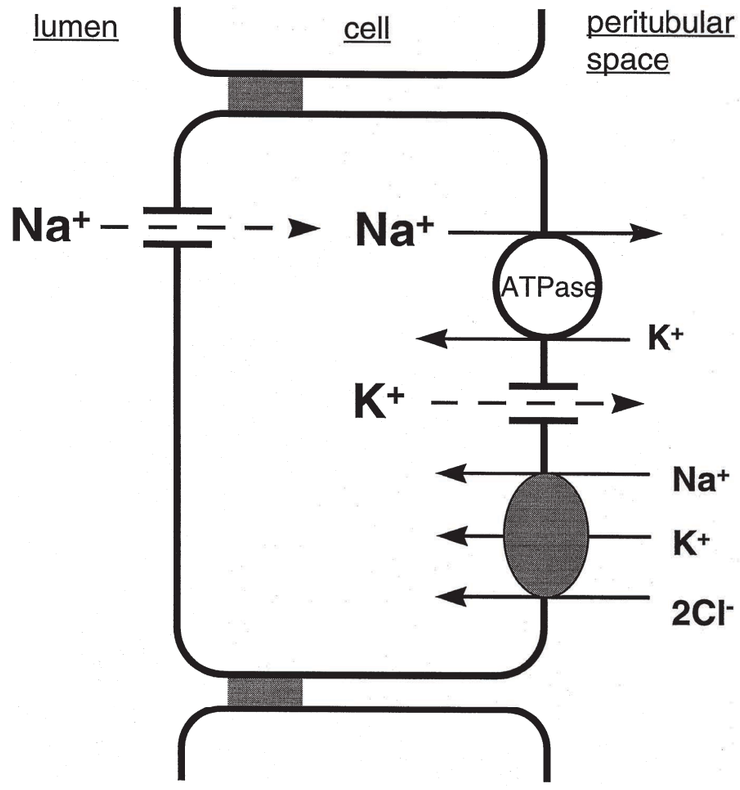

FIGURE 5.11 A model of Na^+ transport in the inner medullary collecting duct. Apical Na^+ entry proceeds via a nonselective amiloride-sensitive cation channel. Basolateral Na^+-K^+-$2Cl^-$ cotransport may be involved in Na^+ secretion.

entry across the apical membrane occurs down its steep electrochemical gradient through amiloride-sensitive Na^+ channels. Na^+ is extruded across the basolateral membrane by the Na^+,K^+–ATPase. The basolateral membrane K^+ conductance serves to recycle the K^+ that enters via the Na^+,K^+–ATPase. The K^+ conductance also hyperpolarizes the cell, thereby favoring Na^+ entry across the apical membrane.

There is some evidence for additional electroneutral Na^+ entry pathways in rat IMCD cells, although their importance in net Na^+ absorption by the IMCD in other species remains unclear. Furosemide and thiazide diuretics both inhibit a portion of Na^+ absorption by rat IMCD segments in vivo.[467,468] However, Zeidel and colleagues[469] failed to demonstrate sensitivity of rabbit IMCDs to loop diuretics and found that conductive Na^+ entry at the apical membrane predominated. A Na^+-K^+-$2Cl^-$ cotransporter appears to be present in the basolateral membrane of terminal IMCD segments.[470] The cloned Na^+-K^+-$2Cl^-$ cotransporter from cultured IMCD cells represents the "secretory" isoform of the Na^+-K^+-$2Cl^-$ cotransporter (NKCC1) rather than the absorptive isoform present in the apical membrane of the thick ascending limb.[471] Finally, the Na^+-HCO_3^- cotransporter NBCn1 has been found in the basolateral membrane of rat IMCDs, which may contribute to cellular defense against both acidification and volume changes in this segment.[472]

Regulation of Na^+ Transport

The IMCD appears to be the major target site for the potent diuretic hormone ANP.[473] This hormone, working through cGMP,[474] inhibits Na^+ entry via apical Na^+ channels. In cell-attached and excised patches of cultured inner medullary cells, both ANP and dibutyryl cGMP inhibited the activity of the cation channel.[475]

In addition to inhibiting Na^+ reabsorption, ANP may stimulate Na^+ secretion in the IMCD.[470] In isolated perfused IMCD segments, ANP increased the bath to lumen flux rate of Na^+ and Cl^-, an effect that was inhibited by peritubular furosemide and by omission of either counterion, thus suggesting the role of a basolateral membrane Na^+-K^+-$2Cl^-$ cotransporter.[476] Sands et al.,[464] however, found no effect of ANP on the Na^+ permeability of the rat IMCD.

In one study,[477] ADH stimulated amiloride-sensitive Na^+ absorption by terminal IMCD segments perfused in vitro. Other studies, however, failed to find an effect of ADH or cAMP on the amiloride-sensitive cation channel in apical membranes of cultured IMCD cells.[464,465]

Micropuncture studies by Ullrich and Papavassiliou[478] demonstrated that mineralocorticoids increased net Na^+ absorption in the terminal IMCD, which was attributed to a decrease in the passive Na^+ permeability of the tubule leading to a decrease in back leak of NaCl into the lumen. Mineralocorticoids may also increase active Na^+ reabsorption in the IMCD. For example, aldosterone produced a three- to seven-fold stimulation of electrogenic Na^+ transport in cultured rat IMCD cells,[479] and chronic mineralocorticoid exposure in vivo increased the activity of Na^+,K^+ ATPase in the IMCD.[480]

CHAPTER

6 Tubular Potassium Transport

David B. Mount

TUBULAR POTASSIUM TRANSPORT

Potassium (K^+) functions in a diversity of physiologic processes. Changes in intracellular K^+ affect cell volume, intracellular pH, enzymatic function, protein synthesis, DNA synthesis, and apoptosis. Changes in the ratio of intracellular to extracellular K^+ affect the cellular resting membrane potential, causing depolarization in hyperkalemia and hyperpolarization in hypokalemia; as a consequence, potassium disorders primarily affect excitable tissues, chiefly heart and muscle. Hypokalemia and hyperkalemia also have a variety of renal and cardiovascular consequences. A large body of experimental and epidemiologic evidence thus implicates hypokalemia or reduced K^+ intake in the pathogenesis of hypertension, heart failure, and stroke.[1] Hypokalemia also causes a host of structural and functional changes in the kidney, whereas hyperkalemia in turn has a significant effect on the ability to excrete an acid urine due to interference with the urinary excretion of ammonium (NH_4^+).

Potassium is almost exclusively an intracellular cation, with only 2% of total body K^+ contained within the extracellular fluid. Extracellular K^+ is maintained within a very narrow range by three major mechanisms. First, the distribution of K^+ between the intracellular and extracellular space is determined by the activity of a number of widely expressed and/or ubiquitous transport pathways. A net increase in cellular uptake can thus cause transient hypokalemia, whereas impairment of cellular uptake can lead to hyperkalemia. Second, the colon has the ability to absorb and secrete K^+, with significant mechanistic and regulatory similarities to renal K^+ transport. However, the colon has a relatively limited capacity for K^+ excretion, and a third mechanism, changes in renal K^+ excretion, plays the dominant role in responding to changes in K^+ intake. Regulated increases in K^+ secretion by the connecting tubule (CNT) and the cortical collecting duct (CCD) play a critical role in the response to hyperkalemia and K^+ loading, whereas inhibition of K^+ secretion and increases in the reabsorption of K^+ by the CCD and the outer medullary collecting duct (OMCD) function in the response to hypokalemia or K^+ deprivation.

This chapter reviews the renal and extrarenal mechanisms of K^+ homeostasis, with primary emphasis on the physiology of renal K^+ transport.

Extrarenal Potassium Homeostasis

The intracellular accumulation of K^+ against its electrochemical gradient is an energy-consuming process, mediated by the ubiquitous Na^+/K^+–ATPase. The Na^+/K^+–ATPase functions as an electrogenic pump, with a transport stoichiometry of three intracellular Na^+ ions to two extracellular K^+ ions. The enzyme complex is made up of a tissue-specific combination of multiple α, β, and γ subunits, which are further subject to tissue-specific patterns of regulation. Cardiac glycosides (i.e., digoxin and ouabain) bind to the α subunits of Na^+/K^+–ATPase at an exposed extracellular hairpin loop that also contains the major binding sites for extracellular K^+.[2] The binding of digoxin and K^+ to the Na^+/K^+–ATPase complex is thus mutually antagonistic, explaining in part the potentiation of digoxin toxicity by hypokalemia.[3] Although the four α subunits have equivalent affinity for ouabain, they differ significantly in the intrinsic K^+/ouabain antagonism.[4] Ouabain binding to isozymes containing the ubiquitous α1 subunit is relatively insensitive to K^+ concentrations within the physiologic range, such that this isozyme is protected from digoxin under conditions wherein cardiac α2 and α3 subunits, the therapeutic targets of digoxin, are inhibited.[4] Notably, the digoxin/ouabain binding site of α subunits is highly conserved, suggesting a potential role in the physiologic response to endogenous ouabain/digoxinlike compounds. Consistent with this hypothesis, a mouse strain that expresses α2 subunits with engineered resistance to ouabain is strikingly resistant to ouabain-induced hypertension and to adrenocorticotrophic hormone-dependent hypertension,[5] the latter of which is known to involve an increase in circulating ouabainlike glycosides.

Potassium can also accumulate in cells by coupling to the gradient for Na^+ entry, entering via the electroneutral Na^+-K^+-$2Cl^-$ cotransporters NKCC1 and NKCC2. The NKCC2 protein is found only at the apical membrane of

the thick ascending limb (TAL) and the macula densa cells, where it functions in transepithelial salt transport and tubular regulation of renin release (see Potassium Transport in the Thick Ascending Limb).[6] NKCC1 is widely expressed in multiple tissues,[6] including muscle, where it modulates extrarenal K^+ homeostasis.[7] The cotransport of K^+-Cl^- by the four K^+-Cl^- cotransporters (KCC1 to 4) can also function in the transfer of K^+ across membranes; although the KCCs typically function as efflux pathways, they can mediate influx when extracellular K^+ increases.[6]

Skeletal muscle contains approximately 75% of the body's potassium and exerts considerable influence on extracellular K^+. Skeletal muscle Na^+/K^+–ATPase activity in particular is a major determinant of the capacity for extrarenal K^+ homeostasis. Hypokalemia induces a marked decrease in muscle K^+ content and Na^+/K^+–ATPase activity, an altruistic[8] mechanism to regulate plasma K^+. This adaptation is primarily mediated by dramatic decreases in the protein abundance of the α-2 subunit of Na^+/K^+–ATPase. In contrast, hyperkalemia due to potassium loading is associated with adaptive increases in muscle K^+ content and Na^+/K^+–ATPase activity.[9] These interactions are reflected in the relationship between physical activity and the ability to regulate extracellular K^+ during exercise[10]; exercise training is associated with increases in muscle Na^+/K^+–ATPase concentration and activity, with reduced interstitial K^+ in trained muscles and an enhanced recovery of plasma K^+ after defined amounts of exercise.[10]

Several hormones have been implicated in the control of extrarenal K^+ homeostasis. In particular, increases in plasma K^+ have a stimulatory effect on insulin levels,[11] which in turn stimulates the uptake of K^+ by muscles, the liver, and other tissues. In contrast, insulin-stimulated K^+ uptake is rapidly reduced by 2 days of K^+ depletion, prior to a modest drop in plasma K^+,[12] and in the absence of a change in plasma K^+ in rats subject to a lesser K^+ restriction for 14 days.[13] Insulin activates muscle Na^+/K^+–ATPase, inducing the translocation of the Na^+/K^+–ATPase α-2 subunit to the plasma membrane with a lesser effect on the α1 subunit.[14] This translocation is dependent on the activity of phosphoinositide-3 (PI-3) kinase,[14] which itself also binds to a proline-rich motif in the N-terminus of the α subunit; the activation of PI3-kinase by insulin induces phosphatase enzymes to dephosphorylate a specific serine residue adjacent to the PI3-kinase binding domain. Trafficking of Na^+/K^+–ATPase to the cell surface also requires phosphorylation of an adjacent tyrosine residue, perhaps catalyzed by the tyrosine kinase activity of the insulin receptor itself.[15] In addition, the serum and glucocorticoid-induced kinase 1 (SGK1) plays a critical role in insulin-stimulated K^+ uptake via stimulatory effects on Na^+/K^+–ATPase activity and/or the Na^+-K^+–$2Cl^-$ cotransport.[16] The hypokalemic effect of insulin plus glucose is thus blunted in SGK1 knockout mice, with a marked reduction in hepatic insulin-stimulated K^+ uptake.[16]

The sympathetic nervous system also affects the balance between extracellular and intracellular K^+. The uptake of K^+ by the liver and muscles is stimulated via β_2 receptors. This hypokalemic effect of catecholamines is independent of changes in circulating insulin and has been reported in nephrectomized animals.[17] The cellular mechanisms whereby catecholamines induce K^+ uptake in muscles include an activation of the Na^+/K^+–ATPase, likely via increases in cyclic-AMP (cAMP).[18] Skeletal muscle β-adrenergic receptors also activate NKCC1, which may account for as much as one third of the uptake response.[7] In contrast to β-adrenergic stimulation, α-adrenergic agonists impair the ability to buffer increases in K^+ induced via intravenous loading or by exercise[19]; the transport mechanisms whereby this occurs are not known. β-adrenergic stimulation increases K^+ uptake during exercise to lessen exercise-induced hyperkalemia, whereas α-adrenergic mechanisms help blunt the ensuing postexercise nadir.[19]

The efflux of K^+ out of cells is primarily mediated by K^+ channels, which comprise the largest group of ion channels in the human genome. There are three major subclasses of mammalian K^+ channels: the six-transmembrane domain (TMD) family, which encompasses both the voltage-sensitive and Ca^{2+}-activated K^+ channels; the two-pore, four TMD family; and the two TMD family of inward rectifying K^+ (Kir) channels. There is tremendous genomic variety in human K^+ channels. Further complexity is generated by the presence of multiple accessory subunits and alternative patterns of mRNA splicing. Not surprisingly, an increasing number and variety of K^+ channels have been implicated in the control of K^+ homeostasis and the membrane potential of excitable cells such as muscle and heart, with important, evolving roles in the pathophysiology of potassium disorders. Adrenal K^+ channels have also been implicated in the adrenal release of aldosterone induced by hyperkalemia.[20,21] The emphasis in this chapter is on renal K^+ channels, particularly those in the distal nephron that mediate K^+ secretion.

Potassium Transport in the Proximal Tubule

The proximal tubule reabsorbs 50% to 70% of filtered K^+ (Fig. 6.1). Proximal tubules generate minimal transepithelial K^+ gradients, and the fractional reabsorption of K^+ by this nephron segment is similar to that of Na^+.[22] K^+ absorption thus follows that of fluid, Na^+, and other solutes,[23] such that proximal tubules do not play a direct role in regulated renal K^+ excretion. However, changes in Na^+-Cl^- reabsorption by the proximal tubule have considerable effects on distal tubular flow and distal tubular Na^+ delivery, with attendant effects on the excretory capacity for K^+. In addition, K^+ loading has significant effects on proximal tubular Na^+-Cl^- reabsorption. Thus, the intravenous infusion of K^+-Cl^- or increases in the peritubular K^+ concentration causes an inhibition of proximal tubular Na^+-Cl^- reabsorption[24]; this serves to increase both distal tubular flow and distal tubular Na^+ delivery, thus increasing distal K^+ secretion after K^+ loading.

The mechanisms involved in transepithelial K^+ transport by the proximal tubule are not completely clear, although

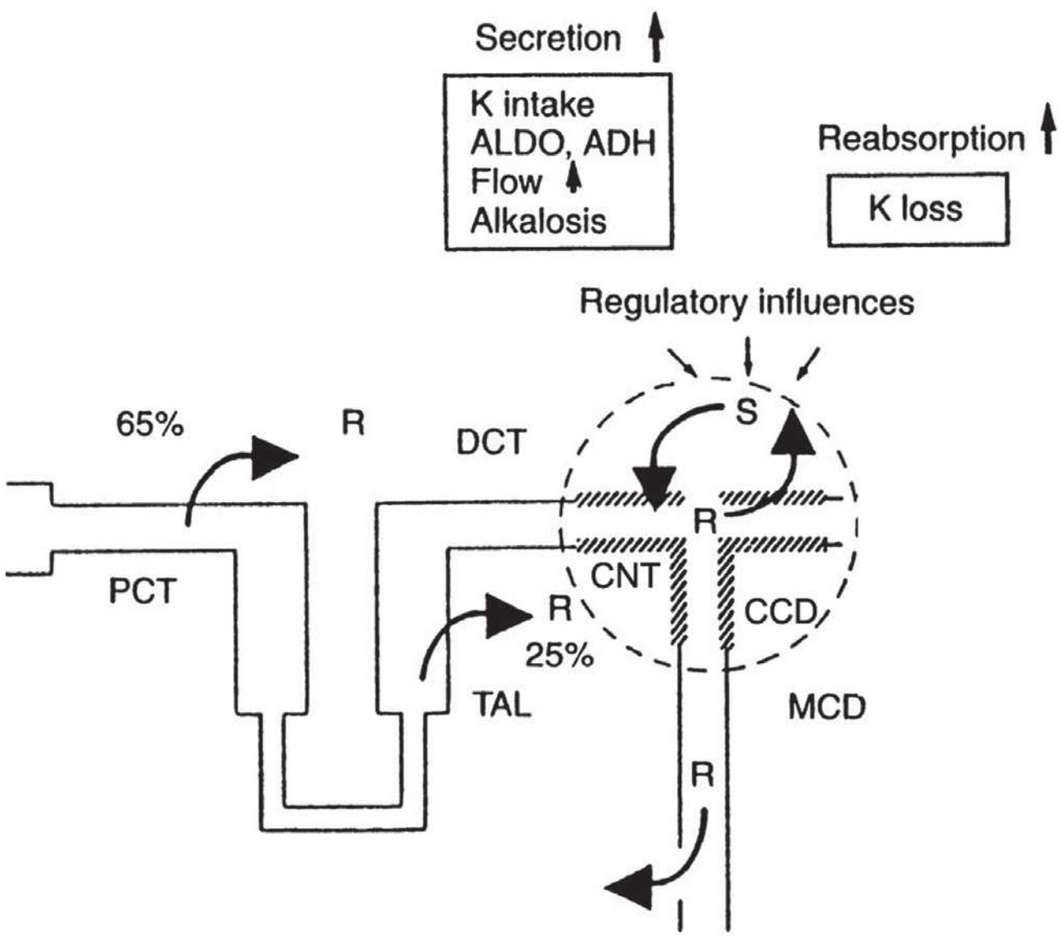

FIGURE 6.1 Potassium transport along the nephron. Approximately 90% of filtered K^+ is reabsorbed by the proximal tubule and the loop of Henle. K^+ is secreted in the connecting tubule and the cortical collecting duct; net reabsorption occurs in response to K^+ depletion, primarily within the medullary collecting duct. *PCT*, proximal tubule; *TAL*, thick ascending limb; *DCT*, distal convoluted tubule; *CNT*, connecting tubule; *CCD*, cortical collecting duct; *S*, secretion; *R*, reabsorption; *ALDO*, aldosterone; *ADH*, antidiuretic hormone; *MCD*, medullary collecting duct.

active transport does not appear to play a major role.[23,25] Luminal barium has modest effects on transepithelial K^+ transport, suggesting a component of transcellular transport via barium-sensitive K^+ channels.[26] However, the bulk of K^+ transport is thought to occur via the paracellular pathway,[26,27] driven by the lumen-positive potential difference in the mid-to-late proximal tubule. The total K^+ permeability of the proximal tubule is thus quite high due to the high permeability of the paracellular pathway.[26, 27] The combination of luminal K^+ concentrations that are ~10% higher than that of plasma, a lumen-positive potential difference of ~2 mV, and high paracellular permeability leads to considerable paracellular absorption in the proximal tubule. The tight junction protein claudin-2 plays a key role in paracellular cation transport by the proximal tubule; targeted deletion in knockout mice generates a "tight" epithelium in the proximal tubule, with a reduction in Na^+, Cl^-, and fluid absorption.[28] The loss of claudin-2 expression does not affect the ultrastructure of tight junctions, but does lead to a reduction in paracellular cation permeability.[28]

The absorption of K^+ across the paracellular pathway is thought to occur via convective transport—solvent drag due to frictional interactions between water and K^+—rather than diffusional transport.[29] Notably, however, the primary pathway for water movement in the proximal tubule is quite conclusively transcellular, via water channels in the apical and basolateral membrane. Therefore, the apparent convective transport of K^+ would have to constitute pseudosolvent drag, with uncharacterized, coordinating interactions between water traversing the transcellular route and the diffusion of K^+ along the claudin-dependent paracellular pathway.[29]

The Loop of Henle and Medullary Potassium Recycling

Transport by the loop of Henle functions in medullary K^+ recycling (Fig. 6.2). A considerable fraction of K^+ secreted by the CCD is reabsorbed by the medullary collecting ducts and is then secreted into the late proximal tubule and/or the descending thin limbs of long-looped nephrons.[30] In potassium-loaded rats there is thus a doubling of luminal K^+ in terminal thin descending limbs, with a sharp drop after the inhibition of CCD K^+ secretion by amiloride.[31] Enhancement of CCD K^+ secretion with the treatment of 1-desamino-8-D-arginine vasopressin (dDAVP) also results in an increase in luminal K^+ in descending thin limbs.[32] This recycling pathway (i.e., secretion in CCD, absorption in the OMCD and the inner medullary collecting duct (IMCD), secretion in the descending thin limb)

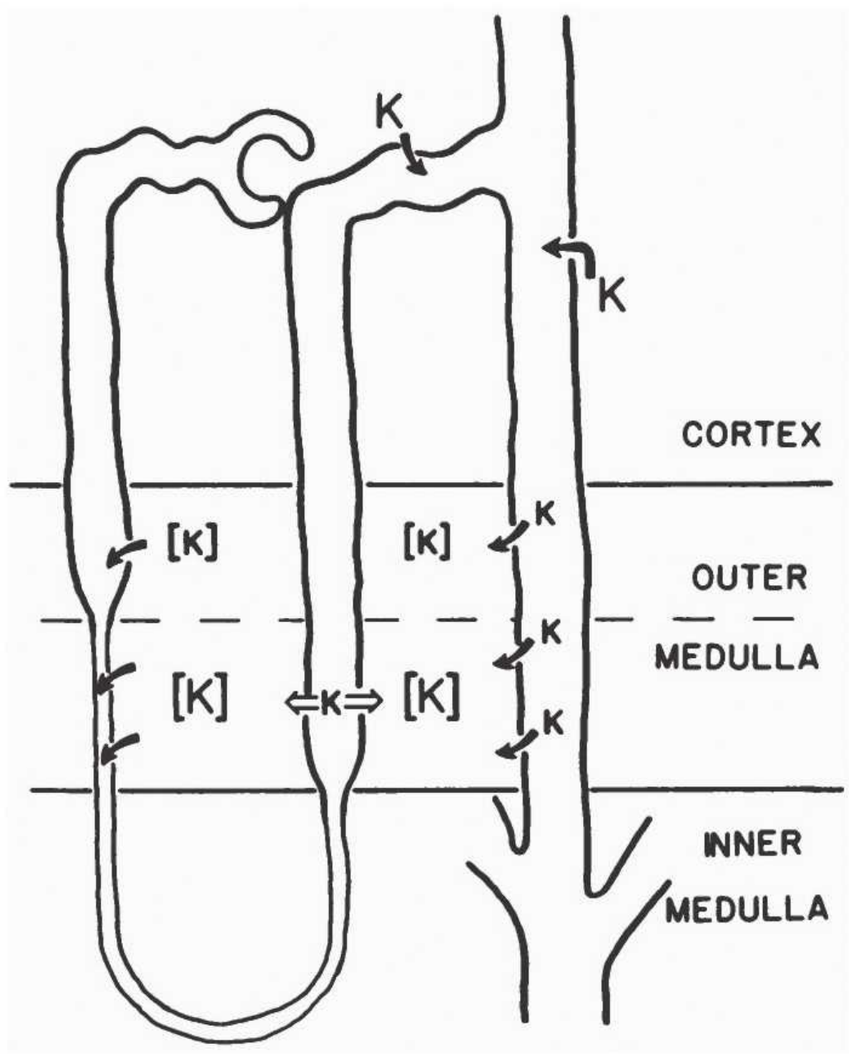

FIGURE 6.2 A schematic representation of medullary K^+ recycling. Medullary interstitial K^+ increases considerably after dietary K^+ loading due to the combined effects of secretion in the cortical collecting duct (CCD), absorption in the outer medullary collecting duct (OMCD), the thick ascending limb (TAL), and the inner medullary collecting duct (IMCD), and secretion in the descending thin limb (see text for details). (From Stokes JB. Consequences of potassium recycling in the renal medulla. Effects of ion transport by the medullary thick ascending limb of Henle's loop. *J Clin Invest*. 1982;70:219–229.)

is associated with a marked increase in medullary interstitial K^+ concentration. Passive transepithelial K^+ absorption by the thin ascending limb and active absorption by the thick ascending limb (TAL)[33] also contribute to this increase in interstitial K^+ (Fig. 6.2). Specifically, the absorption of K^+ by the ascending thin limb, TAL, and OMCD exceeds the secretion by descending thin limbs, thus concentrating K^+ within the interstitium.

K^+ is secreted into descending thin limbs by passive diffusion, driven by the high medullary interstitial K^+ concentration. Descending thin limbs thus have a very high K^+ permeability, without evidence for active transepithelial K^+ transport.[34] Transepithelial K^+ transport by ascending thin limbs has not been measured; however, as is the case for Na^+-Cl^- transport,[35] the absorption of K^+ by thin ascending limbs is presumably passive, via the paracellular pathway.

The physiologic significance of medullary K^+ recycling is not completely clear. However, an increase in interstitial K^+ from 5 to 25 mM dramatically inhibits Cl^- transport by perfused thick ascending limbs.[33] By inhibiting Na^+-Cl^- absorption by the TAL, increases in interstitial K^+ would increase Na^+ delivery to the CNT and CCD, thus enhancing the lumen-negative potential difference (PD) in these tubules and increasing K^+ secretion.[33] A high K^+ diet also reduces the absorption of K^+ by the TAL[36] (i.e., there are direct effects on K^+ secretion by the TAL). The marked increase in medullary interstitial K^+ after dietary K^+ loading is also postulated to limit the difference between luminal and peritubular K^+ in the collecting duct, thus minimizing passive K^+ loss from the collecting duct.

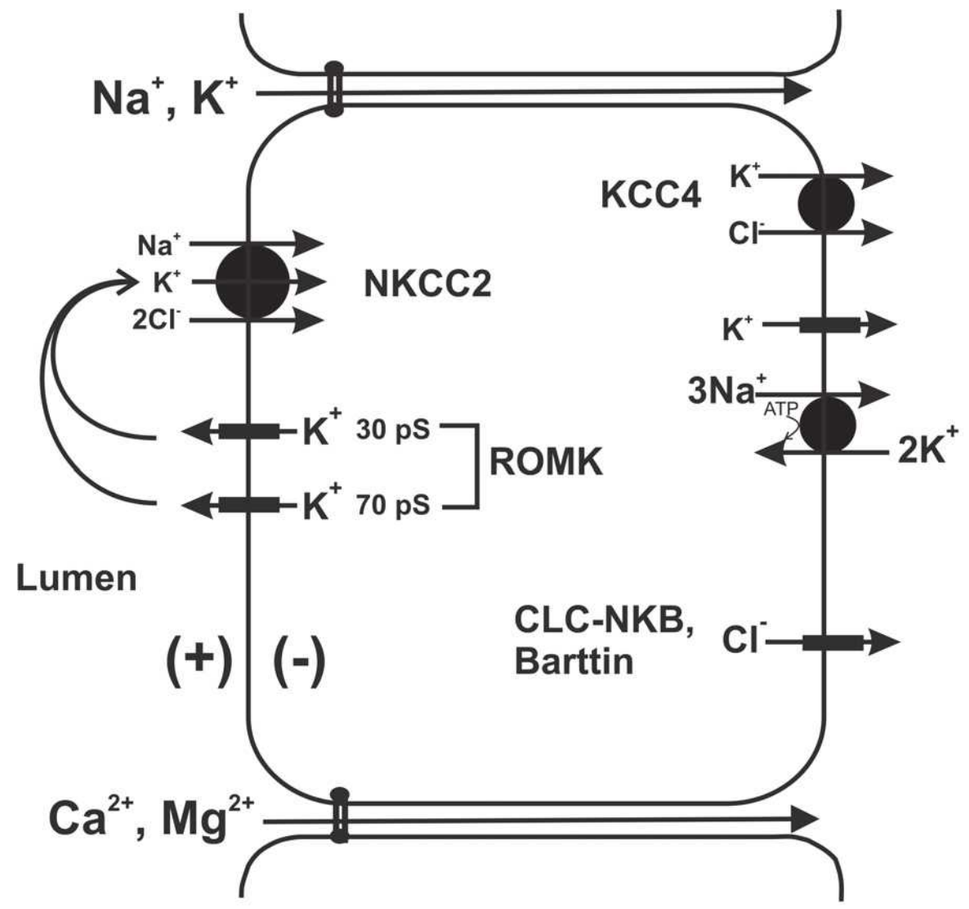

FIGURE 6.3 The potassium transport pathways in the thick ascending limb (TAL); see text for details. *NKCC2*, Na^+-K^+-2Cl– cotransporter 2; *ROMK*, renal outer medullary K^+ channel; *CLC-NKB*, human Cl– channel; *Barttin*, Cl– channel subunit; *KCC4*, K^+-Cl– cotransporter 4.

Potassium Transport in the Thick Ascending Limb

Active transepithelial K^+ transport across the TAL includes both a transcellular component, via the apical Na^+-K^+-$2Cl^-$ cotransporter NKCC2, and a paracellular pathway (Fig. 6.3). Potassium transport appears to differ in the major morphologic subtypes of TAL cells (i.e., rough- and smooth-surfaced cells). Morphologically, the TAL begins abruptly after the thin ascending limb of long-looped nephrons and after the aquaporin-negative segment of short-limbed nephrons. The TAL then extends into the renal cortex, where it meets its parent glomerulus at the vascular pole; the plaque of cells at this junction forms the macula densa, which functions as the tubular sensor for both tubuloglomerular feedback and the tubular regulation of renin release by the juxtaglomerular apparatus. Cells in the medullary TAL are 7 to 8 μm in height, with extensive invaginations of the basolateral plasma membrane and interdigitations between adjacent cells[37]; cells in the cortical TAL are considerably shorter, about 2 μm in height at the end of the cortical TAL in rabbits, with less mitochondria and a simpler basolateral membrane.[37] Macula densa cells also lack the lateral cell processes and interdigitations that are characteristic of medullary TAL cells.[37]

Scanning electron microscopy has revealed that the TAL of both rats[38] and hamsters[39] contains two morphologic subtypes, a rough-surfaced cell type (R cells) with prominent apical microvilli and a smooth-surfaced cell type (S cells) with an abundance of subapical vesicles.[37,40] In the hamster TAL, cells can also be separated into those with high apical and low basolateral K^+ conductance and a low basolateral Cl^- conductance (LBC cells), versus a second population with low apical and high basolateral K^+ conductance, combined with high basolateral Cl^- conductance (HBC) cells.[39,41] The relative frequency of the morphologic and functional subtypes in the cortical and medullary TAL suggests that HBC cells correspond to S cells and LBC cells correspond to R cells.[39]

Morphologic and functional heterogeneity notwithstanding, the cells of the medullary TAL, the cortical TAL, and the macula densa are presumed to share the same basic or at least composite transport mechanisms (see Fig. 6.3). Na^+-Cl^- reabsorption by the TAL is a secondarily active process, driven by the favorable electrochemical gradient for Na^+ established by the basolateral Na^+/K^+–ATPase.[42] The Na^+, K^+, and Cl^- ions are cotransported across by the apical membrane by an electroneutral Na^+-K^+-$2Cl^-$ cotransporter; this transporter generally requires the simultaneous presence of all three ions, such that the transport of Na^+ and Cl^- across the epithelium is mutually codependent and dependent on the luminal presence of K^+. An apical Na^+-K^+-$2Cl^-$ cotransport is mediated by the cation–chloride cotransporter NKCC2, encoded by the SLC12A1 gene.[6] Functional expression of NKCC2 in Xenopus laevis oocytes yields Cl^--dependent and Na^+-dependent uptake of $^{86}Rb^+$ (a radioactive substitute for K^+) and Cl^--dependent and K^+-dependent uptake of $^{22}Na^+$.[6] NKCC2 is sensitive to

micromolar concentrations of furosemide, bumetanide, and other loop diuretics.[6]

Immunofluorescence indicates the expression of the NKCC2 protein along the entire length of the TAL.[6] In particular, immunoelectron microscopy reveals the expression in both rough (R; see previous) and smooth (S) cells of the TAL (see previous).[40] NKCC2 expression in subapical vesicles is particularly prominent in smooth cells,[40] suggesting a role for vesicular trafficking in the regulation of NKCC2. NKCC2 is also expressed in macula densa cells,[40] which have been shown to possess apical Na^+-K^+-$2Cl^-$ cotransport activity. Both tubuloglomerular feedback (TGF) and renal renin secretion are controlled by NKCC2 in the macula densa; luminal loop diuretics block both TGF and the suppression of renin release by the luminal Cl^-.[6]

Microperfused TALs develop a lumen-positive PD during perfusion with Na^+-Cl^-.[43] This lumen-positive PD plays a critical role in the physiology of the TAL, driving the paracellular transport of Na^+, K^+, Ca^{2+}, and Mg^{2+} (see Fig. 6.3). Originally attributed to electrogenic Cl^- transport,[43] the lumen-positive, transepithelial PD in the TAL is generated by the combination of apical K^+ channels and basolateral Cl^- channels.[42] The conductivity of the apical membrane of TAL cells is predominantly, if not exclusively, K^+ selective. Luminal recycling of K^+ via Na^+-K^+-$2Cl^-$ cotransport and apical K^+ channels, along with basolateral depolarization due to Cl^- exit through Cl^- channels, results in the lumen-positive transepithelial PD.[42]

Several lines of evidence indicate that apical K^+ channels are required for transepithelial Na^+-Cl^- transport by the TAL.[42] First, the removal of K^+ from luminal perfusates results in a marked decrease in Na^+-Cl^- reabsorption by the TAL, as measured by a short circuit current; the residual Na^+-Cl^- transport in the absence of luminal K^+ is sustained by the exit of K^+ via apical K^+ channels, because the combination of K^+ removal and a luminal K^+ channel inhibitor (barium) almost abolishes the short-circuit current.[44] Apical K^+ channels are thus required for the activity of NKCC2, the apical Na^+-K^+-$2Cl^-$ cotransporter; the low luminal concentration of K^+ in this nephron segment would otherwise become limiting for transepithelial Na^+-Cl^- transport. Second, the net transport of K^+ across perfused TAL is $<$10% that of Na^+ and Cl^-[33]; ~90% of the K^+ transported by NKCC2 is recycled across the apical membrane via K^+ channels, resulting in minimal net K^+ absorption by the TAL.[42] Third, the intracellular K^+ activity of perfused TAL cells is ~15 to 20 mV above equilibrium, due to furosemide-sensitive entry of K^+ via NKCC2.[45] Given an estimated apical K^+ conductivity of ~12 m per square centimeter, this intracellular K^+ activity yields a calculated K^+ current of ~200 μA per square centimeter; this corresponds quantitatively to the uptake of K^+ by the apical Na^+-K^+-$2Cl^-$ cotransporter. Finally, the observation that Bartter syndrome can be caused by mutations in ROMK (renal outer medullary K^+ channel),[46] a critical component of apical K^+ channels in the TAL (see the following), provides genetic proof for the importance of K^+ channels in Na^+-Cl^- absorption by the TAL. Clearance studies in ROMK-deficient mice also indicate that ~80% of NKCC2 activity is dependent on expression of the ROMK K^+ channel with the TAL.[47]

Three types of apical K^+ channels have been identified in the TAL, a 30 pS channel, a 70 pS channel, and a high-conductance, calcium-activated maxi K^+ channel.[48–50] The higher open probability and greater density of the 30 pS and 70 pS channels, versus the maxi K^+ channel, suggest that these are the primary routes for K^+ recycling across the apical membrane; the 70 pS channel in turn appears to mediate ~80% of the apical K^+ conductance of TAL cells.[51] The low conductance 30 pS channel shares several electrophysiologic and regulatory characteristics with ROMK, the cardinal inward-rectifying K^+ channel (KIR 1.1) that was initially cloned from the renal outer medulla.[52,53] ROMK protein has been identified at the apical membrane of the medullary TAL, the cortical TAL, and the macula densa.[54] Furthermore, the 30 pS channel is also absent from the apical membrane of knockout mice with a homozygous deletion of the gene encoding ROMK.[55] Notably, not all cells in the TAL are labeled with anti-ROMK antibodies,[54,56] suggesting that ROMK might be absent in the HBC cells with high basolateral Cl^- conductance and low apical/high basolateral K^+ conductance (see also previous).[39,41] HBC cells are thought to correspond to the smooth-surfaced morphologic subtype of TAL cells (S cells)[39]; however, distribution of the ROMK protein by immunoelectron microscopy has not as yet been published, hence correlation cannot be made as of yet between morphology and ROMK expression.

Alternative splicing and alternative promoter use of the KCNJ1 gene encoding ROMK/KIR1.1 generates three different protein isoforms, differing in the extreme aminoterminal amino acid sequence: ROMK1, ROMK2, and ROMK3.[57] Although the functional significance of this variation is not clear, these isoforms are differentially distributed along the nephron. ROMK1 is exclusive to the CNT, CCD, and OMCD; ROMK2 is expressed from the TAL to the CCD; and ROMK3 is expressed in the TAL and the distal convoluted tubule (DCT).[57] Apical ROMK channels in the TAL are thus a mixture of ROMK2 and ROMK3 proteins.

ROMK clearly plays a critical role in Na^+-Cl^- absorption by the TAL, given that loss-of-function mutations in this gene are associated with Bartter syndrome.[46] The role of ROMK in Bartter syndrome was initially discordant with the data indicating that the 70 pS K^+ channel is the dominant conductance at the apical membrane of TAL cells[51]; heterologous expression of the ROMK protein in *Xenopus* oocytes had yielded a channel with a conductance of ~30 pS, suggesting that the 70 pS channel was distinct from ROMK. This paradox was resolved by the observation that the 70 pS channel is absent from the TAL of ROMK knockout mice, indicating that ROMK proteins form a subunit of the 70 pS channel.[58] ROMK activity in the TAL is clearly modulated by association with other proteins. That coassociation with other subunits generates the 70 pS channel and is perfectly compatible with

the known physiology of this channel protein. ROMK thus associates with scaffolding proteins NHERF-1 and NHERF-2 via the C-terminal PDZ-binding motif of ROMK; NHERF-2 is coexpressed with ROMK in the TAL.[59] The association of ROMK with NHERFs brings ROMK into closer proximity to the cystic fibrosis transmembrane regulator (CFTR) protein.[59] This ROMK-CFTR interaction is in turn required for reconstitution of the native ATP and glibenclamide sensitivity of apical K^+ channels in the TAL.[60]

TAL cells are phenotypically defined by the apical expression of uromodulin or Tamm-Horsfall glycoprotein (THP), a TAL-specific, GPI-linked membrane protein that is shed into the tubular lumen as the most abundant protein in normal human urine. THP interacts with ROMK protein in yeast two-hybrid screens and activates the channel in coexpression experiments.[61] THP also exhibits functional interactions with NKCC2, activating the cotransporter in coexpression experiments.[62] Membrane trafficking of both ROMK and NKCC2 proteins is affected in THP knockout mice, with greater accumulation of both transport proteins in subapical vesicles. THP knockout mice also exhibit a blunted natriuretic and kaliuretic response to furosemide, which is consistent with a partial deficiency in TAL function.[62] Mutations of the THP gene cause the allelic disorders familial juvenile hyperuricemic nephropathy, medullary cystic kidney disease type II, and glomerulocystic kidney disease. All three disorders share reduced expression of THP at the apical membrane with retention in the endoplasmic reticulum. The associated defects in NKCC2 and ROMK may explain the renal salt wasting and hyperuricemia that can be associated with these genetic disorders.[61,62]

Potassium Secretion by the Distal Convoluted Tubule, Connecting Tubule, and Cortical Collecting Duct

Approximately 90% of filtered K^+ is reabsorbed by the proximal tubule and the loop of Henle (Fig. 6.1); the final adjustments in renal K^+ excretion occur in the downstream distal nephron. The bulk of regulated secretion occurs in the CNT and CCD, whereas K^+ reabsorption primarily occurs in the OMCD (see the following). K^+ secretion is initially detectable in the early DCT, wherein cells expressing the thiazide-sensitive Na^+-Cl^- cotransporter (NCC) express ROMK, the apical K^+ secretory channel (see the following).[54] More recent studies in rat kidneys have localized the protein to both DCT1 and DCT2 segments.[56] Classically, the CCD is considered the primary site for distal K^+ secretion, largely due to the greater ease with which this segment can be perfused and studied. However, as in Na^+ absorption (see below),[63,64] the bulk of distal K^+ secretion appears to occur prior to the CCD,[22] within the CNT.[65] In addition to a lesser endowment with absorptive apical epithelial Na^+ channels (ENaC) and secretory K^+ channels, water absorption in the vasopressin-responsive CCD limits K^+ secretion by allowing the concentration of luminal K^+ to rise toward equilibrium.[66] Water permeability of the CNT is considerably lower than that of the CCD,[66] with a significant number of early (CNT1) CNT cells that do not express aquaporin-2 in the absence of vasopressin. Aquaporin-2 expression is also low or undetectable in CNT1 cells on a high K^+ diet,[56] further optimizing these early CNT segments for K^+ secretion.

The apical membrane of CNT cells and principal cells contain prominent Na^+ and K^+ conductances,[63,65,67] without a measurable apical conductance for Cl^-.[68] The entry of Na^+ occurs via the highly selective ENaC, which is sensitive to micromolar concentrations of amiloride (Fig. 6.4). This selective absorption of a positive charge generates a lumen-negative PD, the magnitude of which varies considerably as a function of mineralocorticoid status and other factors. This lumen-negative PD serves to drive the following critical processes: (1) K^+ secretion via apical K^+ channels, (2) paracellular Cl^- transport through the adjacent tight junctions, and (3) electrogenic H^+ secretion via adjacent type A intercalated cells.

The three ENaC subunits are detectable at the apical membrane of CNT cells and principal cells within the CCD, OMCD, and IMCD. Notably, however, several lines of evidence support the hypothesis that the CNT makes the

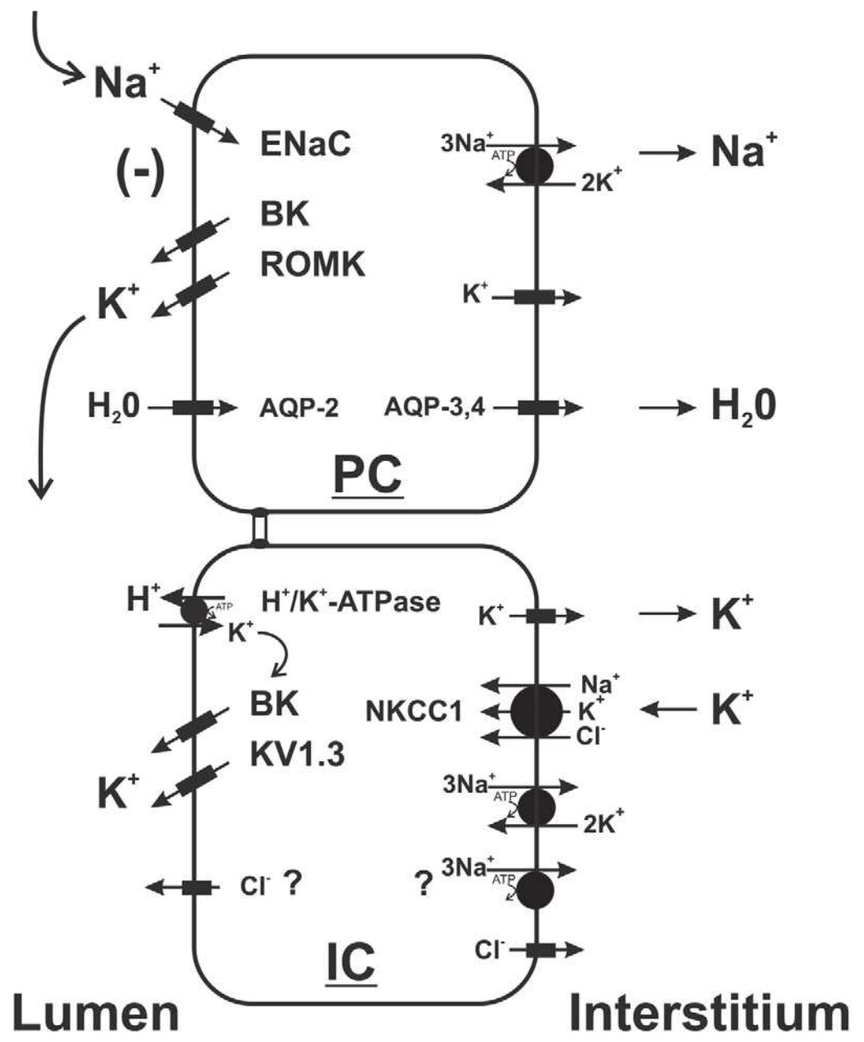

FIGURE 6.4 The transport pathways for potassium in principal/connecting tubule (CNT) cells and intercalated cells. Potassium secretion occurs in CNT and principal cells, driven by the lumen-negative potential difference generated by the epithelial Na^+ channel (ENaC). In intercalated cells, potassium reabsorbed by apical H^+/K^+-ATPase recycles across the apical membrane via K^+ channels; alternatively, in the setting of hypokalemia or potassium deprivation, it exits the cell via basolateral K^+ channels. Potassium that is secreted across intercalated cells enters at the basolateral membrane via NKCC1 and exits via apical BK and Kv1.3 K^+ channels. *BK*, BK K^+ channel; *ROMK*, renal outer medullary K^+ channel; *Kv1.3*, Kv1.3 K^+ channel; *NKCC1*, Na^+-K^+-$2Cl^-$ cotransporter 1.

dominant contribution to amiloride-sensitive Na^+ reabsorption by the distal nephron. First, amiloride-sensitive Na^+ currents in the CNT are two- to fourfold higher than in the CCD; the maximal capacity of the CNT for Na^+ reabsorption is estimated to be ~10 times higher than that of the CCD.[63] Second, targeted deletion of α-ENaC in the collecting duct abolishes amiloride-sensitive currents in CCD principal cells, but does not affect Na^+ or K^+ homeostasis. Thus, the residual ENaC expression in the late DCT and CNT of these knockout mice easily compensates for the loss of the channel in CCD.[69] In contrast, the more extensive deletion of α-ENaC in all aquaporin-2–positive cells in both CNT and CCD causes a profound impairment in Na^+ and K^+ homeostasis.[64] Third, Na^+/K^+–ATPase activity in the CCD is considerably less than that of the DCT[70]; this speaks to a greater capacity for transepithelial Na^+-Cl^- absorption by the DCT and CNT. Fourth, the apical recruitment of ENaC subunits in response to dietary Na^+ restriction begins in the CNT, with progressive recruitment of subunits in the downstream CCD at lower levels of dietary Na^+[71]; under conditions of high Na^+-Cl^- and low K^+ intake, the bulk of aldosterone-stimulated Na^+ transport likely occurs prior to the entry of tubular fluid into the CCD.

In principal cells and CNT cells, the lumen-negative potential difference generated by Na^+ entry via ENaC drives passive K^+ exit through apical K^+ channels. Although there is evolving evidence for ENaC− and Na^+-independent secretion (see also the following),[72] distal K^+ secretion is critically dependent on delivery of adequate luminal Na^+ to the CNT and CCD,[73] essentially ceasing when luminal Na^+ drops below 8 mmol/L.[74] Dietary Na^+ intake also influences K^+ excretion, such that excretion is enhanced by excess Na^+ intake and reduced by Na^+ restriction.[73] Secreted K^+ enters principal cells via the basolateral Na^+/K^+–ATPase, which also generates the gradient that drives apical Na^+ entry via ENaC (Fig. 6.4).

Two major subtypes of apical K^+ channels function in secretion by the CNT and CCD, +/– DCT; a small-conductance (SK) 30 pS channel[55,65] and a large-conductance, Ca^{2+}-activated 150 pS ("maxi-K" or BK) channel.[65,75] The density and high open probability of the SK channel indicates that this pathway alone is sufficient to mediate the bulk of K^+ secretion in the CCD under baseline conditions,[76] hence its designation as the "secretory" K^+ channel. Notably, SK channel density is considerably higher in the CNT than in the CCD,[65] consistent with the greater capacity for Na^+ absorption[63] and K^+ secretion in the CNT. The characteristics of the SK channel are similar to those of the ROMK K^+ channel,[53] and ROMK protein has been localized at the apical membrane of principal cells.[54] SK channel activity is absent from apical membranes of the CCD in homozygous ROMK knockout mice, definitive proof that ROMK is the SK channel.[55] The observation that these knockout mice are normokalemic with an increased excretion of K^+ illustrates the considerable redundancy in distal K^+ secretory pathways[55]; distal K^+ secretion in these mice is mediated by apical BK channels (see the following).[77] Loss-of-function mutations in human KCNJ1 are associated with Bartter syndrome; ROMK expression is critical for the 30 pS and 70 pS channels that generate the lumen-positive PD in the TAL (see Fig. 6.3).[55,58] These patients typically have slightly higher serum K^+ than the other genetic forms of Bartter syndrome,[46] and affected patients with severe neonatal hyperkalemia have also been described; this neonatal hyperkalemia is presumably the result of a transient developmental deficit in apical BK channel activity (see the following).

The apical Ca^{2+}-activated BK channel plays a critical role in *flow*-dependent K^+ secretion by the CNT and CCD.[75] BK channels have a heteromeric structure, with α-subunits that form the ion channel pore and modulatory β-subunits that affect the biophysical, regulatory, and pharmacologic characteristics of the channel complex.[75] BK α-subunit transcripts are expressed in multiple nephron segments, and channel protein is detectable at the apical membrane of principal and intercalated cells in the CCD and CNT.[75] The β subunits are differentially expressed within the distal nephron. Thus β1 subunits are restricted to the CNT,[75] with no expression in intercalated cells,[78] whereas β4 subunits are detectable at the apical membranes of TAL, DCT, and intercalated cells.[78] Increased distal flow has a well-established stimulatory effect on K^+ secretion, due in part to both the enhanced delivery and absorption of Na^+ and to the increased removal of secreted K^+.[73] The pharmacology of flow-dependent K^+ secretion in the CCD is consistent with BK channels,[79] and flow-dependent K^+ secretion is reduced in mice with targeted deletion of the α1 and β1 subunits.[75,80,81] Both mice strains develop hyperaldosteronism that is exacerbated by high-K^+ diet,[81] leading to hypertension in the α1 subunit knockout.[81]

One enigma has been the greater density of BK channels in intercalated cells, in both the CCD[82] and the CNT.[83] This has suggested a major role for intercalated cells in K^+ secretion; however, the much lower density of Na^+/K^+–ATPase activity in intercalated cells has been considered inadequate to support K^+ secretion across the apical membrane.[84] More recent evidence reveals a major role for the basolateral Na^+-K^+-$2Cl^-$ cotransporter NKCC1 in K^+ secretion mediated by apical BK channels (see also Fig. 6.4)[85]; NKCC1 is expressed almost exclusively at the basolateral membrane of intercalated cells,[86] providing an alternative entry pathway for basolateral K^+ secreted at the apical membrane. This still begs the question of how basolateral Na^+ recycles across the basolateral membrane, in the absence of significant Na^+/K^+–ATPase activity; one possibility is an alternative basolateral Na^+ pump, the ouabain-insensitive furosemide-sensitive Na^+–ATPase, a transport activity that has been detected in cell culture models of intercalated cells.[85] At the apical membrane, BK-mediated K^+ secretion is only partially dependent on luminal Na^+[87]; K^+ secretion would eventually hyperpolarize the membrane in the absence of apical Na^+ entry, which is mediated by ENaC in principal cells. An intriguing possibility is that apical Cl^- channels[88] allow for a parallel secretion of K^+ and Cl^- in intercalated cells (see Fig. 6.4).

BK channels also play a critical role in cell volume regulation by intercalated cells, with indirect, flow-mediated influences on distal K^+ secretion. MDCK-C11 cells have an intercalated cell phenotype and express BK α and β4 subunits, as do intercalated cells[78]; shear stress activates BK channels in these cells, leading to a loss of K^+ and cell shrinkage.[89] Mice with a targeted deletion of the β4 subunit exhibit normal K^+ excretion on a normal diet.[84] However, when fed a high K^+ diet, which increases urinary and tubular flow rates and tubular shear stress, the β4-knockout mice develop hyperkalemia with a blunted increase in both K^+ excretion and urinary flow rates. Intercalated cells from β4 knockout may fail to significantly decrease cell volume in response to a high K^+ diet. Intercalated cells thus function as "speed bumps" that protrude into the lumen of distal tubules; flow-activated BK channels reduce the cell volume of intercalated cells after K^+ loading, reducing tubular resistance, increasing tubular flow rates, and increasing distal K^+ secretion.[84]

The physiologic rationale for the presence of two apical secretory K^+ channels—ROMK/SK and BK channels—is not completely clear. However, the high density and higher open probability of SK/ROMK channels is perhaps better suited for a role in basal K^+ secretion, with additional recruitment of the higher capacity, flow-activated BK channels when additional K^+ secretion is required.[75] The evolving evidence also indicates that BK channels function in partially Na^+-independent K^+ secretion by intercalated cells, with ROMK functioning in ENaC- and Na^+-dependent K^+ excretion by DCT, CNT, and CCD cells. Regardless, at the whole organ level, the two K^+ channels can substitute for one another, with BK-dependent K^+ secretion in ROMK knockout mice[77] and an upregulation of ROMK in the distal nephron of α1 subunit BK knockout mice.[80]

Other K^+ channels reportedly expressed at the luminal membranes of the CNT and CCD include voltage-sensitive channels such as Kv1.3,[90] double-pore K^+ channels such as TWIK-1,[91] and KCNQ1.[92] KCNQ1 mediates K^+ secretion in the inner ear and is expressed at the apical membrane of principal cells in the CCD,[92] whereas TWIK-1 is expressed at the apical membrane of intercalated cells.[91] The roles of these channels in renal K^+ secretion or absorption are not fully characterized. However, Kv1.3 may play a role in distal K^+ secretion by intercalated cells (see Fig. 6.4) in that luminal margatoxin, a specific blocker of this channel, reduces K^+ secretion in CCDs of rat kidneys from animals on a high K^+ diet (see also previous).[90] Other apical K^+ channels in the distal nephron subserve other physiologic functions. For example, the apical Kv1.1 channel is critically involved in Mg^{2+} transport by the DCT, likely by hyperpolarizing the apical membrane and increasing the driving force for Mg^{2+} influx via transient receptor potential cation channel 6 (TRPM6); missense mutations in Kv1.1 are a cause of genetic hypomagnesemia.[93]

K^+ channels present at the basolateral membrane of principal cells set the resting potential of the basolateral membrane and function in K^+ secretion and Na^+ absorption at the apical membrane, the latter via K^+ recycling at the basolateral membrane to maintain activity of the Na^+/K^+–ATPase. A variety of different K^+ channels have been described in the electrophysiologic characterization of the basolateral membrane of principal cells, which has a number of technical barriers (reviewed by Gray et al.[94]). However, a single predominant activity can be identified in principal cells from the rat CCD, using whole-cell recording techniques under conditions in which ROMK is inhibited (low intracellular pH or the presence of the ROMK inhibitor tertiapin-Q).[94] This basolateral current is tetraethylammonium (TEA) insensitive, barium sensitive, and acid sensitive (pKa ~6.5), with a conductance of ~17 pS and weak inward rectification. These properties do not correspond exactly to specific characterized K^+ channels, or combinations thereof. However, candidate inward-rectifying K^+ channel subunits that have been localized at the basolateral membrane of the CCD include KIR4.1, KIR5.1, KIR7.1, and KIR2.3.[94] A more recent report suggests that KIR4.1/KIR5.1 channels generate a predominant 40 pS basolateral K^+ channel in murine principal cells.[95] Notably, basolateral K^+ channel activity increases on a high K^+ diet, suggesting a role in transepithelial K^+ secretion.[94]

Similar K^+ channels are found at the basolateral membrane of DCT cells. Cell-attached patches in the basolateral membranes of microdissected DCTs detect an inward rectifying K^+ channel with characteristics similar to heteromeric KIR4.1/KIR5.1 and KIR4.2/KIR5.1 channels.[96] Basolateral membranes of the DCT express immunoreactive KIR4.1[97] and KIR5.1[98] proteins, and DCT cells express KIR4.2 mRNA.[96] Patients with loss-of-function mutations in the KCNJ10 gene that encodes KIR4.1 develop a syndrome of epilepsy, ataxia, sensorineural deafness, and renal tubulopathy.[97,99] The tubulopathy phenotype encompasses hypokalemia, metabolic alkalosis, hypocalciuria, and hypomagnesemia[97,99]; KIR4.1 knockout mice demonstrate a greater natriuresis than littermate controls, in addition to hypocalciuria.[97] As in principal cells, KIR4.1/KIR5.1 and KIR4.2/KIR5.1 channels at the basolateral membrane of DCT cells are hypothesized to function in basolateral K^+ recycling, maintaining adequate Na^+/K^+–ATPase activity for Na^+-Cl^- absorption and other aspects of DCT function.

In addition to apical K^+ channels, considerable evidence implicates apical K^+-Cl^- cotransport (or functionally equivalent pathways)[100] in distal K^+ secretion.[101] In perfused rat distal tubules, a reduction in luminal Cl^- markedly increases K^+ secretion[102]; the replacement of luminal Cl^- with SO_4^- or gluconate has an equivalent stimulatory effect on K^+ secretion. This anion-dependent component of K^+ secretion is not influenced by luminal Ba^{2+},[102] suggesting that it does not involve apical K^+ channel activity. Perfused surface distal tubules are a mixture of the DCT, the connecting segment, and the initial collecting duct; however, Cl^--coupled K^+ secretion is detectable in both the DCT and in the early CNT.[103] In addition, similar pathways are detectable in rabbit CCD, where a decrease in luminal Cl^- from 112 mmol per liter to 5 mmol per liter increases

K^+ secretion by 48%.[104] A reduction in basolateral Cl^- also decreases K^+ secretion without an effect on transepithelial voltage or Na^+ transport, and the direction of K^+ flux can be reversed by a lumen-to-bath Cl^- gradient, resulting in K^+ absorption.[104] In perfused CCDs from rats treated with a mineralocorticoid, vasopressin increases K^+ secretion.[105] Because this increase in K^+ secretion is resistant to luminal Ba^{2+} (2 mmol per liter), vasopressin may stimulate Cl^--dependent K^+ secretion.[106] Recent pharmacologic studies of perfused tubules are consistent with K^+-Cl^- cotransport mediated by the KCCs[101]; however, of the three renal KCCs, only KCC1 is apically expressed in the distal nephron. Other functional possibilities for Cl^--dependent K^+ secretion include the parallel operation of apical H^+-K^+-exchange and Cl^--HCO_3^- exchange in type B intercalated cells[100] and parallel K^+ and Cl^- channels in type A intercalated cells (see Fig. 6.4).[88]

A provocative study by Frindt and Palmer[72] underscores the importance of ENaC-independent K^+ excretion, be it mediated by apical K^+-Cl^- cotransport and/or by other mechanisms (see also Integrated Regulation of Distal Sodium and Potassium Transport). Rats were infused with amiloride via osmotic minipumps, generating urinary concentrations considered sufficient to inhibit >98% of ENaC activity. Whereas amiloride almost abolished K^+ excretion in rats on a normal K^+ intake, acute and long-term high K^+ diets led to an increasing fraction of K^+ excretion that was independent of ENaC activity (~50% after 7 to 9 days on a high K^+ diet).

Potassium Reabsorption by the Collecting Duct

In addition to K^+ secretion, the distal nephron is capable of considerable K^+ reabsorption, primarily during the restriction of dietary K^+.[22,107,108] This reabsorption is accomplished in large part by intercalated cells in the OMCD, via the activity of apical H^+/K^+–ATPase pumps. Under K^+-replete conditions, apical H^+/K^+–ATPase activity recycles K^+ with an apical K^+ channel, without effect on transepithelial K^+ absorption (see Figure 6.4). Under K^+-restricted conditions, K^+ absorbed via apical H^+/K^+–ATPase appears to exit intercalated cells via a basolateral K^+ channel, thus achieving the transepithelial transport of K^+.[109]

H^+-K^+–ATPase holoenzymes are members of the P-type family of ion transport ATPases, which also includes subunits of the basolateral Na^+-K^+–ATPase.[110] HKα-1 and HKα-2 are also referred to as the gastric and colonic subunits, respectively. A specific HKβ subunit interacts with the HKα subunits to ensure delivery to the cell surface and a complete expression of H^+-K^+–ATPase activity; HKα-2 subunits are also capable of interaction with Na^+-K^+–ATPase β subunits. The pharmacology of H^+-K^+–ATPase holoenzymes differs considerably, such that the gastric HKα-1 is classically sensitive to the H^+-K^+–ATPase inhibitors SCH-28080 and omeprazole and is resistant to ouabain; the colonic HKα-2 subunit is usually sensitive to ouabain and resistant to SCH-28080.[110] Within the kidney, the HKα-1 subunit is expressed at the apical membrane of at least a subset of type A intercalated cells in the distal nephron.[111] HKα-2 distribution in the distal nephron is more diffuse, with robust expression at the apical membrane of type A and B intercalated cells and connecting segment cells, and a lesser expression in principal cells.[112]

HKα-1 and HKα-2 are both constitutively expressed in the distal nephron. However, tubule perfusion of K^+-replete animals suggests a functional dominance of omeprazole/SCH-28080-sensitive, ouabain-resistant H^+-K^+–ATPase activity that is consistent with holoenzymes containing HKα-1.[113] K^+ deprivation increases the overall activity of H^+-K^+–ATPase in the collecting duct, with the emergence of a ouabain-sensitive H^+-K^+–ATPase activity.[114] This is consistent with a relative dominance of HKα-2 during K^+-restricted conditions. Consistent with this pharmacology, K^+-restriction also induces a dramatic upregulation of HKα-2 transcript and protein in the outer and inner medulla during K^+ depletion; HKα-1 expression is unaffected.[115,116] Mice with a targeted deletion of HKα-2 exhibit lower plasma and muscle K^+ than wild-type littermates when maintained on a K^+-deficient diet. However, this appears to be due to a marked loss of K^+ in the colon rather than the kidney, because renal K^+ excretion is appropriately reduced in the K^+-depleted knockout mice.[110] Presumably, the lack of an obvious renal phenotype in either HKα-1[110] or HKα-2[110] knockout mice reflects the marked redundancy in the expression of HKα subunits in the distal nephron. Indeed, collecting ducts from the HKα-1 knockout mice have significant residual ouabain-resistant and SCH-28080-sensitive H^+-K^+–ATPase activities, consistent with the expression of other HKα subunits that confer characteristics similar to the "gastric" H^+-K^+–ATPase.[110] However, data from HKα-1 and HKα-2 knockout mice suggest that compensatory mechanisms in these mice are not accounted for by ATPase-type mechanisms.[117]

The importance of K^+ reabsorption mediated by the collecting duct is dramatically illustrated by the phenotype of transgenic mice with generalized overexpression of a gain-of-function mutation in H^+-K^+–ATPase; this effectively bypasses the redundancy and complexity of this reabsorptive pathway. This mutant HKβ subunit has a tyrosine-to-alanine mutation within the C-terminal tail that abrogates regulated endocytosis from the plasma membrane; these mice have higher plasma K^+ than their wild-type littermates, with approximately half the fractional excretion of K^+.[118]

Finally, it should be noted that considerable evidence implicates the H^+-K^+–ATPases in renal acid secretion.[110] In particular, acid extrusion from intercalated cells is markedly reduced in doubly deficient HKα-1/HKα-2 knockout mice.[110] In addition, the H^+-K^+–ATPases may function directly in Na^+ balance, collaborating, for example, with apical Cl^-:HCO_3^- exchangers in the CCD in apical Na^+-Cl^- uptake.[110]

The Regulation of Distal Tubular Potassium Transport

Modulation of ROMK Activity

ROMK and other KIR channels are inward rectifying (i.e., K^+ flows inward more readily than outward). Even though outward conductance is usually less than inward conductance, K^+ efflux through ROMK predominates in the CNT and CCD because the membrane potential is more positive than the equilibrium potential for K^+. Intracellular magnesium (Mg^{2+})[119] and polyamines[120] play key roles in inward rectification, binding and blocking the pore of the channel from the cytoplasmic side.[121] A single transmembrane residue, asparagine-171 in ROMK1, controls the affinity and the blocking effect of both Mg^{2+} and polyamines.[119,120] Intracellular Mg^{2+} in TAL, DCT, CNT, and principal cells is thought to have a significant effect on ROMK activity, because it inhibits outward ROMK-dependent currents in principal cells.[122] The blocking affinity of Mg^{2+} is enhanced at lower extracellular K^+ concentrations,[122] which should aid in reducing K^+ secretion during hypokalemia and K^+ deficiency. A reduction of this intracellular Mg^{2+} block may also explain the hypokalemia associated with hypomagnesemia, wherein distal K^+ secretion is enhanced.[121]

In addition to inward rectification, the endogenous ROMK channels in the TAL and principal cells exhibit a very high channel open probability (P_o). The high P_o of ROMK is maintained by the combined effects of the binding of phosphatidylinositol-4,5-bisphosphate (PIP_2) to the channel protein, direct channel phosphorylation by protein kinase A (PKA), ATP binding to the ROMK-CFTR complex, and cytoplasmic pH. PIP2 binding to ROMK is thus required to maintain the channel in an open state,[123] whereas cytoplasmic acidification inhibits the channel. PKA phosphorylates ROMK protein at one N-terminal serine and two C-terminal serines[124]: S25, S200, and S294 in the ROMK2 isoform. Phosphorylation of all three sites is required for full channel function. The phosphorylation of the N-terminal site overrides the effect of a carboxy-terminal endoplasmic reticulum retention signal, thus increasing the expression of the channel protein at the cell membrane.[125] The phosphorylation of S200 and S294 maintains the channel in a high P_o state, in part by modulating the effects of PIP_2,[126] ATP,[60] and pH.[127]

Because ROMK channels exhibit such a high P_o, the physiologic regulation of the channel is primarily achieved by regulated changes in the number of active channels on the plasma membrane. The associated mechanisms are discussed in the context of the adaptation to K^+ loading/hyperkalemia and K^+ deprivation/hypokalemia.

Aldosterone and Potassium Secretion

Aldosterone has a potent kaliuretic effect,[128] with important interrelationships between circulating K^+ and aldosterone. Aldosterone release by the adrenal is thus induced by hyperkalemia and/or a high K^+ diet,[129] suggesting an important feedback effect of aldosterone on K^+ homeostasis.[130] Aldosterone also has clinically relevant effects on K^+ homeostasis, with a clear relationship at all levels of serum K^+between circulating levels of the hormone and the ability to excrete K^+.

Renin released from the kidney stimulates aldosterone release from the adrenal via angiotensin-II (AT-II). Renin secretion by juxtaglomerular cells within the afferent arteriole is initiated in response to a signal from the macula densa, specifically a decrease in luminal chloride transported through the Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) at the apical membrane of macula densa cells.[6] In addition to this macula densa signal, decreased renal perfusion pressure and renal sympathetic tone stimulate renal renin secretion.

Hyperkalemia is also an independent and synergistic stimulus for aldosterone release from the adrenal gland,[129] although dietary K^+ loading is less potent than dietary Na^+-Cl^- restriction in increasing circulating aldosterone.[130] The resting membrane potential of adrenal glomerulosa cells is hyperpolarized due to the activity of the "leak" K^+ channels TASK-1 and TASK-3; the combined deletion of genes encoding these channels leads to baseline depolarization of adrenal glomerulosa cells and an increase in plasma aldosterone that is resistant to dietary sodium loading.[20] The KCNJ5 K^+ channel also plays a role, in that mutations that produce a depolarizing acquisition of KCNJ5-mediated Na^+ conductance are associated with adrenal adenomas.[21] AT-II and K^+ both activate Ca^{2+} entry in glomerulosa cells via voltage-sensitive T-type Ca^{2+} channels, primarily Cav3.2.[131] Elevations in extracellular K^+ thus depolarize glomerulosa cells and activate these Ca^{2+} channels, which are independently and synergistically activated by AT-II. The calcium-dependent activation of calcium-calmodulin (CaM)-dependent protein kinase, in turn, activates the synthesis and release of aldosterone via the induction of aldosterone synthase. K^+ and AT-II also enhance the transcription of the Cav3.2 Ca^{2+} channel by abrogating repression of this gene by the neuron restrictive silencing factor (NRS); this ultimately amplifies the induction of aldosterone synthase.[131]

The adrenal release of aldosterone due to increased K^+ is dependent on an intact adrenal renin–angiotensin system, particularly during Na^+-Cl^- restriction. Angiotensin converting enzyme (ACE) inhibitors and angiotensin–receptor blockers (ARBs) completely abrogate the effect of high K^+ on salt-restricted adrenals.[132] Direct, G protein–dependent activation of the TASK-1 and/or TASK-3 K^+ channels by AT_{1A} or AT_{1B} receptors is thought to underlie the effect of AT-II on adrenal aldosterone release,[20] with abrogation of this effect by ARBs or ACE inhibitors. Other clinically relevant activators of adrenal aldosterone release include prostaglandins and catecholamines via increases in cAMP.[133] Finally, atrial natriuretic peptide (ANP) exerts a potent negative effect on aldosterone release induced by K^+ and other stimuli,[134] at least in part by inhibiting early events in aldosterone synthesis.[135] ANP inhibits both renal renin release and adrenal aldosterone release, functions that may be central to the roles of this hormone in the pathophysiology of hyporeninemic hypoaldosteronism.[134]

Within the kidney, aldosterone has no effect on the density of apical SK channels in the CCD[136]; it does however induce a marked increase in the density of apical Na^+ channels in the CNT and CCD.[136] Aldosterone activates ENaC via interrelated effects on the transcription, synthesis, trafficking, and membrane-associated activity of the subunits encoding the channel. Aldosterone is thus induced by a high K^+ diet and strongly stimulates apical ENaC activity, which generates the lumen-negative PD that stimulates K^+ secretion by principal cells. The hormone also has significant effects on the basolateral membrane of principal cells, with dramatic changes in cellular morphology and the length of basolateral membranes.[137] This is accompanied by an increase in basolateral Na^+-K^+–ATPase activity, although it has been difficult to determine how much of these cellular and functional changes are due to enhanced Na^+ entry via apical ENaC. It is, however, known that aldosterone increases the expression of the Na^+-K^+–ATPase α1 and β1 subunits in the CCD[138]; these effects are evidently independent of ENaC activity.[139]

Transcriptional effects of aldosterone also include the induction of the α-ENaC subunit via a glucocorticoid-response element in the promoter of the SCNN1A gene. Aldosterone also relieves a tonic inhibition of the SCNN1A gene by a complex that includes the Dot1a (disruptor of telomere silencing splicing variant a) and the AF9 and AF17 transcription factors.[140] This transcriptional activation results in an increased abundance of α-ENaC protein in response to either exogenous aldosterone or dietary Na^+-Cl^- restriction[141]; the response to Na^+-Cl^- restriction is blunted by spironolactone, indicating involvement of the mineralocorticoid receptor. At the baseline, α-ENaC transcripts in the kidney are less abundant than those encoding β- and γ-ENaC. All three subunits are required for the efficient processing of heteromeric channels in the endoplasmic reticulum and trafficking to the plasma membrane, such that the induction of α-ENaC is thought to relieve a major bottleneck in the processing and trafficking of active ENaC complexes.[142]

Aldosterone also plays an indirect role in the regulated trafficking of ENaC subunits to the plasma membrane via the regulation of accessory proteins that interact with preexisting ENaC subunits. Aldosterone rapidly induces the expression of a serine-threonine kinase denoted SGK1.[143] The coexpression of SGK1 with ENaC subunits in *Xenopus* oocytes results in a dramatic activation of the channel due to increased expression at the plasma membrane.[141] Analogous in vivo redistribution of ENaC subunits occurs in the CNT and early CCD from a largely cytoplasmic location during dietary Na^+-Cl^- excess to a purely apical distribution after aldosterone or Na^+-Cl^- restriction.[71,141] Furthermore, there is a temporal correlation between the appearance of induced SGK1 protein in the CNT and the redistribution of ENaC protein to the plasma membrane.[141] The amiloride-sensitive, lumen-negative potential difference generated by ENaC is reduced in SGK1 knockout mice,[144] resulting in a decreased driving force for distal K^+ secretion and marked susceptibility to hyperkalemia.

SGK1 modulates membrane expression of ENaC by interfering with regulated endocytosis of its channel subunits. Specifically, the kinase interferes with interactions between ENaC subunits and the ubiquitin-ligase Nedd4-2.[142] PPxY domains in the C-termini of all three ENaC subunits bind to WW domains of Nedd4-2. Coexpression of Nedd4-2 with a wild-type ENaC channel results in a marked inhibition of channel activity due to retrieval from the cell membrane; Nedd4-2 is thought to ubiquitinate ENaC subunits, resulting in the removal of channel subunits from the cell membrane and degradation in lysosomes and the proteosome.[142] A PPxY domain in SGK1 also binds to Nedd4-2, which is a phosphorylation substrate for the kinase; the phosphorylation of Nedd4-2 by SGK1 abrogates its inhibitory effect on ENaC subunits.[145,146] Aldosterone also stimulates Nedd4-2 phosphorylation in vivo[147] and Nedd4-2 phosphorylation, in turn, results in the ubiquitin-mediated degradation of SGK1.[148]

Finally, aldosterone indirectly activates ENaC channels through the induction of channel activating proteases, which increase open channel probability by the cleavage of the extracellular domain of α- and γ-ENaC. Proteases that have been implicated in the processing of ENaC include furin, elastase, plasmin, kallikrein, and three novel, membrane-associated proteases called channel activating proteases 1, 2, and 3(CAP1, 2, and 3).[149–151] Proteolytic cleavage of ENaC appears to activate the channel by removing the self-inhibitory effect of external Na^+[150]; in furin-mediated proteolysis of αENaC, this appears to involve the removal of an inhibitory domain from within the extracellular loop.[152] The structures of the extracellular domains of ENaC and the related channels resemble an outstretched hand holding a ball, with defined subdomains termed the wrist, finger, thumb, palm, β-ball, and knuckle; functionally relevant proteolytic events target the finger domains of ENaC subunits.[151] Unprocessed channels at the plasma membrane are thought to function as a reserve pool, capable of rapid activation by membrane-associated luminal proteases.[150]

Adaptation to High Potassium Intake

Much of the renal adaptation to high K^+ intake is aldosterone independent. For example, a high K^+ diet increases apical Na^+ reabsorption and K^+ secretion in the CCD in adrenalectomized animals that lack aldosterone.[153] At the tubular level, when basolateral K^+ is increased, there is a significant activation of the Na^+/K^+–ATPase, accompanied by a secondary activation of apical Na^+ and K^+ channels.[154] Increased dietary K^+ also markedly increases the density of SK channels in the CCD (Fig. 6.5), along with a modest increase in ENaC density.[136] This is associated with changes in the subcellular distribution of the ROMK protein, with an increase in apical expression.[155] Notably, this increase in ENaC and SK density in the CCD occurs within hours of assuming a high K^+ diet, with a minimal associated increase in circulating aldosterone.[156] In contrast, a week of low Na^+-Cl^- intake, with almost a 1000-fold increase in aldosterone, has

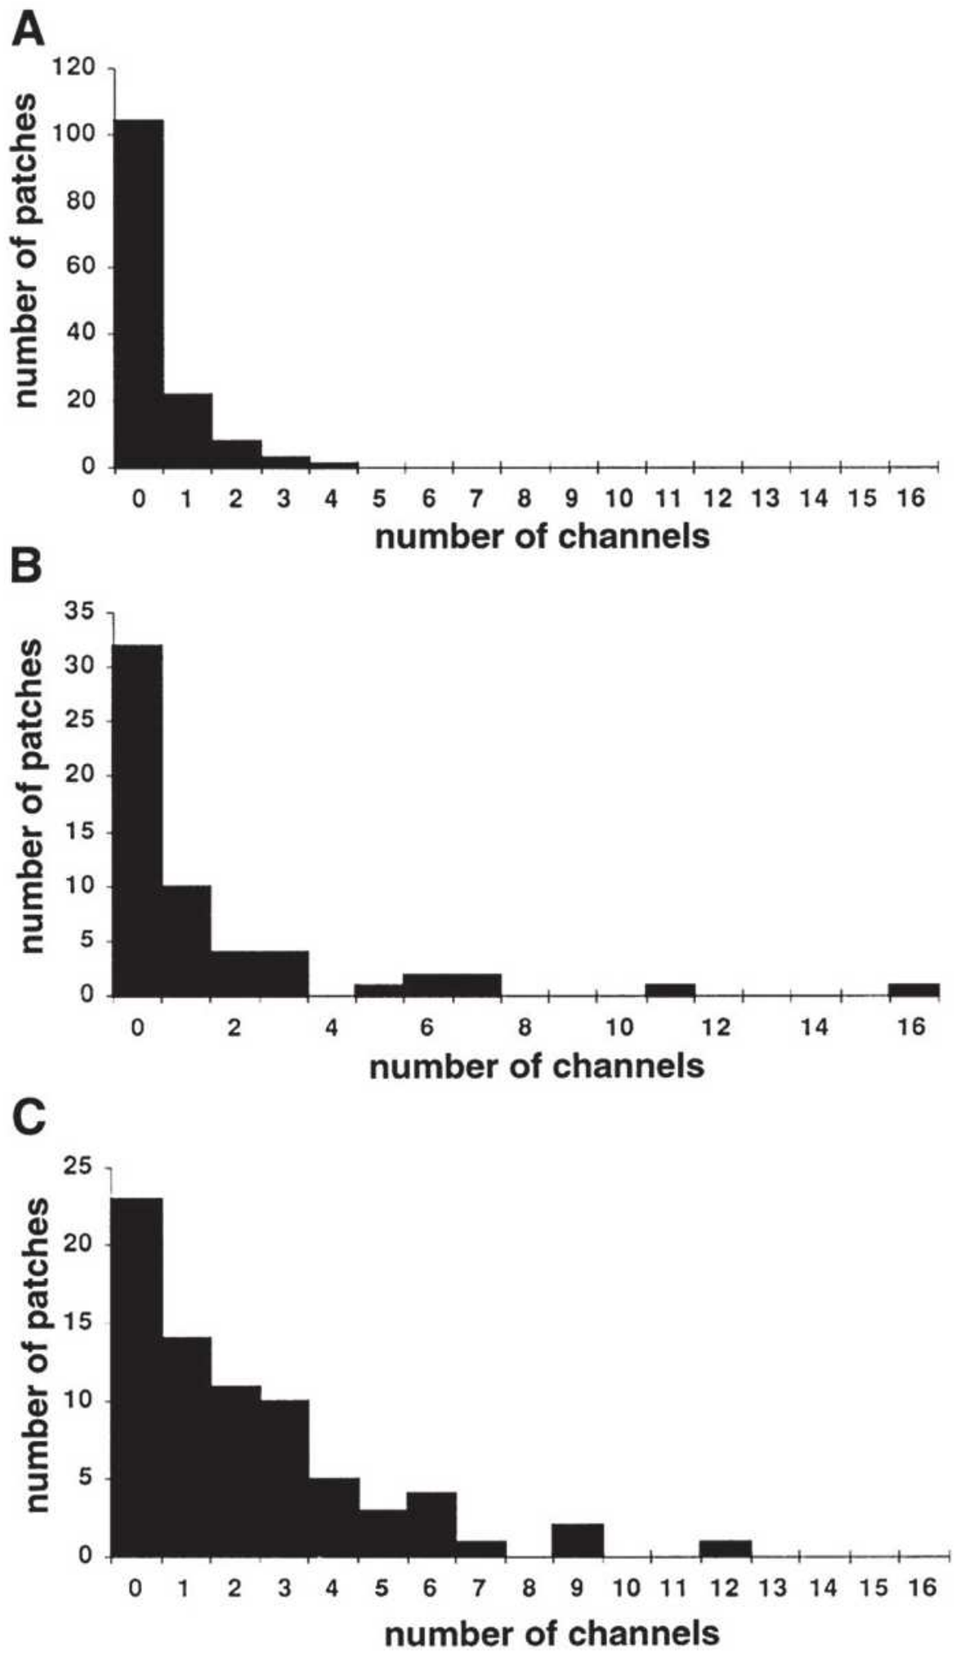

FIGURE 6.5 A high K^+ diet rapidly activates small conductance (SK) channels in the cortical collecting duct (CCD), which is mediated by the renal outer medullary K^+ channel (ROMK) (Kir 1.1) K^+ channel. Histograms of *N* (channels/patch) are shown for rats on a control diet (**A**), on a high K diet for 6 hours (**B**), and on a high K diet for 48 hours (**C**). Each determination of *N* represents a single cell-attached patch. The high K^+ diet results in a progressive recruitment of SK channels at the apical membrane. (From Palmer LG, Frindt G. Regulation of apical K channels in rat cortical collecting tubule during changes in dietary K intake. *Am J Physiol.* 1999;277:F805–812.)

no effect on SK channel density, nor for that matter does 2 days of aldosterone infusion, despite the development of hypokalemia (Table 6.1).[156] Of note, unlike the marked increase seen in the CCD,[136,156] the density of SK channels in the CNT is not increased by high dietary K^+.[65] This appears to be due to difficulties in estimating channel densities in small membrane patches, because the measurement of whole cell currents indicates an upregulation of ROMK activity in the CNT of animals maintained on a high K^+ diet.[157]

BK channels in the CNT and CCD play an important role in the flow-activated component of distal K^+ excretion[75]; these channels are also activated by dietary K^+ loading. Flow-stimulated K^+ secretion by the CCD of both mice[77] and rats[158] is enhanced on a high-K^+ diet, with an absence of flow-dependent K^+ secretion in rats on a low K^+ diet.[158] This is accompanied by commensurate changes in transcript levels for α- and β_{2-4}-subunits of the BK channel proteins in microdissected CCDs (β_1 subunits are restricted to the CNT[75]). Trafficking of BK subunits is also affected by dietary K^+, with largely intracellular distribution of α-subunits in K^+-restricted rats and prominent apical expression in K^+-loaded rats.[158] Aldosterone does not contribute to the regulation of BK channel activity or expression in response to a high K^+ diet.[159]

Regulatory information is notably more extensive for ROMK/SK channels than for BK channels. ROMK channels exhibit a high P_o; physiologic regulation of SK channels is primarily achieved by regulated changes in the number of active channels on the plasma membrane. The changes in trafficking and/or activity of the ROMK channel that are induced by dietary K^+ restriction appear to involve tyrosine phosphorylation of the ROMK protein (see the following); K^+ loading reverses this tyrosine phosphorylation. The forward trafficking of ROMK channels to the apical membrane of CNT and principal cells after K^+ loading is also phosphorylation dependent. PKA phosphorylates ROMK protein at one N-terminal serine and two C-terminal serines.[124] Phosphorylation of the N-terminal serine overrides the effect of a carboxy-terminal endoplasmic reticulum retention signal, thus inducing exit from the Golgi apparatus and expression of the channel protein at the cell membrane.[125] This explains in large part the induction of SK channel density by vasopressin[160] and cAMP.[76] Notably, this N-terminal serine is also a substrate for SGK1, the aldosterone-induced kinase that activates ENaC, which then activates ROMK by increasing membrane expression.[161] Thus, although aldosterone does not appear to have significant effects on SK density,[156] SGK1 is conceivably involved; alternatively, other antagonistic effects of SGK1 on ROMK[162] trafficking abrogate the effect mediated by N-terminal phosphorylation.

A recent series of reports have linked changes in the expression of WNK1 kinase subunits in the response to high K^+ diet. WNK1 and WNK4 were initially identified as causative genes for familial hypertension with hyperkalemia (FHHt), also known as Gordon syndrome or pseudohypoaldosteronism type II.[163] The regulation of NCC, the thiazide-sensitive Na^+-Cl^- cotransporter in the DCT, is a major role of the WNK kinases.[164–166] NCC activity is a major determinant of Na^+ delivery to the downstream CNT, with potent effects on the ability to secrete K^+ (see also Integrated Regulation of Distal Sodium and Potassium Transport). However, the WNK kinases also directly regulate trafficking and activity of both ROMK and BK channels.

ROMK expression at the membrane of Xenopus oocytes is dramatically reduced by the coexpression of WNK4; FHHt-associated mutations dramatically increase this effect, suggesting a direct inhibition of SK channels in FHHt.[167]

6.1 The Effect of a High K^+ Diet, Aldosterone, and/or Na^+-Cl^- Restriction on Small Conductance Channel Density in the Rat Cortical Collecting Duct

Condition	K Channel Density/μm^2	Plasma Aldo (ng/dL)	Plasma K (mM)
Control	0.41	15	3.68
High K diet, 6 h	1.51	36	NM
High K diet, 48 h	2.13	98	4.37
Low Na diet, 7 d	0.48	1260	NM
Aldo infusion, 48 h	0.44	550	2.44
Aldo + high K diet	0.32	521	3.80

K, potassium; h, hour; Na, sodium; d, day; Aldo, aldosterone; NM, not measured.
Modified from Palmer LG, Frindt G. Regulation of apical K channels in rat cortical collecting tubule during changes in dietary K intake. Am J Physiol. 1999;277:F805–F812.

The coexpression of WNK4 also inhibits BK channels in a heterologous expression system, apparently by inducing lysosomal degradation.[168] In the case of WNK1, the analysis is complicated dramatically by the transcriptional complexity of its gene, which has at least three separate promoters and a number of alternative isoforms. In particular, the predominant intrarenal WNK1 isoform is generated by a distal nephron transcriptional site that bypasses the N-terminal exons that encode the kinase domain, thus yielding a kinase-deficient short form of the protein ("WNK1-S").[169] Full-length WNK1 (WNK1-L) inhibits ROMK activity by inducing endocytosis of the channel protein[170–172]; kinase activity and/or the N-terminal kinase domain of WNK1 appear to be required for this effect,[171,172] although Cope et al.[170] have reported that a kinase-dead mutant of WNK1 is unimpaired. WNK1 and WNK4 induce endocytosis of ROMK via an interaction with intersectin, a multimodular endocytic scaffold protein.[173] The additional binding of ROMK to the clathrin adaptor protein autosomal recessive hypercholesterolemia (ARH) is required for basal and WNK1-stimulated endocytosis of the channel protein.[174] The ubiquitination of the ROMK protein is also involved in clathrin-dependent endocytosis, requiring an interaction between the channel and the U3 ubiquitin ligase POSH (plenty of SH domains).[175]

The shorter WNK1-S isoform, which lacks the kinase domain, appears to inhibit the effect of WNK1-L.[171,172] The ratio of WNK1-S to WNK1-L transcripts is reduced by K^+ restriction (greater endocytosis of ROMK)[172,176] and is increased by K^+ loading (reduced endocytosis of ROMK),[171,176] thus suggesting that this ratio between WNK1-S and WNK1-L functions as a "switch" to regulate distal K^+ secretion (Fig. 6.6). The inhibitory effect of WNK1-S tracks to the first 253 amino acids of the protein, encompassing the initial 30

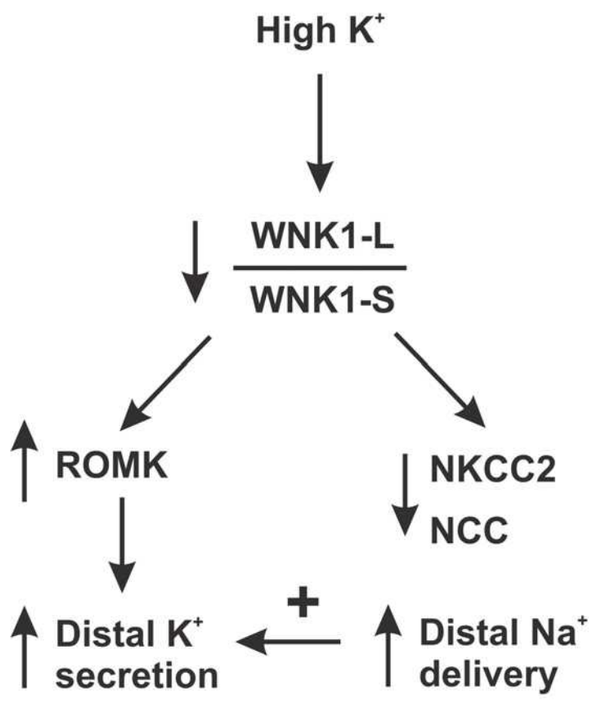

FIGURE 6.6 The balance between the major short (WNK1-S) and long (WNK1-L) isoforms of the WNK1 kinases affects K^+ secretion. The WNK1-S isoform lacks a kinase domain and inhibits the effects of the long isoform. Potassium loading causes a reduction in the ratio of WNK1-L to WNK1-S, resulting in an increased expression of the renal outer medullary K^+ channel (ROMK) at the plasma membrane of connecting tubule (CNT) cells and principal cells, with a concomitant reduction in the apical expression of the thiazide-sensitive Na^+-Cl^- cotransporter (NCC) in the distal convoluted tubule (DCT) and the furosemide-sensitive Na^+-K^+-$2Cl^-$ cotransporter NKCC2 in the thick ascending limb (TAL). The net result is increased Na^+ delivery to the CNT and principal cells with enhanced apical secretory K^+ channel activity, resulting in an enhanced K^+ secretion.

amino acids unique to this isoform and an adjacent autoinhibitory domain.[177] Transgenic mice that overexpress this inhibitory domain of WNK1-S have lower serum K^+ concentrations, higher fractional excretion of K^+, and increased expression of the ROMK protein at the apical membrane of CNT and CCD cells, all of which are consistent with an important inhibitory effect of WNK1-S.[177]

Potassium Deprivation

A reduction in dietary K^+ leads, within 24 hours, to a dramatic drop in urinary K^+ excretion.[176,178] This drop in excretion is due to both an induction of reabsorption by intercalated cells in the OMCD[107,108] and to a reduction in SK channel activity in principal cells.[179] The mechanisms involved in K^+ reabsorption by intercalated cells were previously discussed. Notably, H^+/K^+–ATPase activity in the collecting duct does not appear to be regulated by aldosterone[180]; stimulatory effects of mineralocorticoid on H^+/K^+–ATPase activity are abrogated by K^+ loading, indicating a primary role for hypokalemia.[181]

Dietary K^+ intake modulates trafficking of the ROMK channel protein to the plasma membrane of principal cells, with a marked increase in the relative proportion of intracellular channel protein in K^+-depleted animals[155] and clearly defined expression at the plasma membrane of CCD cells from animals on a high K^+ diet.[155] The membrane insertion and activity of ROMK is modulated by tyrosine phosphorylation of the channel protein, such that the phosphorylation of tyrosine residue 337 stimulates endocytosis and dephosphorylation induces exocytosis.[182,183] This tyrosine phosphorylation appears to play a key role in the regulation of ROMK by dietary K^+.[184] Whereas the levels of protein tyrosine phosphatase-1D do not vary with K^+ intake, intrarenal activity of the cytoplasmic tyrosine kinases c-src and c-yes are inversely related to dietary K^+ intake, with a decrease under high K^+ conditions and a marked increase after several days of K^+ restriction.[179,185] Immunolocalization indicates coexpression of c-src with ROMK in the TAL and the principal cells of the CCD.[155] The inhibition of protein tyrosine phosphatase activity, leading to a dominance of tyrosine phosphorylation, dramatically increases the proportion of intracellular ROMK in the CCD of animals on a high K^+ diet.[155]

The neurohumoral factors that induce the K^+-dependent trafficking and expression of apical ROMK[155] and BK channels[158] have only recently been identified. Several studies have implicated the intrarenal generation of superoxide anions in the activation of cytoplasmic tyrosine kinases and in the downstream phosphorylation of the ROMK channel protein by K^+ depletion.[186,187] Candidates for the upstream kaliuretic factor include AT-II and growth factors such as insulin-like growth factor-1 (IGF-1).[162] AT-II inhibits ROMK activity in K^+-restricted rats, but not in rats on a normal K^+ diet.[188] This inhibition involves the downstream activation of superoxide production and c-src activity, such that the well-known induction of AT-II by a low K^+ diet appears to play a major role in reducing the distal tubular K^+ secretion.[189] IGF-1 is produced in the kidney and upregulated by dietary K^+ restriction[190]. The downstream activation of PI3-kinase by insulin and IGF-1 results in the Akt1- or SGK1-dependent phosphorylation of WNK1, leading to endocytosis of ROMK.[162]

Reports of transient postprandial kaliuresis in sheep, independent of changes in plasma K^+ or aldosterone, suggest that an enteric or hepatoportal K^+ sensor controls kaliuresis via a sympathetic reflex[191]; tissue kallikrein has recently emerged as a candidate mediator for this postprandial kaliuresis (see the following). Regardless of the signaling involved, changes in dietary K^+ absorption have a direct "anticipatory" effect on K^+ homeostasis in the absence of changes in plasma K^+. Such a feed-forward control has the theoretical advantage of greater stability, because it operates prior to changes in plasma K^+.[192] Notably, changes in ROMK phosphorylation status and insulin-sensitive muscle uptake can be seen in K^+-deficient animals in the absence of a change in plasma K^+,[13] suggesting that the upstream activation of the major mechanisms that serve to reduce K^+ excretion (reduced K^+ secretion in the CNT/CCD, decreased peripheral uptake, and increased K^+ reabsorption in the OMCD) does not require changes in the plasma K^+. Consistent with this hypothesis, moderate K^+ restriction—without an associated drop in plasma K^+—is sufficient to induce AT-II-dependent superoxide generation and c-src activation, leading to the inhibition of ROMK channel activity.[189]

Vasopressin

Vasopressin has a stimulatory effect on K^+ secretion by the distal nephron.[32] This serves to preserve K^+ secretion during dehydration and extracellular volume depletion, when circulating levels of vasopressin are high and tubular delivery of Na^+ and fluid is reduced. The stimulation of basolateral V2 receptors results in the activation of ENaC, which increases the driving force for K^+ secretion by CNT cells and principal cells.[193] In addition, vasopressin activates SK channels directly in the CCD,[160] as does cAMP.[76] The ROMK protein is directly phosphorylated by PKA on three serine residues (S25, S200, and S294 in the ROMK2 isoform), with phosphorylation of all three sites required for full activity (see also the previous discussion). Finally, the stimulation of luminal V1 receptors also increases K^+ secretion in the CCD, apparently via the activation of BK channels.[194]

Tissue Kallikrein

The serine protease tissue kallikrein (TK) is involved in the generation of kinins, which ultimately stimulates the formation of bradykinin.[195] Within the kidney, TK is synthesized within CNT cells and is released into the tubular lumen and the peritubular interstitium. Although TK-induced bradykinin has a number of effects on distal tubular physiology,[195] more recent data have revealed a provocative role in postprandial kaliuresis. Thus, oral K^+-Cl^- loading leads to a spike in urinary K^+ and TK excretion in rats, mice, and

humans.[195] The increase in urinary TK after K^+ loading is not accompanied by changes in urinary aldosterone and can be detected in aldosterone synthase knockout mice.[149] Mice deficient in TK demonstrate postprandial hyperkalemia, indicating a role for the protease in postprandial kaliuresis. This transient hyperkalemia is accompanied by a marked increase in K^+ reabsorption by perfused CCDs due to an upregulation of H^+/K^+–ATPase activity and an increase in HKα-2 transcript. The addition of luminal but not basolateral TK inhibits the activated CCD H^+/K^+–ATPase activity in TK knockout mice, which is consistent with direct proteolytic activation. There is also a marked increase in Na^+ reabsorption by perfused CCDs from TK knockout mice, without the development of a lumen-negative PD. This is consistent with an increased activity of the electroneutral Na^+-Cl^- cotransport mediated by the Na^+-driven SLC4A8 Cl^--HCO_3^- exchanger and the SLC26A4 Cl^--HCO_3^- exchanger (see also the following text).[196] This electroneutral transport pathway had previously been shown to be inhibited by bradykinin[197]; hence, the activation by TK deletion presumably reflected a loss of tonic inhibition by TK-generated bradykinin. Prior data had indicated that TK mediates proteolytic cleavage of the γ subunit of ENaC, with reduced ENaC activity in TK-deficient mice[198]; net Na^+ balance is thus neutral in these mice.

In summary, TK secretion from CNT cells is induced by oral K^+-Cl^- loading, causing proteolytic activation of ENaC[198] and thus an increase in ENaC-driven K^+ secretion and the bradykinin-dependent inhibition of electroneutral Na^+-Cl^- cotransport in the CCD.[196,197] Thus, a further augmentation of electrogenic Na^+ transport (favoring K^+ secretion) and a direct luminal inhibition of H^+/K^+–ATPase activity causes a decrease or tonic inhibition of K^+ reabsorption. TK may very well be the postprandial factor[191] that functions in the feed-forward control of plasma K^+.[192]

The Integrated Regulation of Distal Sodium and Potassium Transport

In CNT and principal cells, the lumen-negative potential difference generated by Na^+ entry via ENaC induces the exit of K^+ via apical K^+-selective channels. This arrangement explains much of the known physiology and pathophysiology of renal K^+ secretion, yet has several key consequences that bear emphasis. First, enhanced Na^+-Cl^- reabsorption upstream of the CNT and CCD will reduce the delivery of luminal Na^+ to the CNT and CCD,[73] decrease the lumen-negative potential difference, and thus decrease K^+ secretion; K^+ secretion by the CCD essentially stops when luminal Na^+ drops below 8 mmol per liter.[74] In this respect, the increasingly refined phenotypic understanding of FHHt, caused by kinase-induced gain-of-function of the DCT, has served to underline that a variation in NCC-dependent Na^+-Cl^- absorption, just upstream of the CNT, has major effects on the ability to excrete dietary K^+.[166] Second, aldosterone is a kaliuretic hormone, induced by hyperkalemia. However, in certain circumstances associated with a marked induction of aldosterone, such as dietary sodium restriction, sodium balance is maintained without affecting K^+ homeostasis. This aldosterone paradox—the independent regulation of Na^+-Cl^- and K^+ handling by the aldosterone-sensitive distal nephron—is only recently beginning to yield to investigative efforts. The major factors in the integrated control of Na^+-Cl^- and K^+ transport appear to include electroneutral, NCC-independent, and thiazide-sensitive Na^+-Cl^- transport within the CCD[196,197,199]; K^+-dependent changes in NCC activity within the DCT; ENaC-independent K^+ excretion within the distal nephron[72]; and the differential regulation of various transport and signaling pathways by aldosterone, AT-II, TK, and dietary K^+.[195,200,201]

Thiazide-sensitive electroneutral Na^+-Cl^- transport within the CCD is mediated by parallel activity of the Na^+-driven SLC4A8 Cl^--HCO_3^- exchanger and the SLC26A4 Cl^--HCO_3^- exchanger,[196] expressed in intercalated cells. The molecular identity of this transport mechanism has only recently emerged[196]; hence, regulatory influences are not fully characterized. However, electroneutral Na^+-Cl^- transport within the CCD is evidently induced by both volume depletion and mineralocorticoid treatment.[196,197,199] This mechanism mediates ~50% of Na^+ reabsorption in the CCD under these conditions, all without affecting the lumen potential difference and thus without influencing K^+ excretion. A high K^+ diet also increases the fraction of ENaC-independent, amiloride-resistant K^+ excretion to ~50%; again, this electroneutral, aldosterone-independent pathway for K^+ excretion uncouples distal tubular Na^+ and K^+ excretion.[72]

In a landmark study, Kahle et al.[167] established in 2003 that the WNK4 kinase, encoded by a disease gene for FHHt, inhibits ROMK activity in Xenopus oocytes. This identified WNK-dependent signaling as a major pathway for integrating Na^+-Cl^- and K^+ transport within the distal nephron. Details of the relevant effects of WNK kinases on NCC and ROMK are discussed earlier and elsewhere.[202–204] However, key findings include the differential influence of K^+ intake on circulating AT-II, ROMK activity (i.e., K^+ secretory capacity), the ratio of WNK1 isoforms, and the activity of NCC in the DCT. AT-II activates NCC via WNK4 and the downstream SPAK kinase,[202–204] thus reducing delivery of Na^+ to the CNT and limiting K^+ secretion. AT-II also inhibits ROMK activity via several mechanisms, including the downstream activation of c-src tyrosine kinases.[187–189] Whereas K^+ restriction induces renin and circulating AT-II, increases in dietary K^+ suppress AT-II levels.[189,205] A decrease in circulating and local AT-II explains why NCC phosphorylation and activity is downregulated by a high K^+ diet (Fig. 6.7).[56,206] Teleologically, this serves to increase the delivery of Na^+ to the CNT, thus increasing K^+ secretion. Finally, within CNT cells and principal cells, increases in aldosterone induce the SGK1 kinase, which phosphorylates WNK4 and attenuates the effect of WNK4 on ROMK,[207] while activating ENaC via Nedd4-2-dependent effects. However, when dietary K^+ intake is reduced, c-src tyrosine kinase activity increases under

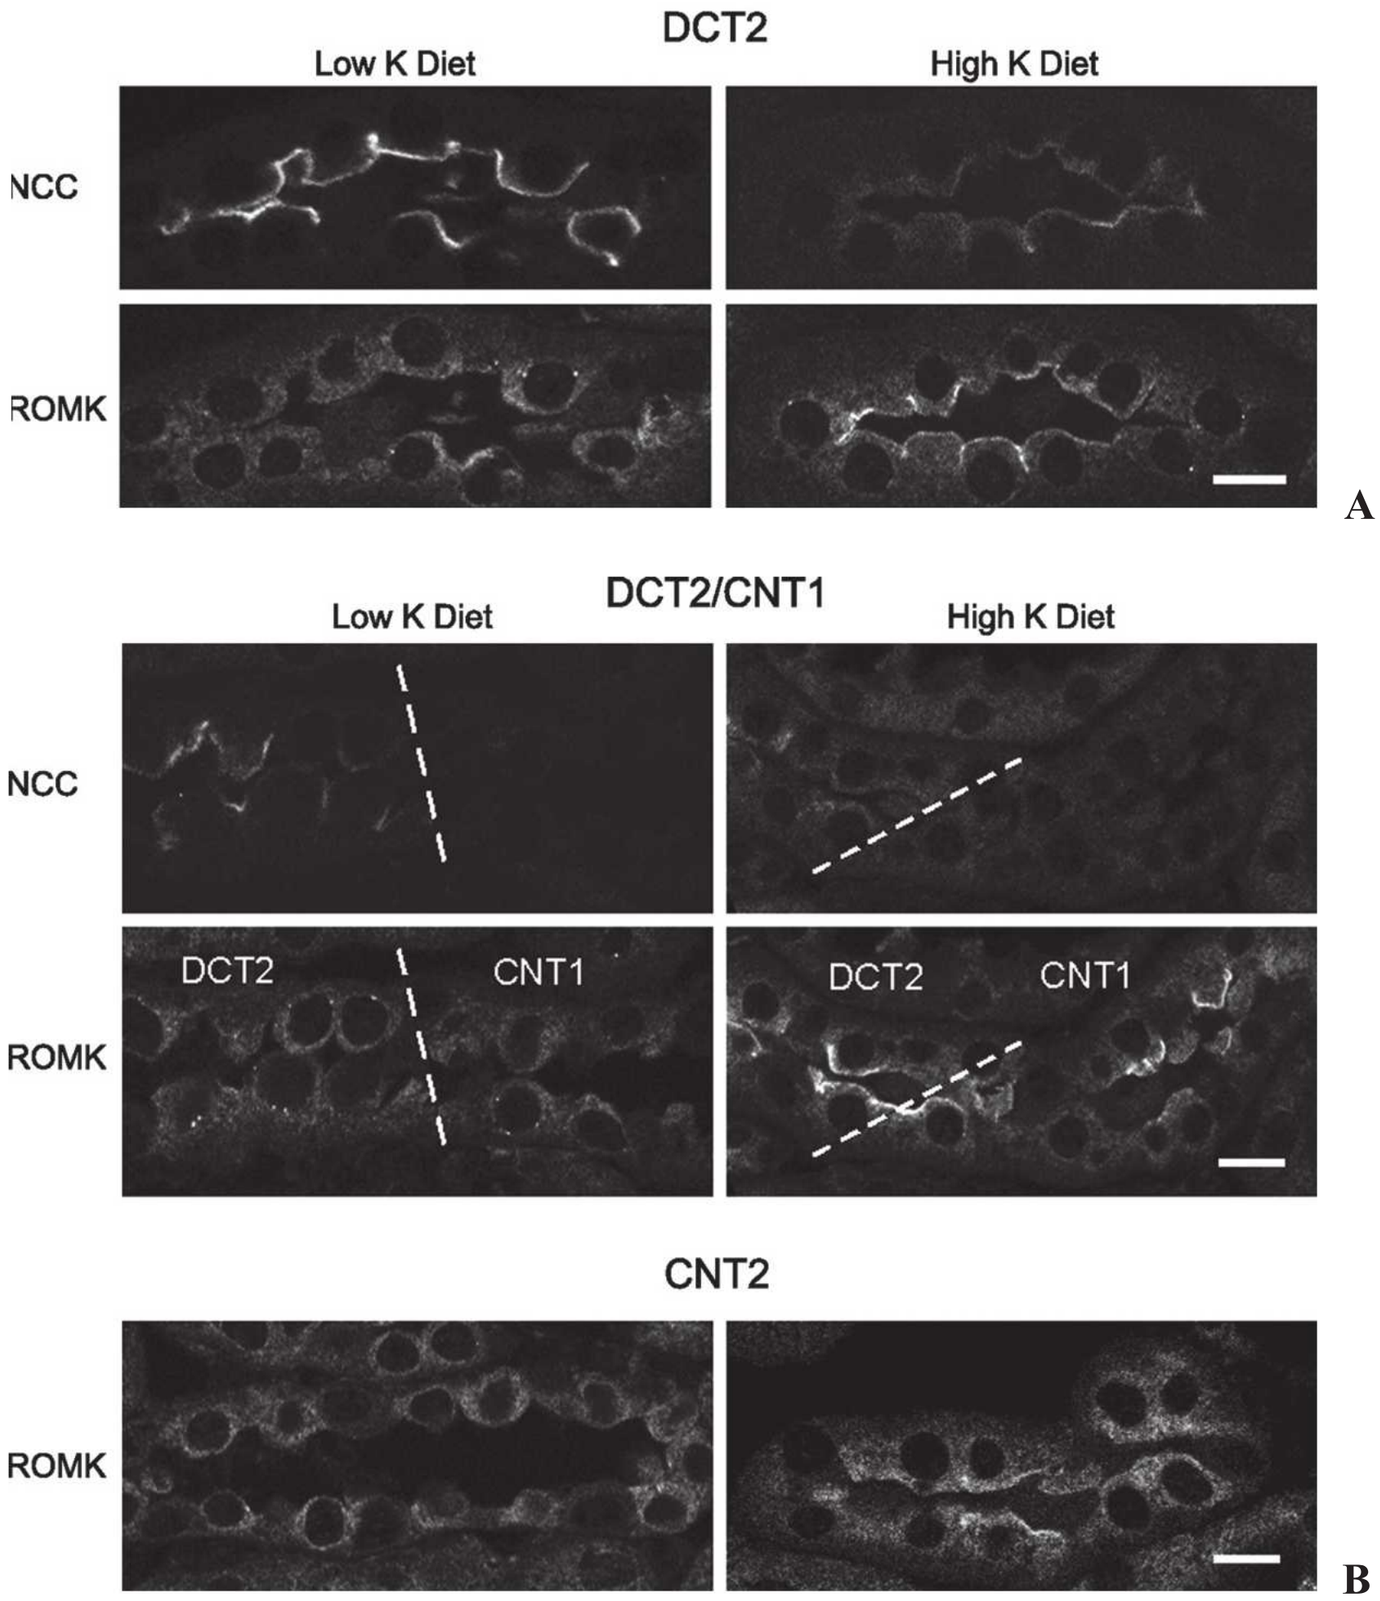

FIGURE 6.7 The differential effects of a high and low K^+ diet on the membrane expression of Na^+-Cl^- cotransporter (NCC) and renal outer medullary K^+ channel (ROMK) in late distal convoluted tubule (DCT) and the connecting tubule (CNT). **A:** Whereas NCC expression at the plasma membrane of DCT2 cells is enhanced in rats treated with a low K^+ diet and is reduced by a high K^+ diet, the opposite occurs for ROMK protein. **B:** This dichotomy persists at the junction between DCT2 and the early CNT (CNT1: the juncture is denoted by a *dashed white line*). However, within CNT2 segments, which lack NCC, apical labeling of ROMK under high K^+ conditions is less striking. (From Wade JB, et al. Differential regulation of ROMK (Kir1.1) in distal nephron segments by dietary potassium. *Am J Physiol.* 2011;300(6):F1385–1393.)

the influence of increased AT-II, causing direction inhibition of ROMK activity via tyrosine phosphorylation of the channel.[182–184] The increase in c-src tyrosine kinase activity also abrogates the effect of SGK1 on WNK4[201]; this latter mechanism can also be induced by AT-II.[208]

The ratio of WNK1 isoforms is also a critical determinant in the balance between distal Na^+ and K^+ transport. The shorter WNK1-S isoform, which lacks the kinase domain, appears to inhibit the effect of WNK1-L.[171,172] The ratio of WNK1-S to WNK1-L transcripts is reduced by K^+ restriction (greater endocytosis of ROMK)[172,176] and is increased by K^+ loading (reduced endocytosis of ROMK).[171,176] This suggests that the ratio between WNK1-S and WNK1-L functions as a switch to regulate distal K^+ secretion (see also Fig. 6.6). Transgenic mice that overexpress this inhibitory domain of WNK1-S have lower serum K^+ concentrations, a higher fractional excretion of K^+, and an increased expression of ROMK protein at the apical membrane of CNT and CCD cells, all of which are consistent with an important inhibitory effect of WNK1-S.[177] In contrast, WNK1-L activates NCC by enhancing expression at the cell membrane; this activation is blocked by WNK1-S. Again, transgenic WNK1-S mice have the expected phenotype, with renal salt wasting and hypotension due to marked suppression of membrane-associated total and phosphorylated NCC in the DCT and NKCC2 in the TAL.[209] In contrast, selective knockout of the WNK1-S exons leads to a major gain in function for NCC and NKCC2.[209] Therefore, K^+ loading will lead to an increase in the ratio of WNK1-S to WNK1-L, reduced endocytosis of ROMK, and enhanced endocytosis of NCC; this will have the effect of reducing Na^+ absorption in the DCT and thus increasing Na^+ delivery and tubular flow rate in the CNT, where ROMK +/– BK channel activity is maximized (see also Fig. 6.6). The converse cascade occurs in K^+ restriction.

CHAPTER

7 Renal Acid–Base Transport

Thomas D. DuBose Jr. • Amanda K. Goode

ACID–BASE HOMEOSTASIS

The body maintains systemic acid–base homeostasis (a pH in the range of 7.35 to 7.45) in two ways: (1) through chemical buffering in extracellular fluid (ECF) and intracellular fluid (ICF), and (2) through physiologic regulation controlled by the metabolic, renal, and respiratory systems. The central nervous and respiratory systems control CO_2 tension (PCO_2), and the kidneys regulate the plasma HCO_3^- concentration. Buffers in the ECF and ICF guard against acid and base retention. These processes serve to dispose of carbonic and nonvolatile acids on a daily basis and pathologic quantities of acid and alkali as needed. This chapter briefly reviews the role of chemical buffers, but focuses primarily on the renal transport and regulatory processes that maintain acid–base balance.

Buffer Systems

The body's buffer systems keep the blood from becoming too basic or too acidic by combining with or releasing H^+, and thus are comprised of a base (i.e., an H^+ acceptor) and an acid (i.e., an H^+ donor). The most prodigious base is bicarbonate (HCO_3^-) and the most common acid is carbonic acid (H_2CO_3). Because buffer systems attenuate system changes, acid or base loads in the presence of a buffer cause smaller changes in the pH than if the buffer were absent. During homeostasis, the extracellular H^+ concentration ($[H^+]_e$) is constant. H^+ concentration can be expressed either directly as $[H^+]$ or indirectly as pH.

When CO_2 is dissolved in water, H_2CO_3 is formed according to the reaction

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \quad (1)$$

The rate of this reaction, in the absence of the enzyme carbonic anhydrase, is slow, with a half-life of about 8 seconds at 37°C. The importance of carbonic anhydrase in bicarbonate equilibrium in the kidneys and lungs are discussed in the following paragraphs. The major portion of CO_2 remains as dissolved CO_2; only about 1 part in 1,000 forms H_2CO_3, a nonvolatile acid. Because H_2CO_3 is a weak acid, it dissociates rapidly to yield H^+ and HCO_3^-.

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \quad (2)$$

Because the concentration of H_2CO_3 remains low and proportional to the concentration of dissolved CO_2, Eqs 1 and 2 can be combined and treated as a single reaction:

$$CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^- \quad (3)$$

The equilibrium constant for this reaction is given by

$$K = \frac{[H^+]\,[HCO_3^-]}{[CO_2]\,[H_2O]} \quad (4)$$

Defining $K' = K[H_2O]$ as the apparent equilibrium constant and using Eq. 4,

$$K' = \frac{[H^+]\,[HCO_3^-]}{\alpha_{co2}\,PCO_2} \quad (5)$$

Taking logarithms of both sides of Eq. 5 and recognizing that $pK' = \log_{10}(K')$, the familiar Henderson-Hasselbalch equation is derived:

$$pH = \frac{pK' + \log_{10}[HCO_3^-]}{(\alpha_{co2}Pco_2)} \quad (6)$$

Using $pK' = 6.1$ in Eq. 6, the Henderson equation is derived, which may be used in the clinical interpretation of acid–base data:

$$[H^+](nmol/L) = \frac{24\ PCO_2\ (mm\ Hg)}{[HCO_3^-]\ (mM)} \quad (7)$$

Physiologic Processes that Protect the Plasma Bicarbonate

Three physiologic processes mitigate changes in the HCO_3^-/CO_2 ratio: (1) metabolic regulation, (2) respiratory regulation, and (3) renal regulation. Metabolic regulation is

of minor importance in terms of the overall physiologic regulation of acid–base balance. Some enzymes are regulated by changes in blood pH. For example, the activity of phosphofructokinase, the pivotal enzyme in the glycolytic pathway, is inhibited by low pH and enhanced by high pH.

Because, under most circumstances, respiratory CO_2 excretion and CO_2 production are matched, the usual steady state arterial PCO_2 ($PaCO_2$) is maintained at 40 mm Hg. Underexcretion of CO_2 produces hypercapnia, and overexcretion produces hypocapnia. Production and excretion are again matched but at a new steady state PCO_2. Therefore, $PaCO_2$ is regulated primarily by neurorespiratory factors and is not subject to regulation by the rate of metabolic CO_2 production. Hypercapnia is primarily the result of hypoventilation, not increased CO_2 production. Increases or decreases in PCO_2 represent derangements of control of neurorespiratory regulation or can result from compensatory changes in response to a primary alteration in the plasma HCO_3^- concentration.

Sources of Endogenous Acids

Pathologically, acid loads may be derived from endogenous acid production (e.g., generation of ketoacids and lactic acids) or loss of base (e.g., through diarrhea) or from exogenous sources (e.g., ammonium chloride or toxin ingestion). Under normal physiologic circumstances, a daily input of acid derived from the diet and metabolism confronts the body. The net result of these processes amounts to about 1 mEq of new H^+ per kilogram per day entering the ECF.[1–4]

Sulfuric acid is formed when organic sulfur from methionine and cysteine residues of proteins are oxidized to SO_4^{2-}. The metabolism of sulfur-containing amino acids is the primary source of acid in the usual Western diet, accounting for approximately 50%. The quantity of sulfuric acid generated is equal to the SO_4^{2-} excreted in the urine.

Organic acids are derived from intermediary metabolites formed by the partial combustion of dietary carbohydrates, fats, and proteins as well as from nucleic acids (uric acid). Organic acid generation contributes to net endogenous acid production when the conjugate bases are excreted in the urine as organic anions. If full oxidation of these acids can occur, however, H^+ is reclaimed and is eliminated as CO_2 and water. The net amount of H^+ added to the body from this source can be estimated by the amount of organic anions excreted in the urine.

Phosphoric acid can be derived from hydrolysis of PO_4^{3-} esters in proteins and nucleic acids if it is not neutralized by mineral cations (e.g., Na^+, K^+, Mg^{2+}). The contribution of dietary phosphate to acid production is dependent on the kind of protein ingested. Some proteins generate phosphoric acid, whereas others generate only neutral phosphate salts.[1–4] Hydrochloric acid is generated by the metabolism of cationic amino acids (lysine, arginine, and some histidine residues) into neutral products. Other potential acid or base sources in the diet can be estimated from the amount of unidentified cations and anions ingested.

Potential sources of bases are also found in the diet (e.g., acetate, lactate, citrate) and can be absorbed to neutralize the acid loads from the three sources just mentioned. The net base absorbed by the gastrointestinal tract is derived from the anion gap (AG) of the diet minus that of the stool. Acid production is partially offset by HCO_3^-, which is produced when organic anions combine with H^+ and are oxidized to CO_2 and H_2O or when dibasic phosphoesters combine with H^+ during hydrolysis. The gastrointestinal tract may modify the amount of these potential bases reabsorbed under particular circumstances of acidosis or growth. It has been confirmed in patients ingesting an artificial diet that urinary net acid excretion is equal to urinary [(SO_4^{2-}) + organic A^- + dietary phosphoester-derived H^+].[1,2,5] Therefore, in summary, the metabolism of certain proteins, nucleic acids, and small fractions of lipids and certain carbohydrates generate specific organic acids that cannot be burned to CO_2 (e.g., uric, oxalic, glucuronic, hippuric acids). In addition, the inorganic acids H_2SO_4 and H_3PO_4, derived respectively from sulfur-containing amino acids and organophosphates, are excreted by the kidneys or the gastrointestinal tract.

Impact of Daily Metabolism on Acid–Base Balance

Human subjects ingesting a typical Western diet are confronted, under most physiologic circumstances, with an acid challenge. Metabolism generates a daily load of relatively strong acids (lactate, citrate, acetate, and pyruvate), but under physiologic circumstances, in the steady state, metabolic production and consumption are matched. However, if production and consumption rates become mismatched, organic acids can accumulate (e.g., lactic acid accumulation with anoxia or ischemia). These acids are buffered by HCO_3^- in the ECF, causing a decline in plasma HCO_3^- concentration as the organic acid concentration increases. During recovery, these organic acids reenter the metabolic pathways to CO_2 production, the removal of H^+, and the generation of HCO_3^- unless the organic anions are excreted (e.g., ketonuria), and thereby are no longer available for regeneration of HCO_3^-.

Both metabolic and renal regulatory mechanisms protect a normal HCO_3^- concentration in blood (25 mEq per liter) despite the daily addition of acid (or alkali) to the ECF. Although the buffering capacity of the body is magnified severalfold by respiratory adjustments in $PaCO_2$, primary changes in $PaCO_2$ may result in acidosis or alkalosis, depending on whether CO_2 is elevated above or depressed below the normal value: 40 mm Hg (*respiratory acidosis* and *respiratory alkalosis*), respectively. A primary change in the plasma HCO_3^- concentration as a result of metabolic production or the retention or excretion of an acid or base by the kidney evokes a ventilator response because a decrease or increase in pH is sensed by chemoreceptors in the circulation and signals the respiratory center to increase or decrease minute ventilation. The respiratory response to acidemia (increase ventilation

and decrease PCO_2) or alkalemia (decrease in ventilation and increase in PCO_2) thereby blunts the change in blood pH that would occur otherwise. Such respiratory alterations that adjust blood pH toward normal are referred to as *secondary* or *compensatory* alterations, because they occur in response to primary metabolic changes. While helpful, respiratory compensation to metabolic acidosis or alkalosis is never sufficient to return blood pH to normal. Therefore, the kidneys must play a very significant role in adjustments to metabolic disturbances by altering bicarbonate reabsorption and net acid excretion.

RENAL PARTICIPATION IN ACID–BASE HOMEOSTASIS

Although temporary relief from changes in the pH of body fluids may be derived from chemical buffering or respiratory compensation, the ultimate defense against the addition of nonvolatile acid or of alkali resides in the kidneys. The addition of a strong acid (e.g., HA) to the ECF titrates plasma HCO_3^-:

$$HA + NaHCO_3 \rightarrow NaA + H_2O + CO_2 \quad (8)$$

The CO_2 is expired by the lungs, and body HCO_3^- declines. This process occurs constantly as endogenous metabolic acids are generated. To maintain a normal plasma HC O_3^- in the face of the constant accession of metabolic acids, the kidneys must (1) conserve the HCO_3^- present in the filtered load (through reclamation), and (2) regenerate the HC O_3^- decomposed by reaction with metabolic acids (Eq. 8).

The first function of the kidneys in maintaining acid–base homeostasis is to reclaim or reabsorb filtered HCO_3^-. The kidneys filter approximately 4,000 mEq of bicarbonate daily (defined as the product of the glomerular filtration rate [GFR] and the plasma HCO_3^- concentration), and the excretion of any significant portion of this leads to metabolic acidosis. The renal tubules essentially reabsorb all of the filtered HCO_3^-, or may excrete excessive HCO_3^- when needed, to maintain the normal plasma HCO_3^- concentration of 25 mEq per liter.

HCO_3^- reclamation is accomplished principally in the proximal tubule. There is a subsequent contribution by the loop of Henle and a minor contribution by more distal nephron segments. Under most circumstances, the filtered load of HCO_3^- is absorbed almost completely, especially during an acid load. Nevertheless, when less acid is generated or if the plasma HCO_3^- concentration increases above the normal value of 25 mEq per liter, HCO_3^- will be excreted efficiently into the urine.

The generation of acid in the body by metabolism is referred to as *net acid production*. Because a typical Western diet generates fixed acids at 50 to 70 mEq per day, net acid excretion must be affected to maintain acid–base balance. Therefore, net acid excretion approximates 50 to 70 mEq per day. If acid production remained stable and unabated by net acid excretion, metabolic acidosis would ensue. Conversely, an increase in net acid excretion above the level of net acid production results in metabolic alkalosis. Each milliequivalent of net acid excreted corresponds to 1 mEq of HCO_3^- returned to the ECF. This process is called HCO_3^- regeneration and is necessary for replacing the HCO_3^- lost by the entry of fixed acids into the ECF or, less commonly, replacing the HCO_3^- excreted in stool or urine.

To prevent metabolic acidosis, this excreted acid must be recovered. The kidney recovers this acid through the second process, HCO_3^- regeneration, which is represented by the renal output of acid or **net acid excretion (NAE)**, or the sum of ammonia (NH_3)/ammonium (NH_4^+) plus excreted titratable acids (TA) minus any bicarbonate excreted.

$$\text{Net acid excretion (NAE)} = (U_{NH_4^+}V) + (U_{TA}V) - (U_{HCO_3^-}V) \quad (9)$$

where V is urinary volume per 24 hours and U refers to the concentration of the moiety in the urine.

TA excretion in the urine is represented by buffers that are filtered at the glomerulus and then titrated to acid moieties in the tubule lumen. Because renal H^+-secretory mechanisms cannot generate such steep pH gradients between the cell (pH ~7.3) and lumen, excretion of 70 mEq of acid per day requires that most of this acid be buffered in the luminal fluid.

Buffers with a *pK* between 5.0 and 7.4, the pH range of the luminal fluid, are most effective chemically. In this regard, the most abundant and effective buffer in the urine is the phosphate buffer pair, $H_2PO_4^- - HPO_4^{2-}$, with a p*K* of 6.9. The excretion of phosphate, the major titratable buffer, is usually regulated in accordance with phosphate homeostasis. Phosphate excretion increases modestly in metabolic acidosis, but the magnitude of the increase is limited by the filtered load of phosphate and, therefore, is significantly regulatable. In general, the buffers responsible are the $NH_3 - NH_4^+$ and titratable buffer, such as $HPO_4^{2-} - H_2PO_4^-$, systems. Physiologically, the most significant of these is the NH_3–NH_4^+ system.

Ammoniagenesis

Ammoniagenesis by protein catabolism is balanced by the generation of new HCO_3^- through renal NH_4^+ and TA excretion (Fig. 7.1A). The products of these neutral reactions are HCO_3^- and NH_4^+. Most ammoniagenesis occurs in the proximal tubule. NH_4^+ produced by the metabolism of amino acids reacts with HCO_3^- or forms urea and thus has no impact on acid–base balance. A portion of this NH_4^+ is diverted to glutamine synthesis, the amount of which is regulated by pH. Acidemia promotes and alkalemia inhibits glutamine synthesis. Each glutamine molecule metabolized produces two NH_4^+ and two HCO_3^- molecules (Fig. 7.1A) (water, CO_2, and glucose are also formed). This breakdown occurs as follows: glutamine is transported into the proximal

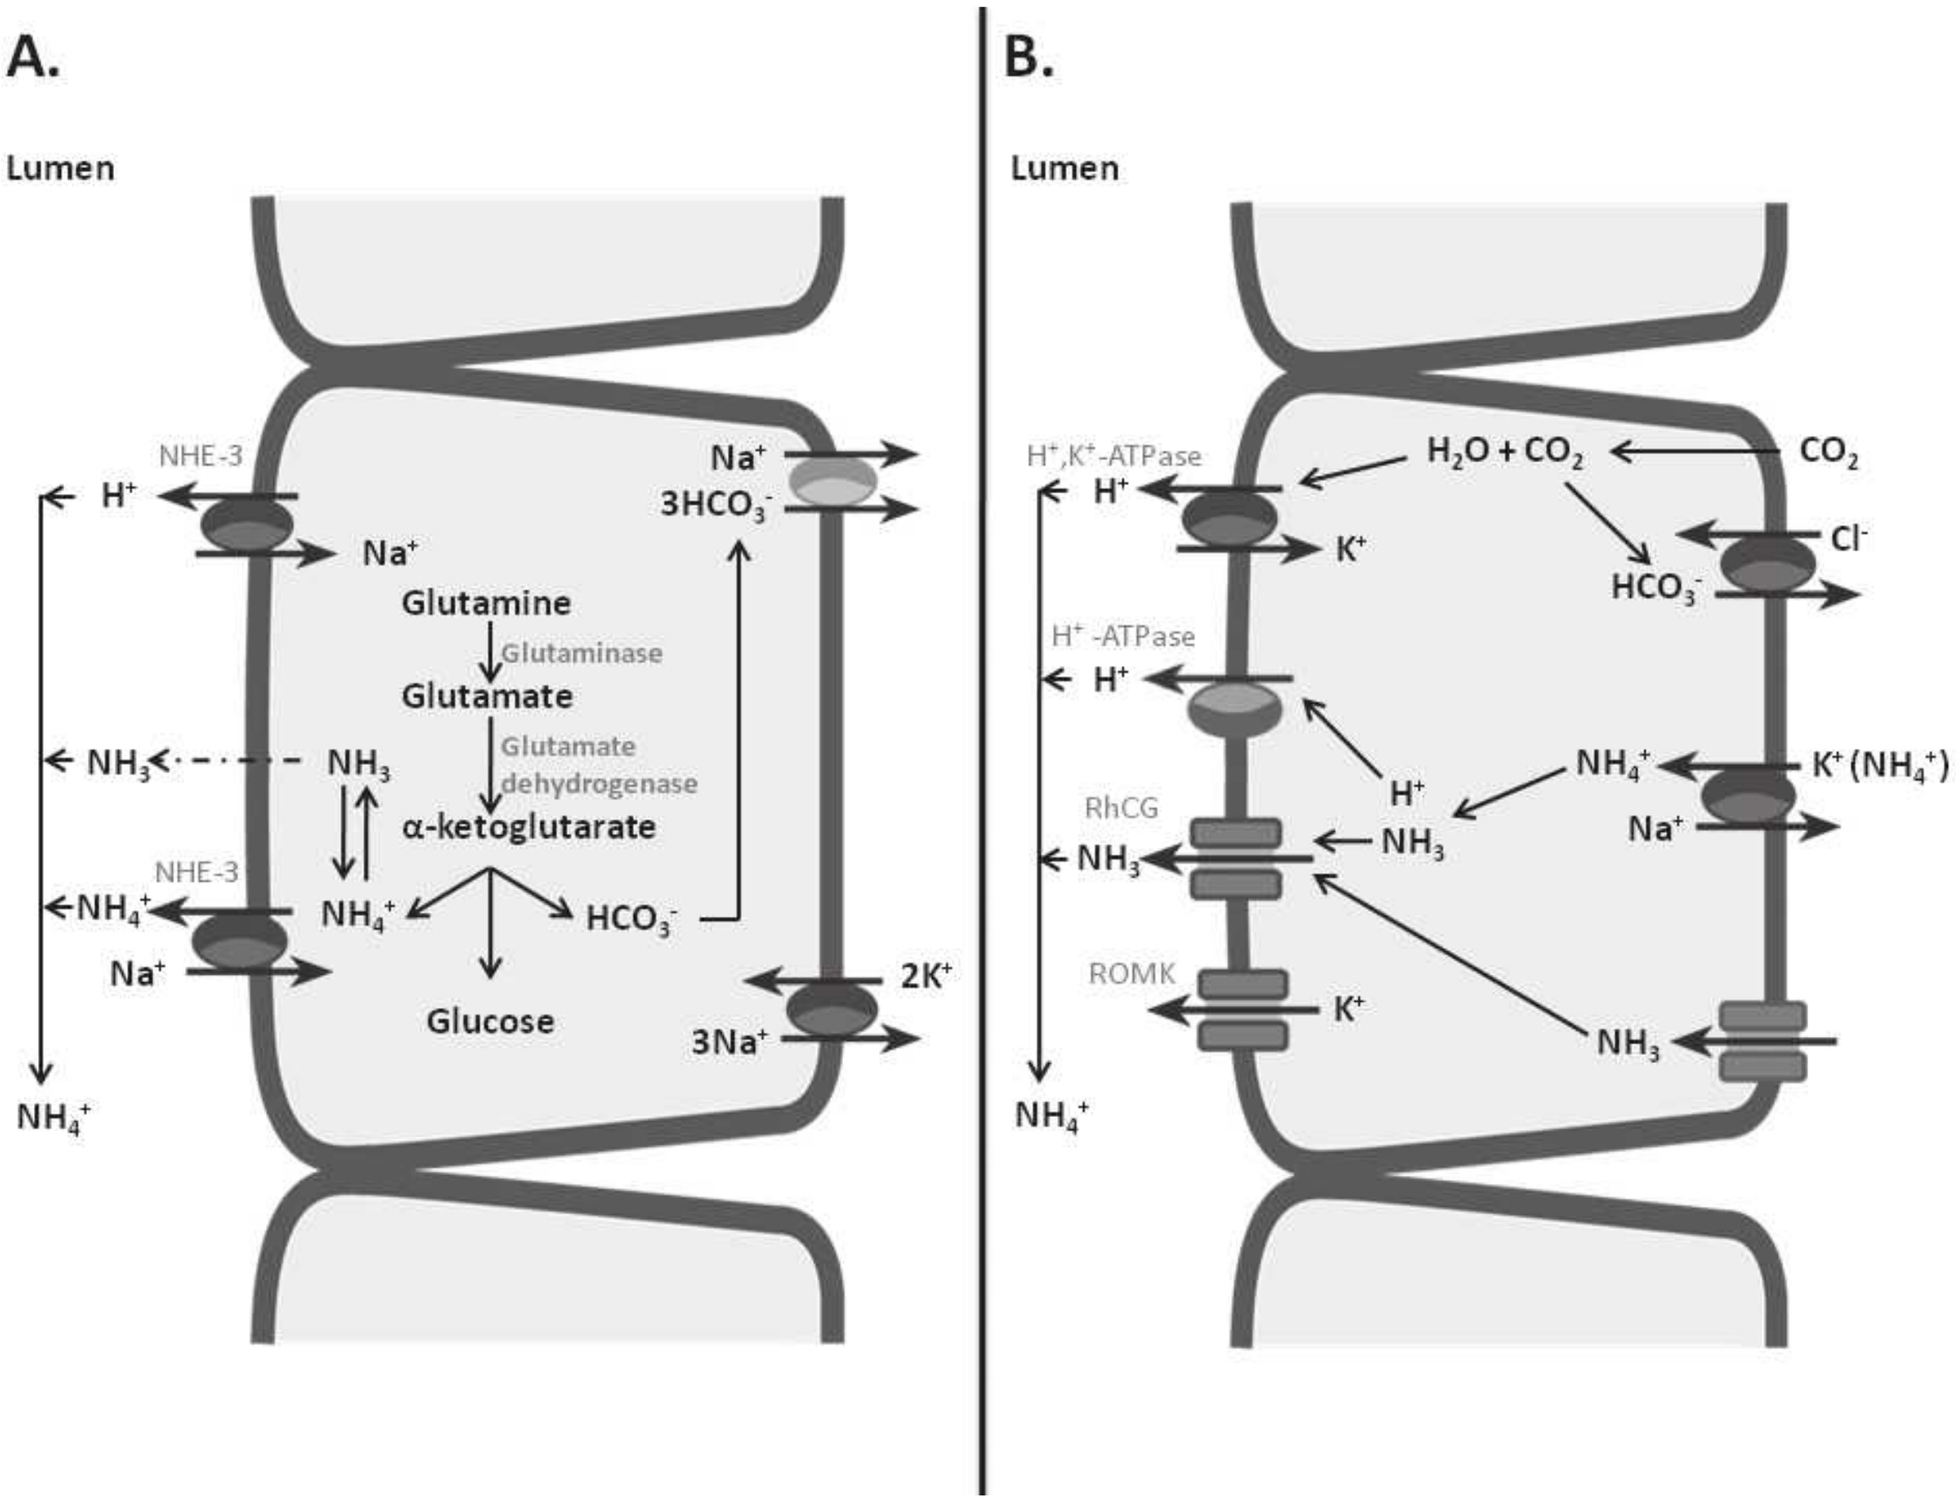

FIGURE 7.1 Cell models of ammonia synthesis and excretion pathways. **A:** A proximal convoluted tubule. Ammonia is derived from glutamine precursors to produce 2 NH_4^+ and 2 HCO_3^- molecules through an enzymatic pathway activated by acidemia and hypokalemia and inhibited by alkalemia and hyperkalemia. **B:** A type A intercalated cell in the collecting tubule. Ammonium enters across the basolateral membrane through the substitution of K^+ for NH_4^+ in K^+ conductance and is secreted across the apical membrane via renal outer medullary potassium (ROMK) or RhCG (see text). In both **A** and **B**, NH_3 diffusion coupled with H^+ secretion traps NH_4^+ in the tubule lumen.

tubule across the apical and basolateral membranes and is then transported into the mitochondria. In the mitochondria, an NH_4^+ molecule is formed when glutamine is deaminated by glutaminase to glutamate. When glutamate is then deaminated to α-ketoglutarate, a second NH_4^+ molecule is formed. Finally, the α-ketoglutarate molecule is metabolized in the Krebs cycle to CO_2, H_2O, glucose, and the two HCO_3^- molecules. Glutamine deamination in the kidney is highly regulated by systemic pH, so that acidemia augments and alkalemia inhibits NH_4^+ and HCO_3^- production. Hepatic regulation of NH_4^+ metabolic pathways appears to facilitate glutamine production when NH_4^+ excretion is stimulated by acidemia or, conversely, blunts glutamine production when excretion is inhibited by alkalemia.[5]

Renal Excretion of Ammonia/Ammonium

The ultimate control, however, resides in the renal excretion of NH_4^+, because the NH_4^+ must be excreted to escape entry into the hepatic urea synthetic pool. Hepatic urea synthesis would negate the new HCO_3^- realized from α-ketoglutarate in the kidney. Thus, ammoniagenesis does not contribute to acid–base homeostasis until the urine is acidified and the HCO_3^- produced by glutamine metabolism is added to the ECF. In order for this to occur, the ammonia synthesized in the proximal tubule has to be transported to the terminal nephron segments and is then excreted by the kidney (the pathway is described in detail in the following paragraphs). This ammonia transport occurs through both nonionic diffusion (for NH_3) and ionic transport (for NH_4^+). NH_3 quickly and easily diffuses across the plasma membrane to compartments of lower pH, where it is rapidly converted to NH_4^+, thus leading to accumulated NH_4^+ in acidic compartments. NH_4^+ can diffuse across tight junctions or can substitute on transporters such as the apical membrane Na^+–H^+ (NHE-3) antiporter (as Na^+–NH_4^+ exchange).[6] In general, NH_3 has a higher membrane permeability than NH_4^+, but the concentration of NH_4^+ exceeds that of NH_3 by approximately 100-fold at a pH 7.4 (pK 9.3). Thus, the relative

permeability of the two moieties defines whether either crosses membranes by nonionic NH_3 diffusion or ionic NH_4^+ transport; for example, if the NH_4^+ moiety is transported in a specific nephron segment as in the thick ascending limb of the loop of Henle by substitution for potassium on the Na^+–K^+–$2Cl^-$ cotransporter.

The first step of ammonia transport and urinary excretion following ammoniagenesis in the proximal tubule is for the ammonia to enter the proximal tubule lumen, and it can do so in two ways. Because the luminal pH is lower than cell pH, much of the NH_3 is diffused into the tubule fluid and is converted into NH_4^+. The apical membrane Na^+-H^+ antiporter also plays an important role in NH_3–NH_4^+ transport (Fig. 7.1A).[7,8] Transport mechanisms for NH_3–NH_4^+ in more distal segments function to ensure that the NH_3– NH_4^+ issuing out of the proximal tubule fluid is excreted into the urine in a regulated fashion.

From the lumen, ammonia enters the medullary interstitium (Fig. 7.2) via the thick ascending limb of the loop of Henle. If ammonia did not enter the interstitium, it would return to the distal nephron and diffuse back into the blood, thereby failing to be excreted in the urine. The thick ascending limb of the loop of Henle also creates a "corticomedullary concentration gradient" for NH_3–NH_4^+. The NH_3–NH_4^+ transported into the medullary interstitium accumulates at a higher concentration by countercurrent multiplication and can reenter the collecting tubule for a final excretion in a more regulated way. Nonionic diffusion of NH_3 into the medullary interstitium is not possible because the thick ascending limb's apical membrane is highly impermeable to NH_3.[9] NaCl transport enables the ionic transport of NH_4^+ into the interstitium. NH_4^+ can substitute for K^+ on the Na^+–K^+–$2Cl^-$ cotransporter, or it can be transported via the renal outer medullary potassium (ROMK) channel for transport across the apical membrane (Fig. 7.1B). Alternatively, lumen-positive voltage can drive NH_4^+ diffusion across the tight junction. NH_4^+ that enters the thick ascending limb cell can exit the basolateral membrane by nonionic diffusion driven by cell-to-interstitial NH_3 concentration gradient. Once in the interstitium, the NH_3

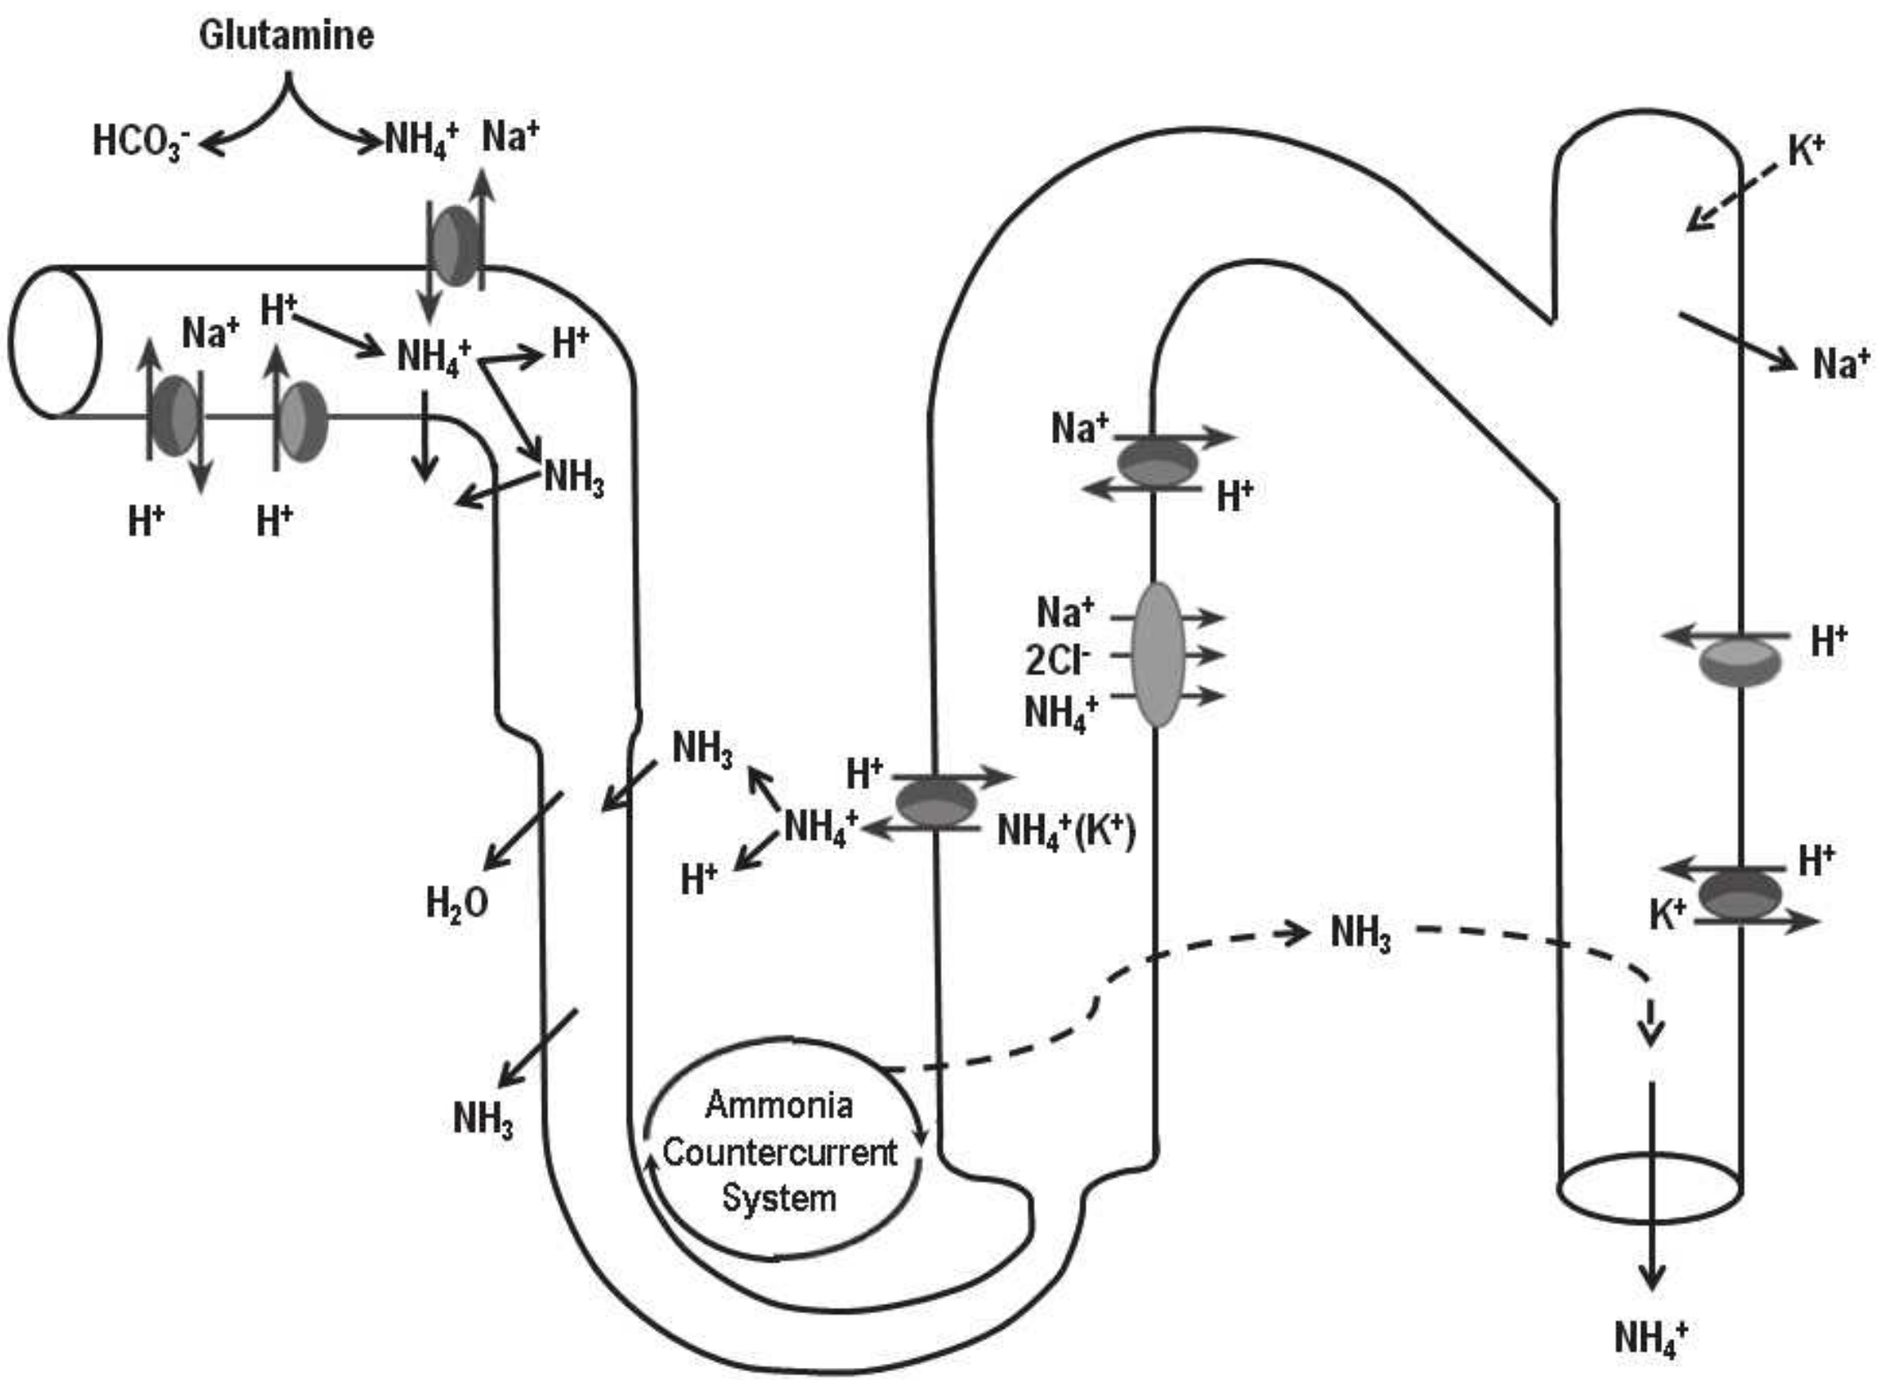

FIGURE 7.2 Nephron sites of ammonia production, secretion, transport, and ultimately, excretion. Note that approximately 75% of ammonia/ammonium delivered to the loop of Henle is transported into the medullary interstitium and is accumulated through countercurrent multiplication, thus resulting in higher concentrations from the cortex to the medulla. In acidosis, both the production of ammonia/ammonium and the transport, multiplication, and excretion of NH_4^+ is augmented. Therefore, the physiologic response of the kidney to an acid load is to increase bicarbonate reabsorption and ammonia production and excretion. The resulting urine should demonstrate a pH $<$5.5 and a higher concentration of ammonium. If these conditions are met, a normal gap metabolic acidosis would be nonrenal in origin.

will again accept a H^+, forming NH_4^+. Furosemide, which inhibits the Na^+–K^+–$2Cl^-$ cotransporter and secondarily inhibits the lumen-positive voltage, significantly inhibits all three mechanisms of thick ascending limb NH_3–NH_4^+ absorption.[6,10,11]

Through these processes, NH_3–NH_4^+ accumulates in the renal medulla (Fig. 7.2). The countercurrent system concentrates the solute toward the tip of the medulla and preserves the cortical-to-medullary gradient. Blood in the descending vasa recta has lower NH_3–NH_4^+ concentrations than the surrounding interstitium, allowing net entry. Conversely, blood in the ascending vasa recta has a higher NH_3–NH_4^+ concentration than the surrounding interstitium, causing net efflux. In patients with an intact urinary concentrating system and medullary architecture, the net result is a steep gradient, with the highest concentrations of NH_3–NH_4^+ in the inner medullary interstitium.

Ultimately, NH_3–NH_4^+ is transported from the medullary interstitium into the lumen of the collecting tubule for final urinary excretion (Figs. 7.1B and 7.2). The apical and basolateral membranes of the medullary collecting tubule are permeable to NH_3, allowing nonionic diffusion to be driven by the low pH of the collecting tubule fluid. In addition, NH_4^+ can be transported from the medullary interstitium into the collecting tubule cell on the Na^+, K^+-ATPase.[12] Once inside the cell, the dissociation of NH_4^+ into NH_3 and H^+ provides a source of H^+ for transport into the luminal fluid by the vacuolar H^+-ATPase. H^+ secreted into the luminal fluid will combine with secreted NH_3 to form NH_4^+, maintaining the gradient for nonionic NH_3 diffusion into the luminal compartment, which has a much lower pH, and this way NH_4^+ is "trapped" in tubule fluid and is swept into the collecting system. Medullary interstitial NH_3–NH_4^+ concentrations are determined by the rate of ammonia synthesis in the proximal tubule, the efficiency of ammonia transport into the lumen of the proximal tubule and subsequently into the medullary interstitium in the thick ascending limb, and the efficiency of countercurrent trapping of ammonia in the medullary interstitium. Both ammonia synthesis and each step in the highly integrated response by the nephron to excrete ammonia are upregulated by metabolic acidosis and chronic hypokalemia, and are inhibited by alkalosis and hyperkalemia (see Chapter 18).

The Rh glycoprotein (RhCG/Rhcg), which is expressed not only in both principal and intercalated cells but also in the distal convoluted tubule, connecting tubule, initial collecting tubule, cortical collecting duct, and the outer and inner collecting ducts, is now thought to be critical for the excretion of ammonia by the kidney (Fig. 7.1B).[13,14] RhCG expression is greater in A-type intercalated cells than in principal cells but is not detectable in B-type intercalated cells.[15] RhCG is thought to play a role in renal ammonia excretion because of some recent genetic studies. Biver and colleagues[16] found that global RhCG deletion impaired ammonia excretion in the urine and decreased basal ammonia excretion in response to metabolic acidosis. Similar findings were observed when RhCG was deleted only from the collect ducts.[17] In summary, that both intercalated and principal cells express RhCG and that metabolic acidosis increases RhCG in both cell types suggests that RhCG contributes to transepithelial ammonia secretion.[16]

Therefore, the sum of TA and ammonia/ammonium excretion is represented, as noted previously, as net acid excretion (Eq. 9). All three components of net acid excretion are dependent on the operation of an H^+ secretory mechanism into the tubule fluid. Therefore, increases in the rate of H^+ secretion will increase urinary ammonium and TA excretion and will lower urinary HCO_3^- excretion. A protein-rich diet leads to acid production, so the kidneys must both reclaim the filtered bicarbonate and also excrete an acid equivalent to that produced in the diet. In this way, in a steady state, net acid production equals net acid excretion, and acid–base balance is maintained. In the presence of nonprotein-rich diets, the tubules do not reclaim all of the filtered bicarbonate and they decrease production of new bicarbonate in order to maintain acid–base homeostasis.

SPECIFIC MECHANISMS OF H^+–HCO_3^- TRANSPORT ALONG THE NEPHRON

How the transport of H^+ and HCO_3^- in the nephron occurs is generally defined by the specific characteristics of each epithelium and cell type within the nephron segments. Bicarbonate reabsorption is largely the responsibility of the proximal tubule and net acid secretion is largely of the distal tubule. A number of transport mechanisms across either the apical (for H^+) or basolateral (for alkali) membranes have been identified and are detailed in the following paragraphs.

Apical Membrane H^+-Transport Mechanisms

Renal tubule cells use both primary and secondary transport mechanisms for active H^+ secretion. A primary transport couples the metabolism to a transport mechanism, whereas a secondary transport couples the transporter to the metabolism, which generates a concentration gradient for a solute.

There are two mechanisms for primary active H^+ secretion, both of which are directly related to the metabolism of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate (P_i). The first and quantitatively most important mechanism involves the vacuolar H^+-ATPase, or V-type ATPase, a multisubunit protein complex that secretes H^+,[18] and is electrogenic, thereby generating a positive charge in the tubule lumen. The ability of the H^+-ATPase to affect H^+ secretion depends on where it is located; when it is in the proximal tubule, it minimally mediates H^+ secretion into the lumen, but in type A (acid secreting) intercalated cells of the collecting tubule, it significantly mediates H^+ secretion into the lumen. This

mechanism is able to adapt as needed by increasing mRNA and protein abundance to protect against metabolic and respiratory acidosis.

The second mechanism for primary active H^+ secretion involves P-type ATPases. The P-type ATPases, which are isoforms of the H^+–K^+–ATPase ($HK\alpha_1$, the gastric isoform, and $HK\alpha_2$, the colonic isoform), participate importantly in H^+ transport by the collecting tubule. These P-type ATPases are coupled to ATP metabolism, have a phosphorylated high-energy intermediate, and possess α and β subunits. Both the gastric and colonic isoforms are expressed on the apical membranes of type A intercalated cells (IC) in the cortical collecting tubule, and the outer and inner medullary collecting tubules.[19–24] These transport processes are electroneutral, mediating H^+ secretion across the apical membrane into the tubule lumen in exchange for K^+ entry (into the cell). Both isoforms react to metabolic or respiratory acidosis by increasing in abundance and activity. Alternatively, the two types of H^+-transporters are also located on the basolateral membranes of type B (bicarbonate secreting) ICs in the cortical and outer collecting tubule.[25–29] The H^+-ATPase or H^+, K^+-ATPase in this location mediates H^+ transport across the basolateral membrane into the interstitium.

The secondary active H^+ transporter is an isoform of the Na^+-H^+ antiporter, NHE-3. Although there are eight known isoforms of the Na^+-H^+ antiporter, NHE-3 (*SLC9A3*) is the most important for bicarbonate reabsorption. It is located in the S_1 and S_2 proximal tubule and thick ascending limb of the loop of Henle on the apical membrane and mediates H^+ secretion into the tubule fluid.[30–33]

Basolateral Bicarbonate Transport

Two transporters mediate passive base efflux along the nephron. One transporter is the electroneutral Cl^-/HCO_3^- exchanger, which carries HCO_3^- out and Cl^- into the cell across the basolateral membrane in the S3 segment of the proximal tubule, the thick ascending limb of the loop of Henle, and the cortical and medullary collecting tubules. This Cl^-/HCO_3^- exchanger is a member of the anion exchanger 1 (AE1) family and is a truncated form of the red cell AE1 Cl^-/HCO_3^- exchanger,[34–37] or kAE1 (*SLC4A1*). The mRNA lacks the first three exons of red cell mRNA,[38] but the net result of this truncation is a protein with similar transport characteristics but altered cytoskeletal interactions. Cl^- enters the cell in exchange for HCO_3^- and exits the basolateral membrane through a Cl^- conductance.[39,40]

The second is the sodium bicarbonate cotransporter (NBC), of which there are four isoforms. The NBCe1 (*SLC4A4*) isoform is the most important for base efflux, mediating the majority of base efflux (~80%) out of the cell and into the interstitium.[41–44] It is present on the basolateral membrane of the proximal tubule and is electrogenic because it transports three base molecules with one Na^+ ion ($Na^+/n\ HCO_3^-$ or *SLC4A4*).[41–44]

SEGMENTAL CONTRIBUTION TO BICARBONATE ABSORPTION AND ACIDIFICATION OF THE URINE

Proximal Tubule

The proximal tubule reabsorbs approximately 80% of the filtered HCO_3^- load; the HCO_3^- concentration at the end of the proximal tubule is approximately 8 mEq per liter and the pH is 6.7.[45,46] The reabsorption rate is a function of proximal tubule segmentation, so the rate of HCO_3^- reabsorption is highest in the early segment (S_1), decreases in the midsegment (S_2), and is lowest in the terminal segment (S_3).

The specific mechanisms responsible for H^+–HCO_3^- transport in the proximal tubule are shown in Figure 7.3. Approximately two-thirds of H^+ secretion is mediated by the apical membrane Na^+–H^+ antiporter, and the remaining one-third is mediated by the vacuolar H^+–ATPase.[47–49]

The active secretion of H^+ into HCO_3^--rich glomerular ultrafiltrate by the NHE-3 results in the formation of H_2CO_3. Luminal carbonic anhydrase (type IV) facilitates the conversion of H_2CO_3 to CO_2 and H_2O and prevents the generation of limiting pH gradients across the proximal convoluted tubule.[50] CO_2 diffuses readily into the cell where, under the influence of cytoplasmic carbonic anhydrase (type II), it forms H_2CO_3 that dissociates rapidly to H^+ and HCO_3^-, which are transported, respectively, across the apical and basolateral membranes. Studies from Weinman's group[51] have clearly established that NHERF-1 (sodium-hydrogen exchange factor 1) is required for a protein kinase A (PKA)–associated downregulation of NHE-3 activity. NHE-3 has a specific requirement for NHERF-1 for cAMP-mediated phosphorylation and inhibition. In addition to H^+ secretion via NHE-3, an apical H^+-ATPase is also responsible for a small but significant fraction of bicarbonate reclamation in the proximal tubule.

HCO_3^- generated in the proximal tubule cell exits passively across the basolateral membrane Na^+/n-HCO_3^- cotransporter, or NBCe1, encoded by *SLC4A4* which, as mentioned previously, transports the equivalent of three HCO_3^- ions out in parallel with one Na^+ out (Fig. 7.3).[41–44,52,53] This is a passive process because this transporter carries a net of two negative charges, and the negative cell voltage provides a strong, favorable driving force for base efflux.

As noted previously, in addition to bicarbonate reabsorption, a second function of the proximal tubule in acid–base balance is to synthesize the NH_3 needed for HCO_3^- regeneration (see Fig. 7.1A) (see previous discussion on ammoniagenesis and ammonia/ammonium transport).

The Loop of Henle

Approximately 50% to 70% of the HCO_3^- delivered out of the proximal tubule is reabsorbed in the thick ascending limb of the loop of Henle.[54] The secretion of H^+ across the apical membrane is mediated by NHE-3 as in the proximal tubule (Fig. 7.4B).[30,54] A low cellular Na^+ concentration, as in the proximal tubule, is maintained by the

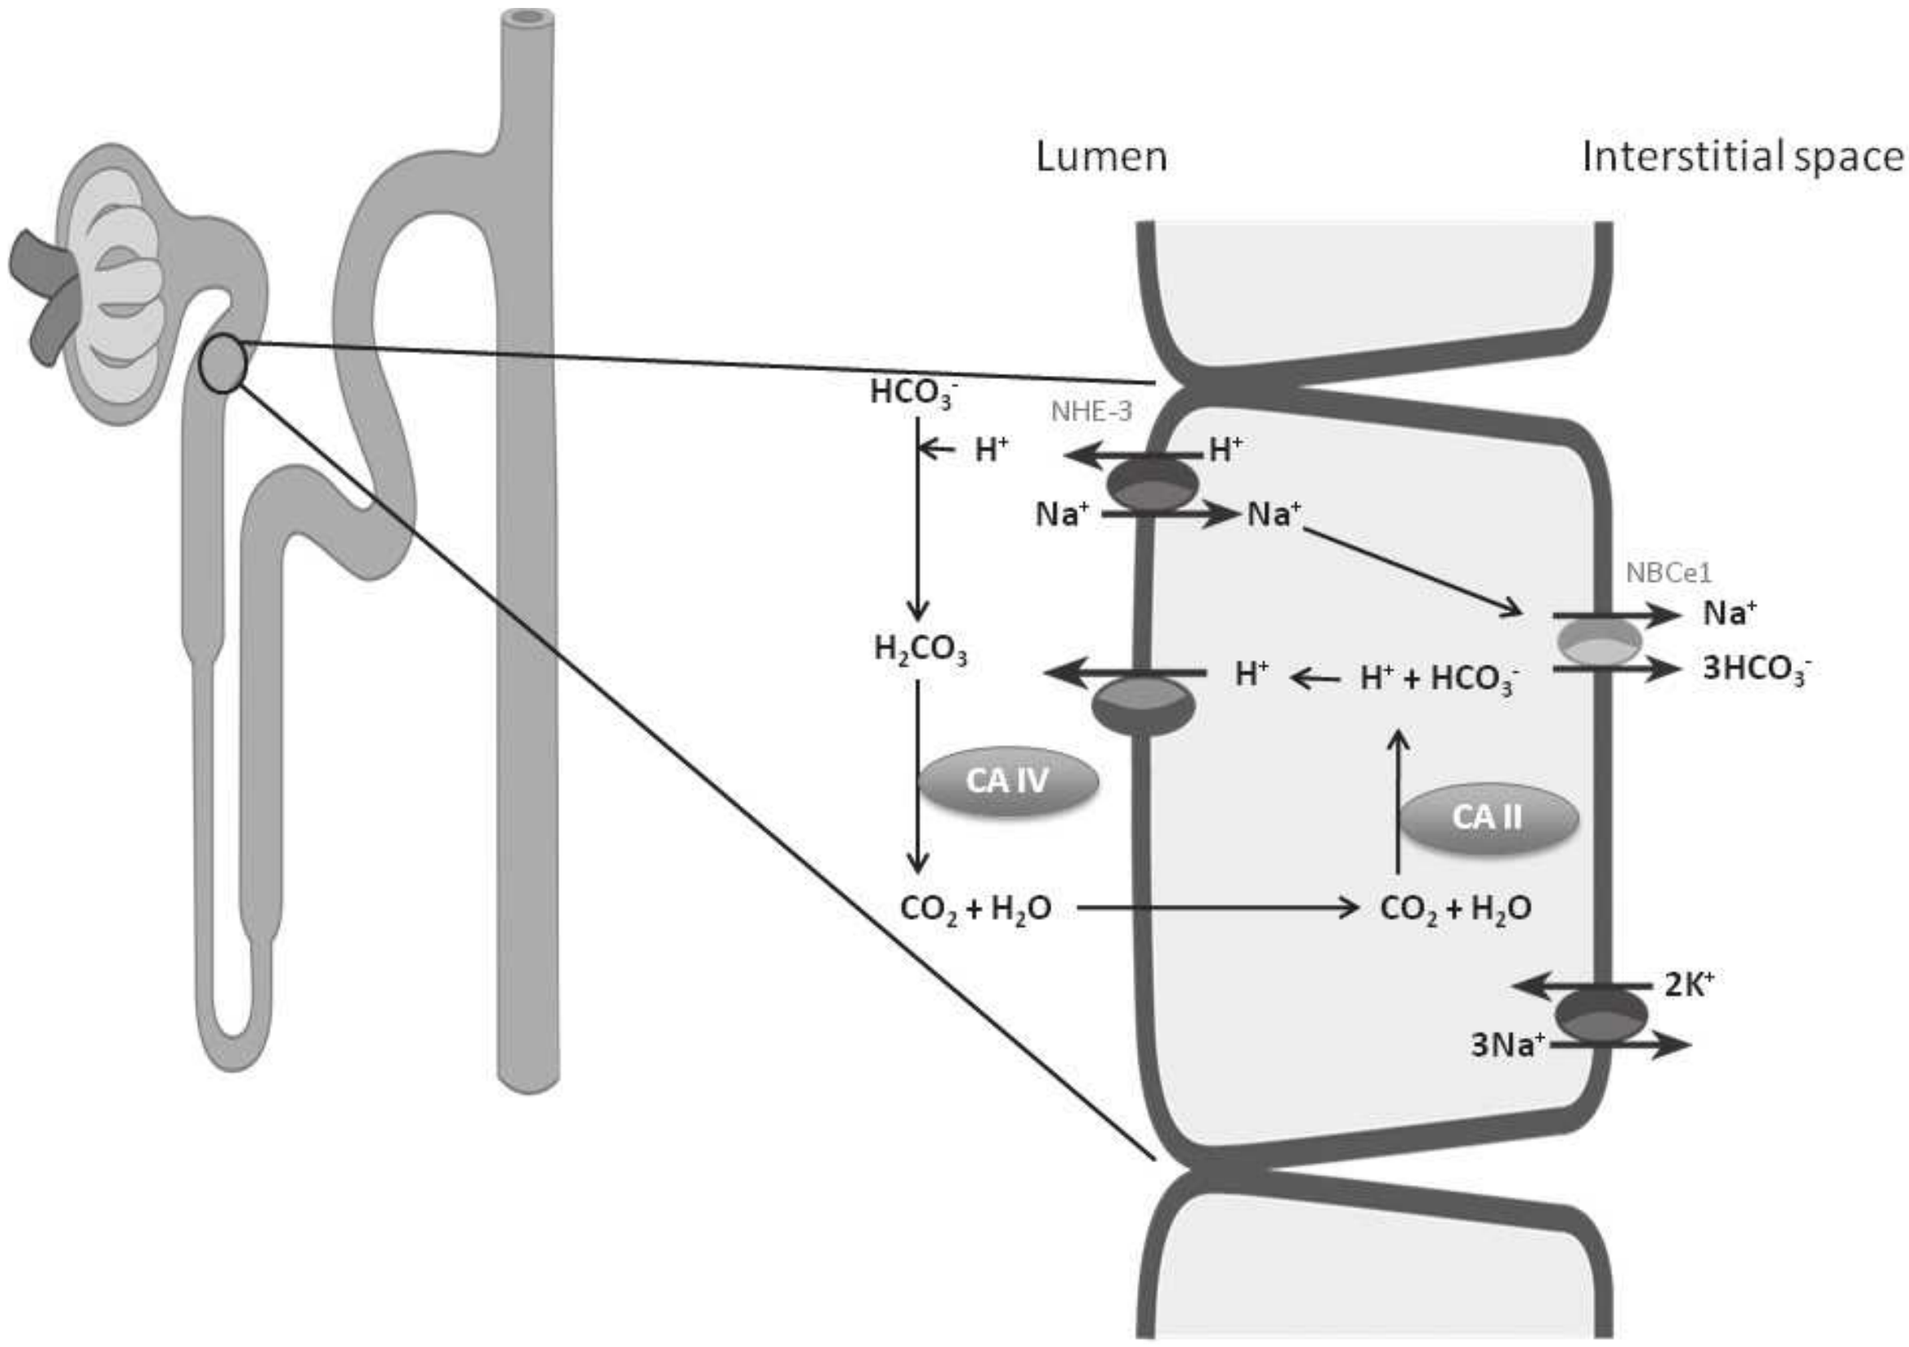

FIGURE 7.3 Aproximal convoluted tubule: the coupled apical and basolateral transporters responsible for bicarbonate reabsorption.

basolateral membrane Na^+, K^+-ATPase, to provide the driving force for operation of the Na^+/H^+ exchanger. Both AE1 (chloride–bicarbonate exchange) and NBC-2 or -3 (sodium–bicarbonate cotransport) are expressed on the basolateral membrane, where they mediate bicarbonate exit across the basolateral membrane.[55–57]

The Distal Tubule and the Collecting Duct

The distal tubule and the collecting duct are responsible for the final acidification of the urine. This process involves three steps: (1) the residual HCO_3^- in tubule fluid is reabsorbed; (2) the final titration of buffers is accomplished (TA excretion); and (3) the H^+ secreted traps ammonium in the lumen so that the majority of ammonia produced is excreted as NH_4^+ (Fig. 7.2). Stoichiometrically, excretion of NH_4^+ is necessary to regenerate the HCO_3^- lost in the buffering of acid products of metabolism. Therefore, each NH_4^+ excreted replenishes one HCO_3^- that is returned to the ECF via the renal vein. If the NH_4^+ is not excreted by the kidney, NH_3 is returned to the liver where each NH_3 molecule generates $2H^+$ in ureagenesis. Conversely, when the kidney is required to excrete alkali, the distal nephron is able to secrete HCO_3^-.[58]

The distal nephron, which begins at the macula densa, is a short segment that exhibits a small amount of amiloride-sensitive HCO_3^- reabsorption mediated by an apical membrane Na^+-H^+ antiporter isoform NHE2 (Fig. 7.4C).[29,59–61] Subsequent segments, including the connecting tubule, the initial cortical collecting tubule, and the cortical collecting tubule all possess ICs that mediate H^+–HCO_3^- transport. Type A ICs secrete H^+ into the tubule fluid and type B ICs secrete HCO_3^- across the apical membrane (Fig. 7.4D).

Type A ICs accomplish H^+ ion secretion through a process mediated by two ATP-dependent H^+ pumps, a V-type H^+-ATPase, and an H^+, K^+-ATPase (which is a P-type ATPase) (Fig. 7.5). There is abundant evidence supporting a role for both transporters. The H^+-ATPase has been localized by (1) the labeling of cells with antibodies against subunits of the vacuolar H^+-ATPase,[25,26] (2) the inhibition of H^+ transport by bafilomycin A_1, a specific inhibitor of vacuolar H^+-ATPases,[27,29] and (3) the electrogenicity of acidification in this nephron segment.[62] With regard to the latter, luminal acidification is associated with a lumen-positive voltage. Generation of a transepithelial voltage requires electrogenic or conductive processes on both apical and basolateral membranes. Because the IC does not possess significant apical membrane conductance,[39,40] electrogenic acidification requires an electrogenic H^+ pump.

Immunohistochemical studies show localization of the electroneutral H^+, K^+-ATPase to the apical membrane of a type A IC using antibodies against both the gastric ($HK\alpha_1$) and the colonic ($HK\alpha_2$) H^+, K^+-ATPase isoforms (Fig. 7.5).[63–65] Bicarbonate transport and potassium absorption are both

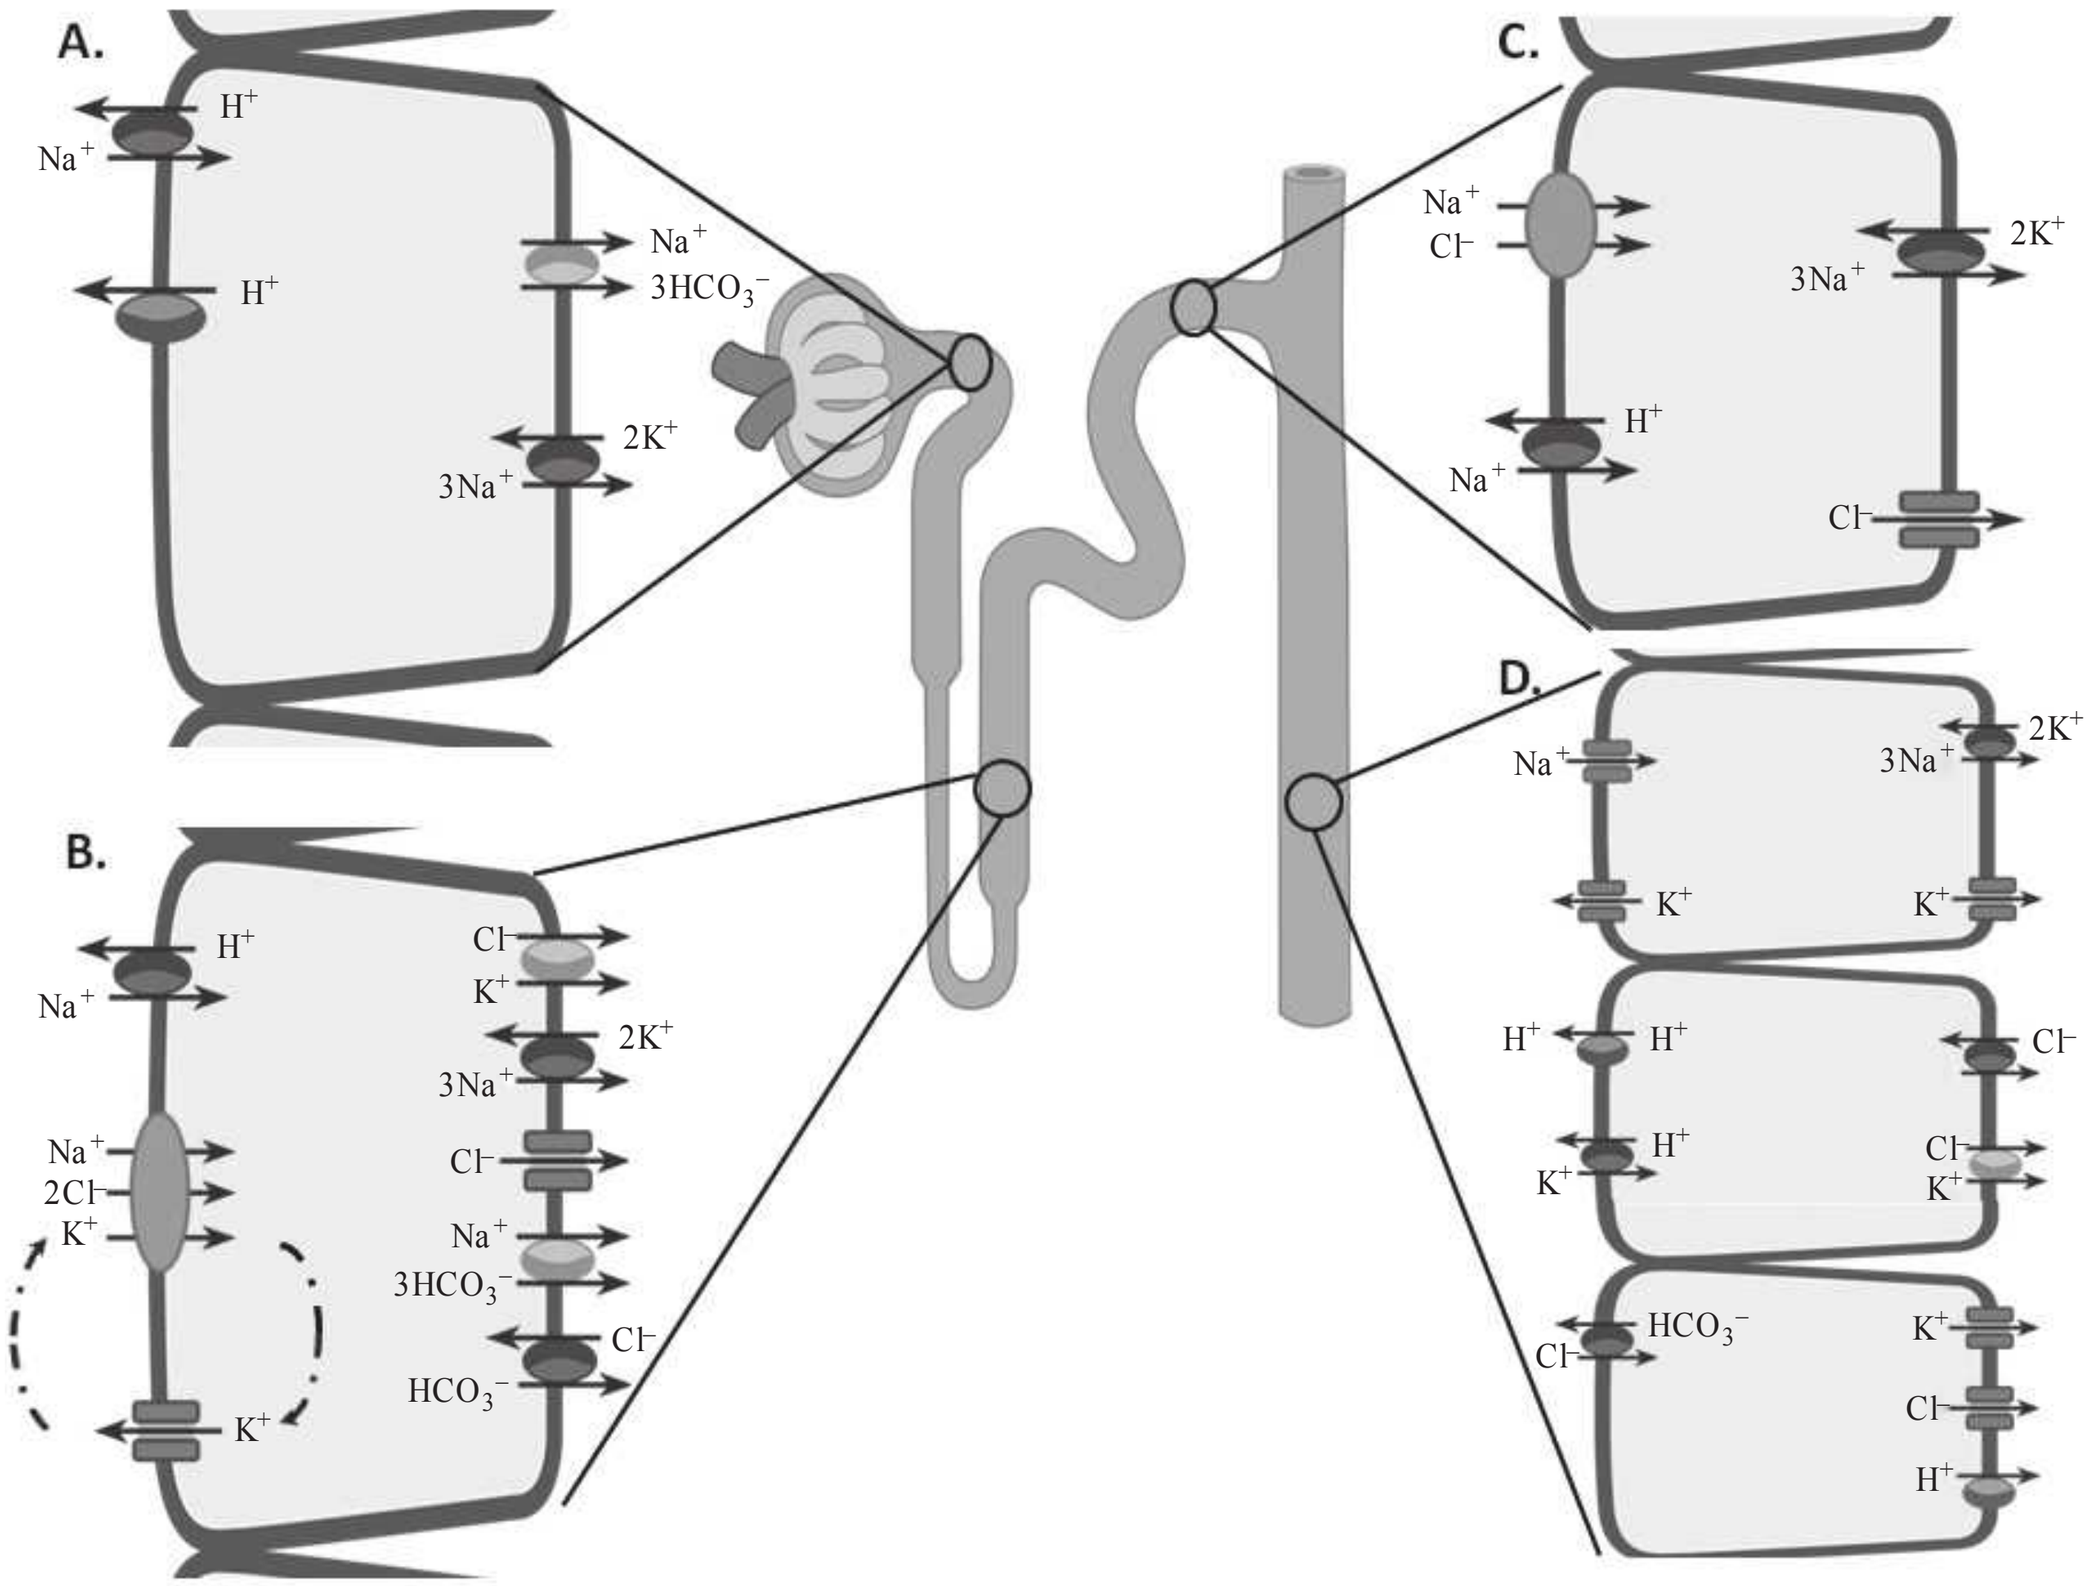

FIGURE 7.4 The H^+–HCO_3^- transport in the proximal tubule (*A*), the thick ascending limb of the loop of Henle (*B*), the distal convoluted tubule (*C*), and the collecting duct (*D*). Note that three cell types are displayed for the collecting tubule (*D*): the principal cell that does not participate directly in H^+ secretion, the type A intercalated or acid-secreting cell, and the type B intercalated or base-secreting cell.

inhibited by SCH 28080, a specific inhibitor of the gastric H^+, K^+-ATPase.[29,66–69]

The colonic isoform of H^+, K^+-ATPase, $HK\alpha_2$, is highly responsive to and upregulated by chronic potassium depletion. The site of regulation is most robust in the outer and inner medulla. The H^+, K^+-ATPase may play a highly significant role in potassium depletion, when its expression is significantly increased to minimize K^+ loss in the urine.[24,70] This regulatory response may explain the role of persistent chronic hypokalemia in the maintenance of metabolic alkalosis by maintaining H^+ secretion mediated by the H^+, K^+-ATPase, to prevent dangerous hypokalemia. In addition, both $HK\alpha_1$ and $HK\alpha_2$ increase abundance and activity due to either metabolic or respiratory acidosis. There is no specific inhibitor for $HK\alpha_2$ but Li and associates[71] in the DuBose laboratory have shown inhibition by intermediate concentrations of ouabain in vitro. Therefore, in summary, both the V-type H^+-ATPase and the H^+, K^+-ATPases contribute to H^+ secretion, although their relative contributions appear to be nephron segment–specific.

Type BICs secrete HCO_3^- into tubule fluid through the coupling of active secretion of H^+ across the basolateral membrane into the interstitium (Fig. 7.5) by both a vacuolar H^+-ATPase and an H^+, K^+-ATPase.[66] Therefore, these cells are mirror images of type A ICs and appear to be involved in protecting against metabolic alkalosis through a more efficient excretion of chronic bicarbonate loads. Type B ICs secrete HCO_3^- across the apical membrane into the collecting duct via a Cl^-/HCO_3^- exchanger. However, this Cl^-/HCO_3^- exchanger is not the same AE1 Cl^-/HCO_3^- exchanger found on the basolateral membrane of the proximal tubule. Rather, the anion exchanger pendrin, which is encoded by *SLC26A4*, is localized to the apical membrane of nonacid-secreting ICs in the kidney cortical collecting duct (CCD) (Fig. 7.5). Cl^- that enters the cell in exchange for HCO_3^- exits the cell through a basolateral membrane Cl^- conductance. This process does not generate a transepithelial voltage, because there is no net transcellular current.

The ability to secrete HCO_3^- disappears in the outer medullary collecting tubule. Here, the H^+ ion secretion is mediated by cells that are functionally similar to type A ICs.

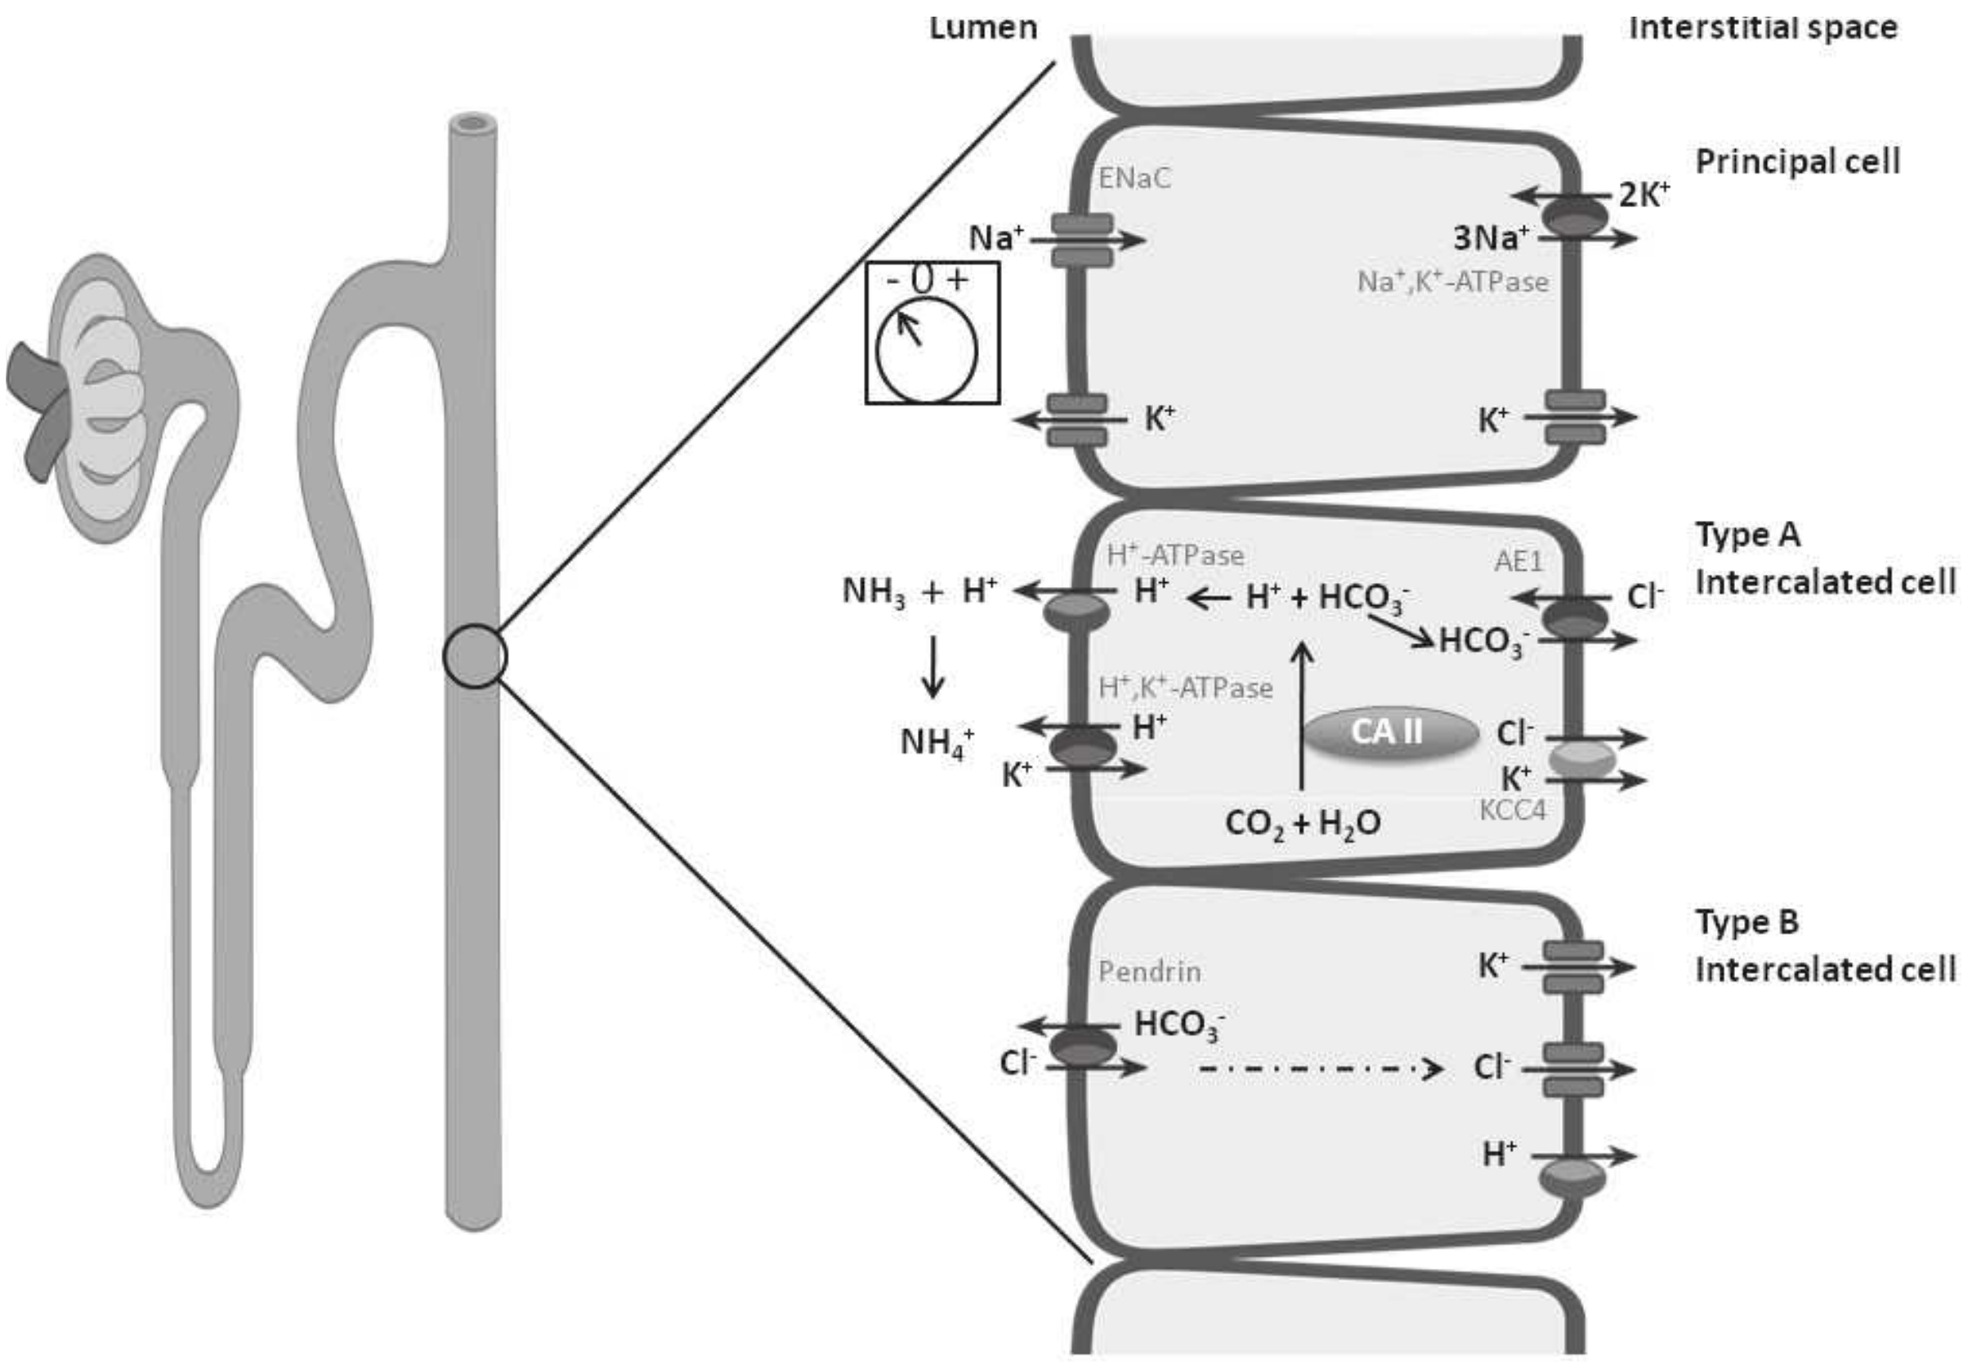

FIGURE 7.5 The H^+–HCO_3^- transport in the collecting tubule, which occurs in type A and type B intercalated cells.

In some cases, these cells are designated as non-A and non-B intercalated cells. The inner stripe of the outer medullary collecting tubule is a high-capacity segment for H^+-secretion. The inner medullary collecting tubule has been difficult to study because of the difficulty in isolating this nephron segment for tubular perfusion. Nevertheless, studies in our laboratory provide evidence for a mechanism of H^+ secretion similar to that described for the type A ICs.[24,70] Moreover, it should be emphasized that this key segment is responsible for the final acidification of the tubule fluid and generates the low urinary pH typical of high acid excretion states.

INTEGRATED KIDNEY REGULATION OF URINARY ACIDIFICATION AND EXCESS BASE EXCRETION

The integrated response of heterogeneous nephron segments to regulate acid–base balance requires the regulation of transport in each of the nephron segment in concert (Fig. 7.4). In the following sections, the most important regulatory responses of H^+–HCO_3^- transport are emphasized.

Luminal HCO_3^- Delivery

In order to avoid metabolic acidosis or alkalosis, H^+ ion secretion and HCO_3^- reabsorption must work in concert. GFR increases lead to luminal flow rate increases, which in turn signal the tubules to secrete H^+ more rapidly. If the rate of acid excretion did not change, too little bicarbonate would be reabsorbed and the luminal pH would decrease too slowly. Alkaline tubule fluid stimulates apical membrane H^+ transporters.[72] The tubule flow rate can also directly regulate the rate of proximal tubule H^+ secretion, regardless of HCO_3^- concentration or luminal composition.[73]

Systemic pH

As noted previously, the kidneys respond to changes in systemic arterial pH (PCO_2) by either increasing urinary acidification (for acidosis) or by inhibiting acidification and increasing bicarbonate excretion (for alkalosis). Because changes in plasma pH cause changes in renal interstitial pH, the mechanisms influencing bicarbonate efflux on the basolateral membrane are also affected. Acidosis enhances HCO_3^- efflux and alkalosis inhibits basolateral membrane HCO_3^- efflux. Thus, in acidosis, cell pH decreases; whereas in alkalosis, it increases.[74] It is the change in intracellular pH that determines apical membrane H^+ ion secretion; relative acidity stimulates H^+ secretion, whereas a more alkaline pH reduces or inhibits H^+ secretion.

The Na^+-H^+ antiporter is activated by decreases in intracellular pH,[75] which also stimulates the insertion of H^+ transporters into the apical membrane.[76,77] These "reserved" H^+ ions in the apical membrane can enhance the rate of H^+

transport when needed. Long-term adaptations in tubular function result from chronic systemic pH changes. In the proximal tubule, chronic metabolic and respiratory acidosis enhances the proximal tubule capacity for H^+ secretion and ammoniagenesis.[78,79] These changes are mediated by parallel increases in apical membrane Na^+-H^+ antiporter and electrogenic basolateral membrane Na^+/n-HCO_3^- cotransporter activity.[80–83]

Such transporter adaptations are known to be a direct effect of pH because they can be experimentally induced by incubating cultured proximal tubule cells in acid media.[84] Enhanced activity of the apical Na^+-H^+ antiporter is mediated by the trafficking of NHE-3 to the apical membrane, and increasing whole cell NHE-3 abundance.[85] Several groups have demonstrated that endothelin-1 (ET-1) increases the activity of NHE-3 and that metabolic acidosis stimulates renal proximal tubule ET-1 expression.[86–89] Studies in ET_B receptor knockout mice demonstrate that the ET-1/ET_B signaling pathway mediates acid stimulation of NHE-3 activity.[90,91] In addition, a consensus sequence (KXXXVPKXXXV) in the second intracellular loop of the ET_B receptor appears to be responsible for ET-1/ET_B stimulation of NHE-3 activity.[92]

How the extracellular pH and the systemic acid–base status are sensed by renal epithelial cells and initiate a regulatory response has not been elucidated. Factors such as pH, PCO_2 and bicarbonate, along with possible hormonal stimuli[28] have all been proposed at one time or another. Early studies by Pitts dating to the 1940s indicated that metabolic acidosis induced by the infusion of 0.1 N HCl causes an increase in net acid excretion, predominately as ammonium excretion.[93,94] Schwartz and Al-Awqati[77] demonstrated that an increase in ambient PCO_2 stimulated proton secretion in isolated perfused proximal tubules and in the collecting ducts of rabbit nephrons. It was later shown that respiratory acidosis was associated with the apical insertion of the H^+-ATPase. Recent studies have suggested that the nonreceptor tyrosine kinases Pyk2 and c-Src may represent a possible signaling pathway involved in the increase in NHE-3 function in the proximal tubule in response to metabolic acidosis.[95–97] Although there is preliminary evidence that Pyk2 is expressed and may also function in the collecting tubule as a pH sensor, the signaling pathway has not yet been delineated (K. Fisher, personal communication, February 2012).

Recently, a small number of G protein-coupled receptors (GPCR) have been identified, the activation of which is stimulated by a reduction in extracellular pH, prompting them to be termed "proton-sensing" receptors. One of these putative proton-sensing GPCRs is the orphan receptor GPR4.[98] GPR4 is an upstream activator of cAMP-PKA signaling, and our preliminary studies implicate GPR4 in the upregulation of proton transporters in the collecting duct of the kidney. Together with existing literature on the activation of other proton translocating ATPases, these findings indicate the presence of an underlying signaling network involved in coordinating the renal adaptive response to acidosis.

Petrovic and colleagues[99] recently reported that deletion of GPR4 in vivo was associated with a reduction in net acid excretion and a relatively alkaline urine pH, parallel with a spontaneous nongap metabolic acidosis, thus providing evidence for an acidification defect in this model. Moreover, some of the features of the renal acidification defect in GPR4-/- resemble that which is reported for mice with the deletion of one of the genes that encodes for the rate-limiting bicarbonate transporter, AE1, in the kidney collecting tubule. Therefore, GPR4 appears to function as a pH sensor in the collecting tubule.

Recent studies have revealed that soluble adenylyl cyclase (sAC) is highly expressed in the collecting tubule and may colocalize with the H^+-ATPase in the apical membrane of type A ICs.[100] It has been suggested that sAC-regulated cAMP signaling may constitute a general sensing mechanism for regulating H^+-ATPase-mediated proton transport. Although parallels exist in the male reproductive tract,[101] how sAC functions to sense bicarbonate, primarily, and how it might function to play a regulatory role in the response to an acid intracellular or extracellular pH, which is pivotal for the renal defense against metabolic acidosis, has not been satisfactorily explained to date.

INTEGRATION OF KIDNEY RESPONSE TO DEFEND AGAINST ACID–BASE DISTURBANCES

As noted previously, a high-protein diet, such as that consumed by most Westerners, requires renal reclamation of most of the filtered bicarbonate as well as net acid excretion that is equivalent to net acid production. The ammonia produced in the kidney is derived from the synthesis of glutamine, and the amount produced is regulated by pH. Acidemia promotes and alkalemia inhibits glutamine synthesis.

Long-term changes in dietary acidity can cause chronic changes in H^+ and HCO_3^- secretion. For example, in the cortical collecting tubule, chronic increases in dietary acid result in an increased capacity for H^+ secretion into the lumen, whereas chronic increases in dietary alkali lead to an increased capacity for HCO_3^- secretion.[102] As noted previously, type A ICs mediate H^+ secretion and type B ICs mediate HCO_3^- secretion. The elegant studies of Schwartz and Al-Awqati[103] over many years have demonstrated that these cells can "switch" phenotypes based on chronic metabolic changes. For example, during metabolic acidosis, the number of type B ICs decreases and the number of type A ICs increases, but the total number of intercalated cells does not change.[104–107] This "switch" could be due to an extracellular protein called hensin.[103] Recent results demonstrate that acidosis induces the polymerization of this novel extracellular matrix protein as follows: The deposition of hensin in the matrix leads to the conversion of a HCO_3^--secreting epithelium to an acid-secreting epithelium. Hensin is deposited in the extracellular matrix of H^+-secreting type A ICs following acid incubation.[108] Alternatively, this "switch" could also be due to the exocytotic insertion of H^+-ATPase into the

apical membrane of type A ICs and the endocytic retrieval of the Cl^-/HCO_3^- exchanger from the apical membrane of the type B ICs.

As noted previously, the kidneys eliminate the acid that is produced daily and have the capacity to increase urinary net acid excretion (and, hence, HCO_3^- generation) in response to endogenous or exogenous acid loads. The renal excretion of acid is usually matched to the net production of metabolic and dietary acids, so little disturbance in systemic pH occurs.

As an acid load is incurred, the kidneys respond to restore balance by increasing the ammonium excretion (TA excretion has limited capacity for regulation). With continued acid loading, the renal net acid excretion increases over the course of 3 to 5 days (Fig. 7.2) but does not quite achieve the level of acid production. Progressive positive acid balance ensues, which is presumably buffered by bone carbonate.

K^+ DEFICIENCY AND HYPERKALEMIA

Chronic K^+ deficiency leads to adaptations in H^+ ion secretion that are similar to those evoked by chronic metabolic acidosis. Thus, chronic K^+ deficiency leads to an increased capacity for transepithelial H^+ secretion by the proximal tubule through parallel increases in the activities of NHE-3 and the basolateral membrane Na^+–$3HCO_3^-$ cotransporter[109] and increases in activities of ammoniagenesis that are also stimulated by chronic metabolic acidosis (Fig. 7.1A).[110] The similarity between these two responses may be the result of chronic K^+ deficiency, which decreases intracellular pH and increases the NHE-3 transport rate.[111,112]

In the collecting tubule, chronic K^+ deficiency increases H^+ secretion through the insertion of H^+ pumps into the apical membrane of H^+-secreting cells (A-type ICs) and through a robust increase in the activity of the H^+, K^+-ATPase (Fig. 7.1B).[70,113–115] The result of the latter is to enhance H^+ ion secretion while, at the same time, to enhance K^+ absorption by the distal nephron. The stimulation of renal acidification in chronic K^+ deficiency explains the association of K^+ deficiency with chronic metabolic alkalosis and is primarily an adaptive upregulation of the H^+, K^+-ATPase, thus offering an explanation for the paradoxical increase in bicarbonate absorption in the face of chronic metabolic alkalosis with hypokalemia.[116] Furthermore, the metabolic alkalosis associated with hypokalemia cannot be corrected until the potassium deficiency is repaired.

Hyperkalemia appears to have the opposite effect on acid–base balance because hyperkalemia inhibits proximal tubule ammoniagenesis and ammonium transport. This decrease in ammonium excretion due to hyperkalemia contributes to the acidification defect characteristic of type 4 renal tubular acidosis.[117,118] Hyperkalemia not only suppresses ammoniagenesis, but also inhibits NH_4^+ reabsorption in the thick ascending limb, resulting in low NH_3 levels in the renal medulla, and, thus, a reduced capacity to buffer H^+ secreted in the collecting tubule.[118] Correcting hyperkalemia increases net acid excretion and helps correct the acidosis in disorders associated with hyperkalemia and the metabolic acidosis of renal origin.[20,114]

THE EFFECT OF MINERALOCORTICOIDS ON URINARY ACIDIFICATION

Mineralocorticoids such as aldosterone stimulate urinary acidification through a number of different mechanisms. Aldosterone binds to its intracellular mineralocorticoid receptor in collecting tubule cells and stimulates the rate of H^+ ion transport[119,120] by parallel increases in the activities of the apical membrane V-type H^+-ATPase[121] and the basolateral membrane Cl^-/HCO_3^- exchanger.[122] It also has indirect effects on H^+ secretion by increasing Na^+ reabsorption in the cortical collecting tubule (CCT) through increasing the open probability of the apical sodium channel in principal cells. This secondarily increases the transepithelial negative potential difference, which is an important driving force for H^+ secretion.[123]

Effective Arterial Volume

Effective arterial volume is an important regulator of renal acidification and is reviewed in the following paragraphs.

Extracellular Volume Expansion

The addition of sodium bicarbonate to the body results in prompt cellular buffering and respiratory compensation. However, as with an acid load, the kidneys have the ultimate responsibility for the disposal of base to restore a normal serum bicarbonate concentration. The renal response is more rapid with the addition of HCO_3^- than with acid ingestion. The speed and efficiency by which HCO_3^- can be excreted renders it challenging to cause more than mild metabolic alkalosis in a patient with normal renal function even with as much as 24 mEq per kilogram per day of sodium bicarbonate over several weeks.[124,125] Type B ICs in the collecting tubule are capable of HCO_3^-/Cl^- exchange (bicarbonate secretion). However, the role of HCO_3^- secretion in chronic alkali loading has never been quantitated precisely in whole organ clearance studies. Presumably, HCO_3^- secretion by the type B IC moderates the development of a more severe alkalosis, enhancing the HCO_3^- excretory response (Fig. 7.5).

The proximal tubule is principally responsible for HCO_3^- excretion when the blood HCO_3^- concentration increases. Absolute proximal HCO_3^- reabsorption does not increase in proportion to the load of HCO_3^- because alkalemia suppresses proximal acidification,[126] causing an increase in the HCO_3^- delivery to the distal nephron. The limited capacity of the distal nephron to secrete H^+ can be overwhelmed easily, and bicarbonaturia increases progressively. NH_4^+ and TA excretion are moderated in response to the increasing urine pH.[124,126]

Acute graded HCO_3^- loads that concomitantly increase ECF also function in human subjects to progressively increase urinary HCO_3^- excretion as the plasma HCO_3^- concentration increases.[126] In summary, an acute base load is excreted entirely when the kidney function is normal, and the blood HCO_3^- concentration is returned to normal within 12 to 24 hours because of the depression of fractional proximal HCO_3^- reabsorption. In addition to the suppression of the filtered HCO_3^- load reabsorption, direct HCO_3^- secretion by the CCT is another means for HCO_3^- disposal during metabolic alkalosis.[124]

The increased delivery of HCO_3^- out of the proximal tubule in response to an increased blood HCO_3^- concentration (filtered HCO_3^- load) in the setting of ECF expansion facilitates HCO_3^- excretion and the return of blood pH to normal. However, other factors may independently enhance distal H^+ secretion sufficiently to prevent HCO_3^- excretion and thus counterbalance the suppressed fractional proximal HCO_3^- reabsorptive capacity. Under these circumstances, the alkalosis is maintained. For example, in the setting of primary hyperaldosteronism, despite the expanded ECF, a stable mild alkalotic condition persists in most experimental models owing to augmented collecting duct H^+ secretion.[124] In such cases, concurrent hypokalemia facilitates the generation and maintenance of metabolic alkalosis by enhancing NH_4^+ production and excretion.[124,126] Moreover, chronic hypokalemia dramatically enhances the abundance and functionality of the H^+, K^+-ATPase in the medullary collecting tubule, thus increasing rather than decreasing bicarbonate absorption.[124,127–129] Enhanced nonreabsorbable anion delivery, as with drug anions, also increases the net collecting tubule H^+ secretion by increasing the effective luminal negative potential difference or by suppressing HCO_3^- secretion in the cortical collecting duct (CCD).

Extracellular Volume Contraction

The renal response to an increase in plasma HCO_3^- concentration can be modified significantly in the presence of ECF contraction.[128,130] Because the distribution volume of Cl^- is approximately equal to ECF, the depletion of the ECF is roughly equivalent to the depletion of Cl^-. The critical role of effective ECF and K^+ stores in modifying net HCO_3^- reabsorption has been demonstrated in numerous experimental models.

In most cases, metabolic alkalosis is maintained by decreases in effective arterial volume. This is due, in part, to volume-induced decreases in GFR (leading to a decrease in filtered HCO_3^- load).[131] Moreover, a decrease in effective arterial volume increases renal acidification by (1) decreasing paracellular HCO_3^- permeability in the proximal tubule, which inhibits HCO_3^- back leak[132]; (2) decreasing the distal delivery of Cl^-, thus inhibiting HCO_3^- secretion in the cortical collecting tubule (by limiting the apical membrane Cl^-–HCO_3^- exchange); and (3) secondarily increasing aldosterone and angiotensin II, as well as renal nerve activity. When taken together, these factors enhance HCO_3^- reabsorption and regeneration.

Deficiency of both Cl^- and K^+ is common in metabolic alkalosis because of renal and/or gastrointestinal losses that occur concurrently with the generation of the alkalosis.[129,130] With Cl^- depletion, the normal bicarbonaturic response to an increase in plasma HCO_3^- is prevented, and metabolic alkalosis can develop. Potassium depletion, even without mineralocorticoid administration, can cause metabolic alkalosis in rats and humans. When Cl^- and K^+ depletion coexist, severe metabolic alkalosis may develop in all species studied.

Two general mechanisms exist by which the bicarbonaturic response to hyperbicarbonatemia can be prevented by Cl^- and/or K^+ depletion: (1) As the plasma HCO_3^- concentration increases, there is a reciprocal fall in GFR and, if inversely proportional to the rise in the plasma HCO_3^- concentration, the filtered HCO_3^- load would not exceed the normal level. Accordingly, normal rates of proximal and distal HCO_3^- reabsorption would suffice to prevent bicarbonaturia. (2) Cl^- deficiency or K^+ deficiency increases the overall renal HCO_3^- reabsorption in the setting of a normal GFR and a high filtered HCO_3^- load. In this case, overall renal HCO_3^- reabsorption, and therefore acidification, would be increased. An increase in renal acidification might occur as a result of an increase in H^+ secretion by the proximal or the distal nephron or by both nephron segments.[124,127,129]

The augmented HCO_3^- absorption in distal nephron segments appears to be due to a primary increase in H^+ secretion that is independent of the delivered HCO_3^- load. Chronic hypokalemia dramatically enhances the abundance and function of the colonic isoform of the H^+, K^+-ATPase in the medullary collecting tubule, which may serve as a significant factor in the maintenance of chronic metabolic alkalosis.[70,115,127]

In summary, the physiologic response by the kidney to a base load associated with volume expansion is to excrete the base. Base is retained, however, if there is enhanced distal HCO_3^- reabsorption as a result of K^+ and/or Cl^- deficiency.

HORMONAL MODULATION OF NEPHRON FUNCTION: AN OVERVIEW

Modulation of Glomerular Filtration Rate

The major physiologic determinants of single nephron glomerular filtration rate (GFR) are glomerular plasma flow (Q_A), glomerular transcapillary hydraulic pressure (P_{GC}), and the ultrafiltration coefficient (K_f).[1] These variables are determined, in part, by the contractile state of the afferent arteriole, efferent arteriole, and mesangial cells. K_f also varies with alterations in the hydraulic permeability of the capillary filtration barrier, which consists of endothelial cells, visceral epithelial cells, and the glomerular basement membrane. By binding to specific receptors on cellular and structural components of the glomerulus, circulating and locally produced hormones influence one or more of the physiologic determinants of GFR. Figure 8.1 summarizes the effects of different hormones on pregomerular, glomerular, and postglomerular contractility. Because the same substance can act at different sites in the glomerular unit, the net effect on GFR will depend on whether its actions are antagonistic or complementary. For example, atrial natriuretic peptide (ANP) decreases afferent arteriolar resistance, whereas increasing efferent arteriolar resistance results in an augmented P_{GC} and a rise in GFR.[2] Under certain conditions, ANP also increases K_f, which, in turn, contributes to the enhancement of GFR.[3] On the other hand, angiotensin (Ang) II-mediated constriction of both afferent and efferent arterioles results in opposite effects on glomerular plasma flow and P_{GC} and, therefore, no change in single nephron GFR.[4] Regulation of glomerular hemodynamics is further complicated by multiple interactions between hormones in the kidney. For example, infusion of Ang II along with a cyclooxygenase inhibitor causes a significant decrease in single nephron GFR, suggesting that endogenous prostaglandin production antagonizes the glomerular effects of Ang II.[5] The net effects of renally relevant hormones on GFR are discussed in more detail later in this chapter.

Modulation of Tubule Water and Electrolyte Transport

Renal tubule cells express receptors for many circulating and locally synthesized hormones. The effects of a particular hormone on water or electrolyte transport are partly determined by the differential distribution of its receptor on functionally specialized segments of the renal tubule. For example, arginine vasopressin (AVP) binds almost exclusively to principal cells in the collecting tubule (CT), where it influences the physiologic functions of this segment, primarily water and urea absorption.[6] Parathyroid hormone (PTH), on the other hand, exerts its biologic actions on renal tubule segments proximal to the collecting duct, where it modulates calcium, phosphate, magnesium, sodium, and bicarbonate transport.[7] Table 8.1 summarizes the net effects of renally relevant hormones on water and solute handling in different tubule segments. Each hormone is discussed in detail in the sections that follow. As in the glomerulus, hormones may modulate their own actions by altering the production of counterregulatory hormones. For example, AVP induces local synthesis of prostaglandin E (PGE), which opposes the effect of AVP on water permeability in the CT.[8]

ARGININE VASOPRESSIN

In 1895, Oliver and Schafer were the first to describe a substance with potent vasopressor effects originating from the posterior pituitary, hence the name, vasopressin.[9] It was not until later in the 20th century that the effects of this hormone on modulation of water excretion by the kidney were discovered. In fact, vasopressin, also called AVP or antidiuretic hormone (ADH), is a key hormone for osmoregulation and maintenance of body homeostasis.[10] AVP was also found to exert effects on body temperature, glucose metabolism, memory, social behavior, and the hypothalamic-pituitary-adrenal axis.

Structure and Synthesis of Arginine Vasopressin

AVP is a 9-amino acid neuropeptide synthesized by magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus.[11] The AVP gene, located on chromosome 20, consists of three exons that encode the signal peptide, AVP, neurophysin II (NPII), and a glycopeptide.[10] After cleavage of the signal peptide within the ER, the resulting prohormone is folded and packaged into secretory granules in neuronal bodies. These granules are then transported along the axons to nerve terminals in the posterior pituitary (neurohypophysis).[12] During axonal transport, further processing of the prohormone within secretory granules yields AVP, neurophysin II (NpII), and a glycopeptide. Interestingly, mutations of NpII impair AVP secretion, suggesting that NpII assists in the processing or secretion of AVP.[13] In addition to the posterior pituitary, AVP synthesis has been detected in the pancreas, adrenal gland, ovary, testis, and regions of the brain.[14] Its physiologic function in these sites, however, remains to be clarified.

Physiology of Arginine Vasopressin in the Kidneys

The most sensitive stimulus for AVP secretion into the bloodstream is increased plasma osmolality. Osmosensitive neurons that respond to changes in plasma osmotic pressure by varying their intracellular water content have been identified in the anterior hypothalamus, specifically in the organum vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO).[15] When stimulated by osmosensitive neurons, the magnocellular neurons release the stored AVP into the posterior pituitary (an area that lacks a blood–brain barrier) and AVP enters the general circulation. As little as 1% change in plasma osmolality leads to a change in AVP concentration that is sufficient to modify renal water excretion.[16] AVP secretion is almost completely suppressed when plasma osmolality decreases below an average of 280 mOsm per kg of water in humans.[17]

Secretion of AVP is also influenced by alterations in intravascular volume and blood pressure, sensed by baroreceptors located in the heart, aortic arch, and carotid sinus.[18] These signals are transferred through the vagal nerves to the

8.1 Hormonal Modulation of Tubular Transport

	Hormones with Major Effects		
	Reabsorption	**Stimulatory**	**Inhibitory**
Proximal tubule	Na	Ang II, catecholamines, insulin	Dopamine, PTH
	P_i	IGF-1	PTH
	HCO_3	Ang II	PTH
	Ca		PTH
TALH	Na	AVP,[a] catecholamines	PGE
	Ca	PTH, calcitonin, glucagon	
	Mg		AVP, PTH, calcitonin, glucagon
DCT	P_i		PTH
	Ca	PTH	
CCD	H_2O	AVP	PGE, bradykinin, ANP, α-adrenergic agents
	Na	Aldosterone	ANP, PGE, EGF
IMCD	Urea	AVP	
SECRETION CCD	K	AVP, aldosterone	β_1 agonists
	H	Aldosterone	

[a]Unlikely in humans.
TALH, thick ascending limb of the loop of Henle; DCT, distal convoluted tubule; CCD, cortical collecting duct; IMCD, inner medullary collecting duct; Ang II, angiotensin II; IGF, insulinlike growth factor; AVP, arginine vasopressin; PTH, parathyroid hormone; PGE, prostaglandin E; EGF, epidermal growth factor.

nucleus solitarius in the brainstem, from which postsynaptic pathways project to the magnocellular neurons. Whereas a 5% to 8% decrease in blood volume or systemic arterial pressure has little effect, further hemodynamic compromise leads to a steep increase in circulating AVP levels. Significant reductions (10%–30%) in circulatory arterial volume or blood pressure can override osmoregulation and result in markedly increased AVP levels in the face of decreased plasma osmolality.[19] Other less potent stimuli for AVP secretion include fever, emesis,[20] and oropharyngeal osmoreceptors.[21]

AVP circulates in the plasma nearly in an unbound form. Levels of circulating AVP depend on both the rate of AVP release from the posterior pituitary and the rate of AVP degradation. As discussed, the major factor controlling AVP release is plasma osmolality. The liver and the kidney both contribute to the breakdown of AVP and the decline in AVP levels when secretion ceases. In fact, the half-life of AVP in the circulation is 18 minutes due to rapid clearance by hepatic and renal vasopressinases.[22] Under physiologic conditions, plasma vasopressin concentrations vary with serum osmolarity between 0 to 5 pg per mL.[22]

It is noteworthy that AVP levels are difficult to measure in plasma because of the instability of this peptide and the low sensitivity of available AVP antibodies. Copeptin (or C-terminal proarginine vasopressin, CT-proAVP) is the C-terminal part of AVP, which is secreted stoichiometrically with AVP in a manner similar to C-peptide and endogenous insulin.[23] CT-proAVP provides a reliable means for estimating prevailing AVP levels in the circulation, thus facilitating the study of AVP in human diseases. A recent cohort study in renal transplant patients suggests that high CT-proAVP strongly correlates with a negative renal prognosis. In fact, in this study, the plasma concentrations of CT-proAVP predicted renal function loss over a 3.2-year follow-up.[24]

AVP exerts its biologic actions through three specific cell-surface AVP receptors identified as V_1R (also called $V_{1a}R$), V_2R, and V_3R (also $V_{1b}R$).[25] These receptors belong to the G protein coupled receptor superfamily (Table 8.2). In the human kidney, mRNA for V_1Rs predominates in cortical collecting ducts (CCD), gradually decreasing as the collecting duct enters the medulla.[26] In addition, whereas V_1R mRNA is diffusely expressed in the CCD, it is restricted to the intercalated cells in OMCD. V_1Rs are responsible for mediating vascular smooth muscle cell vasoconstriction by activating G protein-dependent phospholipase C (PLC) and the downstream effectors, diacylglycerol (DAG), and inositol 1,4,5-triphosphate (IP_3). In turn, DAG stimulates protein kinase C (PKC), whereas IP_3 increases cytosolic Ca^{2+}, thus

8.2 Vasopressin Receptor Types, Genetics, Location, and Main Physiologic Effects

Receptor	Chromosome location	No. of amino acids	Site of action	Main second messenger	Main effects
V_1 (V_1a)	12 (q14–q15)	418	Vascular smooth muscle, platelets, liver, testes, brainstem, adrenal glands	PLC→IP3 + DAG/calcium and PKC	Vasoconstriction, platelet aggregation, glycogenolysis, stimulation of aldosterone and cortisol synthesis
V_2	X (q28)	371	Collecting duct cells of kidney, inner medulla, heart, pancreas	Adenylate cyclase/cAMP	Water retention, stimulation of atrial natriuretic peptide, stimulation of insulin synthesis, coronary and pulmonary artery vasodilation
V_3 (V_1b)	1 (q32)	553	Hypothalamus, anterior pituitary gland	PLC→IP3 + DAG/calcium and PKC	Modulation of ACTH synthesis; stimulation of ACTH, GH, and procaltin release
Oxytocin	3 (p25)	389	Uterus, breast, vascular endothelium	PLC→IP3 + DAG/calcium and PKC	Myometrial contraction, ductal myoepithelial contraction, vasodilation
P_2 Purinergic	11 (q13.5–14.1)		Cardiac endothelium	ATP	Vasoconstriction, reduced cardiac output

initiating the second-messenger cascade responsible for the cellular actions of AVP.[25] Stimulation of V_1R, although not directly involved in control of tubular water and electrolyte transport, increases sodium excretion because of the influences on blood pressure, effective arterial circulating volume, glomerular filtration rate, and circulation in the vasa recta system.[27,28] Additional biologic effects of AVP mediated through V_1Rs include platelet aggregation[29] and increased glycogenolysis and gluconeogenesis in the liver.[30]

The V_3R ($V_{1b}R$), also coupled to PLC signaling, is present on neurons in the anterior pituitary (adenohypophysis) and is thought to mediate AVP-induced corticotropin secretion.[25,31,32] They are also found elsewhere in the brain, especially in the pyramidal neurons of the hippocampal CA2 field, in which they mediate fundamental physiologic actions such as memory and body temperature control as well as social behavior.[33] In addition, this receptor has been localized to pancreatic islet cells, modulating insulin secretion.[34] However, its presence and role at the level of the medulla in rat kidney remain unclear.

V_2Rs, on the other hand, are heavily expressed in the medullary TAL, macula densa (MD), connecting tubule, and cortical and medullary collecting duct, as well as weakly expressed in cortical thick ascending limb (TAL) and distal convoluted tubule.[35] These are the best characterized and studied vasopressin receptors. By binding to V_2R, AVP increases water reabsorption through multiple mechanisms.[31] Activation of V_2R results in increased cyclic adenosine monophosphate (cAMP) levels and activation of PKA, which promotes insertion of water channels into the luminal suface of the epithelial tubular cells.[36] This ultimately mediates the antidiuretic effect of AVP by allowing back diffusion of water down its concentration gradient.[37] In addition, V_2Rs modulate sodium reabsorption through the epithelial Na^+ channel (ENaC) across principal cells.[38–41] This facilitates free water reabsorption by supporting the axial corticomedullary hyperosmotic gradient. It was also recently shown in rats that AVP modulates sodium reabsorption even in the distal convoluted tubule by acting on the thiazide-sensitive Na^+-Cl^- cotransporter (NCC).[42] NCC is important in defining sodium delivery to the collecting duct,

which is necessary for ENaC activity. Finally, V_2Rs activate urea transporters, such as UTA1, in the distal nephron.[43–45] This increase in urea reabsorption and recycling maximizes sodium reabsorption in the TAL by supporting the axial hyperosmotic gradient drawing water from the distal nephron.[46] The clinical importance of the V_2R in water balance disorders is underlined by the current use of V_2R antagonists in a clinical setting (see later).

It is noteworthy that AVP also binds to two nonspecific receptors: oxytocin receptors and P2 purinoreceptors. Oxytocin receptors are found in the breast, ovary, uterus, and hypothalamus. Since the affinity of this receptor for vasopressin is relatively low, the clinical effects of this hormone are limited under physiologic conditions.[47] AVP may also act on P2 purinoreceptors in the heart, causing coronary vasoconstriction and contributing to the reduction in cardiac output.[48]

Water Channels

The discovery of the family of aquaporin water channels was crucial to the understanding of the mechanism by which AVP can increase water permeability in the kidney. The group of Peter Agre discovered the first aquaporin in human erythrocytes.[49] To date, seven different aquaporin (AQP) have been shown to be expressed in the human kidney and to be involved in renal water reabsorption.[50]

AQP2 is the vasopressin-sensitive water channel expressed in the principal cells of the collecting duct, where it shuttles between intracellular storage vesicles and the apical membrane.[51] Knocking out the AQP2 gene produces a severe concentration defect in these mice, resulting in postnatal death.[52] It has now been shown to be involved in many clinical disorders (see later). AQP1 is constitutively expressed on the basolateral and apical membrane of epithelial cells lining the proximal tubule and thin descending limb, as well as endothelial cells of the descending vasa recta. It not only plays a role in water reabsorption from urine in these segments but is also critical for a functional countercurrent multiplication system.[53] AQP3 and AQP4 are expressed on the basolateral membrane of the principal cells of the collecting duct, and they represent an exit pathway from these cells for water entering through AQP2.[54,55] Similar to AQP1, AQP7 is expressed at the apical membrane of proximal tubules (S3 segment) and has been shown to mediate glycerol reabsorption in addition to water.[56] AQP6 is found in intracellular vesicles of acid-secreting α-intercalated cells in the collecting duct.[57] It is thought to be involved in urinary acid secretion. AQP11 is localized to the endoplasmic reticulum (ER) in the proximal tubule. Interestingly, knocking out the AQP11 gene in mice is fatal because of the onset of polycystic kidney disease.[58]

Clinical Pathophysiologic Role of Arginine Vasopressin in the Kidneys

AVP is implicated in major clinical syndromes of alterations in water metabolism, namely nephrogenic diabetes insipidus (NDI) and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). In addition to water metabolism, it has been recently suggested that AVP may play a role in the initiation and the progression of chronic kidney disease (CKD) and in the most prevalent form of hereditary renal disease, namely the adult polycystic kidney disease (Fig. 8.2).[59]

NDI is characterized by impaired AVP-induced water reabsorption, resulting in polyuria and polydipsia.[60] If water intake is inappropriate, patients with NDI may fail to thrive, suffer from mental retardation, and die early. NDI can be acquired such as following lithium treatment, hypokalemia, hypercalcemia, or ureteral obstruction, all of which lead to downregulation of AQP2.[61–64] NDI can also be inherited (congenital).[65] In fact, two gene mutations have been linked to congenital NDI: one in the AVPR2 gene encoding V_2R (X-linked NDI) or mutations in the AQP2 gene (autosomal recessive or autosomal dominant NDI). More than 90% of patients with congenital NDI suffer from X-linked NDI. In both cases, patients cannot concentrate their urine despite normal or elevated plasma concentrations of vasopressin, leading to a massive loss of water through the kidney. So far, NDI is managed by salt restriction combined with hydrochlorothiazide diuretics to reduce urine output.[66] However, no cure is available so far.

Abnormal water handling of central origin includes SIADH in which AVP levels are abnormally elevated and not suppressed when plasma osmolality concentration falls below the osmotic threshold for physiologic AVP secretion.[67] SIADH is characterized by impaired water excretion in the absence of renal insufficiency, adrenal insufficiency, or any recognized stimulus for AVP secretion. Renal water retention and extracellular fluid expansion are compensated for by increased urinary Na^+ excretion leading to life-threatening hyponatremia. The most common causes of the syndrome of inappropriate AVP secretion are neoplasia, neurologic disorders, congestive heart failure, liver cirrhosis, preeclampsia, and drugs such as thiazide diuretics or selective serotonin reuptake inhibitor antidepressants.[67] Four patterns of AVP dysregulation in patients with SIADH have been observed.[68] The most common pattern (in ~40% of patients with SIADH) is the excessive and unregulated release of AVP, which is unrelated to plasma osmolality. In the second most common pattern (~30% of patients), referred to as "reset osmostat," AVP release continues to regulate water excretion at a lower plasma osmolality set-point. Although most tumors (e.g., lung carcinoma) manifest the first type of SIADH, some also present with the second type, thus the pattern of abnormal AVP secretion cannot be utilized to predict the cause of SIADH. A third rare pattern is characterized by an inability to stop AVP secretion at low plasma osmolalities, but the osmoregulation of AVP is otherwise normal. This pattern may be due to dysfunction of inhibitory hypothalamic neurons, leading to persistent low-grade basal AVP secretion. In the fourth pattern, a rare clinical picture of SIADH, the normal osmoregulation of AVP secretion is not altered (~10% of patients) but AVP levels are low or undetectable. It is thought that a nephrogenic SIADH

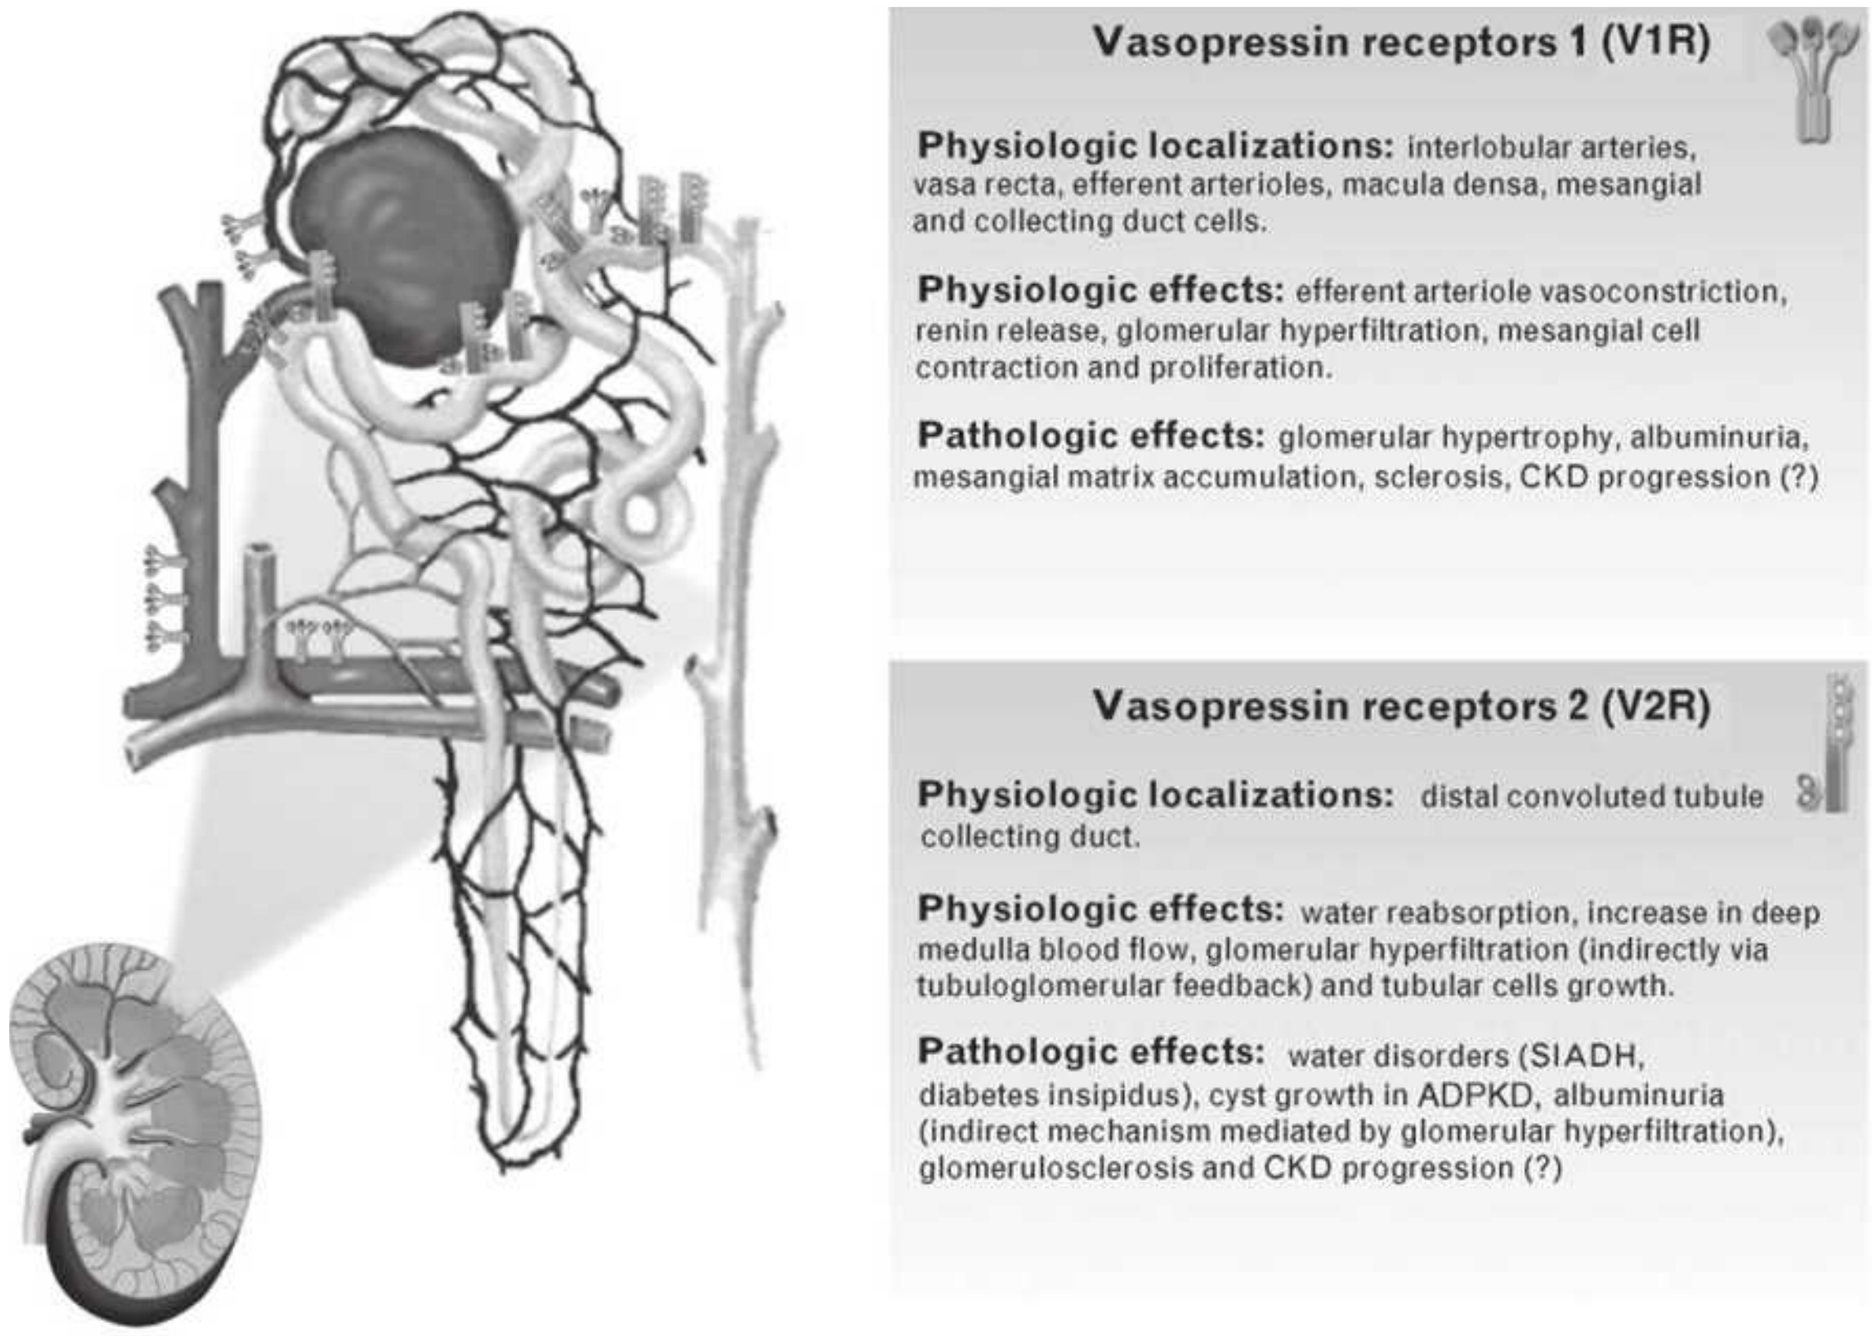

FIGURE 8.2 Vasopressin receptors: physiology and pathologic involvement in renal diseases. (Reproduced from Bolignano D, Zoccali C. Vasopressin beyond water: Implications for renal diseases. *Curr Opin Nephrol Hypertens*. 2010;19(5):499–504.)

(NSIADH) may be responsible for this picture. In fact, in some children, it appears to be due to an activating mutation of V_2R. In other patients, it may be due to abnormal control of aquaporin-2 water channels in renal collecting tubules or production of an antidiuretic principle other than AVP.[69] In a study with SIADH patients, treatment with V_2R antagonists, commonly referred to as vaptans, increased serum Na^+ concentration and decreased its excretion. Tolvaptan has been recently approved in the United States and Europe for the treatment of hyponatremia associated with SIADH, as well as cirrhosis and congestive heart failure. Recently, a dual vasopressin V_1R and V_2R antagonist, conivaptan, improves hyponatremia in rats with SIADH, suggesting a therapeutic potential for conivaptan in the treatment of SIADH.[70]

AVP has also been shown to modify vascular tone in renal microvessels. Short-term infusion of AVP does not alter either renal blood flow or the GFR.[71] Alternatively, chronic AVP administration increases the intraglomerular capillary pressure and GFR through tubuloglomerular feedback.[72] In addition, a sustained increase in water intake and the consequent AVP suppression reduce proteinuria and the severity of glomerular and tubular damage in 5/6 nephrectomized rats.[73,74] Thus, it seems likely that a chronic AVP-induced hyperfiltration may alter the glomerular barrier and start a series of events leading to enhanced protein loss and glomerulosclerosis. An increase in urinary albumin excretion represents an early predictor of glomerular damage in diabetes mellitus and a risk factor for cardiovascular complications in hypertension. Studies show that the Brattleboro rat, a model of central diabetes insipidus with complete lack of AVP, is protected from hyperfiltration, albuminuria, and renal hypertrophy after streptozotocin-induced diabetes mellitus.[75] This suggests that AVP plays a role in hyperfiltration and glomerular damage induced by diabetes. These observations are also of relevance to humans. A marked increase in AVP plasma levels is well documented in diabetes mellitus.[76] AVP through V_1R induces contraction of cortical efferent, but not afferent, arterioles. Administration of a V_1R selective antagonist to noninsulin-dependent diabetic patients modestly reduces albuminuria partly by decreasing intraglomerular capillary pressure.[77] Thus, although V_1Rs (but not V_2Rs) are downregulated in diabetes mellitus, they could mediate part of the increase in albumin excretion. Interestingly, administering desmopressin, a selective V_2R agonist, to healthy humans and patients with central diabetes insipidus significantly increases urinary albumin excretion, but this effect is absent in those with hereditary nephrogenic diabetes insipidus secondary to V_2R mutations.[78] These findings suggest that the AVP-induced rise in albuminuria depends on V_2Rs. This is further confirmed by the observation that plasma copeptin levels correlate with microalbuminuria

in the PREVEND study.[79] However, V_2 receptors have not been found in glomeruli or proximal tubules, suggesting indirect effects. Recent evidence suggests a strong interaction between AVP and the renin-angiotensin system (RAS).[80,81] In fact, chronic RAS blockade by angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) prevents the desmopressin-induced albuminuria, indicating that RAS mediates the effects of AVP on glomerular hemodynamics.[82] Recent studies using V_1R knockout mice show that AVP regulates body fluid homeostasis and the GFR by activating RAS through V_1Rs in MD cells, and subsequently the V_2R-aquaporin 2 system.[83] Simultaneous AVP and RAS blockade may represent a good therapeutic approach for delaying renal disease progression.

Another interesting observation is that mesangial cells express V_1Rs, which mediate AVP-induced cell contraction.[84] In addition, prolonged exposure to AVP promotes mitogenesis and proliferation of these cells, which ultimately leads to an increased accumulation of extracellular matrix, a pathologic feature found in various glomerular diseases.[85,86] In fact, addition of AVP to cultured mesangial cells increases in a dose-dependent manner the synthesis and release of matrix proteins, such as type I and IV collagen, fibronectin, and transforming growth factor β.[87] In addition, AVP inhibited the synthesis of matrix metalloproteinase (MMP)-2, which degrades matrix proteins including type IV collagen, and stimulated endothelin (ET)-1 secretion from mesangial cells, another mitogenic factor.[88]

In the remnant kidney model in rat, a model of progressive CKD in humans, V_1R antagonists (but not V_2R) prevent proteinuria and glomerulosclerosis in the initial phases of disease, but have limited effectiveness in established renal damage.[89,90] Similar observations were reported in 5/6 nephrectomized, salt-loaded spontaneously hypertensive rats (SHRs), in which the increase in urinary protein excretion and the progression of nephrosclerosis were attenuated with a V_1R antagonist but not with a V_2R antagonist.[91]

AVP has also been linked to autosomal dominant polycystic disease (ADPKD), an inherited disorder characterized by the development within renal tubules of innumerable cysts that progressively expand to cause renal insufficiency.[92] It has been shown that 3′-5′-cyclic adenosine monophosphate (cAMP) stimulates tubule cell proliferation and transepithelial fluid secretion, both of which contribute to enlarge renal cysts.[93] AVP operates continuously in ADPKD patients to promote cAMP production in the distal nephron and collecting ducts via V_2Rs, thereby contributing to cyst enlargement and renal dysfunction.[94] Studies in animal models of ADPKD provide compelling evidence that blocking AVP's actions dramatically improves disease progression.[95,96] This prompted the initiation of an international clinical trial[97] testing the efficacy of tolvaptan, a V_2R inhibitor, in the treatment of ADPKD.[98] Alternatively, a recent review discusses that the impact of simply increasing the amount of solute-free water drunk evenly throughout the day by patients with ADPKD on decreasing plasma AVP concentrations and mitigating the actions of cAMP on the renal cysts.[99]

In conclusion, in recent years, AVP has been implicated in the initiation and progression of many kidney diseases, playing a role beyond water metabolism. Further studies are required to determine whether AVP antagonists and/or AVP suppression by a high water intake can be useful for the treatment of nephropathies, from ADPKD to diabetic and nondiabetic CKD.

THE RENIN-ANGIOTENSIN SYSTEM

Historical Review

The discovery of renin goes back to 1898, when the Finnish physiologist Robert Tigerstedt and his student Per Gunnar Bergman found that extracts of rabbit renal cortex had a slowly developing and sustained pressor effect. Based on its origin, they named this substance renin.[100] This effect was not observed with extracts of renal medulla and persisted despite removal of sympathetic activation. Subsequently, efforts to verify these experiments were unsuccessful until the 1930s when Harry Goldblatt and his colleagues demonstrated that clamping the renal artery in dogs produced chronic hypertension.[101] This work converged with other subsequent experiments performed by leading scientists such as Juan Fasciolo and Bernardo Houssay to suggest the presence of a vasoactive substance produced by the kidney, other than renin.[102,103] This substance was later isolated from the blood and was named hypertensin. Based on their physiologic properties, renin and hypertensin were clearly two different compounds, but the relationship between them was not established. Renin was later identified by an Argentine group as a proteolytic enzyme that acts on a plasma constituent to produce hypertensin as the final product of the enzymatic reaction.[104] Subsequent research led to the characterization of the components of the renin–angiotensin system and Braun-Menéndez and Page gave the final nomenclature of the whole enzymatic system in 1958: the renin substrate was named angiotensinogen, hypertensin renamed angiotensin, and the enzymes that metabolize angiotensin were named angiotensinases.[105,106]

Components of the Renin-Angiotensin-Aldosterone System

Angiotensinogen

Angiotensinogen is a large molecular weight globulin primarily formed by hepatic cells. It is constitutively secreted into the circulation by the liver, therefore plasma levels are generally stable.[107] Other sources of angiotensinogen have been identified and mRNA expression detected in tissues such as the kidney, heart, brain, vessels, placenta, and adrenal glands.[108] It is currently accepted that intrarenal angiotensinogen is formed and secreted locally for several reasons: first, the molecular size of the molecule makes it unlikely for it to filter through the glomerular capillaries; second, intrarenal angiotensinogen mRNA and protein have been identified in proximal tubule cells[109]; third,

concentrations of angiotensinogen in the proximal tubule of anesthetized rats greatly exceeded the free angiotensin I and II concentrations[110]; and fourth, human angiotensinogen was not detected in urine of normotensive rats infused with the molecule.[111]

Renin and Prorenin

Renin is produced and stored in granular juxtaglomerular cells, which are modified smooth muscle cells found in the media of afferent arterioles.[112–114] Genomic analysis of the renin gene identified a single locus in humans and rats designated Ren-1, whereas mice have two renin genes, designated Ren-1 and Ren-2.[112] This duplicated renin gene in mice leads to production of substantial amounts of renin from submandibular and submaxillary glands.[115] Renin is synthesized in an inactive precursor form, preprorenin. Cleavage of the signal peptide from the carboxyl terminal of preprorenin results in prorenin, which is also biologically inactive. Subsequent glycosylation and proteolytic cleavage leads to formation of renin, a 37 to 40 kDa proteolytic enzyme. Both circulating active renin and prorenin are released mostly from the kidneys; however, other tissues also secrete these substances.[116,117] Because prorenin is the major circulating form, it is postulated that significant conversion of prorenin to renin follows secretion. Prorenin-activating enzymes have been localized to neutrophils, endothelial cells, and the kidney.[112] In addition to juxtaglomerular cells, renin production has also been detected in the submandibular gland, liver, brain, prostate, testis, ovary, spleen, pituitary, thymus, and lung.[112] Circulating renin, however, appears to be derived entirely from the kidney.

Angiotensin I

Angiotensin I is an inactive decapeptide formed upon cleavage of angiotensinogen by active renin in the circulation. Its rate of formation is highly determined by renin activity. Angiotensin I is easily hydrolyzed to angiotensin II given the widespread availability of ACE on endothelial cells of many vascular beds, including the lungs; the octapeptide angiotensin II is therefore formed by cleavage of the C-terminal dipeptide of angiotensin I.[107]

Angiotensin-converting Enzyme

The ACE, also known as kininase II, is a membrane-bound peptidase that catalyzes the conversion of angiotensin I (Ang I) to angiotensin II (Ang II), the primary active product of the renin-angiotensin-aldosterone system (RAAS). This enzyme is localized on the membrane of various cell types, mostly the endothelial cells. Other cell types include the epithelial cells of the kidney (e.g., the brush border of the proximal tubule cells) and the neuroepithelial cells. The ACE exists also in the plasma as a soluble circulating enzyme, but it is thought that the membrane-bound form is the physiologically active one.[107] Other metabolic activities of ACE include the inactivation of the vasodilator peptides bradykinin and kallidin. Therefore, the functional activity of ACE results in enhanced vasoconstriction and reduced vasodilation. Differences between humans and various animal species regarding ACE localization in the kidney have been reported. Normal nonhypertensive human subjects show a widespread expression of ACE on the brush border of tubule epithelial cells and less expression on glomerular vascular endothelial cells, whereas the renal microvasculature of rats show more preponderant ACE expression compared to epithelial cells. These findings imply that the contribution of circulating angiotensin I to the local formation of angiotensin II in the kidney may be minimal.[118]

In the plasma, all conversion of Ang I to Ang II occurs by the activity of ACE with no species variation reported. However, non–ACE-dependent pathways exist at the tissue level and have species variation. In humans, tissue activity of chymase can allow for the local formation of Ang II in the heart, arteries, and kidney. In rats and rabbits, tissue activity of chymase is associated with the local degradation (instead of formation) of Ang II. Therefore, one must carefully evaluate experimental animal data when pharmacologic blockade of the renin-angiotensin system is used.[119]

Angiotensin Peptides

Ang II is the primary active product of the RAAS. It is an octapeptide derived from Ang I after cleavage of the C-terminal dipeptide by the ACE. Most of the physiologic actions of the RAAS on the vasculature and transport functions are mediated by Ang II action on angiotensin receptors, primarily type 1 (AT1) receptors. However, other angiotensin peptides with reported biologic activity have been identified, such as angiotensin III (Ang III) and IV (Ang IV), which are formed from Ang II by the sequential removal of amino acids from the N-terminus by aminopeptidases (Fig. 8.3). They are predominantly seen in the kidney and brain, where aminopeptidases A and N are prevalent.[107,117] Ang III, also known as angiotensin 2-8, is a heptapeptide with suggested role in blood pressure maintenance in the brain. Ang IV (angiotensin 3-8), on the other hand, is a hexapeptide that possibly enhances Ang II signaling. The heptapeptide Ang (1-7) is currently considered one of the biologically active end products of the RAAS. It is formed from Ang I or Ang II in the kidney and heart by the action of tissue peptidases at the C-terminus. Once formed, it is rapidly hydrolyzed by ACE; in conditions of ACE inhibition or AT_1 receptor antagonism, its concentration may increase severalfold. There are two major interactions between Ang (1-7) and bradykinin (BK): potentiation of BK by Ang (1-7) and mediation of vascular actions of Ang (1-7) by kinins. Both mechanisms are involved in the cardioprotective effects of ACE inhibitors. At the kidney level, the proposed role of Ang (1-7) is natriuresis and diuresis as opposed to Ang II, an effect blocked by AT_1 receptor antagonists like losartan. In the vascular bed, it antagonizes the vascular effect of Ang II by acting as a competitive antagonist to AT_1 receptors.[120]

Angiotensin II Receptors

Circulating Ang II exerts its biologic effects by binding to specific receptors on the cell surface.[112,121] At least four angiotensin receptor subtypes have been identified. AT_1 receptors bind Ang II with higher affinity than Ang III and are selectively blocked by the biphenylimidazole compound losartan. AT_2 receptors bind Ang II and III with similar affinity and are selectively blocked by tetrahydroimidazopyridines, such as PD123177.[122] The type 3 angiotensin receptor AT_3 has no known function and the type 4 (AT_4) is thought to mediate the release of plasminogen activator inhibitor by Ang II, III, and IV.

Megalin is an abundant membrane protein heavily involved in receptor-mediated endocytosis. Megalin is a receptor for Ang II and Ang II internalization in some tissues is megalin-dependent. Megalin may play a role in regulating proximal tubule Ang II levels.[123] Ang (1-7) exert its vasodilator and natriuretic actions presumably through its binding to a unique receptor, the Mas receptor.[124]

In rodents, two isoforms of AT_1 receptors exist: AT_{1A} (nephron) and AT_{1B} (glomerulus), whereas in humans there is only one AT_1 isoform. The AT_1 receptor has widespread expression in the human adult and is found in the kidney, adrenal gland, heart, and brain. In the kidney, AT_1 receptors are found in the glomeruli, proximal tubule brush border and basolateral membranes, thick ascending loop, proximal convoluted tubule, renal vasculature, the proximal and distal nephron segments, and in both cortical and medullary regions.[125,126]

Aldosterone

Aldosterone was identified by Simpson SA in 1953 and named electrocortin.[127] Later studies characterized more the nature of this hormone and identified it as a mineralocorticoid synthesized and secreted by the zona glomerulosa of the adrenal cortex. The physiology of aldosterone action has been well established after several breakthroughs in research experiences, such as the identification of the mineralocorticoid receptor (MR) as the principal aldosterone receptor, the characterization of sites of aldosterone action in target tissues such as the ENaC, and the demonstration of post-receptor processes involved in physiologic responses to aldosterone.[128–130] Aldosterone secretion is determined by several stimuli, the most important being Ang II and plasma potassium concentration. The MR is the principal receptor for aldosterone, but other target proteins can also bind aldosterone, such as the glucocorticoid receptor. Aldosterone has been implicated in the pathophysiology of several cardiovascular and renal diseases and will be discussed in details in other sections.[129]

Physiologic Actions of Angiotensin II

Systemic Effects of Angiotensin II

AT_1 receptors have been shown to mediate many of the functions of Ang II in the regulation of blood volume, cell contraction, cell proliferation, aldosterone secretion, pressor and tachycardic responses, increased thirst, and hypertension secondary to renal artery stenosis. AT_1 receptors are positively coupled to phospholipase C and mitogen-activated protein kinases (PI3 and MAP) and negatively to adenylate cyclase.[122,125,131] The predominant function of the renin-angiotensin system is regulation of vascular tone and renal salt excretion in response to changes in the volume of extracellular fluid or blood pressure. Ang II represents the effector limb of this hormonal system, acting on several organs, including the vascular system, heart, adrenal glands, central nervous system, and kidneys. Through direct action on smooth muscle cells, Ang II significantly increases arteriolar resistance in renal, mesenteric, dermal, coronary, and cerebral vascular beds.[132] Skeletal muscle and pulmonary vessels, on the other hand, are not affected because of Ang II-stimulated production of vasodilatory prostaglandins by endothelial and smooth muscle cells in these vascular beds.[133,134] Ang II exerts indirect pressor effects via the central and peripheral nervous systems. Its effects on the central nervous system include increased sympathetic discharge and decreased vagal tone.[135] Peripherally, Ang II augments the vasoconstrictive response to renal nerve stimulation in

dogs[136] and its inhibition attenuates the pressor response to norepinephrine in humans.[137] Experimental data suggest the presence of a local renin–angiotensin system in the vasculature that contributes to the regulation of vascular tone.[112]

A more recently recognized function of Ang II is its growth-promoting effects in smooth muscles of the vasculature, heart, and the kidney. Ang II has been shown to induce hypertrophy and mitogenesis in cultured vascular smooth muscles.[138,139] This effect is at least, in part, mediated through autocrine production of growth factors such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β).[140] Some studies suggest that the renin–angiotensin system contributes to neointimal formation and restenosis after angioplasty.[112] Ang II has been shown to have direct inotropic, chronotropic, mitogenic, and hypertrophic effects on isolated atria and ventricles.[112] Amelioration of hypertensive cardiomyopathy by ACE inhibitors suggests that the renin-angiotensin system plays a role in cardiac hypertrophy.[112]

The predominant physiologic role of the AT_2 receptor is to initiate vasodilation and natriuresis as a counterregulatory response to the vasoconstriction caused by activation of the AT_1 receptor.[141] Other functions include inhibition of growth and hypertrophy, and stimulation of apoptosis.[142] This has been most clearly demonstrated in AT_2 receptor knockout mice that have slightly elevated blood pressure in the basal state, but have an exaggerated increase in blood pressure in response to Ang II infusion compared to wild type mice.[143,144] The intracellular signaling pathways coupled to the AT_2 receptor are unclear. However, there is evidence that the AT_2 receptor may be coupled to the production of a variety of renal vasodilator substances, counterregulating the pressor effects of Ang II via AT_1 receptors.[142] The most likely candidates are bradykinin and nitric oxide (NO)-stimulated cyclic guanosine monophosphate (cGMP),[145,146] but other candidates include products of cyclooxygenase, such as PGE_2 and PGI_2.[141]

Renal Effects of Angiotensin II

Ang II serves at least three important functions in the kidney: regulation of blood flow and GFR, reduction of salt excretion through direct and indirect actions on renal tubule cells, and growth modulation in renal cells expressing AT_1 receptors.

In conditions of decreased renal blood flow, GFR is preserved at nearly constant value over a wide range of perfusion pressures. This phenomenon is known as autoregulation of GFR. At low levels of renal perfusion pressures, Ang II contributes to this phenomenon.[147] Micropuncture studies have shown that Ang II exerts substantial effects on the renal microvasculature and hemodynamics; however, the individual contribution of the systemic and local renin-angiotensin systems to the overall regulation is still controversial. Ang II constricts both the afferent and efferent arterioles, reduces single nephron glomerular filtration rate and plasma flow, increases the filtration fraction, and decreases glomerular filtration coefficient. Other studies have shown that Ang II infusion preferentially vasoconstricts efferent arterioles counteracted by endothelial-derived NO[148] and constricts descending vasa recta (DVR) through Ca^{2+} signaling in pericytes.[149] The disproportionate increase in postglomerular resistance results in a marked increase in glomerular capillary hydrostatic pressure (P_{GC}), ultrafiltration pressure, and filtration fraction, thus preserving GFR in the face of declining renal plasma flow (RPF). The selectivity of the vasoconstrictive action of Ang II for the efferent arteriole results from stimulation of vasodilatory prostacyclin synthesis by the afferent arteriole and not a preferential action of Ang II on the efferent arteriole.[150] In fact, Ang II increases both afferent and efferent resistance in the presence of a cyclooxygenase inhibitor.[150] Under certain pathophysiologic conditions, afferent arteriolar constriction predominates, leading to a decrease in both RPF and GFR.[151] Deep nephrons have higher postglomerular Ang II tone and also higher Ang II sensitivity than superficial nephrons. The better preserved GFR in deep cortex during Ang II action may contribute to maintaining the renal-concentrating ability by providing NaCl for reabsorption by the ascending limb of the loop of Henle.[152]

In addition to its vascular effects, Ang II induces mesangial cell contraction, which leads to decreased K_f in vivo.[153,154] This effect, however, is attenuated by the concomitant production of prostaglandins by mesangial cells.[155]

Ang II is one of the most potent sodium-retaining hormones in the body. Increased tubular sodium reabsorption is enhanced by both direct and indirect tubular effects of Ang II. Physiologic concentrations of Ang II (10^{-12} to 10^{-10} M) stimulate proximal tubule NaCl and $NaHCO_3$ absorption at the proximal tubule.[156] Indirectly, Ang II stimulates ion transport in the proximal tubule by changing the peritubular milieu. Ang II can both decrease peritubular capillary hydrostatic pressure and increase peritubular oncotic pressure, resulting in an increased driving force for ion reabsorption. Directly, Ang II can stimulate transport in the proximal tubule through interaction with the AT_1 receptors found on both the apical and basolateral membranes of the tubule cells.[157,158] It also stimulates calcineurin phosphatase activity in proximal tubule epithelial cells through a mechanism involving AT_1 receptor-mediated tyrosine phosphorylation of the PLC isoform, both linked to sodium transport in the proximal tubule.[159] Specifically, Ang II stimulates the activity of apical membrane Na–H antiporters and basolateral membrane Na–HCO_3–CO_2 cotransporters[160] and the activity of Na–K-ATPase by changing phosphorylation and conformation of Na–K-ATPase.[161] The net effect is increased proximal tubule reclamation of Na and HCO_3. Denervation of the proximal tubule results in attenuation of the Ang II-stimulated NaCl, but not $NaHCO_3$ absorption, suggesting that Ang II enhances proximal Na transport indirectly by increasing presynaptic catecholamine release.[159] Of note is that supraphysiologic concentrations of Ang II (10^{-9} to 10^{-7} M) inhibit NaCl and water reabsorption in the proximal tubule and also inhibit Na–glucose cotransporter translocation by inactivation of PKA and decrease of PI3-kinase activity mediated through the AT_1 receptor.[162,163] Ang II increases proximal tubule phosphate absorption by

direct stimulation of Na/P_i cotransport activity as a result of increase in the expression of brush-border membrane NaPi-IIa protein level and that stimulation is most likely mediated by posttranscriptional mechanisms.[164]

Intraluminal conversion of Ang I to Ang II can occur in the cortical collecting duct, resulting in enhanced apical sodium entry.[165] The AT_2 receptor regulates epithelial sodium channel (ENaC) abundance, consistent with a role for Ang II in regulation of collecting duct function via AT_1 receptors.[166,167]

Ang II increases basolateral K-channel activity via the stimulation of AT_1 receptors and the stimulatory effect of Ang II is mediated by a NO-dependent cGMP pathway.[168]

Other effects of Ang II on proximal tubule cells include enhanced gluconeogenesis and ammonia production.[169] The effects of Ang II on distal tubule transport of Na and K are mediated through aldosterone release.[170] In addition to proximal tubule epithelial cells, vasa recta and outer medullary vascular bundles express high density of AT_1 receptors.[121] ACE inhibitors increase descending vasa recta blood flow, whereas Ang II infusion markedly decreases medullary blood flow in rats.[171] It is postulated that Ang II influences urinary dilution and concentration by modulating blood flow to the medulla.

Ang II induces hypertrophy of proximal tubule epithelial cells in vitro.[172] It also exerts similar growth-promoting effects on mesangial cells.[173] The signaling mechanism by which Ang II exerts this effect is not precisely known, but p27Kip1 is required for Ang II-induced hypertrophy.[174] Downstream potential targets of Ang II are the extracellular signal-regulated kinases 1 and 2 (ERK1/ERK2) and Ang II activates ERK1/ERK2 via the AT_1 receptor.[175] Studies have shown that connective tissue growth factor (CTGF) might be an important mediator of Ang II-induced renal hypertrophy, which suggests that inhibiting the production of CTGF might be the new strategy in early prevention of renal fibrosis.[176] Ang II can stimulate human kidney fibroblast (KFB) proliferation and enhance the expression of interleukin-6 in KFB. These findings suggest that Ang II might play a part in the mechanisms for modulating tubulointerstitial changes and inducing renal fibrosis.[177]

Previous in vivo studies in cardiomyopathic hamsters suggested that the expression of vasopressin (AVP) V_2 mRNA is upregulated by Ang II. Ang II caused a significant increase in the AVP V_2 mRNA in a dose-dependent manner mediated by PKA, whereas PKC suppresses the expression of V_2 mRNA in the inner medullary collecting duct (IMCD) of the rat kidney.[178]

The role of Ang II in the pathogenesis of hypertension is complex. Several studies have demonstrated a crucial role of the intrarenal renin-angiotensin system in the development of hypertension and kidney disease.[117] Animal studies have shown that blockade of the AT1 receptor resulted in increased plasma Ang II levels while it limited renal Ang II contents in response to Ang II infusion.[179] This dissociation between systemic and local Ang II regulation has been demonstrated in several animal hypertension models including renovascular hypertension.[180,181] Clinical studies have also shown that local intrarenal Ang II formation was central to the development of hypertension in humans.[182]

In addition to its effects on the maintenance of blood pressure, AT_1 receptors may play a role in embryonic nephrogenesis. Blockage of the renin-angiotensin system with ACE inhibitors or AT_1 inhibitors results in abnormal renal development that is characterized by both papillary and tubular atrophy and by interstitial fibrosis and infiltration. In addition, knockout mice lacking both the AT_{1A} and AT_{1B} receptor have similar renal abnormalities.[183] Ang II also modulates mesangial cell growth, and induces proximal tubular cell hypertrophy in humans, effectively inhibited by irbesartan, an Ang II receptor antagonist.[184]

The AT_2 receptor is expressed predominantly in fetal tissues, but in almost all tissues there is postnatal downregulation. AT_2 receptor mRNA is expressed in the fetal and neonatal rat kidney, but disappears after the neonatal period and is not expressed in the normal adult. Although the AT_2 receptor mRNA is not found in the adult kidney, both immunohistochemistry and Western blot analysis have detected AT_2 receptor protein in the glomeruli, cortical tubules, and interstitial cells of the adult kidney.[121,185] It was thought that AT_2 receptors might play a role in the development of the kidney and urinary tract given the high levels of expression in the fetus. However, although early studies of AT_2 receptor knockout mice showed no gross morphologic abnormalities of the kidney,[143,144] a more recent study has demonstrated the presence of increased numbers of congenital anomalies of the urinary tract.[186] The AT_2 receptor may be implicated in some congenital abnormalities of the urinary tract or may be involved in the pathophysiologic response to ureteral obstruction by protecting against the formation of interstitial fibrosis.[186,187] Ang II modulates the over-expression of AT_2 receptors in renal ablation experiments through its own AT_2 receptor and functional expression of this effect may represent a counterregulatory mechanism to modulate the renal damage induced by renal ablation.[188]

Ang II regulates renal parathyroid hormone-related protein (PTHrP), a vasodilator and mitogenic agent upregulated in kidney injury, and its type-I receptor (PTH1R) system via AT_1 receptors.[189]

Local Effects of Ang II in Nonrenal Organs

Ang II exerts its actions on other organs, such as the adrenals and the brain. At the level of the adrenals, it stimulates aldosterone synthesis and secretion.[170] Acute angiotensin administration stimulates the activity of 11β-hydroxysteroid dehydrogenase (HSD) type 2 in human kidneys and exerts a dual effect on the MR receptor (i.e., an indirect agonistic effect by increasing aldosterone availability and a direct or indirect antagonistic effect by stimulation of renal 11β HSD type 2 activity).[190]

At the central nervous system (CNS) level, it stimulates thirst and salt appetite[191,192] and may increase secretion of

vasopressin and oxytocin from the posterior pituitary, and adrenocorticotropic hormone (ACTH), prolactin, and luteinizing hormone from the anterior pituitary.[193]

Regulation of the Systemic Renin-Angiotensin-Aldosterone System

Ang II in the systemic circulation is produced primarily from circulating angiotensinogen through the proteolytic action of renin. Most of the circulating renin is derived from the kidney, although other organs can secrete prorenin in the circulation. Angiotensinogen is mostly formed and secreted in the circulation by liver cells, allowing for systemic formation of angiotensin peptides, principally Ang II. The circulating concentrations of angiotensinogen are more than 1,000 times greater than those of Ang I and Ang II, therefore changes in plasma renin activity is the major determinant of Ang I formation (Fig. 8.3). Renin secretion is stimulated by various dynamic parameters such as renal perfusion pressure, tubular fluid sodium chloride concentration at the MD, sympathetic discharge to the kidney, and endocrine and paracrine hormones and growth factors.[107]

Stimulation of renin release by juxtaglomerular cells is mediated by increased intracellular cAMP, whereas a rise in cytosolic free calcium is inhibitory.[194] Renin release responds inversely to changes in renal perfusion pressure.[114] Elevation of intrarenal arterial pressure inhibits renin release and induces a "pressure" natriuresis. At least two mechanisms have been postulated. Increased afferent arteriolar wall tension secondary to increased renal perfusion elevates intracellular calcium in juxtaglomerular cells and inhibits renin secretion.[114,194] Increased perfusion pressure also stimulates NO production and release by endothelial cells. NO, in turn, suppresses renin secretion.[195,196] Conversely, decreased renal perfusion results in increased production of prostacyclin (prostaglandin I_2), which enhances renin release.[197] Mechanical strain leads to upregulation of the AT1 receptor and increased Ang II production in conditionally immortalized podocytes. The resulting activation of a local tissue angiotensin system leads to an increase in podocyte apoptosis, mainly in an AT1 receptor-mediated fashion.[198]

Decreased NaCl delivery to MD cells stimulates renin secretion, whereas increased urinary NaCl exerts an opposite effect.[180] Schlatter and coworkers[199] demonstrate that changes in luminal Cl^- concentration alter the rate of Na^+-K^+-$2Cl^-$ transport in MD cells.[199] The precise mechanism by which variation in the activity of this transporter translates to a signal that regulates renin release by adjacent juxtaglomerular granular cells is not entirely clear. Postulated mediators include adenosine, which inhibits renin secretion via activation of A_1 receptors on juxtaglomerular cells, and alterations in interstitial osmolality, which may affect renin secretion directly.[96] Experimental evidence also suggests that NO produced by MD cells and endothelial cells regulates renin secretion.[195,200]

The importance of renal sympathetic innervation in controlling renin secretion is well recognized.[201] Stimulation of postjunctional β-adrenergic receptors increases renin release. The role of α-adrenergic receptors, on the other hand, is controversial.[201] Ample evidence suggests that dopamine stimulates renin secretion by direct activation of dopamine A1 (DA_1) receptors on juxtaglomerular cells.[201,202]

Several endocrine and paracrine hormones regulate renin secretion by the kidney. ANP has been shown to inhibit renin release from isolated juxtaglomerular cells.[203] Other inhibitory hormones include AVP, endothelin, and adenosine (A_1-receptor agonists).[114,195] Regulation of renin secretion by Ang II is probably the most physiologically relevant.[169] Ang II inhibits renin secretion and renin gene expression in a negative feedback loop. Treatment of transgenic mice bearing the human renin gene with an ACE inhibitor increases renin expression in the kidney by five- to tenfold.[204] Similarly, ACE inhibition in rats augments renal renin mRNA expression, an effect that is reversed by infusion of Ang II.[205] The effects of Ang II are believed to be direct and not dependent on changes in renal hemodynamics or tubular transport. Arachidonic acid metabolites produced in the kidney also play an important role in renin secretion.[195] Intrarenal infusion of arachidonic acid increases (and indomethacin decreases) plasma renin activity in rabbits.[206] Several studies have since confirmed that prostaglandins of the I series are potent stimulators of renin secretion.[195,197] On the other hand, lipoxygenase products of arachidonic acid metabolism (12-HPETE, 15-HPETE, and 12-HETE) and cytochrome P450-mediated epoxides (14,15-epoxyeicosatrienoic acid) have been shown to inhibit renin release in renal cortical slices.[207,208]

The Local Renin-Angiotensin System

The renin-angiotensin system has been characterized as an endocrine, paracrine, and autocrine system. Contribution of systemically formed mediators to local control of dynamics within tissues is difficult to delineate. Recent evidence suggests that local formation is a major determinant of Ang levels in organs and tissues. In the brain, for example, Ang peptide levels are regulated in an autonomous manner.[209] Local renin-angiotensin systems have been identified in several organs, including the kidney, heart, vasculature, brain, and adrenals.[210] Although most organs have elements of the renin-angiotensin system, the adult kidney is unique in expressing all the components of the system.[156,169]

Compared with plasma levels, the renal Ang II contents are much higher despite suppression of renin secretion and release.[126] Renin is principally produced by juxtaglomerular cells of the distal afferent arteriole, but has been shown to be expressed in the proximal tubule cells,[126] whereas its substrate, angiotensinogen, is expressed by proximal tubule cells. ACE activity in the kidney has also been localized to the proximal tubule, with the highest concentration present on the brush border. Several studies have provided evidence for production of Ang II by the kidney, mainly concentrated in the proximal tubules,[126] suggesting that the intrarenal renin-angiotensin

system is, indeed, functional.[156] Some investigators have proposed that this local system plays a role in proximal tubule NaCl and HCO_3 absorption, pathogenesis of essential hypertension, and expression of the phenotype of autosomal dominant polycystic kidney disease.[156] Independent regulation of renal Ang II production has not been definitively demonstrated. Circulating Ang II stimulates renal angiotensinogen mRNA production and intact urine angiotensinogen suggests its presence along the whole nephron and that renin and ACE activity are available all through the nephron.[126]

Endogenous Ang II in both peritubular blood and luminal fluid is important for maximal expression of the stimulatory influence of this peptide on proximal tubule fluid uptake.[211] Intraluminal conversion of Ang I to Ang II can occur in the cortical collecting duct, resulting in enhanced apical sodium entry.[165]

Renal degradation of Ang II is constitutively high, unaffected by chronic levels of arterial blood pressure, and is independent of long-term changes in levels.[212]

Low-density lipoproteins (LDLs) increase Ang II production by mesangial cells, which, in turn, results in increased O_2 production, cell proliferation, and hypertrophy—these effects of Ang II are mediated by the AT_1 receptor.[213]

Established Clinical Pathophysiologic Role of the Renin-Angiotensin-Aldosterone System in Humans

The RAAS has been implicated in the pathophysiology of several diseases of the cardiovascular system and the kidney, mostly hypertension and renal injury. The local renal renin-angiotensin system is activated in the renovascular type of hypertension in the stenotic kidney and accounts for most of the Ang II concentration in the renal tissue.[214] In addition, it plays a crucial role in other forms of hypertension. Administration of a renin inhibitor to normal subjects and hypertensive patients showed sustained local renal vascular responses but time-dependent decreased drug activity at the systemic level.[215] Several other studies demonstrated the importance of the intrarenal renin-angiotensin system in the pathophysiology of hypertension.[216,217]

Ang II promotes fibrogenesis and oxidative stress in the kidney by stimulating fibrogenic mediators, altering renal hemodynamics especially facilitating glomerular hypertension, inducing tubulointerstitial hypoxia, and enhancing free radical formation. Studies have shown that the degree of mesangial hypercellularity and expansion in IgA nephropathy correlated closely with glomerular expression of mRNAs for renin, ACE, chymase, and AT1 and AT2 receptors.[217,218] The role of the intrarenal renin angiotensin system has been also established in the pathogenesis of membranous nephropathy.[219] In diabetic nephropathy, the renin-angiotensin system plays a crucial role in disease progression: the intrarenal generation of Ang II is increased, despite suppression of the systemic RAAS. Details of the pathophysiologic mechanisms implicated in diabetic nephropathy are beyond the scope of this chapter.

The role of the RAAS in end-stage renal disease (ESRD) is even more complicated and implicates many parameters related to residual renal function, presence of renal replacement therapy and modality, and drug treatment of associated conditions. In addition, renal transplantation adds a new dimension to the complexity by introducing an immune component through graft rejection and immunosuppressive drugs. Despite the substantial decrease in renal blood flow and function in patients with ESRD on dialysis, studies have shown that those with remaining kidneys have an activated intrarenal renin-angiotensin system.[117] On the other hand, renal transplant diseases, especially rejection and cyclosporine-induced nephropathy, were associated with increased activity of systemic and local RAAS in several studies.[220,221]

In conclusion, the RAAS is one of the most powerful pressure and volume regulatory systems in the body, involved in physiologic responses and pathophysiologic processes at both the systemic and local levels. Autonomous and independent control of local renin-angiotensin systems in various organs and tissues may exist and contribute to disease progression. New areas of interest in the RAAS are continuously emerging, facilitating the understanding of mechanisms of diseases and development of specific drug targets.

ATRIAL NATRIURETIC PEPTIDE

Molecular and Biochemical Properties of Atrial Natriuretic Peptide

The cDNA for human ANP was isolated in 1984 and, shortly afterward, the gene was localized to the short arm of chromosome 1.[222,223] The chromosomal gene consists of three exons and two introns encoding for a mature mRNA transcript approximately 900 bases long.[223]

Translation of human ANP mRNA results in a 151-amino acid preprohormone.[224] Pro-ANP, a 126-residue molecule, is formed after cleavage of the signal peptide sequence of prepro-ANP and represents the major storage form of the hormone in atrial granules.[225] The circulating, biologically active form of ANP, often referred to as $AN_{99–126}$ or ANP_{1-28}, is a peptide comprising the 28 carboxy-terminal amino acids of the parent molecule.[224] The amino acid sequence of $ANP_{99–126}$ is highly conserved among mammalian species.[224] A disulfide bond between cysteine residues 105 and 121 gives $ANP_{99–126}$ its ring structure, which is essential for biologic activity.[226]

Pro-ANP (1–30), (31–67), and (68–98) are secreted from the heart and circulate in the plasma. Pro-ANP (1–30) and (31–67) increase sodium and water excretion and binding sites have been found in the proximal tubules and collecting ducts. Pro-ANP (31–67) inhibits the Na^+-K^+ pump at the medullary collecting duct through a prostaglandin-dependent mechanism and no effect on cGMP production. Pro-ANP (1–30) infusion in rats clearly increases urine output, sodium, and potassium excretion, the mechanism of which still needs to be elucidated.[227]

Secretion and Physiologic Regulation of Atrial Natriuretic Peptide$_{99–126}$

Cardiac atria contain the highest concentrations of ANP and serve as the major source of circulating hormone.[224] $ANP_{99–126}$ secretion from cardiomyocytes occurs largely in response to atrial stretch resulting from increased atrial transmural pressure.[228] Physiologic stimuli for the release of $ANP_{99–126,}$ include acute salt and volume loading, supine posture (head-down tilt), and head-out water immersion.[228–230] An increased rate of atrial contraction has also been shown to stimulate $ANP_{99–126}$ secretion.[231,232] Ang II, vasopressin, epinephrine, and phenylephrine stimulate $ANP_{99–126}$ secretion from the heart largely because of their systemic vasopressor effects.[233] On the other hand, glucocorticoids and endothelin raise $ANP_{99–126}$ levels possibly by acting directly on atrial myocytes.[234] Leptin decreases ANP secretion via an NO-mediated mechanism.[235] Physiologic and pathologic conditions in which elevated plasma levels of $ANP_{99–126}$ have been detected are summarized in Table 8.3.

The local synthesis of natriuretic peptides is increased in the kidney and in the vasculature in obstructive uropathy.[236] The activation of the renin-angiotensin system during low sodium intake antagonizes the biologic effect of ANP by interfering in the intracellular metabolism of cGMP.[237]

8.3 Conditions Associated with Increased Levels of Circulating Atrial Natriuretic Peptide

Physiologic	Pathologic
Acute volume expansion	Congestive heart failure
Supine posture	Atrial tachycardias
Head-out water immersion	Myocardial ischemia
Mineralocorticoid escape	Acute and chronic renal failure
Exercise	Postobstructive diuresis
Neonatal period	Nephrotic syndrome (subset) Cirrhosis with ascites Severe hypertension Primary hyperaldosteronism Hypoxia Other (SIADH myxedema)

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Physiologic Actions of Atrial Natriuretic Peptide$_{99–126}$

Three subtypes of ANP receptors (NPRs) have been identified.[238–240] NPR-A and -B have intrinsic guanylate cyclase activity that catalyzes production of cGMP after ligand binding. cGMP then serves as an intracellular second messenger that mediates the biologic activities of $ANP_{99–126}$.[241] NPR-B appears to have 50-fold higher affinity for a related natriuretic factor originally purified from porcine brain, known as C-type natriuretic peptide (CNP).[242] NPR-C, previously known as the (clearance) receptor, is devoid of guanylate cyclase activity and, therefore, does not confer biologic activity and is thought to mediate clearance of circulating ANP along with metalloendoprotease (E.C.3.4.24.11)[242] and of other related hormones, such as brain natriuretic peptide (BNP).[243] Selective downregulation of NPR-C in the kidney in response to dietary salt supplementation may contribute to local elevation in ANP levels and may be functionally significant in attenuating the development of salt-sensitive hypertension.[244] NPR density is decreased in diabetic rats with significant increase in plasma ANP levels.[245] ANP also antagonizes AVP-mediated increases in water permeability in IMCD cells.[246]

The major sites of action of $ANP_{99–126}$ are the kidneys, adrenal glands, and vascular smooth muscle.[247] Short-term administration of $ANP_{99–126}$ in laboratory animals and in humans induces pronounced natriuresis, diuresis, alteration in renal hemodynamics and tubular function, suppression of renin release, inhibition of aldosterone secretion by the adrenal glands, and decreased vasomotor tone, resulting in transient drop in systemic blood pressure. From these actions it has been postulated that ANP plays an important physiologic role in protecting against extracellular volume overload.[248]

Renal Actions of Atrial Natriuretic Peptide$_{99–126}$

ANP-induced increase in the GFR is well established.[249–251] $ANP_{99–126}$ increases efferent arteriolar resistance, resulting in increased P_{GC} and filtration fraction.[249] In addition, $ANP_{99–126}$ relaxes mesangial cells in vitro, suggesting that it can increase filtration area by cGMP generation in podocytes[252] and K_f in vivo.[253] Indeed, when baseline K_f is low, as in water-deprived animals, $ANP_{99–126}$ enhances GFR mainly by increasing K_f.[253] If preexisting vascular constriction is present in isolated perfused kidney, ANP tends to vasodilate renal vessels and increase renal blood flow (RBF).[254] In whole animals, however, $ANP_{99–126}$ infusion causes either a decline or no change in RBF.[254] The effects of $ANP_{99–126}$ on RBF are influenced by its systemic actions on blood pressure and the renin-angiotensin system. ANP seems to increase NO production at both renal and cardiac levels, further explaining its natriuretic and diuretic effects.[255] Finally, ANP has been reported to induce redistribution of blood flow from the cortex to the medulla and to increase vasa recta flow, leading to dissipation of the medullary solute gradient.[256,257]

$ANP_{99–126}$ has both direct and indirect effects on tubular transport of Na, chloride, and water.[258] In the proximal tubule, $ANP_{99–126}$ antagonizes Ang II-induced Na reabsorption[259] and, along with endothelin-3, inhibits the sodium-glucose transporter[260] and, like urodilatin, inhibits Na^+-ATPase activity.[261] In the IMCD, it directly inhibits Na transport by binding to ANP-R1 receptors and influencing amiloride-sensitive Na channels and the activity of apical Na-K-2Cl cotransporters.[262] Other mechanisms by which $ANP_{99–126}$ induces natriuresis and diuresis include suppression of renin and aldosterone release,[263] inhibition of the tubular actions of AVP,[246] and dissipation of the medullary solute gradient by impairing the increase in intracellular Ca^{2+} concentration. ANP blocks both the stimulatory and inhibitory effects of AVP on Na^+-dependent pHi recovery.[264]

Atrial Natriuretic Peptide Transgenic Mice

Transgenic mice over-express pro-ANP in hepatocytes. These transgenic animals have a hypotensive phenotype (20 to 30 mm Hg lower than control littermates) without compensatory tachycardia. GFR remained normal despite hypotension. Moreover, significant diuresis or natriuresis during steady state was not detected. Contrary to observations made after short-term infusion of $ANP_{99–126}$, plasma renin activity also did not change while aldosterone levels were elevated.[265–267]

Physiologic Consequences of Interrupting the Atrial Natriuretic Peptide Pathway

Disruption of the gene that encodes pro-ANP results in knockout mice that lack expression of ANP. Homozygous ANP knockout mice fed a standard diet have both mildly elevated blood pressure (average increase of 8 mm Hg) and cardiac hypertrophy compared to wild type mice, suggesting that ANP has a physiologic role in maintaining the normotensive state. This hypertension appears to be sensitive to dietary salt intake as feeding the homozygous ANP knockout mice a diet with an intermediate salt content (2%) would further increase blood pressure by an average of 20 mm Hg compared to wild type mice.[268] Knockout mice lacking ANP-R1 activity (known as GC-A null mice) have both elevated blood pressure and cardiac hypertrophy, similar to pro-ANP knockout mice, but the GC-A null mice have a salt-insensitive form of hypertension.[267] It is unclear why there should be a difference in the phenotype of these two types of knockout mice. It is possible that other guanylyl cyclase receptors, such as guanylyl cyclase C, can help regulate blood pressure in the face of changes in dietary salt intake and compensate for the lack of GC-A receptors.[268] ANP (−/−) mice have a blunted pressure-natriuresis response and suppressed expression of local renal renin-angiotensin system.[269]

Atrial Natriuretic Peptide-Related Peptides[149,212]

BNP is a 32-amino acid peptide with structural homology to $ANP_{99–126}$. Although originally isolated from porcine brain,[270] it is also secreted by cardiac ventricles and, to a lesser extent, from atria. The biologic effects of BNP infusion are similar to those of $ANP_{99–126}$. Unlike ANP, BNP secretion seems to be constitutive and unrelated to myocyte stretch. The kidney-specific degradation of ANP provides a mechanism for preferential regulation of kidney function by BNP, independent of peripheral ANP concentration.[270] In 1990, another homologous peptide, CNP, was isolated from porcine brain.[271] CNP is produced in the brain, where it achieves concentrations much higher than those of ANP and BNP. In contrast, circulating levels of CNP are lower. CNP lacks natriuretic, diuretic, and hypotensive effects and probably acts in a paracrine fashion in the CNS. The physiologic significance of BNP and CNP remains unclear.

Clinical Use of Atrial Natriuretic Peptide and Atrial Natriuretic Peptide Analogs in the Diagnosis and Treatment of Kidney Injury and Congestive Heart Failure

Measurement of circulating ANP and ANP analogs is now a well established marker in assessment of volume overload and left ventricular dysfunction and for predicting mortality, in the presence or absence of renal dysfunction.[272–276] A number of studies, reviewed recently,[277] provide support for the use of ANP/ANP analogs in protection against and treatment of acute kidney injury (AKI).[278–281] In these studies, low (but not high)-dose ANP infusions reduced the need for renal replacement therapy and hospital and intensive care unit length of stay, but did not appear to improve mortality in the management of cardiac surgery–associated AKI. Hyporesponsiveness to ANP in congestive heart failure may be due to reduced NPR-A expression.[282] In dogs, maximizing cGMP action with type V phosphodiesterase inhibitors augments the natriuretic responses to exogenous ANP.[283] Animal studies have shown the usefulness of encapsulated ANP gene transfected cells as a new tool for ANP gene delivery with possible implication for future therapy.[284]

URODILATIN OR RENAL NATRIURETIC PEPTIDE

Urodilatin is best described as a paracrine renal natriuretic peptide (RNP).[285] It was first isolated from human urine in 1988.[286] Its amino acid sequence is identical to $ANP_{99–126,}$ except for an additional four amino acids at the amino terminal. Despite its high degree of homology to $ANP_{99–126,}$ specific antihuman RNP polyclonal antibody has been generated and RNP levels can be measured by radioimmunoassay.[287] To date, RNP has not been detected in the circulation and the kidney is presumed to be its site of synthesis and action.[285]

RNP binds to ANP receptors in the kidney and stimulates cGMP production.[288] Its renal actions parallel those of $ANP_{99–126}$ and include more potent hyperfiltration, diuresis, and natriuresis.[288] RNP, like $ANP_{99–126}$, inhibits sodium uptake by inner medullary duct cells by inhibiting entry of Na

through apical sodium channels.[289] It appears that the natriuretic effect of RNP is more potent than that of ANP, possibly because it is resistant to degradation by renal cortical metalloendopeptidase.[290] Systemic infusion of RNP results in effects similar to those of $ANP_{99–126}$.

Several physiologic studies suggest that RNP functions as a paracrine hormone that regulates renal Na excretion. Drummer and coworkers[291] demonstrated in the human that urinary excretion of RNP, but not plasma ANP concentration, correlates with circadian variation in sodium excretion over a 9-day period. Moreover, acute infusion of normal saline in healthy subjects, balloon dilatation of left atrium, and water immersion induce a significant increase in urinary RNP.[292,293]

GUANYLIN AND UROGUANYLIN

Guanylin and uroguanylin are cGMP-regulating agonists isolated in 1994, respectively, from rat intestine and human/opossum urine that appear to have natriuretic properties.[294,295] In humans and mice, earlier studies reported that both genes for guanylin and uroguanylin are located close to each other on chromosomes 1 and 4, respectively, near the ANP A and B genes and probably arising from an ancestral uroguanylin/guanylinlike gene.[296] Preproguanylin and preprouroguanylin probably derived from a common precursor gene, as they share approximately 35% homology.[297] Bioactive uroguanylin can be found in the urine at higher concentrations than guanylin, suggesting that uroguanylin may be a hormonal link between the intestine and the kidney.[298] Uroguanylin, prouroguanylin, and proguanylin peptides have been shown to circulate in the plasma of humans and other animals.[299]

CORTICOSTEROIDS

Corticosteroids are steroid hormones synthesized by the adrenal cortex. On the basis of their physiologic functions, corticosteroids are traditionally divided into two groups—glucocorticoids (cortisone and cortisol) and mineralocorticoids (aldosterone)[300]—based on their potency in electrolyte and metabolism regulation.

Corticosteroids bind to intracellular receptors: the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). They are both part of the nuclear receptor family that also includes receptors for steroid and thyroid hormones, vitamin D_3, and retinoic acids. These receptors translocate to the nucleus after ligand binding[301] and regulate nuclear gene transcription at specific DNA response elements located in the five regulatory regions near the promoters of specific target genes (Fig. 8.4).[302] Both glucocorticoids and mineralocorticoids modulate renal function. Aldosterone-sensitive tissues include the distal parts of the nephron (distal tubule, connecting tubule, and all along the collecting duct), the surface epithelium of the distal colon (where it increases sodium absorption and potassium excretion), and other specific nuclear-binding sites for aldosterone in the thick ascending limb of Henle's loop and salivary and sweat glands. All MR-expressing tissues also express GR. In the kidney, evidence exists for distribution of the GR receptors along the whole parts of the nephron, except for the proximal tubule. No evidence exists for a glucocorticoid role in the colon.[303–305]

MR has the same affinity for both aldosterone and glucocorticoids. Glucocorticoids concentration in plasma is 100- to 1,000-fold higher than aldosterone and only 10% of it circulates as free, whereas all circulating aldosterone is free. MR selectivity exists to prevent complete occupancy of the MR receptor by glucocorticoids at physiologic concentrations. This is mainly mediated by the colocalization of the 11β-hydroxysteroid dehydrogenase 2 (11β-HSD2) enzyme in the distal nephron, along with MR. This enzyme transforms glucocorticoids (cortisol in humans) into metabolites (cortisone) that have weak affinity to MR.[301,305–307] 11β-HSD has two main isoforms. 11β-HSD1 acts predominantly as a reductase in vivo in many tissues, regenerating biologically active glucocorticoids (mainly cortisol in human and corticosterone in rodents) from their inactive forms (cortisone in human and 11-dehydrocorticosterone in rodents). 11β-HSD2, on the contrary, is a dehydrogenase that inactivates glucocorticoids.[308] The major role of 11β-HSD2 is highlighted in clinical situations, such as the syndrome of apparent mineralocorticoid excess where it is inactivated or after ingestion of excessive amounts of licorice where glycyrrhetinic acid, a derivative of licorice, has been described to inhibit 11β-HSD2.[309,310] Both of these conditions lead to hypokalemic hypertension with low renin and aldosterone levels. In cirrhosis also, there is MR activation by cortisol explained by a reduced activity of 11β-HSD2, which allows promiscuous activation of MR by the glucocorticoid cortisol as suggested by Frey.[311]

GRs have approximately equal affinities for aldosterone and endogenous glucocorticoids, but have the highest affinity for dexamethasone, a synthetic glucocorticoid.[301] Because mineralocorticoids circulate at much lower concentrations than glucocorticoids, significant binding of mineralocorticoids to GR does not occur under physiologic conditions.

Nongenomic Actions of Aldosterone

The effects of aldosterone on its target cells have long been considered to be mediated exclusively through the genomic pathway and were characterized by a 45-minute lag period; however, evidence has been provided for rapid effects of the hormone that may involve nongenomic mechanisms.[5–7,19,32] On the other hand, in a series of in vitro studies, aldosterone was shown to have a half maximal effect on both rapid (15 minutes) and delayed (120 minutes) Na flux.[4,32] The Na/H exchanger has been identified as a target for nongenomic regulation. Aldosterone rapidly increases Na/H exchanger activity in a variety of cells, including distal colon and renal epithelial cell lines,[3] but rapidly inhibits apical NHE_3 and HCO_3^- reabsorption in medullary thick ascending limb (MTAL) and has a dose-dependent biphasic effect on the Na/H exchanger (low doses stimulate and high doses inhibit it).[312]

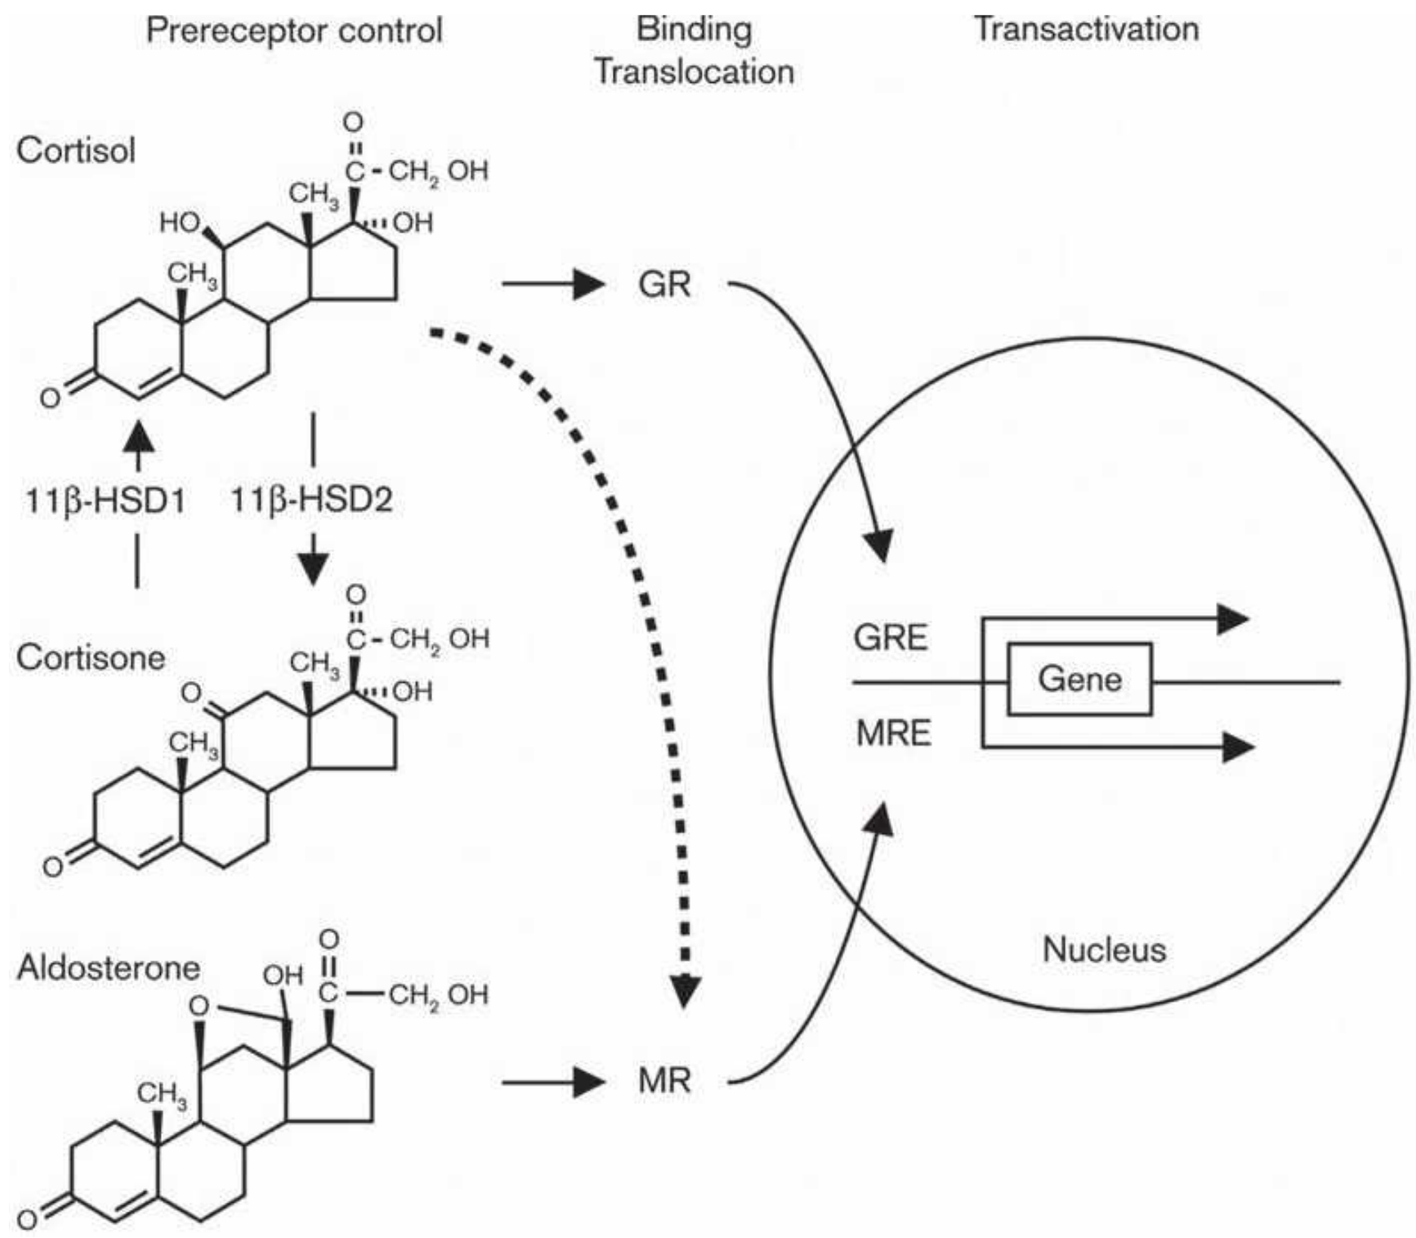

FIGURE 8.4 The intracellular concentrations of steroid molecules available for binding to glucocorticoid receptor (GR) or mineralocorticoid receptor (MR) depend on the free extracellular concentrations available for diffusion into the cytoplasm and the intracellular prereceptor control mechanism constituted by the 11β-hydroxysteroid dehydrogenase type 1 and 2 (11β-HSD1, 11β-HSD2) enzymes. Whereas 11β- HSD1 acts predominantly as a reductase and converts the 11-ketosteroid cortisone with virtually no affinity for MR and GR into the 11β-hydroxyglucocorticoid cortisol with a high affinity for both GR29,58 and MR, 11β-HSD220 is exclusively an oxidase and inactivates cortisol into cortisone, which allows protection of MR-expressing cells from promiscuous activation of MR by the glucocorticoid hormone cortisol. *GRE*, glucocorticoid-response element; *MRE*, mineralocorticoid-response element. (Frey FJ, Odermatt A, Frey BM. Glucocorticoid-mediated mineralocorticoid receptor activation and hypertension. *Curr Opin Nephrol Hypertens*. 2004;13:451–458.)

Aldosterone acts through nongenomic pathways to regulate many different ion transport proteins and signaling pathways in a variety of renal epithelial cells, such as proximal tubule cells derived from human renal cortex, MDCK-C11 cells (a cell line that exhibits properties of collecting duct intercalated cells), and principal cells isolated from rabbit cortical collecting duct and both M-1 and RCCD2 cortical collecting duct cell lines.[6] Studies using isolated perfused tubules also demonstrate that aldosterone, via nongenomic mechanisms, regulates the transepithelial transport function of different nephron segments, such as proximal S3 segment,[21] renal MTAL, type A intercalated cells of outer medullary collecting ducts, and principal cells in the connecting tubule and inner medullary collecting ducts.[6,313] In renal epithelial cells, an elevation in cytosolic Ca_2 serves as a second messenger for the nongenomic Na^-/H exchanger activation initiated by aldosterone.[2] The existence of a nongenomic action of aldosterone is in general attributed to conditions where this action is observed over a short period of time (minutes) against the much longer time (hours, days) needed for a genomic action.[313]

Rapid nongenomic aldosterone effects are characterized by their rapid onset of action (within minutes) and an insensitivity to inhibitors of transcription (e.g., actinomycin D) and of protein synthesis. Aldosterone also acts via rapid nongenomic effects in vivo in humans at the renal vasculature. Antagonizing the endothelial NO synthase unmasks these effects. Therefore, rapid nongenomic aldosterone effects increase renal vascular resistance and thereby mediate arterial hypertension if endothelial dysfunction is present.[314] Evidence suggests that there is a nonclassical membrane-bound aldosterone receptor.[315] These data come from kinetic studies that demonstrate saturable, radiolabeled binding of aldosterone to cell surface membranes that have kinetics compatible with physiologic activity.[316,317] In some cell lines, aldosterone can have very rapid physiologic effects that are not blocked by inhibitors of cell transcription and translation. For instance, in human mononuclear leukocytes, aldosterone can stimulate release of IP_3 or calcium within 30 seconds of exposure.[318,319] These membrane-bound receptors may explain some of the effects of aldosterone that occur prior to gene transcription, such as early stimulation of

sodium reabsorption[320] or early stimulation of salt intake,[321] possibly via phospholipase C/PKC signaling pathways.

Mineralocorticoid Actions in the Kidney

Aldosterone originates primarily from the zona glomerulosa of the adrenal glands. Some recent studies have suggested that the heart, vasculature, and brain can also synthesize aldosterone in response to local tissue injury, although extraadrenal synthesis in humans is still debated.[6–8,11,17,322] It is the chief mineralocorticoid of the body. Its physiologic role as a regulator of sodium and volume balance also allows aldosterone the potential to play a pathologic role in the development of hypertension in patients with renal disease.[322] It is also implicated in the pathophysiology of cardiac fibrosis and cardiac hypertrophy in end-stage heart failure.[3,4,323]

The major action of aldosterone in the kidney is regulation of Na, K, and H handling by the distal part of the nephron. Mineralocorticoid deficiency is associated with volume depletion, hyperkalemia, and mild metabolic acidosis. Conversely, mineralocorticoid excess leads to Na retention, hypokalemia, and metabolic alkalosis.

Ang II, high serum K^+ levels, and ACTH stimulate aldosterone secretion from the adrenal gland.[324] ANP and dopamine, on the other hand, suppress aldosterone secretion. Dietary sodium also modulates aldosterone release through its effects on the renin-angiotensin system. In addition to sodium and volume homeostasis, other triggers for aldosterone release have been cited, including hyperglycemia, adrenocorticotropic hormone (ACTH), and, more importantly in patients with CKD, angiotensin II and potassium.[49]

Sodium Reabsorption

One of the best-documented functions of aldosterone is its ability to increase Na reabsorption in the distal tubule and collecting duct.[325–327] The rate-limiting step to sodium reabsorption across tight epithelia is the permeability of the apical membrane of the transporting cell. Aldosterone increases apical Na permeability of tight epithelia, such as those found in the mammalian distal tubule and descending colon, by increasing the activity of the amiloride-sensitive epithelial sodium channel (ENaC). ENaC is formed by three subunits (alpha, beta, and gamma) and, based on coexpression studies in Xenopus oocytes, these subunits assemble into a complex heterooligomer forming the amiloride-sensitive pore.[328–330]

Other characterized aldosterone-induced targets include the serum and glucocorticoid-regulated kinase-1 (SGK-1), an important mediator of renal sodium homeostasis; corticosteroid hormone-induced factor (CHIF), which regulates the activity of the sodium and potassium-dependent adenosine triphosphatase pump (Na-KATPase); the glucocorticoid-induced leucine zipper protein; a transcription factor; and the G protein K-Ras2.[10–12] SGK-1 is thought to regulate Na^+ flux by increasing ENaC activity at the apical surface of epithelial cells. Aldosterone treatment of a rat collecting duct cell line as well as an adrenalectomized rat model demonstrated a rapid induction of SGK-1 mRNA within 30 minutes of treatment.[13,14] However, SGK-1 null mice only show mild abnormalities in sodium homeostasis, suggesting that other genomic targets are important for overall regulation of sodium transport.[15] Wong et al. demonstrated that ET-1 is a direct aldosterone gene target in the kidney and colon in Sprague dawly rats and may play an important role in aldosterone-regulated ion homeostasis.[323]

Aldosterone also enhances Na reabsorption by increasing Na–K-ATPase activity in basolateral membranes of principal cells in mammalian collecting duct and distal tubule.[327] Studies in toad bladder and mammalian nephron suggest that aldosterone upregulates Na–K-ATPase activity by at least three mechanisms: increased Na influx due to opening of amiloride-sensitive Na channels, induction of Na–K-ATPase subunit expression at the gene level, and induction of intracellular alkalosis, which occurs in tissues that contain aldosterone-sensitive Na/H exchangers.[331] Other hormones also modulate aldosterone's action on Na transport; for example, ANP is inhibitory and vasopressin is stimulatory (Table 8.3).[332]

Hypersecretion of endogenous mineralocorticoids or the administration of mineralocorticoids lead to transient sodium retention followed by a return to Na balance within a few days.[333] The return to Na balance despite elevation of circulating mineralocorticoid levels is referred to as aldosterone or mineralocorticoid "escape." During mineralocorticoid escape, increased Na reabsorption by the distal tubule and collecting duct remains unchanged, but is offset by decreased Na reabsorption in other nephron segments.[332,334] The latter results from increased renal arterial pressure and elevated plasma ANP levels, both of which suppress proximal tubule transport of Na. Mineralocorticoid escape is also, in part, mediated by decreased Na and water reabsorption in the loop of Henle.[334] Other factors, such as TGF-β and interleukin-1 (IL-1), may play a role in regulation of mineralocorticoid escape. These factors have been recently found to inhibit the action of aldosterone on the cells of the IMCD.[335]

Ang II binds to Ang II type 1 (AT-1) receptors in the kidney, which leads to glomerular hypertension, sclerosis, renal fibrosis, and cardiac remodeling, possibly through a TGF-β-mediated pathway.[30–32] ACE inhibitors provide renoprotection by inhibiting the conversion of Ang I to Ang II and precluding the negative effects of AT-1 receptor activation. Studies have shown that Ang II can be generated by ACE-independent pathways such as chymase in the heart,[33] which leads to "angiotensin escape." Angiotensin escape is one of the factors frequently cited to explain aldosterone breakthrough, which may be secondary to the generation of non-ACE mediated angiotensin II.[34] Potassium and adipocyte-released factors may also contribute to the phenomenon of aldosterone breakthrough. Continual dietary intake of potassium in the setting of reduced GFR may promote elevated potassium levels that subsequently trigger aldosterone secretion, as seen in the rat remnant kidney model.[28] ACE inhibitors and ARBs are also known to reduce

potassium excretion, so prolonged use of such agents may enhance potassium retention and predispose a patient to aldosterone breakthrough. Recent studies in rat models of metabolic syndrome with early nephropathy have shown enhanced aldosterone secretion due to adipocyte activity that was not abolished by candesartan administration.[35] These results suggest that adipocyte-released factors outside of Ang II may enhance aldosterone secretion and lead to increased proteinuria and podocyte injury in rats.[35] Thus, potassium, angiotensin II, and adipocyte-released factors may all contribute to the increase in aldosterone secretion in patients on prolonged ACE inhibitors or ARB therapy. The exact definition of aldosterone breakthrough has been a subject of controversy, as there is no current consensus on its precise definition. One of the common definitions is a rise in plasma aldosterone concentration, often past baseline values, following an initial decrease after the initiation of ACE inhibitor or ARB therapy.[322]

Potassium Secretion

Mineralocorticoids are the predominant hormonal influence on K secretion by principal cells of the collecting duct and connecting segment of the distal tubule.[335,336] Although mineralocorticoids always increase K secretion by these nephron segments, this does not necessarily translate into a kaliuresis because of the strong dependence of K excretion on distal Na delivery and urinary flow rate.[337] For example, in conditions of decreased Na delivery and urinary flow to the distal nephron, the kaliuretic effect of aldosterone is either diminished or abolished. The mechanisms by which aldosterone stimulates K secretion by principal cells overlap with those responsible for its Na-retaining action. The late distal convoluted and connecting tubules (CNTs) and cortical collecting duct (CCD) of the distal nephron mediate, in large part, the final regulation of urinary K^+ excretion.[19] The traditional model by which K^+ secretion is accomplished in these segments can be summarized as follows. Na^+ enters the CNT and principal cell from the urinary fluid through the apical amiloride-sensitive ENaC and is then transported out of the cell at the basolateral membrane in exchange for uptake of K^+ via the basolateral Na^+-K^+-ATPase. The high K^+ concentration within the cell and lumen-negative voltage, established by electrogenic Na^+ reabsorption, create a favorable electrochemical gradient for K^+ to diffuse into the urinary space through apical K^+-selective channels. Thus vectorial K^+ secretion in these segments requires a favorable electrochemical gradient and an apical permeability to K^+ increases in extracellular K^+ concentration directly stimulate aldosterone production in zona glomerulosa cells of adrenal glands.[6,59,338]

Aldosterone-induced Na influx through the apical membrane leads to the generation of a lumen-negative potential difference that favors K secretion.[326,327] In addition, although mineralocorticoids do not increase the density of active K channels in the apical membrane, they increase the conductance of apical and basolateral K channels independent of Na flux.[327,339] Physiologically, it is difficult to understand how one hormone can regulate the concentration of two different solutes that have varying levels of dietary intake. Patch-clamp experiments have demonstrated that other nonaldosterone circulating factors exist that can regulate K channel activity. Infusion of aldosterone by osmotic minipump will increase the density of EnaC, but not of K channels.[339] However, an increase in dietary K does increase the K-channel density.[340] Currently, it is unknown what other circulating factor controls K secretion.

A large body of evidence suggests that SGK1 mediates, at least in part, the effect of aldosterone on renal K secretion.[41,88,113,116] This notion is supported by studies performed in SGK1 knockout mice demonstrating that the phenotype of SGK1 deletion is similar to MR knockout mice and displays impaired renal K secretion in response to high dietary K intake.[41,341]

Renal Acidification

The role of mineralocorticoids in regulation of renal acidification is supported by several clinical observations. Syndromes of aldosterone deficiency are associated with metabolic acidosis because of reduced urinary acid excretion, whereas mineralocorticoid excess results in metabolic alkalosis. Aldosterone enhances urinary acidification through direct actions on epithelial cells in the collecting duct and indirectly by influencing various intrarenal and extrarenal factors.[342] Aldosterone increases H secretion by type A intercalated cells in the collecting duct via two mechanisms: direct stimulation of the proton pump (H-translocating ATPase), and indirectly by stimulating Na influx, which creates a lumen-negative potential difference.[342] As with K, the overall effect of aldosterone on renal acid excretion depends on Na delivery to the distal part of the nephron. Reduction of Na transport in the collecting duct, because of either decreased Na delivery or inhibition of distal Na reabsorption by amiloride, significantly attenuates the effect of aldosterone on net H excretion.[343] Aldosterone regulates the expression of aquaporin, AQP3, with no effect on AQP1 and AQP2, in the collecting duct, independently of Na intake.[344]

Effect on Inflammation

Besides its classical effects on salt homeostasis in renal epithelial cells, aldosterone promotes inflammation and fibrosis and modulates cell proliferation. As outlined by recent reports, mineralocorticoid also mediates inflammation and fibrosis through NF-κB activation in liver, heart, and glomerular mesangial cells[9–13] via a pathway involving the aldosterone early-induced gene, serum, and glucocorticoid-induced kinase 1 (SGK1).[11,12,345]

Studies in vitro revealed that aldosterone could induce proliferation of rat glomerular mesangial cells and promote collagen gene expression and synthesis via activation of extracellular signal-regulated kinase 1 and 2 (ERK1/2) mitogen-activated protein (MAP) kinase in renal fibroblast. Aldosterone

treatment of renal tubular epithelial cells increases calcium inflow and intracellular cyclic adenosine monophosphate levels. The results suggest that aldosterone plays a pivotal role in tubulointerstitial fibrosis by promoting tubular epithelial–mesenchymal transition and collagen synthesis in proximal tubular cells. The process is MR-dependent, and mediated by ERK1/2 mitogen-activated protein kinase pathway.[346]

Clinical trials have shown a potential role for MR blockers to further delay the development of end-stage renal disease by completing renin–angiotensin blockade. MR blockade produces a significant antiproteinuric effect and has minimal risk of causing hyperkalemia if the condition of the patient is closely monitored. As well as in the collecting ducts, mineralocorticoid receptors are distributed throughout the body, including the proximal tubule, thick ascending segment of the nephron, the heart, and the brain.[14,20,21,31] Aldosterone is thought to mediate fibrosis by activating factors such as reactive oxygen species; TGF-β; and increasing collagen synthesis, the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and plasminogen activating factor I (PAI-1).[7,20,22,23] The fibrotic effect of aldosterone is often enhanced by high dietary salt intake.[24] Fibrosis and kidney damage induced in uninephrectomized rats placed on a high-salt diet and treated with angiotensin II were reduced by treatment with spironolactone and an aldosterone synthase inhibitor, FAD286.[32,322]

Quan et al. studied chronic kidney disease in rats subjected to subtotal nephrectomy.[37] Rats with intact adrenal glands were found to have increased proteinuria, renal histopathologic changes, and decreased inulin clearance when compared with rats subjected to adrenalectomy. Furthermore, the difference in the severity of kidney disease between rats that had undergone adrenalectomy and those that had not was not abolished with corticosteroid administration, which suggested that some other factor from the adrenal gland was responsible for the renal defects.[322]

Experiments conducted on saline drinking, stroke prone, spontaneously hypertensive (SHRSP) rats have shown that inhibition of mineralocorticoid receptor activation may delay renal disease. Spironolactone, a mineralocorticoid receptor blocker, implanted into SHRSP rats results in a reduction in proteinuria. The expression of TGF-β, NADPH oxidase, and collagen I/IV was increased in the untreated diabetic rats, but was reduced in spironolactone-treated rats. Aldosterone was found to increase collagen expression in rat renal fibroblasts, which may contribute to fibrosis.[20] Studies of humans have also shown that the deleterious effects of aldosterone are enhanced by high dietary salt intake, which is typical of the Western diet. A study involving 2,700 participants in the Framingham Offspring Study has shown that greater excretion of urinary sodium (a marker for dietary salt intake) correlates strongly with elevated urinary albuminuria and weakly (albeit nonlinearly) with serum aldosterone levels.[52] In a subsequent study conducted on patients with resistant hypertension despite the use of three antihypertensive medications, elevated dietary salt intake correlated with higher levels of proteinuria in patients with elevated urinary aldosterone levels.[53] This suggests that aldosterone may work in concert with dietary salt to accelerate kidney injury.[322] Studies designed to delineate the factors responsible for the renal injury associated with aldosterone have also been performed in humans. Sato and Saruta measured the urinary excretion of collagen type IV (a turnover product of fibrosis) by patients with diabetes and found that those on spironolactone showed a significant decrease in urinary collagen excretion, which suggests that collagen may be one factor associated with aldosterone-mediated fibrosis.[57] Because aldosterone is a major regulator of sodium and volume balance, it could also, theoretically, mediate its negative effects by increasing blood pressure.[322]

Glucocorticoid Actions in the Kidney

Glucocorticoids appear to be important for the normal maintenance of GFR.[347] In both adrenalectomized animals and in humans with adrenal insufficiency, GFR is reduced compared to controls. Adrenalectomized rats given physiologic doses of glucocorticoids regain a normal GFR.[348] Furthermore, short-term administration of pharmacologic doses of glucocorticoids has been reported to increase inulin clearance in both normal animals and humans.[349,350] Micropuncture studies in normal rats indicate that glucocorticoids enhance GFR by increasing glomerular plasma flow.[347,351] The latter results from selective vasodilation of both afferent and efferent renal arterioles.[351] The mechanisms by which glucocorticoids alter the glomerular microcirculation remain obscure. Because amino acid infusion causes similar glomerular hemodynamic changes, Baylis and colleagues suggest that glucocorticoids may increase GFR through their effects on catabolism of proteins to free amino acids.[347]

Glucocorticoid actions on the proximal tubule include enhancement of gluconeogenesis, ammoniagenesis, and Na reabsorption.[352] Lag in ammonium excretion resulting in acid retention is well described in subjects in a glucocorticoid-depleted state.[353] In adrenalectomized animals, glucocorticoid replacement restores proximal tubule ammoniagenesis and the ability of the kidney to respond to the chronic phase of acidosis.[354] Furthermore, in whole animals, glucocorticoid excess accelerates renal base generation, resulting in metabolic alkalosis.[355] Glucocorticoids regulate ammoniagenesis possibly through altering glutamine uptake and metabolism by proximal tubule cells.[355] Glucocorticoids increase proximal tubule Na reabsorption by at least two mechanisms: enhanced Na–K-ATPase activity and Na–H exchange.[356,357] Several experiments suggest that glucocorticoids inhibit Na-dependent phosphate and sulfate reabsorption in the proximal tubule.[352] These observations are supported by clinical reports of phosphaturia and lower serum phosphate levels in patients with Cushing disease and subjects given high doses of glucocorticoids.[358]

Both patients with Addison disease and adrenalectomized animals have decreased urinary concentrating ability,[359] due in part to reduction in RBF, GFR, and hydroosmotic

permeability of the collecting tubule.[360] In addition, adrenal corticosteroids contribute to urinary concentration by stimulating Na, K, and HCO_3 transport in the thick ascending limb of Henle's loop.[361] It is not entirely clear whether glucocorticoids, mineralocorticoids, or both mediate the effects of corticosteroids on renal-concentrating mechanisms.

Systemic excess of glucocorticoids is known to cause hypertension. The effect of glucocorticoids may be in part mediated by the suppression of endothelial nitric oxide synthase (eNOS).[2] Acute administration of glucocorticoids, however, may have beneficial effects on the cardiovascular system in part through nontranscriptional activation of eNOS.[308]

CATECHOLAMINES

Structure and Biosynthesis of Catecholamines

Norepinephrine (noradrenaline), epinephrine (adrenaline), and dopamine are collectively called catecholamines. These endogenous amines are derived from the amino acid tyrosine and the enzymes involved in their biosynthesis have been identified, cloned, and characterized[362] and include: tyrosine hydroxylase, dopa decarboxylase, dopamine β-hydroxylase, and phenylethanolamine-N-methyltransferase. The first step in catecholamine synthesis involves the hydroxylation of tyrosine by tyrosine hydroxylase, which is regarded as a rate-limiting step. This enzyme is activated by stimulation of sympathetic nerves or the adrenal medulla and is subject to feedback inhibition by catechol compounds. Catecholamines are synthesized in nerve terminals of the postsynaptic neurons of the sympathetic nervous system and in the adrenal medulla. Most of the steps occur in the cytoplasm whereas some take place in storage vesicles.[363] Storage of catecholamines in vesicles ensures their regulated release, protects them from enzymatic degradation, and prevents their leakage outside the cell. Termination of action of norepinephrine and epinephrine includes reuptake by nerve terminals, reuptake by nonneuronal cells, and metabolic transformation. Major enzymes involved in catecholamine metabolism include monoamine oxidase (MAO) and catechol-O-methyl transferase (COMT). The main source of epinephrine in the body derives from the adrenal medulla whereas noepinephrine originates mostly from nerve terminals.[363] At the renal level, catecholamines derive from renal efferent nerves (norepinephrine and, to a lesser extent, dopamine), from the circulation (epinephrine and norepinephrine), from the adrenal medulla (epinephrine), and from renal proximal tubule cells (dopamine) via α_1, α_2, β_1, and β_2 receptors for epinephrine and norepinephrine and D_1- and D_2-like receptors for dopamine.[364–367]

Physiology of Catecholamine Action in the Kidney

Catecholamines play an important role in the regulation of RBF, GFR, renin secretion, and tubular transport. Their effects depend on site of action and receptor type. The kidney is one of the major long-term regulators of blood pressure (BP). This is achieved by the interplay of several hormonal, neural, and humoral factors that would regulate principally two parameters: sodium homeostasis and peripheral vascular resistance.[368] In the following section, we discuss the renal functions of catecholamines separately on their receptors.

Alpha-adrenergic Stimulation in the Kidney

Both α_1- and α_2-adrenergic receptors have been localized to vascular smooth muscle and tubule cells of the nephron. Norepinephrine is the major agonist at these levels and adrenergic stimulation causes renal arteriolar vasoconstriction (increased afferent and efferent arteriolar resistance) by activating mainly α_1 receptors on vascular smooth muscle cells.[369] This α_1-mediated renal vasoconstriction results in decreased RBF and GFR. Recent evidence suggested that norepinephrine increases afferent arteriolar sensitivity to angiotensin II through activation of α receptors and secondary increase in calcium sensitivity of mouse afferent arteriole.[370]

In the proximal convoluted tubule, where α_1- and α_2-adrenergic receptors are expressed in high density, norepinephrine increases Na and water reabsorption, in part, by stimulation of Na^+-K^+-ATPase activity.[371–373] This activity is partially dependent on the cosecretion of neuropeptide Y that acts to synergize the stimulatory α-adrenergic effects of norepinephrine and to antagonize the inhibitory β-adrenergic effects. This is demonstrated by the fact that norepinephrine alone does not affect Na^+-K^+-ATPase activity in the proximal convoluted tubule unless neuropeptide Y or other β-adrenergic inhibitors are present.[374] In isolated rat and rabbit proximal convoluted tubule cells, α_1 and α_2 agonists stimulate Na^+–H^+ exchange, the overall effect of which is enhanced Na^+ and fluid absorption.[375,376]

In the loop of Henle, experimental evidence showed that α-adrenergic stimulation increases sodium and water reabsorption at the thick ascending limb level through α_1- and α_2-mediated activation.[377,378] In the collecting duct, Krothapalli and Suki[379] report that α_2 agonists inhibit vasopressin-stimulated water reabsorption by inhibiting adenylate cyclase activity.[379] Other investigators, however, challenge this observation.[380]

Beta-adrenergic Stimulation in the Kidney

β-adrenergic receptors have been identified in the glomerulus, juxtaglomerular apparatus, thick ascending limb of loop of Henle, distal convoluted tubule, and collecting duct.[380,381] β_1 stimulation enhances renin release from the juxtaglomerular cells of the afferent arterioles. Otherwise, there are few β receptors in renal vessels. Although β receptors have not been localized to the proximal tubule, physiologic studies suggest that β-adrenergic stimulation increases Na^+ and fluid transport in this nephron segment independently of enhanced renin secretion and angiotensin II production.[380] In the thick ascending limb, β-adrenergic receptor activation stimulates cAMP production and NaCl reabsorption.[380] β agonists also

increase Cl^-–HCO_3^- exchange and H^+-K^+-ATPase activity in the collecting duct.[371] The latter effect results in enhanced K^+ reabsorption by type A intercalated cells (and an apparent decrease in K^+ secretion).[371] A potential mechanism of action involves β-adrenergic stimulation of cAMP production and subsequent conversion to adenosine.[381]

Dopamine and the Kidney

Dopamine is the immediate metabolic precursor of norepinephrine and epinephrine. Locally, dopamine is synthesized by proximal tubule cells via enzymatic decarboxylation of L-dopa by aromatic amino acid decarboxylase (AADC). L-dopa reaches the tubule cell after filtration and Na^+-coupled reabsorption because renal proximal tubule cells lack tyrosine hydroxylase. The contribution of presynthesized and stored dopamine to local renal physiology is not yet clearly established.[368,382] High salt intake increases AADC activity and dopamine synthesis in proximal tubule possibly by enhancing Na^+-coupled uptake of L-dopa.[383,384] Regulation of intrarenal dopamine concentrations can occur at several levels: synthesis, storage, or degradation. Dopamine is a substrate for both MAO and COMT. Synthesis and metabolism of dopamine differs between neural and nonneural cells. Dopamine synthesized in the proximal tubule does not undergo further metabolism to norepinephrine and epinephrine because of the lack of dopamine β-hydroxylase[385]; instead, it diffuses to peritubular space and tubular lumen where it acts locally on its receptors.

Dopamine receptors are members of the G protein-coupled superfamily of heptahelical receptors. At least five receptors have been identified, subclassified into D_1- and D_2-like subfamilies based on their molecular structure and pharmacology. Both of the cloned members of the D_1-like receptor group (D_1 and D_5, also known as D_{1A} and D_{1B} in rodents) are coupled with the stimulating G protein, $G_s\alpha$, and stimulate adenylyl cyclase. All three of the cloned D_2-like receptors (D_2, D_3, and D_4) are associated with the inhibitory G protein, G_i/G_0, and inhibit adenylyl cyclase. Both families of receptors are expressed in the kidney. D_1 and probably D_5 are localized in the smooth muscle layer of renal arterioles, juxtaglomerular cells, proximal tubules, and cortical collecting duct. The D_3 receptor is present in arterioles, glomeruli, proximal tubules, MTAL of loop of Henle, and the collecting duct. The D_4 receptor is localized in the cortical collecting duct.[386,387]

Locally produced dopamine plays a central role in the regulation of sodium excretion. Circulating dopamine concentrations are in the picomolar range, hence not sufficiently high to activate dopamine receptors. The major signaling mechanism by which dopamine induces natriuresis is by inhibiting Na^+-K^+-ATPase in all the segments of the nephron via D_1-like receptors, whereas D_2-like receptors stimulate this enzyme. The end result of Na^+-K^+-ATPase inhibition is a dopamine-induced natriuresis. Several investigators suggest that the role of dopamine is to counterbalance the effects of antinatriuretic factors in the kidney.[383] Interestingly, Kuchel and Kuchel[388] point out that dopamine is the predominant catecholamine in fish, in which salt excretion is a priority. On the other hand, norepinephrine predominates in terrestrial animals, in which salt retention is essential for survival. In addition to inhibition of Na^+-K^+-ATPase activity, other studies suggest that dopamine suppresses Na^+–phosphate cotransporter, antagonizes the stimulatory effect of Ang II on Na^+–H^+ exchange in cortical brush-border membranes mediated by cAMP and PKA,[389,390] and stimulates renin synthesis in cultured rat juxtaglomerular cells.[391] Studies in humans have shown that dopamine does not induce natriuresis in Na^+-depleted subjects and that its natriuretic effect is more pronounced during conditions of volume expansion.[368,392] This demonstrates again that the natriuretic and diuretic effects of D_1-like receptors are dependent on sodium balance.

In the whole kidney, dopamine increases RBF and GFR through its D_1 receptor-mediated vasodilatory effects.[383,392] Supraphysiologic concentrations of dopamine, however, stimulate α-adrenergic receptors, which lead to vasoconstriction and decreased RBF. The natriuretic and vasodilating effects of dopamine have suggested a therapeutic role in patients with volume expansion, particularly when administered in low doses that do not activate adrenergic receptors. However, several studies have shown that dopamine has no major role as a therapeutic strategy in the prevention of further renal damage in acute kidney injury.[393,394] Moreover, dysfunction of the renal dopamine system has been postulated to contribute to the pathogenesis of systemic hypertension.[368,383] Results from at least two studies suggest that defects in renal generation of dopamine are common in patients with essential hypertension.[395,396]

The ability of the D_1 receptor to induce both natriuresis and vasodilation makes D_1 agonists, such as fenoldopam, potential therapeutic agents for the treatment of both hypertensive urgencies and acute renal failure. In healthy normotensive volunteers, fenoldopam has been shown to significantly increase renal plasma flow while only minimally reducing systemic blood pressure.[397] In people with hypertensive urgencies, fenoldopam has been shown to reduce systemic blood pressure by 23% while increasing natriuresis by 200%, diuresis by 46%, and renal blood flow by 42%.[398] Although the selective increase in renal plasma flow could be advantageous in the treatment of certain forms of acute renal failure, further studies must be done to define the specific utility of fenoldopam in this setting.

THE RENAL KALLIKREIN-KININ SYSTEM

In 1909, Abelous and Bardier reported for the first time the hypotensive effect of human urine when injected into the bloodstream of dogs.[399] Further studies by Werle and colleagues from 1926 to 1939 attributed these effects to the kallikrein-kinin system (KKS) and described its basic components: kallikreins, kinins, kininogens, and kininases. The

major actions of this system are mediated by bradykinin, a peptide hormone that exerts potent proinflammatory and vasodilatory effects. Interestingly, all components of the KKS are also expressed in the kidney, especially in the distal convoluted and connecting tubule as well as in the collecting duct, and have been shown to regulate renal hemodynamic and tubular function. In addition, in the last few years, studies have linked the KKS to different pathologic states including the diabetic nephropathy as reviewed here.

Structure and Synthesis of Kinins

The KKS is a complex multienzyme system that can be divided into two types: (1) a circulating KKS that belongs to the coagulation system and (2) a tissue KKS that acts in a paracrine or autocrine fashion. The KKS leads to the production of kinins, namely bradykinin and lys-bradykinin (kallidin), from kininogens through the action of kininogenase, namely kallikrein (Fig. 8.5).[399] Two types of kallikreins have been identified—a plasma and a tissue kallikrein—both of which are serine proteases that are encoded by different genes and differ in their distribution and regulation.[399] Mice lacking tissue kallikrein show dramatically reduced levels of renal kinin, suggesting that tissue kallikrein is the main system involved in the kidney,[400] although little is known regarding the putative role of plasma kallikrein under pathologic conditions. Renal tissue kallikrein is synthesized in large amounts by connecting tubule cells and is mainly secreted into the urinary fluid and to a lesser extent to the peritubular interstitium.[399]

In humans, two types of kininogens have so far been described: a high molecular weight (HK) form present in blood and a low molecular weight (LK) form present in various tissues. It is generally accepted that tissue kallikrein prefers LK but is capable of cleaving HK, whereas plasma kallikrein cleaves HK exclusively.[399] Kininogens are synthesized in the liver and circulate in blood plasma at concentrations of 45 to 120 μg per mL for LK and of 65 to 115 μg per mL for HK, but are also found in other body fluids and organs such as kidney.[401]

Novel functions of kininogens have been recently discovered. Derivatives of HK have been shown to be involved in the regulation of endothelial cell proliferation, angiogenesis, and apoptosis.[402] In addition, some seem to possess potent and broad-spectrum microbicidal properties against both gram-positive and gram-negative bacteria, and thus may represent an alternative to conventional antibiotic therapy.[402]

Physiology of Kallikrein-Kinin System in the Kidneys

Tissue kallikrein is secreted by many cells throughout the body but some tissues produce particularly large quantities such as the kidney, lung, intestine, brain, and glandular tissues (salivary and sweat glands and pancreatic exocrine gland). This enzyme is activated intracellularly from a precursor, prokallikrein, to produce tissue kallikrein.[403] The enzyme responsible for this conversion has not yet been identified.

Regulatory mechanisms of tissue kallikrein remain partly unknown. Aprotinin, a polypeptide purified from the lung, and kallistatin have been shown to inhibit the activity of renal and other tissue kallikreins.[404] In addition, it has been shown that salt restriction stimulates the synthesis of renal kallikrein through an unclear mechanism, possibly implicating aldosterone.[405] Interestingly, it was also recently shown that potassium intake triggers an increase in renal kallikrein secretion through an aldosterone-independent mechanism

involving membrane depolarization of kallikrein-secreting cells in the renal connecting tubules, followed by enhanced calcium influx.[406,407] In addition to dietary sodium and potassium intake, hereditary factors may determine tissue kallikrein activity. In fact, a loss of function polymorphism in the human tissue kallikrein gene (R53H) has been identified with a frequency of 0.03 in Caucasians.[408] Interestingly, these partially tissue kallikrein-deficient subjects develop a form of arterial dysfunction characterized by remodeling of the brachial artery, which is not adapted to a chronic increase in wall shear stress.[408]

Although of little relevance for the kidney, it is noteworthy that plasma kallikrein is regulated through a different, more complex, mechanism. Plasma kallikrein is synthesized and secreted by the liver as an inactive zymogen. It is activated by the intrinsic coagulation cascade whereby contact of plasma with negatively charged macromolecular surfaces initiates a proteolytic cascade that ultimately converts prekallikrein to plasma kallikrein.[409]

The half-life of bradykinin in plasma is short (~30 seconds), suggesting that its actions are regulated locally through its production and degradation within tissues. In fact, both bradykinin and kallidin can be metabolized through two pathways.[410] Kininase I (also called carboxypeptidase-N), as well as carboxypeptidase-M, remove the C-terminal arginine from the kinins to generate their des-Arg derivatives, which are agonists of B1R (see later). Kininase II (also known as ACE), neprilysin (endopeptidase 24.11), and endothelin-converting enzyme cleave off the two C-terminal amino acids (Phe and Arg) of the kinins, thereby inactivating them.[411,412] It is noteworthy that kallidin can be converted into bradykinin by a plasma aminopeptidase.

Kinins exert their biologic effects by acting on two types of G protein-coupled receptors called bradykinin B1 receptor (B1R) and B2 receptor (B2R) (Fig. 8.6). Although B2R is ubiquitous and expressed throughout the kidney, B1R is mainly expressed after induction by endotoxin, cytokines, ischemia, and other noxious stimuli.[411] Interestingly, treatment with an inflammatory signal (lipopolysaccharide) induces the expression of B1R mRNA in all renal segments except the outer medullary collecting ducts. B1R, once induced by inflammatory mediators and tissue damage, assumes some of the physiologic roles of B2Rs.[413] Bradykinin and kallidin are equipotent and both have higher affinity for B2R. Interestingly, metabolites (des-Arg9-BK [DABK] and Lys-DABK) of bradykinin and kallidin, which result from the action of carboxypeptidases, have higher affinity for B1R.

Both receptors activate similar intracellular signaling cascades involving phospholipase C activation and intracellular calcium mobilization. In addition, through calcium-dependent and -independent mechanisms, KKS increases NO and prostaglandin synthesis, both of which seem to mediate some of the effects of kinins.[410] Alternative mediators of kinins also include endothelium-derived hyperpolarizing factor (EDHF), norepinephrine, substance P, cytokines, and tissue plasminogen activator.[410]

Experimental evidence suggests that kinins regulate renal blood flow and renal excretion of sodium and water.[414,415] Studies on the role of the renal KKS, using congenitally kininogen-deficient Brown-Norway Katholiek rats and B2R knockout mice, amongst other models, revealed that this system starts to induce natriuresis and diuresis when sodium accumulates in the body as a result of excess sodium intake or aldosterone release, for example, by angiotensin II. Thus, it is hypothesized that the system works as a safety valve for sodium accumulation. In fact, mice lacking B2R and/or B1R develop salt-sensitive hypertension.[416] Interestingly, humans with essential hypertension have low levels of urinary

kallikrein.[405] Conversely, hypertensive mice and rats over-expressing the human kallikrein develop hypotension.[417] However, the renal KKS seems to be involved only in the long-term regulation of blood pressure under conditions of hypertensive insult such as high salt intake.[418] Evidence suggests that bradykinin promotes natriuresis, in part, by decreasing sodium reabsorption in the distal part of the renal nephron. Bradykinin has been shown to inhibit the amiloride-sensitive component of conductive sodium uptake in inner medullary collecting duct cells[419] and to cause a reversible inhibition of sodium reabsorption ex vivo in rat cortical collecting ducts.[420] Furthermore, inhibition of B2Rs in rats fed a normal salt diet decreases fractional sodium excretion with little effect on medullary and cortical perfusions or on GFR.[421] Recently, Zaika et al. confirmed that bradykinin inhibits ENaC in the aldosterone-sensitive distal nephron.[422] It is noteworthy that during volume expansion, a condition that requires further sodium reabsorption, at least one additional mechanism is activated: kinins mediate the increase in papillary blood flow, thereby indirectly inhibiting further tubular electrolyte reabsorption.[421]

The renal KKS is believed to operate in concert with the renin-angiotensin system to physiologically regulate the distribution of RBF and the excretion of water and electrolytes. It has been confirmed that the effects of kinins antagonize the effects of RAAS on blood pressure and sodium handling. In fact, reduced KKS activity may contribute to the establishment of a pathophysiologic state characterized by unopposed hyperactivity of the renin-angiotensin system, resulting in salt retention.[423] It has been shown that this reduced activity of the KKS predominates over renin-angiotensin system overactivity in all conditions of sodium balance in essential and family-related hypertension.[424] KKS and the renin-angiotensin system are functionally coupled at the level of ACE. Inhibition of this enzyme not only blocks angiotensin II production but also increases bradykinin production. It was shown that the beneficial effects of ACE inhibitors were mainly due to NO production following B2R activation.[425] Interestingly, chronic treatment with ACE inhibitors induces B1R expression in vasculature and in the kidney, which could mediate the renoprotective effects of ACE inhibition.[426]

Interestingly, the contribution of the KKS to renal handling of potassium has been recently addressed by Chambrey's group.[407] Usually, potassium is almost completely reabsorbed by the end of the loop of Henle and active secretion in the late distal nephron determines the fraction that needs to be excreted in the urine. Thus, except in a situation of potassium depletion, in which net potassium absorption also occurs in the collecting system, the latter is generally a site of net potassium secretion. It was recently shown that cortical collecting ducts isolated from mice with tissue kallikrein gene disruption do not secrete potassium but instead exhibit net transepithelial potassium absorption due to abnormal activation of H^+-K^+-ATPase.[407] This suggests that potassium absorption is constantly under the negative control of tissue kallikrein. However, the mechanism or signaling pathway by which tissue kallikrein controls H^+-K^+-ATPase remains to be determined.

In addition to sodium and potassium, the KKS seems to regulate the metabolism of calcium, through a B2R/B1R-independent mechanism. Picard et al. showed that knocking out tissue kallikrein in mice leads to hypercalciuria of renal origin.[427] In fact, the distribution of tissue kallikrein overlaps that of the epithelial calcium channel (TRPV5) in the distal nephron. Furthermore, kallikrein gene expression was increased by a low-calcium diet.[427] Interestingly, no such abnormalities were observed in B2R knockout mice with or without treatment with B1R antagonist. This suggests that the effect of kallikrein on calcium excretion is independent of kinin production.

Furthermore, products of the KKS may modulate cell growth. Experimental evidence suggests that while under certain conditions, in vitro bradykinin may inhibit growth of normal renal fibroblasts.[428,429] It can also stimulate the growth of fibroblasts, mesangial cells, and arterial smooth muscle cells in other conditions.[430] Over-expression in hypertensive Dahl salt-sensitive (DSS) rats of the human kallikrein gene by adenoviral delivery results in reversal of the changes associated with hypertensive nephrosclerosis.[430] Chao et al. further confirmed that kinin exerts its renoprotective effects against salt-induced renal injury in the DSS rat model by inhibiting cellular apoptosis, inflammatory cell recruitment, and fibrosis through suppression of oxidative stress, TGF-β expression, and MAPK activation, with no effect on blood pressure.[431] To a large degree, the benefits of kinins in that study were dependent on the elevated levels of renal NO.[431] NO has been shown to play an important role in protection against hypertension and glomerulosclerosis in DSS rats.[432] These renoprotective effects of NO may be attributed to a decrease in oxidative stress. In fact, NO can scavenge superoxide anions. It can also inhibit the assembly of a functional NADH/NADPH oxidase, thereby attenuating the production of superoxide.[433] In addition, given that oxidative stress can stimulate the expression of proinflammatory and profibrotic molecules, the increase in NO production triggered by kinins could not only decrease oxidative stress but consequently attenuate the inflammatory and fibrotic responses.[434] Tissue kallikrein has also been reported to attenuate salt-induced renal damage by activation of B2R.[435,436] The protective effect of the KKS against renal injury was also confirmed in B2R knockout mice.[437] In addition, a human B2R gene polymorphism has been demonstrated in patients with chronic renal failure, suggesting a role of this receptor in the early development of this pathology.[438]

Furthermore, as mentioned previously, bradykinin, through its receptors, increases prostaglandin production in at least three ways. First, it promotes translocation into the cell membrane and phosphorylation of cytosolic phospholipase A2 through a Ca^{2+}-dependent phosphorylation. Second, it activates membrane-associated phospholipase A2 through a Ca^{2+}-independent mechanism. Phospholipase A2 frees arachidonic acid from membrane phospholipids.

This arachidonic acid gets converted to prostaglandins by cyclooxygenase. The third mechanism by which bradykinin increases the production of prostaglandins is by inducing cyclooxygenase-2.[403,433] It has been shown that the prostaglandins formed following stimulation of the bradykinin receptors act through their specific receptors to mediate some of the effects of kinins on vascular tone and on mitochondrial respiration. Of potential relevance to the kidney, Kopp and Smith[439] demonstrated in a rat model of unilateral ureteral obstruction that indomethacin abolished BK-induced natriuresis and diuresis in the contralateral kidney.[439] Further studies are required to determine the role of bradykinin-induced prostaglandins in the healthy and diseased kidney, especially because renal diseases present with several characteristics including inadequate filtration of proteins and inflammatory cell recruitment.

Finally, recent evidence suggests that bradykinin participates in the regulation of neonatal glomerular function and acts as a growth regulator during renal development. An intact KKS is necessary for the normal functional development of the kidney.[440] During nephrogenesis, tubular and glomerular growth and differentiation, and acquisition of specialized functions, are coordinated in time and space with renal vasculogenesis, glomerulogenesis, and regional hemodynamic changes. The end result ensures that tubular structure and function are tightly coordinated with glomerular filtration during normal kidney development. To achieve this delicate task of glomerulotubular balance, the developing kidney produces growth factors and vasoactive hormones that act in a paracrine manner to regulate nephrovascular growth, differentiation, and physiologic functions. One such paracrine system is the KKS, which generates bradykinin. Bradykinin activates B2R to regulate RBF and salt and water excretion. Gene-targeting studies indicate that the fetal KKS plays an important role in the maintenance of terminal epithelial cell differentiation.[441] In fact, gestational salt loading induces abnormal renal development in B2R knockout mice.[442] It was also recently shown that B1R is unlikely to play a role in early nephrogenesis but its enrichment in the maturing proximal tubule suggests a potential role for this receptor in terminal differentiation of the proximal nephron.[443]

Clinical Pathophysiologic Role of the Kallikrein-Kinin System in the Kidneys

Diabetic nephropathy occurs in ~30% of all patients with diabetes. ACE inhibition is protective in many models of diabetic nephropathy, a protection partly mediated by the KKS. In fact, it has been shown in different diabetic models that the beneficial effects of ACE inhibitors were attenuated by a B2R antagonist.[444–447] The same findings were observed in diabetic mice lacking B2R.[448,449] Albuminuria, glomerular sclerosis, interstitial fibrosis, lipofuscin accumulation in proximal tubules, and lifespan shortening were enhanced in this model. Corroborating these findings, human tissue kallikrein gene delivery efficiently attenuated insulin resistance and prevented diabetic nephropathy in streptozotocin-induced diabetic rats.[450] Once again, NO seems to be mediating this renoprotective role. In fact, L-arginine, a substrate of NO synthase (NOS), reduces proteinuria associated with streptozotocin-induced diabetes.[451] Conversely, an NOS inhibitor as well as an endothelial NOS (eNOS) deficiency accelerates the severity of diabetic nephropathy.[452–455] Interestingly, cicaprost, a prostacyclin analog, also delays the pathogenesis of the diabetic nephropathy, suggesting that prostaglandins in addition to NO mediate the beneficial effects of the KKS.[456] It is noteworthy that some groups have reported that deletion of B2R protects against the streptozotocin-induced diabetic nephropathy.[457] In addition, it has been shown that glomerular kinin receptors are induced by diabetes and this may contribute to the development of glomerular injury and to the development of microvascular complications of diabetes.[458] Bradykinin also regulates the expression of connective tissue growth factor (CTGF), TGF-β receptor II, and collagen I in mesangial cells, which provides a mechanistic pathway through which B2R activation contributes to the development of diabetic nephropathy.[459] In addition, Christopher et al.[460] demonstrated that glucose by itself regulates the expression of B2R in vascular smooth muscle cells. These contradictory results may be attributed to the differences between strains of mice and/or the methods of induction of diabetes.

Furthermore, immune-mediated nephritis plays a major role in the pathogenesis of systemic lupus erythematosus (SLE) and Goodpasture syndrome, which is the experimental model of glomerulonephritis caused by antibodies against glomerular basement membrane (anti-GBM). Liu et al. recently showed that mouse strains with upregulated expression of renal and urinary kallikreins are less susceptible to anti-GBM antibody-induced nephritis and lupus nephritis.[461] In addition, administration of kallikreins decreased the anti-GBM antibody-induced nephritis, demonstrating a link between KKS and immune-mediated renal damage.[461] These findings corroborate the aforementioned results that attribute a renoprotective role for KKS in nephritis following insults such as salt imbalance and diabetes.

The KKS has also been shown to protect against aminoglycoside-induced renal injury. Aminoglycoside antibiotics have been used to treat infections by aerobic gram-negative bacteria. However, they cause ototoxicity and nephrotoxicity. Interestingly, administration of tissue kallikrein is protective against gentamicin-induced renal injury in rats partly by inhibiting the inflammatory response and apoptosis through suppressing of oxidative stress.[462] In addition, L-arginine also prevents gentamicin-induced tubular damage in rats, whereas a NOS inhibitor aggravates the renal failure.[463] Similarly to the diabetic nephropathy, endogenous prostacyclin production also prevented the apoptosis and oxidative stress induced by gentamicin.[464] Thus, the renoprotective effects of tissue kallikrein against gentamicin toxicity seems to be once more mediated by NO and prostacyclin.

Furthermore, KKS seems to play a protective role in ischemic acute renal failure (IARF). As previously discussed,

NO production induced by B2Rs is an important player in the protective effects of ACE inhibitors.[425] In addition, ARBs seem to be less protective than ACE inhibitors against ischemia-reperfusion injury,[465] suggesting that ACE inhibitors may partly mediate their beneficial effects by inhibiting the inactivation of the kinins than by suppressing angiotensin II formation. In addition, studies have reported that deleting B1R and/or B2R aggravates renal damage following IARF; however, the double knockout had more detrimental effects than a deficiency in B2R only, emphasizing that both B1R and B2R are necessary for protection in IARF.[466] In addition to NO, older studies have shown that prostaglandins E1, E2, and I2 are also protective mediators of the KKS in IARF.[467] Contrary to these findings, results from exogenously administered bradykinin on IARF are conflicting and suggest that it aggravates IARF, although suppression of the endogenous KKS is also detrimental.[468] Thus, it seems that the physiologic levels of bradykinin produced endogenously are important for the functional recovery after IARF, but the higher levels achieved with exogenously administered bradykinin are detrimental.

In support of the aforementioned results in animal models, genetic studies in humans revealed that polymorphisms in several KKS-related genes are associated with higher incidence of renal problems. In fact, ACE polymorphism seems to influence diabetic nephropathy[469] and a polymorphism in the human B2R gene has been correlated with a higher susceptibility for nephropathy in diabetic patients.[470] Both human SLE and spontaneous lupus nephritis were also recently found to be associated with polymorphism in the kallikrein gene family, particularly KLK1 and KLK3.[471] Other studies have shown that the ACE D/D genotype is a risk factor for progression to chronic renal failure in patients with IgA nephropathy.[472,473] In addition, this ACE D/D genotype is also a risk factor for patients with autosomal dominant polycystic kidney disease (ADPKD) to develop ESRD at an earlier age.[474] In fact, polymorphisms in most of the genes in the KKS have been associated with the progression of chronic renal failure to ESRD, including ACE,[475] B1R and B2R,[476] and eNO.[477]

ADENOSINE

Adenosine, a purine nucleoside, is a paracrine hormone that regulates cellular and physiologic functions in many tissues. Three major pathways produce adenosine: the intracellular pathway, the extracellular ATP pathway, and the transmethylation pathway. Intracellular generation of adenosine results from the action of 5′-nucleotidase on adenosine monophosphate (AMP) during hypoxia (sequential dephosphorylation of intracellular ATP to adenosine). In cells that rapidly consume ATP, enhanced utilization of ATP increases the intracellular production rate of adenosine. In the kidney there are two prime examples of the intracellular ATP pathway. Increased delivery of Na^+ to the thick ascending limb of loop of Henle stimulates Na^+-K^+-ATPase activity in the basolateral membrane of epithelial cells through the increased flux of Na^+ across the luminal membrane. Oxygen availability in the renal medulla is marginally adequate; consequently, increased Na^+-K^+-ATPase activity may deplete ATP levels and lead to dephosphorylation of adenine nucleotides to form adenosine. Reactive ischemia is a second example of the intracellular ATP pathway in the kidney. A short period of ischemia in the kidney triggers a brief increase in renal vascular resistance, a phenomenon known as reactive ischemia. Renal ischemia activates the intracellular ATP pathway of adenosine production and adenosine causes reactive ischemia via activation of A_1 receptors in the preglomerular microvessels.[478] Adenosine, produced intracellularly, can traverse cell membranes by facilitated diffusion and function in a paracrine or autocrine fashion.

The extracellular ATP pathway is yet another mechanism of adenosine production in the kidney. Extracellular production of adenosine from AMP is possible because of the presence of ecto-5′-nucleotidase on the surface of many cell types. Release of adenine nucleotides into the extracellular compartment from renal sympathetic nerve terminals, intrarenal platelets, renal endothelial cells, renal vascular smooth muscle cells, and/or renal epithelial cells exposes extracellular ATP to ecto-ATPases, ecto-ADPases, and ecto-5′-nucleotidases, and these enzymes metabolize adenine nucleotides to adenosine.[478] In the kidney, ecto-5′-nucleotidase activity is expressed on tubular luminal membranes, fibroblasts, and mesangial cells and is believed to be the major source of renal adenosine.[479]

When oxygen supply is adequate, enzymatic hydrolysis of S-adenosyl homocysteine (SAH) to L-homocysteine and adenosine constitutes the major production pathway. It is the transmethylation pathway of adenosine production. Approximately one-third of the adenosine release to the extracellular space by cardiomyocytes is through the transmethylation pathway, but the importance of this pathway in the kidney is unclear.[478]

Adenosine Receptors

Purinoceptors or adenosine receptors, also called P_1 receptors, are classic G protein-coupled receptors with four known subtypes (A_1, A_2A, A_2B, and A_3 receptors).[478,480] A_1 receptors (A1Rs) have a high affinity for adenosine, whereas the affinity of A_2A receptors for adenosine is approximately threefold less compared with that of A1R. A_2B and A_3 receptors are low-affinity adenosine receptors.[478,480–482]

A1Rs are present in afferent arterioles, glomeruli including mesangial cells, juxtaglomerular cells, vasa recta, as well as in various segments of the tubular and collecting duct system including proximal tubule, thin limbs of Henle, TAL, and collecting ducts.[483] They evoke vasoconstriction by inhibiting adenylate cyclase activity (via activation of G_i and G_o), thereby reducing cAMP generation in vascular smooth muscle and signaling.[478] In renal epithelial cells and isolated rabbit afferent arterioles, A1R activation also appears to stimulate phospholipase C activity. A_2A and A_2B receptors produce vasodilation by stimulating adenylate cyclase

activity to increase cAMP generation; A_2A signal by engaging G_s, G_{olf}, and p21ras and A_2B receptors are also known to stimulate phospholipase C via G_q. A_3 receptors are thought to exert their physiologic effects through activation of calcium signaling pathways (phospholipase via G_q families) and perhaps inhibition of cAMP accumulation (via G_i), but their role in regulating the renal microvascular and epithelial function has not been extensively examined.[478,480]

P_2 receptors were originally described as purinergic receptors, reflecting the idea that they responded to ATP released as a neurotransmitter from peripheral sympathetic nerves. Currently P_2 receptors are divided into two distinct families: P_2X and P_2Y.[480]

Distinct genes code for each receptor family and there are marked differences in the structural and signal-transduction characteristics between the two families.

Renal Actions of Adenosine

Adenosine regulates a wide array of physiologic functions, including cardiac rate and contractility, vascular smooth muscle tone, neurotransmitter release, lipolysis, leukocyte function, platelet function, and renal hemodynamics and electrolyte transport.[481,484,485]

Adenosine is produced in the kidney and acts in an autocrine or paracrine fashion.[479,481] Both high-affinity A1R and low-affinity A2R are widely distributed throughout the renal vasculature and the nephron.[481,486] The renal effects of adenosine are diverse and include alterations in RBF, GFR, hormone production, neurotransmitter release, and tubular absorption (Table 8.4).

8.4 Renal Actions of Adenosine

Function	Effect	Receptor
Renal blood flow	Transient ↑ Delayed slight ↑	A_1 A_2
GFR	↓↓	A_1 and A_2
Renin production	↓↓ ↑	A_1 A_2
Erythropoietin production	↓ ↑	A_1 A_2
Sodium excretion	↑↑ ↓	A_2 A_1
GMC production and proliferation	↓	A_2B

↓, decrease; ↑, increase; GFR, glomerular filtration rate; GMC, glomerular mesangial cells.

Effect on Renal Blood Flow and Glomerular Filtration Rate

Infusion of adenosine into animals' renal artery results in transient reduction of RBF secondary to A1R mediated afferent arteriolar vasoconstriction, followed by a delayed A2R mediated postglomerular vasodilation and return of RBF to normal.[487–489] Selective A2R agonists increase RBF via vasodilation of the medullary renal microcirculation. A1R importantly regulate renal function. Infusion of A1R agonists into the renal interstitium diminishes blood flow to both superficial and deep nephrons. In the outer cortex, A1R-induced vasoconstriction is most likely caused by contraction of preglomerular, rather than postglomerular, microvessels; however, in juxtaglomerular nephrons, A1R mediate vasoconstriction by contracting preglomerular microvessels, efferent arterioles, and outer medullary descending vasa recta. Ang II strongly enhances A1R-induced preglomerular vasoconstriction. Contraction of preglomerular microvascular smooth muscle cells by A1R underlies the mediator role of adenosine in tubuloglomerular feedback (TGF) (Fig. 8.7), explains the ability of adenosine to decrease GFR, and potentiates postjunctional vasoconstrictor responses to renal sympathetic neurotransmission in the kidney.[478] It is conceivable that A1R are present in endothelial cells along the renal vasculature and that adenosine causes the release of NO and perhaps other endothelial vasodilators when administered from the vascular, but not from the interstitial, aspect of the vessel. The resulting A1R-induced constriction would, therefore, be blunted by endothelial factors only when adenosine is given intravascularly. In a study in dogs, the administration of NOS inhibitors caused a marked augmentation in the constrictor response of RBF to bolus injections of adenosine, whereas the dilator effect of the A_2 agonist CGS-21680 was unaffected, indicating that adenosine may cause NOS activation through an A1R-mediated mechanism. It is now well recognized that the majority of vasodilator agents act by binding to their receptors on endothelial cells and by eliciting the generation and release of endothelial relaxing factors, most notably NO, endothelial hyperpolarizing factor, and prostaglandins. However, in a number of studies, adenosine appears to augment NOS activity and NO release through an A2R-mediated process, an action that would enhance the dilator component rather than diminish the constrictor component of the adenosine actions. Also adenosine has been shown to consistently stimulate the production of NO in cultured endothelial cells, usually through an A2AR-dependent mechanism.[489]

Adenosine induces a sustained decrease in GFR secondary to reduced P_{GC}.[490] Infused in humans, it results in an insignificant increase in RBF and a significant, moderate decrease in GFR.[491,492] It is postulated that adenosine-mediated reduction in GFR constitutes the underlying mechanism of TGF.[493,494] The hypothesis states that increased solute delivery to the MD stimulates sodium transport, resulting in ATP hydrolysis and generation of adenosine. Adenosine, in turn, completes the feedback loop by decreasing GFR and

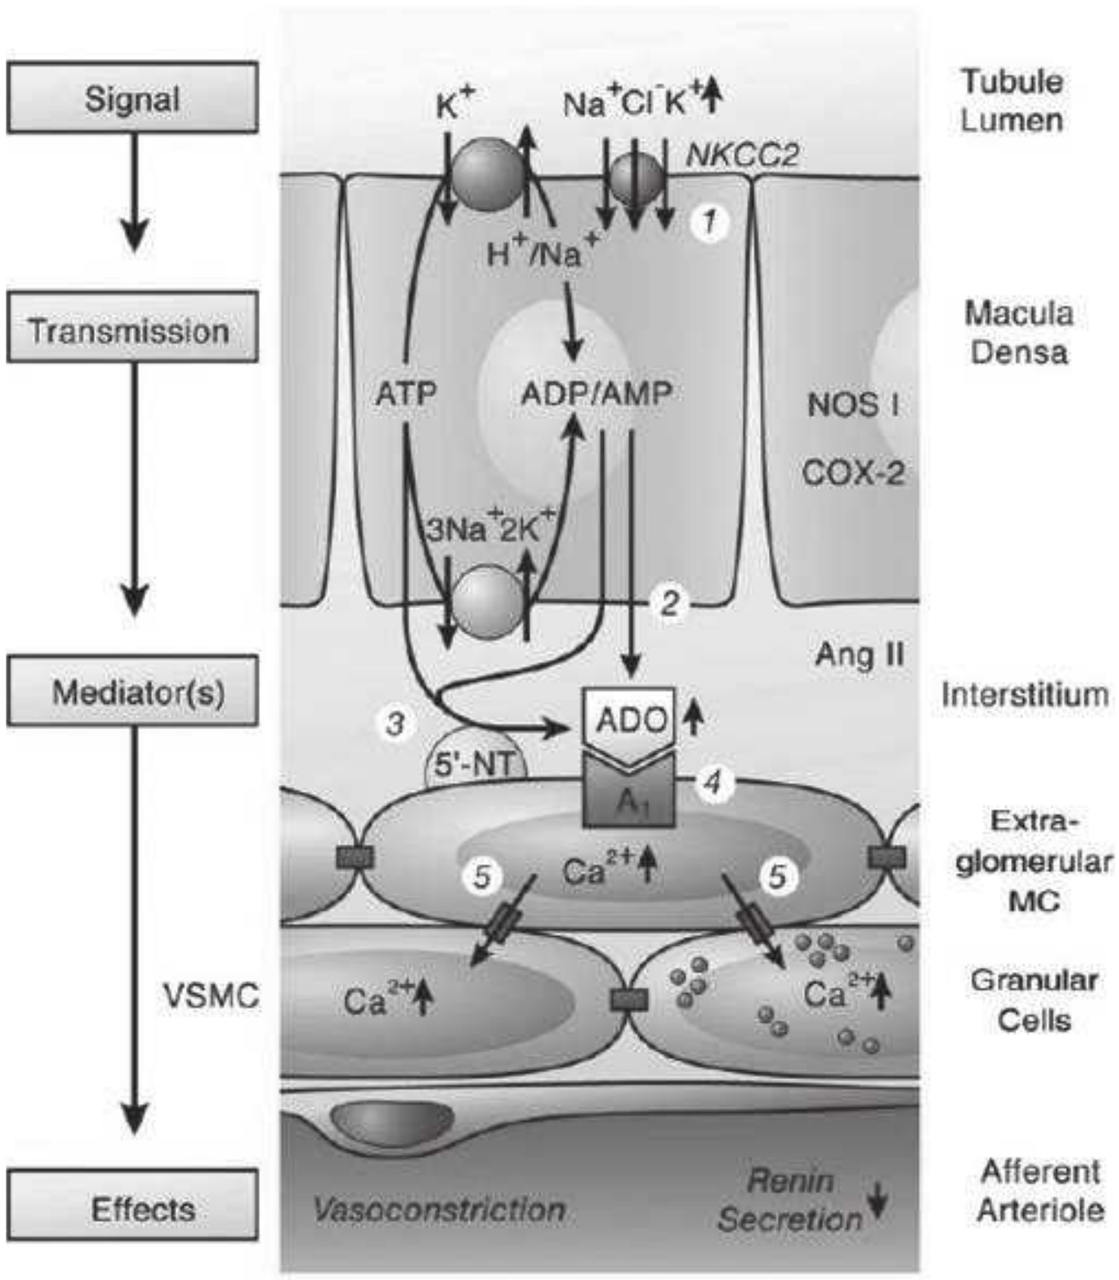

FIGURE 8.7 Proposed mechanism of adenosine acting as a mediator of the tubuloglomerular feedback. Numbers in circles refer to the following sequence of events. *1*, Increase in concentration-dependent uptake of nitrogen (N), potassium (K), and chlorine (Cl) via the furosemide-sensitive Na-K-2Cl cotransporter (NKCC2); *2* and *3*, transport-dependent, intra- and/or extracellular generation of adenosine (ADO); the extracellular generation involves ecto-5′-nucleotidase (5′-NT); *4*, extracellular ADO activates adenosine A1 receptors triggering an increase in cytosolic Ca^{2+} in extraglomerular mesangium cells (MC); *5*, the intensive coupling between extraglomerular MC, granular cells containing renin, and smooth muscle cells of the afferent arteriole (VSMC) by gap junctions allows propagation of the increased Ca^{2+} signal resulting in afferent arteriolar vasoconstriction and inhibition of renin release. Factors such as nitric oxide, arachidonic acid breakdown products, or angiotensin (Ang) II modulate the described cascade. *NOS I*, neuronal nitric oxide synthase; *COX-2*, cyclooxygenase-2. See text for further explanations. (Adapted from Vallon V, Muhlbauer B, Osswald H. Adenosine and kidney function. *Physiol Rev*. 2006;86(3):901–940.)

normalizing solute delivery to the distal nephron. The hypothesis is supported by experiments demonstrating that A1R blockade inhibits TGF.[495,496,497]

Effect on Sodium Reabsorption and Renal Tubular Transport

In contrast to A1R, which directly stimulate Na^+ reabsorption by increasing epithelial transport mechanisms, activation of A2R in microvessels of juxtaglomerular nephrons and in the medullary microcirculation enhances medullary blood flow, thus altering peritubular forces that modulate Na^+ reabsorption. The net result is an increase in Na^+ excretion.[478] Adenosine-induced decrease in solute excretion, particularly sodium, has been generally attributed to the concomitant reduction in GFR and urine flow. The presence of A1R and A2R on renal epithelial cells, however, suggests that adenosine has direct effects on tubular transport.[481] In rats, for example, infusing adenosine or adenosine receptor agonists in a dose that does not alter systemic blood pressure, RBF, or GFR still leads to sodium and water retention.[498,499] This effect was independent of renal enervation, at least for A1-specific agonists, and suggested a direct tubular effect of adenosine on A1R to stimulate sodium reabsorption.[499] A1R in the nephron are linked to Na^+ transport in several segments. However, the natriuresis and diuresis associated with systemic inhibition of A1R are due primarily to reduced proximal tubule (PT) reabsorption. Studies on kidney fluid and electrolyte transport show that activation of A1R stimulates NaCl reabsorption in cortical proximal tubule, which is a tubular segment with relatively high basal oxygen supply. In contrast, adenosine inhibits NaCl reabsorption in medullary TAL and IMCD—that is, nephron segments with relatively low oxygen delivery.[483] Caffeine and theophylline are nonselective adenosine antagonists, and reports suggest high levels of each induced diuresis.[500]

Adenosine acts as a mediator of the TGF, which establishes an inverse relationship between GFR and the NaCl concentration at the MD. In the juxtaglomerular apparatus, extracellular formation of adenosine by ecto-5′-nucleotidase contributes to the adenosine pool that mediates TGF-induced afferent arteriolar vasoconstriction. The TGF mechanism stablizes the NaCl load to the distal nephron, which facilitates fine regulation of body NaCl balance at these sites. Endogenous adenosine, the synthesis of which is increased by enhanced NaCl transport, limits via adenosine A1R activation the oxygen demand in relatively hypoxic nephron segments by directly and differentially affecting reabsorption along the nephron.[483]

Activation of basolateral P2 receptors in the collecting duct inhibits vasopressin-stimulated water reabsorption, and stimulation of apical P2 receptors can affect solute transport in both the proximal and the distal nephron: an in vivo micropuncture study in the rat showed that stimulation of apical P2Y1 receptors inhibits proximal tubular bicarbonate reabsorption through suppression of NHE3 activity,[1] and in vitro and in vivo evidence indicates that stimulation of apical P2 receptors in the distal nephron inhibits amiloride-sensitive sodium reabsorption[2,3] and reduces the activity of apical K secretory channels.[4,501]

Effect on Renin

Adenosine suppresses renin release by the kidney.[481] In sodium-depleted animals, renin release is inhibited by maneuvers that increase renal adenosine production,[502,503] an effect that results from direct action of adenosine on renin-producing cells.[504] Inhibition of renin release is most likely mediated by binding of adenosine to high-affinity A1R.[505] In this regard, A1R restrain renin release responses, a theory known as the adenosine-brake hypothesis. A1R are coupled to G_i and, therefore, inhibit adenylyl cyclase. Because stimulation of renin release from juxtaglomerular cells by many stimuli involves activation of adenylyl cyclase, activation of juxtaglomerular A1R attenuates renin release and antagonism of renal A1R increases renin release.[478] In contrast, agonists selective for the low-affinity A2R stimulate renin release, particularly when administered in high doses.[481,506] This suggests that adenosine regulates renin release by exerting either an inhibitory or stimulatory effect, depending on its local concentration. Studies employing acute blockade or chronic deficiency of adenosine A1R receptors rather indicate a modulating, tonic inhibition of the renin system by adenosine. In addition, an MD-dependent source of adenosine and activation of adenosine A1R contribute to renin release inhibition under conditions of high NaCl concentrations at the MD. An increase in intracellular cAMP is an important stimulator of renin release. Part of the cAMP could be released by renin-secreting cells and is extracellularly converted to adenosine, which acts as a negative feedback control or brake when renin secretion is stimulated.[483]

Effect on Renal Medullary Oxygenation

Renal medullary hypoxia is an obligatory part of the process of urinary concentration. When O_2 supply is further impaired, however, medullary hypoxic injury can develop. Various mechanisms act in concert to minimize medullary hypoxia. Adenosine-mediated actions like maintaining high proximal reabsorption, inhibiting reabsorption in the medullary TAL, and reducing GFR by the TGF mechanism, when distal NaCl concentrations increase, can be part of these mechanisms. Furthermore, in the deep cortex and medulla, adenosine via A2R activation causes vasodilation, which increases medullary blood flow and medullary oxygenation. Thus, adenosine through distinct actions on the vasculature and tubular transport system contributes to the stabilization of the O_2 demand-to-supply ratio particularly in the renal medulla.[483] Nishiyama and associates[480,507] demonstrated that hypoxia-induced renal vasoconstriction was associated with elevated interstitial adenosine levels and could be blocked by adenosine A1R antagonists. Adenosine plays a role in balancing oxygen supply and demand during renal hypoxia by regulating RBF, GFR, renin secretion, and solute transport.[493]

Pathophysiologic conditions associated with increased renal production of adenosine include ARF, myoglobinuric ARF, and mercuric chloride-induced ARF.[508–510] A1R may also be involved in other drug-induced nephrotoxicity. For example, selective antagonism of A_1 receptors attenuates nephropathy caused by nephrotoxins such as cisplatin, gentamicin, cephaloridine, glycerol, and radiocontrast media.[478]

A2R and Diabetic Nephropathy

Awad et al. showed that streptozotocin (STZ)-induced diabetes in rodents leads to marked proteinuria and decreased renal function that is attenuated with continuous subcutaneous administration of A2R agonists. Both nephrin and podocin mRNA levels were reduced after STZ-induced diabetes, an effect completely restored with A2R agonist treatment.[511] They also demonstrated that chronic administration of selective A2A agonists attenuates renal lesions and functional abnormalities characteristic of diabetic nephropathy. The renal tissue protective effect of the A2A agonist is believed to be mediated primarily by abrogating the inflammatory response associated with diabetes. Chronic A2R activation in diabetic rats ameliorates histologic and functional changes in kidneys induced by diabetes and causes reduced inflammation associated with diabetic nephropathy.[511]

Ischemia and Reperfusion Injury

Activation of A1R in many organs, including the kidney, initiates several cytoprotective kinase cascades including ERK MAPK, Akt, and PKC. Activation of cell surface A1R produces cytoprotective effects against ischemia and reperfusion (IR) injury in many organ systems including the heart, kidney, and brain. Joo et al. demonstrated that transient A1R activation produces both acute and delayed protective effects in the kidney including reduced renal cortical necrosis and apoptosis after IR injury. Renal apoptosis is an important component in the development of ARF after IR injury.[512] A2R exert important anti-inflammatory actions that may protect the kidneys from injury (Fig. 8.8). Their activation strongly inhibits neutrophil endothelial cell interactions in vitro and, in vivo, and markedly decreases the renal infiltration of neutrophils and attenuates renal dysfunction following IR injury.[478]

Adenosine 5′-tetraphosphate

Adenosine 5′-tetraphosphate (AP4) is the most potent vasoactive purinergic mediator identified to date, exerting the vasoconstriction predominantly through P2X1 receptor activation. The fact that AP4 is more resistant to degradation further favors potent and prolonged vasoconstrictive effects. The vasoconstrictive in vitro effects of AP4 are paralleled by hypertensive effects in vivo. Therefore, it may be speculated that AP4 is a vasoconstrictor secreted by human endothelial cells, which also plays a role in the regulation of systemic blood pressure under physiologic and pathologic conditions.[513]

Adenosine and Angiotensin II

Certain actions of adenosine, such as vasoconstriction of the renal afferent arteriole, are either dependent on or significantly enhanced by Ang II.[481,514] Evidence suggests that a reduction in, or prevention of, Ang II formation and action

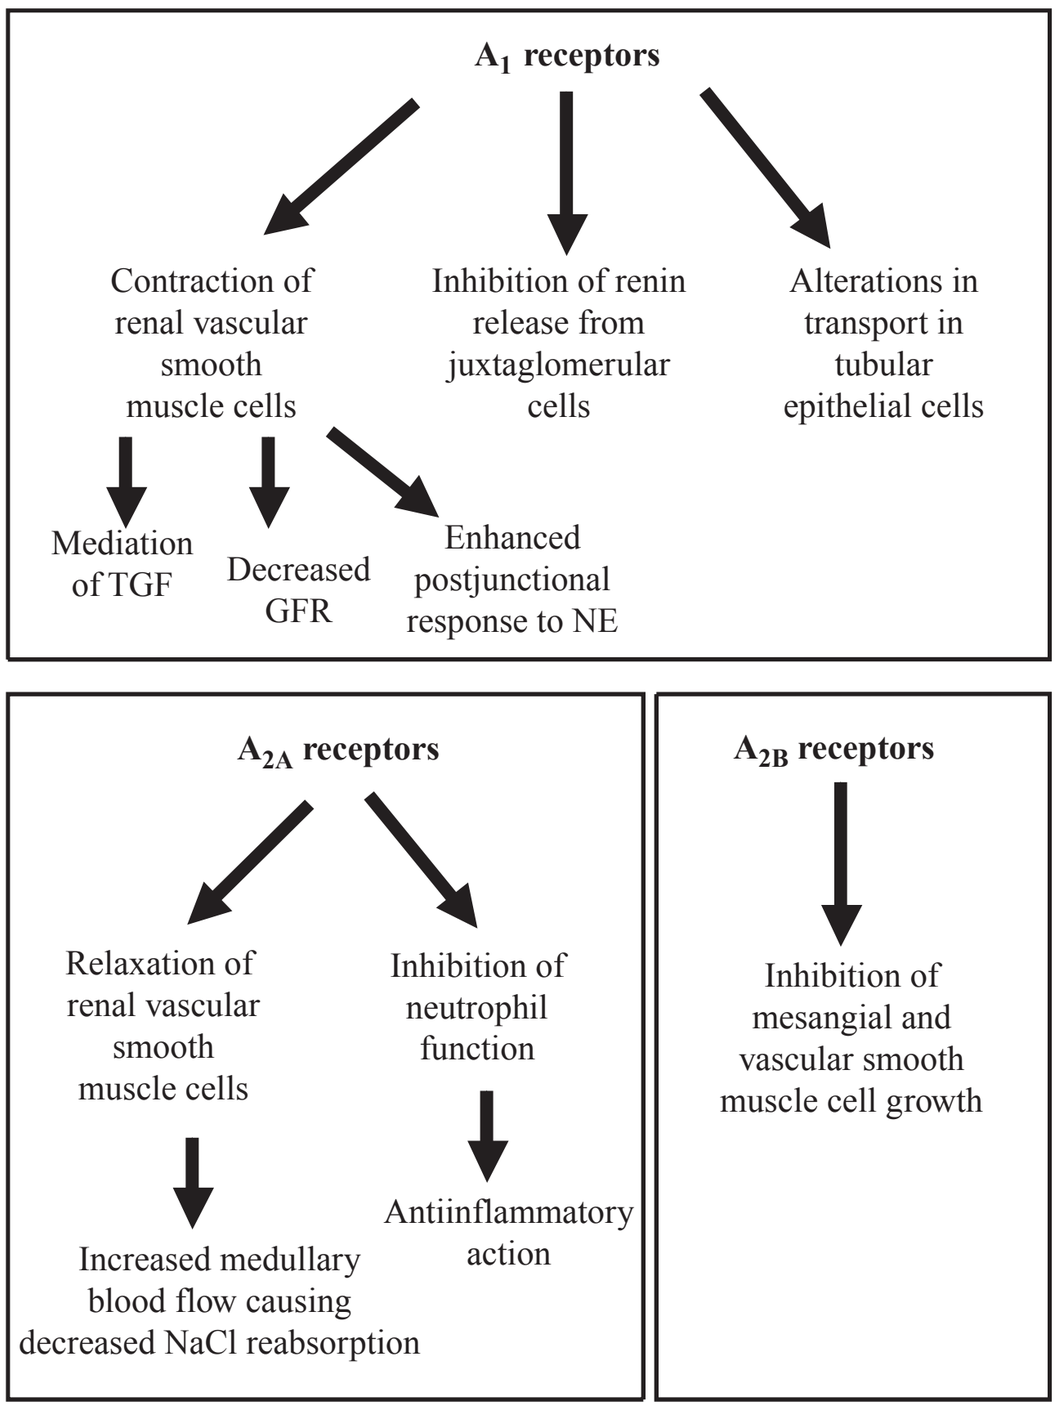

FIGURE 8.8 Regulation of renal function by adenosine. *TGF*, tubuloglomerular feedback; GFR, glomerular filtration rate; *NE*, norepinephrine. (From Bulut OP, Dipp S, El-Dahr S. Ontogeny of bradykinin B1 receptors in the mouse kidney. *Pediatr Res.* 2009;66(5):519–523.)

cause a marked attenuation of the vasoconstrictor response of the intact kidney to adenosine. Conversely, an elevation of ambient Ang II concentrations enhances the constrictor effect of A1R activation.[489]

Effects on Glomerular Mesangial Cells

A2B receptors' activation attenuates vascular smooth muscle cell proliferation and collagen and protein synthesis (Fig. 8.8). Studies with a number of adenosine receptor agonists and antagonists and with antisense oligodeoxynucleotides against the A2B receptor indicate that the growth inhibitory effects of adenosine on vascular smooth muscle cells are mediated by these receptors.[478]

Effect on Erythropoietin

A1R stimulation inhibits erythropoietin (EPO) synthesis, whereas that of A2R enhances EPO synthesis.[515]

Effect on Norepinephrine

Activation of A1R on sympathetic neurons in the kidney causes presynaptic inhibition of norepinephrine (NE) release.[516] Postjunctionally, however, adenosine seems to enhance sensitivity to NE.[516] Because renal denervation does not alter adenosine-induced changes in RBF and GFR, the hemodynamic actions of adenosine in the kidney are most likely independent of its effect on neurotransmitter release.[481]

Pancreatohepatorenal Extracellular cAMP-Adenosine Pathway

In addition to an autocrine/paracrine role in the kidney, the extracellular cAMP-adenosine pathway may also function as an endocrine system by which the pancreas and liver regulate renal function. The pancreas releases glucagon directly into the portal circulation in response to appropriate stimuli. Glucagon in the portal circulation stimulates hepatic adenylyl cyclase, which results in secretion of cAMP by hepatocytes into the venous circulation. Liver-derived cAMP circulates to the kidney, where it is filtered into the proximal tubule and then metabolized to adenosine. Adenosine would then engage A1R in epithelial cells to enhance electrolyte transport. It is important to note that, in contrast to cAMP, which is stable in blood, adenosine has a half-life in human blood of less than 1 second. The liver has the capacity to release significant amounts of cAMP into the hepatic vein.[478]

The most recent studies strongly suggest that an autocrine/paracrine extracellular cAMP-adenosine pathway, in fact, does not participate in the regulation of Na^+ transport by proximal epithelial cells. It appears that the pancreatohepatorenal extracellular cAMP pathway is more important in modulating proximal tubular function. Although intrarenal infusions of glucagons do not reduce Na^+ excretion, intraportal infusions of glucagon in sheep cause a marked antidiuresis. Although speculative, it is conceivable that the pancreatohepatorenal cAMP-adenosine pathway participates in physiologic adjustments of renal transport, as well as in pathophysiologic processes. In normal mammals, both hypoglycemia and exercise are powerful stimulants to glucagon release. Activation of the pancreatohepatorenal cAMP-adenosine pathway by glucagon in response to hypoglycemia might increase Na^+ glucose symport in proximal tubules and, thus, increase the efficiency of glucose transport, an adaptive mechanism to combat hypoglycemia. Activation of the pancreatohepatorenal cAMP-adenosine pathway by glucagon during exercise might enhance Na^+ transport in the proximal tubules and thus increase the efficiency of Na^+ reabsorption, an adaptive mechanism to avoid volume depletion during sustained physical exertion. The pancreatohepatorenal cAMP-adenosine pathway might be overly activated in the metabolic syndrome. Although oral glucose normally strongly inhibits glucagon secretion by the pancreas, in animals and people with the metabolic syndrome, an oral glucose challenge markedly stimulates pancreatic glucagon secretion by approximately 200%. If the pancreatohepatorenal cAMP-adenosine pathway exists, each time such a patient ingests a high carbohydrate meal the renal tubules would be exposed to a wave of excess adenosine

production. Because adenosine causes increased reabsorption of Na^+ and vasoconstriction of the preglomerular microcirculation, this could contribute to the pathophysiology of hypertension in the metabolic syndrome. Importantly, adenosine receptors also inhibit lipolysis in fat cells and may reduce insulin sensitivity in skeletal muscle. However, at this time, both the physiologic and pathophysiologic roles of the putative pancreatohepatorenal cAMP-adenosine pathway are speculative.[478]

PARATHYROID HORMONE AND PARATHYROID HORMONE–RELATED PEPTIDE

In response to low levels of extracellular Ca, parathyroid glands secrete parathyroid hormone (PTH), an 84-amino acid polypeptide hormone.[517] PTH is initially synthesized as a 115-amino acid polypeptide, pre-pro-PTH, which is cleaved within parathyroid cells at the N-terminal portion first to pro-PTH (90 amino acids) and then to PTH (84 amino acids). PTH-related peptide (PTHrP) was first identified as a cause of humoral hypercalcemia of malignancy and is secreted predominately as a 141-amino acid peptide. PTH and PTHrP have sequence homology in the first 13 amino acids (the amino terminus).[518] Increased circulating PTH or PTHrP leads to mobilization of Ca from bone, enhancement of Ca reabsorption in the renal tubule, and increased production of 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$) from 25 hydroxyvitamin D_3(25-OH D_3) by proximal tubule cells through 1α hydroxylase stimulation. $1,25(OH)_2D_3$, in turn, increases Ca absorption by the intestine and possibly Ca reabsorption by the kidney. The combined actions of PTH and $1,25(OH)_2D_3$ result in normalization of the extracellular Ca concentration. In addition to its regulatory actions on calcium balance, PTH can regulate phosphorus balance by inhibiting its reabsorption in the proximal and distal tubules of the nephron.

PTH synthesis and secretion by the parathyroid gland is tightly regulated.[517] Although a decreased extracellular Ca level stimulates PTH synthesis and secretion, increased extracellular levels of either Ca or $1,25(OH)_2D_3$ are inhibitory. The extracellular phosphorus level regulates PTH production directly at a posttranscriptional level[519] and indirectly by altering circulating Ca and $1,25(OH)_2D_3$ concentrations. Increased serum phosphorus secondary to renal insufficiency, for example, decreases Ca concentration and $1,25(OH)_2D_3$ production, leading to stimulation of PTH release, but can itself increase PTH level without alterations in ionized calcium or serum $1,25(OH)_2D_3$ levels.[520,521]

Magnesium also regulates PTH secretion and its depletion can decrease PTH secretion. Fibroblast growth factor 23 (FGF23) decreases PTH mRNA and secretion. Ben-Dov et al. showed that FGF23 acts directly on the parathyroid through the MAPK pathway to decrease serum PTH.[522]

The biologic activity of PTH resides in its amino-terminus. There is increasing evidence that the C-terminal fragment of PTH, PTH(7-84), exerts a hypocalcemic effect that is reversed by PTH(1-34) and PTH(1-84). PTH(7-84) inhibits PTH(1-84)-induced bone resorption. Nakajima et al. studied the effect of PTH(7-84) on PTH(1-34)-induced production of $1,25(OH)_2D_3$ in primary cultured murine renal tubules. PTH(1-34) stimulated the conversion of 25-OH D_3 to $1,25(OH)_2D_3$, and PTH(7-84) dose-dependently inhibited this process. Real-time polymerase chain reaction (PCR) revealed that PTH(1-34) increased the expression level of 1α-hydroxylase mRNA, whereas PTH(7-84) did not. This may at least partly account for the decreased serum level of $1,25(OH)_2D_3$ in patients with severe primary hyperparathyroidism with renal failure.[523]

Once secreted, PTH is rapidly cleared from plasma through uptake principally by the liver and kidney, where PTH(1-84) is cleaved into amino- and carboxyl-terminal fragments that are then cleared by the kidney. Hepatic clearance of PTH involves rapid proteolysis by Kupffer cells to N-terminal fragments and C-terminal fragments (CPTH). CPTH fragments can exert direct effects on bone cells via CPTH receptors. They are cleared predominantly by the kidney and accumulate disproportionately during renal failure.[524] Intact PTH has a plasma half-life of 2 to 4 minutes. In comparison, the C-terminal fragments, which are cleared principally by the kidney, have half-lives that are five to ten times greater.

Parathyroid Hormone and Parathyroid Hormone–Related Peptide Receptors

Two types of receptors exist. Type 1 PTH receptors (PTH1R) bind PTH and PTHrP. Binding to PTH1R occurs in the 15- to 34-amino acid region of both hormones (N-terminal sequence). It is interesting that these two peptides bind with almost equal affinity and yet do not share sequence homology in this region. The PTH1R mediates the biologic activity of PTH and PTHrP. PTH1R is heavily expressed in bone and kidney, and is also present in other tissues such as breast, skin, heart, blood vessels, pancreas, and other tissues. It activates multiple cellular signaling pathways including cAMP, PLC pathway, PKC, and release of intracellular calcium stores. Muller et al. showed also that activation of PTH1R engages major apoptosis signaling pathways, namely in apoptosis of differentiating embryonic cells.[525] Type 2 PTH receptors (PTH2R), which share 51% homology with PTH1R, can bind PTH but they do not bind PTHrP with high affinity. PTH2Rs are expressed in only a few tissues—their biologic significance is unknown.[518] Increasing evidence points to the presence of novel PTH receptors (CPTHR) with specificity for the carboxyl-terminal region of PTH. This portion of the hormone was previously thought to be biologically inert but has now been shown to possess hypocalcemic activity. The CPTHRs are present in various tissues but are most heavily expressed in bone.

Although PTH is a well-characterized endocrine regulator of mineral homeostasis, PTHrP is a key regulator of placental calcium transport in the fetus, and it appears to

be a physiologic modulator of smooth muscle tone. Current concepts indicate that PTHrP is a developmental and/or growth-regulating factor, much more similar to other known cytokines and growth factors than to PTH.[526] Under physiologic conditions, PTHrP levels are increased during pregnancy and lactation.[527] However, as described earlier, it appears to play a predominately pathophysiologic role in the adult, causing hypercalcemia.

Renal Actions of Parathyroid Hormone

PTH receptors and PTH-sensitive adenylate cyclase have been identified in glomeruli and basolateral membranes of epithelial cells in the proximal tubule, thick ascending limb of Henle's loop, and distal convoluted tubule (DCT).[7,528] PTH has three major effects on the kidney: increased Ca reabsorption, inhibition of phosphate reabsorption, and stimulation of $1,25(OH)_2D_3$ synthesis. Its other actions on the kidney include modulation of GFR, gluconeogenesis, magnesium reabsorption, and acid-base handling.

PTH decreases renal Ca excretion through multiple mechanisms. Ichikawa et al.[529] demonstrated that PTH infusion in rats decreases GFR by reducing K_f. A decreased GFR leads to decreased filtered load of Ca and, therefore, Ca excretion. PTH also enhances tubular Ca reabsorption by stimulating active Ca transport in the thick ascending limb of Henle's loop and distal tubule.[530,531] The effect of PTH on Ca transport in the proximal tubule varies and is probably related to Na and water reabsorption in this nephron segment.

PTH causes phosphaturia primarily by inhibiting phosphate transport in the proximal tubule, specifically by inhibiting sodium-phosphate (Na-P) cotransport.[532] Two different renal Na-P cotransporters have been identified and have been termed type 1 (Npt1) and type 2 (Npt2). Npt2 is a target for regulation by PTH and decreases Na-P transport by endocytic retrieval and lysosomal degradation of the Npt2 protein.[533] This endocytic retrieval can occur either from proximal tubules exposed to apical or basolateral PTH and can signal via either the cAMP-PKA or the PLC-PKC pathway.[534] Mice that are Npt2 null have profound phosphate wasting.[535] Npt2-null mice are resistant to further phosphaturic effects from exogenous PTH.[536] α_2-Adrenergic receptor stimulation blunts the phosphaturic response to PTH.[537] PTH-stimulated synthesis of $1,25(OH)_2D_3$ in the proximal tubule is discussed in the next section.

Although no single hormone has been specifically shown to regulate Mg homeostasis, PTH appears to increase Mg reabsorption in the kidney.[538] PTH also plays a role in acid–base homeostasis by enhancing urinary acid excretion.[539] Although PTH inhibits bicarbonate reabsorption in the proximal tubule, it indirectly stimulates distal hydrogen ion secretion and titratable acid excretion by increasing phosphate delivery to the distal nephron. PTH has also been shown to enhance proximal tubular gluconeogenesis[540] and renin secretion by juxtaglomerular cells.[541]

Renal Actions of Parathyroid Hormone–Related Peptide

In the kidney, PTHrP appears to modulate RPF and GFR, and induces proliferative effects on both glomerular mesangial and tubuloepithelial cells. PTHrP is known to be upregulated in several experimental nephropathies such as acute renal failure, obstructive nephropathy, as well as diabetic nephropathy. In transgenic mice models and in the former condition, PTHrP appears to contribute to the progression of renal damage by increasing tubulointerstitial cell survival, inflammation, and renal fibrogenesis. In diabetic nephropathy, PTHrP can promote renal hypertrophy and proteinuria. Ang II, a critical factor in the progression of renal injury, appears to be, at least in part, responsible for endogenous PTHrP upregulation in these pathophysiologic settings.[526] PTHrP also participates in the hypertrophic signalling triggered by high glucose on podocytes. In this condition, Ang II induces the upregulation of PTHrP, which in turn might induce both TGF-β1 and p27Kip1 expression and thereby promotes the hypertrophy of podocytes.[542]

Conventional renal cell carcinoma (CRCC) originates from the renal proximal tubular epithelium, a target tissue for PTHrP proliferation effects.[543] It was shown that PTHrP, acting through its receptor PTH1R, is an essential growth factor for CRCC in vitro and in vivo and a new target for the VHL gene products.[544,545] It seems that PTHrP induces tumor cell survival through inhibition of cell apoptosis.[546]

VITAMIN D

Along with PTH, vitamin D plays a central role in calcium and phosphate homeostasis. The active form of vitamin D, $1,25(OH)_2D$, is a steroid molecule synthesized from either vitamin D_3 (cholecalciferol) or vitamin D_2 (ergocalciferol). These two forms of vitamin D differ only by the side chain to the sterol skeleton. Vitamin D_3 is present in the diet (animal sources, mainly fish oil) and is also synthesized by the skin from 7-dehydrocholesterol upon exposure to ultraviolet light. Vitamin D_2 is available only from dietary sources (plants, yeast, and fungi). Vitamins D_3 and D_2 are biologically inactive. They require activation in the liver and kidney. After binding to carrier proteins, in particular, vitamin D-binding protein (DBP), vitamin D is transported to the liver where it is enzymatically hydroxylated to 25-hydroxyvitamin D (calcidiol, 25[OH]D) through the action of hepatic microsomal and mitochondrial cytochrome P450 vitamin D–25-hydroxylase. Subsequently, 25(OH)D, bound to DBP, is transported to the kidneys where it is hydroxylated exclusively in the proximal tubule by the mitochondrial 25(OH)D–1α-hydroxylase.[547] 1α-Hydroxylation is the rate-limiting step in the formation of the most abundant active metabolite $1,25(OH)_2D_3$.[548–550] This step is tightly regulated through multiple feedback mechanisms,[549,550] mainly PTH, calcium, phosphate, fibroblast growth factor 23 (FGF23), and $1,25(OH)_2D_3$ itself (Fig. 8.9). An increase

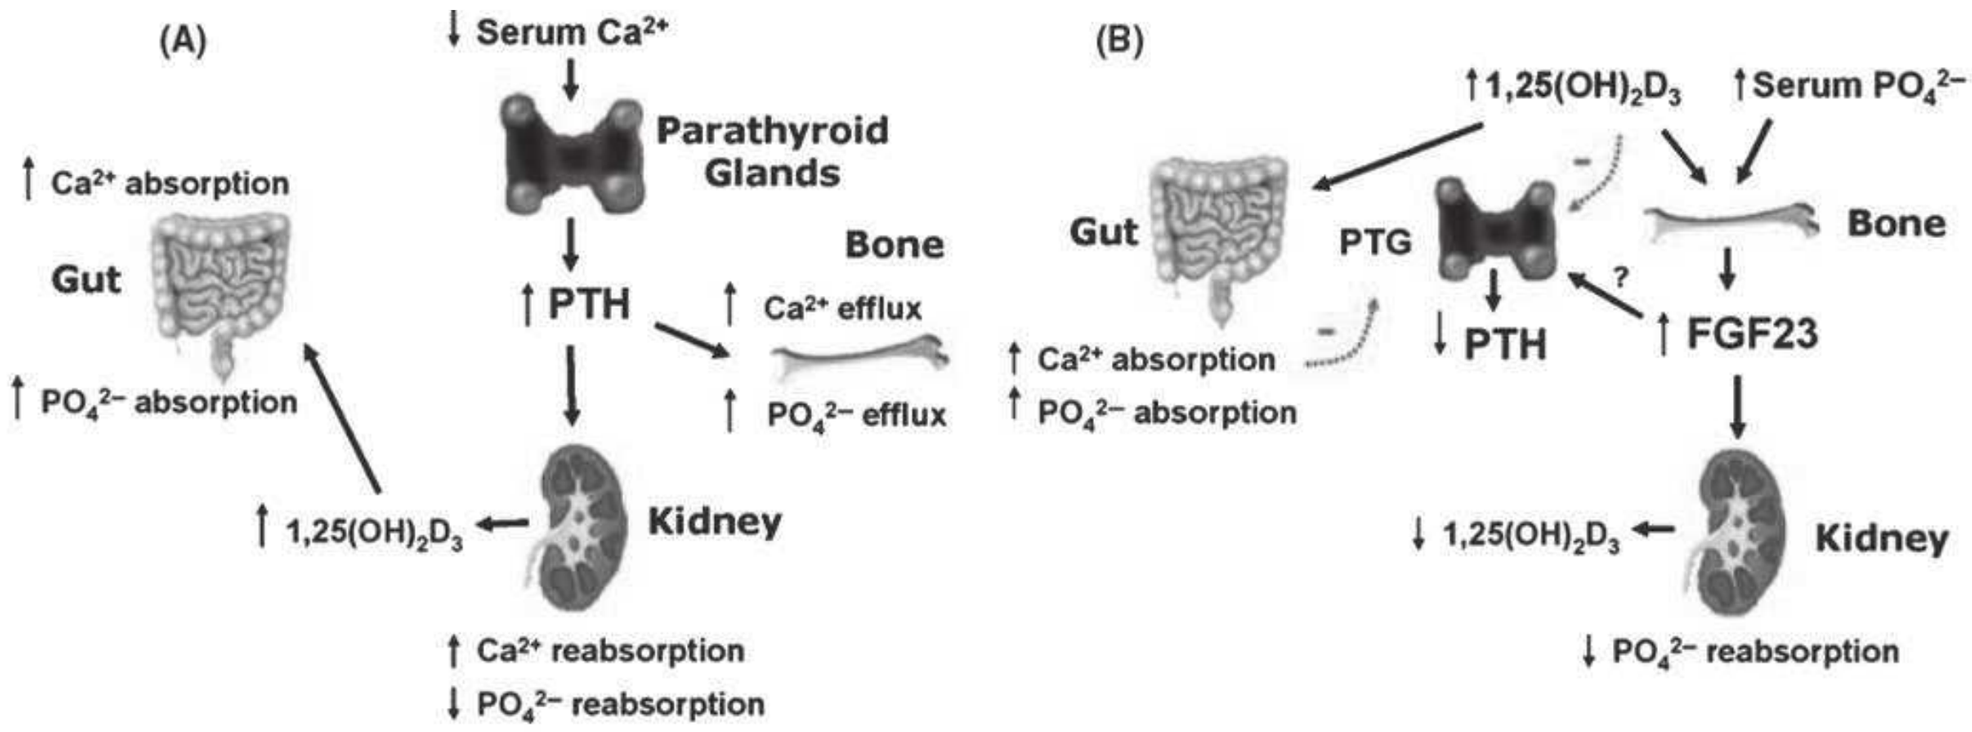

FIGURE 8.9 **A:** Calcium–parathyroid hormone (PTH)–vitamin D axis. The calcemic hormone PTH produced by the parathyroid gland targets kidney to increase calcium absorption and $1,25(OH)_2D_3$ production and bone to increase calcium efflux. $1,25(OH)_2D_3$ stimulates calcium absorption from the gut, which, along with renal and bone calcium, restores serum calcium to normal. **B:** Fibroblast growth factor 23 (FGF23)–bone–kidney axis. FGF23 produced by bone osteocytes has phosphaturic effects and suppresses $1,25(OH)_2D_3$, thereby providing a means to lower serum phosphate in a PTH-independent manner. (From Stubbs J, Liu S, Quarles LD. Role of fibroblast growth factor 23 in phosphate homeostasis and pathogenesis of disordered mineral metabolism in chronic kidney disease. *Semin Dial*. 2007;20(4):302–308.)

in PTH levels, secondary to decreased serum Ca, stimulates 1α-hydroxylase activity in the kidney. A low serum phosphorous or $1,25(OH)_2D_3$ concentration also activates 1α-hydroxylase, whereas elevated $1,25(OH)_2D_3$ levels and the phosphaturic FGF23 are inhibitory. Other less established stimulators of 1α-hydroxylase activity include calcitonin, growth hormone, insulin, insulin-like growth factor, estrogen, and prolactin.[548–550]

In addition to the kidney, extrarenal sites of 1α-hydroxylase activity have been identified. These include macrophages, keratinocytes, hepatocytes, and human placenta, as well as skeletal muscle cells[551] and various bone cell preparations,[552,553] although the regulatory processes for this conversion are not well understood. Extrarenal production of $1,25(OH)_2D_3$ can lead to hypercalcemia in certain pathologic situations, as in patients with active sarcoidosis or in patients with lymphoma.

The first step in the inactivation and catabolism of vitamin D is hydroxylation of 25(OH)D and $1,25(OH)_2D$ by 24-hydroxylase, which is present in the kidney, intestine, and several other tissues that possess $1,25(OH)_2D_3$ receptors.[547,550] Importantly, kidney 24-hydroxylase and 1α-hydroxylase are reciprocally regulated.[547,550,554] $1,25(OH)_2D_3$ and hypophosphatemia increase 24-hydroxylase activity whereas vitamin D deficiency and PTH (via CAMP) suppress it.[554]

25(OH)D has a long half-life (approximately 3 weeks) and is the best measure of vitamin D status. Calcitriol has a short half-life (4 to 6 hours) and exists at circulating levels 1/1,000 of those of 25(OH)D. $1,25(OH)_2D_3$ exerts its biologic actions by binding to intracellular vitamin D receptors (VDR), which in the unliganded form are located in the cytosolic and nuclear compartments.[555] Like other members of the steroid-thyroid family of receptors, the liganded form of VDR functions as a transcription factor in the nucleus. The VDR–$1,25(OH)_2D_3$ complex regulates transcription of more than 60 genes by interacting with DNA sequences known as vitamin D response elements. Central to its role in Ca homeostasis, $1,25(OH)_2D_3$ induces the transcription of genes coding for Ca-binding proteins.[556] Vitamin D-dependent Ca-binding proteins (CaBP-Ds) are found in high concentrations in Ca-transporting tissues, such as the kidney, intestine, and placenta. CaBP-Ds bind calcium with high affinity and are associated with Ca transport in these organs.

Another potential regulatory site for vitamin D signaling, other than the synthesis and degradation of $1,25(OH)_2D_3$, is by regulation of VDR expression. Receptor regulation has been shown to be physiologically important, as $1,25(OH)_2D_3$ signaling is dependent on both the number and occupancy of VDRs on the cell surface membrane.[557]

Aside from its biologic effects in the kidneys, calcitriol is transported by DBP to other vitamin D receptor VDR-positive target tissues (mainly bone, intestine, and parathyroid gland) to act in a genomic or nongenomic manner. Regulation of gene expression by calcitriol is mediated by VDR and takes place within hours. By contrast, nongenomic responses of calcitriol are probably mediated by a specific membrane-bound VDR and occur within seconds to minutes. Nongenomic effects of calcitriol include rapid changes in phosphoinositide metabolism, increases in intracellular calcium levels, stimulation of intestinal calcium transport and phosphate fluxes, elevation in cyclic guanosine monophosphate (cGMP) levels, and activation of protein kinase C.[558] These activities have been found in many cells, including keratinocytes, enterocytes, muscle cells, osteoblasts, and chondrocytes. VDR seems to be necessary for some of these

nongenomic transduction processes; however, another protein named 1a,25-dihydroxy-membrane associated rapid response steroid binding (MARRS) is also seemingly involved in these rapid nongenomic actions.[558]

Physiologic Actions of $1,25(OH)_2D_3$

$1,25(OH)_2D_3$ participates in a hormonal system that tightly regulates the extracellular Ca concentration.[556] A decline in serum Ca stimulates PTH release, which acts on the kidney to increase production of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$, in turn, stimulates intestinal absorption of Ca and decreases its excretion by the kidneys. $1,25(OH)_2D_3$ also acts on bone to stimulate Ca mobilization.[559] Normalization of serum Ca shuts off this cascade by suppressing 1α-hydroxylase activity in the kidney and release of PTH from the parathyroids. Increased $1,25(OH)_2D_3$ also contributes to turning off Ca-correcting mechanisms by inhibiting its own production.[560] In addition to its effects on Ca homeostasis, $1,25(OH)_2D_3$ also enhances phosphate absorption in the intestine and kidney.

About 50% to 60% of filtered Ca is reabsorbed in the proximal tubule. This process is Na-dependent, and the majority of Ca is reabsorbed via a paracellular pathway.[561,562] Approximately 20% of filtered Ca is reabsorbed in Henle's loop, 10% to 15% in the distal tubule, and 5% in the collecting duct. Unlike the proximal tubule, Ca reabsorption in the distal tubule appears to be Na-independent.[561] In addition to VDR, distal tubule epithelial cells contain CaBP-Ds and ATP-dependent plasma membrane Ca pumps.[563] It has been postulated, therefore, that $1,25(OH)_2D_3$ enhances renal Ca reabsorption by direct action on the distal tubule in a manner analogous to stimulation of Ca absorption by intestinal cells.[556] Several experimental studies support this hypothesis: Concentrations of CaBP-Ds and Ca transport rates in renal cells are increased by vitamin D, whereas vitamin D deficiency abolishes CaBP-D synthesis and decreases Ca absorption.[556] Experimental studies also suggest a role for $1,25(OH)_2D_3$ in phosphate handling by the kidney. In isolated perfused proximal tubule segments, low concentrations of $1,25(OH)_2D_3$ antagonize the phosphaturic action of PTH.[563] In rats in which vitamin D deficiency was induced, but the diet was manipulated to maintain normocalcemia, normophosphatemia, and normal PTH levels, $1,25(OH)_2D_3$ stimulated tubular reabsorption of phosphate.[564] It was thought that $1,25(OH)_2D_3$ regulates phosphate reabsorption by direct modulation of Na-P cotransport in renal tubule cells.[565] However, data on rats subjected to a low phosphate diet suggest that the Na-P cotransport in the kidney cannot be explained by the $1,25(OH)_2D$–VDR axis.[566]

In patients with renal failure requiring dialysis, serum phosphate levels increase as a result of the decreased capacity of the kidney to excrete phosphate; the elevated serum phosphate inhibits $1,25(OH)_2D_3$ formation and leads to decreased serum Ca levels and to increased PTH secretion (secondary hyperparathyroidism). PTH would lead to worsening of hyperphosphatemia with more phosphate released from bone than excreted in the kidney with diminished PTH sensitivity, ultimately leading to renal osteodystrophy and possible calcium phosphate precipitation in tissues and vessels with an associated increase in cardiovascular events. The use of active vitamin D analogs in an attempt to remedy secondary hyperparathyroidism may increase Ca while worsening hyperphosphatemia, therefore increasing the Ca × P product and rendering CaP precipitation more likely. Phosphate binders can help decrease serum phosphate levels.

A new set of agents called calcimimetics have been approved in this setting (e.g., cinacalcet). They bind to CaSR in the parathyroids and increase its sensitivity to Ca, therefore counteracting the excessive PTH secretion in a dose-dependent manner and decreasing the Ca × P product.[567]

The presence of VDR on monocytes/macrophages and activated lymphocytes suggests that $1,25(OH)_2D_3$ plays a role in regulating the functions of these cells.[568]

Renoprotective Effects of Vitamin D

It has been demonstrated that $1,25(OH)_2D_3$ possesses renoprotective property against hyperglycemia-induced renal injury by suppressing the renal RAS. Evidence suggests that $1,25(OH)_2D_3$ is a negative endocrine regulator of renin biosynthesis and directly transrepresses renin gene transcription. $1,25(OH)_2D_3$ suppresses renin biosynthesis in mice, and vitamin D deficiency stimulates renin production. VDR knockout mice and those missing the 1α-hydroxylase enzyme develop hypertension and cardiac hypertrophy and high renin levels.[569] Also, diabetic mice lacking VDR develop more severe renal damage than wild type mice because of more robust activation of the intrarenal RAS, including more induction of renin and angiotensinogen.[570] Deb et al. demonstrated that $1,25(OH)_2D_3$ suppresses hyperglycemia-induced angiotensinogen expression in the kidney by blocking NF-κB activation of the angiotensinogen gene transcription.[571] Forman et al. showed that, among normotensive individuals, lower 25(OH)D levels were associated with higher circulating Ang II levels and a blunted renal plasma flow response to exogenous Ang II infusion, both findings consistent with activation of the RAS in the setting of lower plasma 25(OH)D.[572] Melamed et al. showed that low 25(OH)D levels are associated with the development of ESRD.[573] In animal studies, vitamin D and VDR agonists (VDRA) were shown to ameliorate glomerulosclerosis, glomerular hypertrophy and inflammation, podocyte hypertrophy, mesangial proliferation, albuminuria, and interstitial fibrosis.[574,575] These effects may be independent of BP and PTH. In the kidney, vitamin D may be important for maintaining podocyte health, preventing epithelial-to-mesenchymal transformation, and suppressing renin gene expression and inflammation. In human studies, CKD is associated with a very high prevalence of 25(OH)D deficiency. Emerging evidence in patients with CKD show that vitamin D can reduce proteinuria or albuminuria even in the presence of ACE inhibition.

In addition to reducing proteinuria, VDRA may reduce also insulin resistance, BP, and inflammation and preserve podocyte loss providing biologic plausibility to the notion that the use of VDRA may be associated with salubrious outcomes in patients with diabetic nephropathy.[575]

Fibroblast Growth Factor 23

FGF23, a 30-kDa protein primarily synthesized by osteoblasts and osteocytes, controls renal phosphate excretion by regulating renal Na-dependent phosphate cotransporters (NaPi2a and NaPi2c). It is phosphaturic and decreases 1α-hydroxylase levels by a VDR independent mechanism, and induces 24-hydroxylase activity, therefore reducing $1,25(OH)_2D_3$ by a VDR-mediated mechanism.[576] In vivo studies have shown that FGF23 is one of the most potent phosphatonins that induces renal phosphate wasting and reduction of $1,25(OH)_2D_3$.[577] Another unique characteristic of FGF23 is that this molecule derives from bone and exerts its hormonal effects in the kidney despite the ubiquitous presence of its receptors (FGFRs).

FGF23 directly acts on parathyroid glands and attenuates secretion of PTH in the presence of Klotho, an antiaging protein, as a cofactor. Klotho mutant mice display a phenotype identical to that of FGF23 null mice, both of which are characterized by premature aging–related phenotypes associated with hypercalcemia, hyperphosphatemia, and paradoxically high $1,25(OH)_2D$ levels. Klotho is predominantly expressed in the distal tubule of the kidney. Aside from its function as a cofactor for the stimulation of FGF-23, it also colocalizes with epithelial Ca channel transient receptor potential vallinoid-5 (TRPV5). Mice overexpressing the Klotho gene age slowly through a mechanism that involves insulin and oxidant stress resistance.[574] Klotho is expressed in limited tissues such as the kidney, parathyroid, and pituitary gland.[577]

The identification of FGF23 and Klotho as a physiologic regulator of phosphate and vitamin D metabolism has considerably advanced the understanding of the mineral and bone disorder in CKD. It is now clear that FGF23 plays a central role in the pathogenesis of altered mineral metabolism and secondary hyperparathyroidism in CKD patients.[577] The primary systemic stimuli of FGF23 secretion are increased $1,25(OH)_2D$ levels and increased dietary phosphorus intake. In kidney failure, FGF23 levels increase early and steadily rise with progression of kidney disease, likely as an appropriate physiologic adaptation to maintain normal phosphorus balance by helping to augment urinary phosphate excretion in conjunction with increased PTH levels and by decreasing gut phosphorus absorption through decreased $1,25(OH)_2D$. In the long term, this compensation may become maladaptive by causing a progressive decline in $1,25(OH)_2D$ levels with attendant consequences such as secondary hyperparathyroidism. Moreover, excess FGF23 levels have been independently linked with cardiovascular disease and mortality, suggesting that chronically elevated FGF23 levels may directly contribute to adverse CKD outcomes.[578]

FGF23 has been also implicated in the pathogenesis of X-linked hypophosphatemic rickets/osteomalacia (XLH), tumor-induced osteomalacia (TIO), and autosomal-dominant hypophosphatemic rickets/osteomalacia (ADHR)—all entities with common features, including hypophosphatemia because of renal phosphate wasting and impaired mineralization of bone with normal serum Ca and PTH.[579,580]

EICOSANOIDS

The eicosanoids are a group of locally acting hormones or autacoids that are derived from dietary polyunsaturated fatty acids. In humans, arachidonic acid, an essential fatty acid esterified into cellular membrane phospholipids, is the most abundant and important precursor. After deesterification by phospholipases, free arachidonic acid may either rapidly reesterify into membrane lipids, avidly bind intracellular proteins, or undergo enzymatic oxygenation to yield the various biologically active molecules referred to as eicosanoids. The type of product formed depends on the enzymes involved in the oxygenation process (Fig. 8.10).[581] Oxygenation of arachidonic acid by cyclooxygenase results in prostaglandin and thromboxane (TX) synthesis. Oxygenation by lipoxygenase generates hydroxyeicosatetraenoic acids and leukotrienes. These two major enzymatic pathways are all expressed in the kidney.[582,583] The specific nature of the products generated varies with both cell type and initial stimulus for arachidonic acid release. Eicosanoids have diverse biologic effects in the kidney, the significance of which will be discussed later.

Cyclooxygenase Products

Prostaglandins

Prostoglandins (PGs) are a unique group of cyclic fatty acids with diverse biologic effects that are produced throughout the body. The kidney is a major site of PG production, metabolism, and action.[584,585] PGs are important modulators of renal function in both physiologic and pathophysiologic settings. The spectrum of their effects in the kidney encompasses modulation of RBF, GFR, salt and water transport, and the release of renal hormones. It is within the setting of compromised renal status that maintenance of renal function is most dependent on PGs. Under these circumstances, inhibition of PG synthesis with nonsteroidal anti-inflammatory drugs (NSAIDs) is likely to impair renal function.[586]

Structure and Synthesis of Prostaglandins Arachidonic acid (eicosatetraenoic acid) is the major substrate for the synthesis of PGs in humans. The initial step is catalyzed by cyclooxygenase (COX), a major therapeutic target of analgesic, antipyretic, and anti-inflammatory actions of NSAIDs. COX converts arachidonic acid to PGH_2, which is subsequently metabolized by various PG synthases to more stable, biologically active, prostanoids, namely PGE_2, prostacyclin (PGI_2), $PGF_{2\alpha}$, PGD_2, and thromboxane A_2 (TxA_2) (Fig. 8.10). For a detailed description of the biosynthetic pathways leading to the

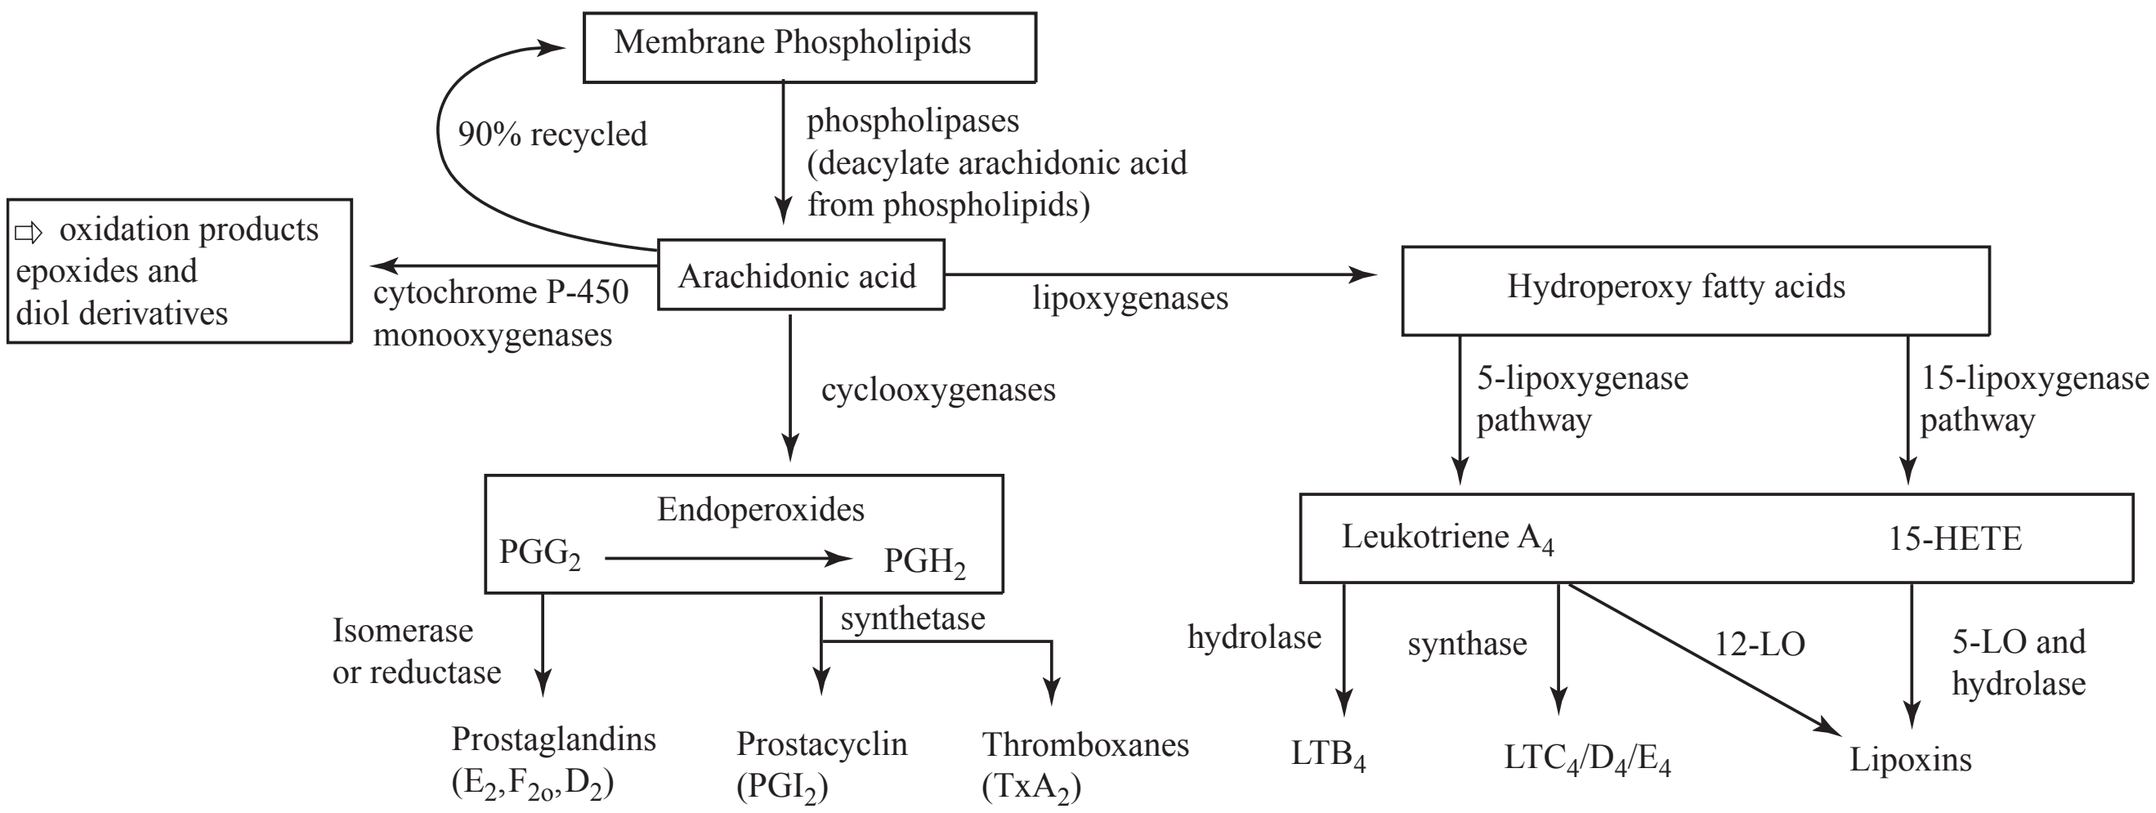

FIGURE 8.10 Renal eicosanoid synthesis. The oxygenated products of arachidonic-acid (eicosatetraenoic-acid) metabolism are referred to as eicosanoids. These include lipoxygenase, cytochrome P450 monooxygenase, and cyclooxygenase products. The lipoxygenase pathway yields hydroxy fatty acids and leukotrienes. The cytochrome P450 monooxygenase pathway yields ω-oxidation products and diol derivatives. The cyclooxygenase pathway yields the prostanoids, which include the prostaglandins (PGE_2, PGF_2, PGD_2, and prostacyclin) and thromboxane. The most important prostaglandins are dienoic (i.e., possessing two double bonds outside the ring structure)—hence the subscript 2.

different types of PGs and thromboxanes, collectively called prostanoids, the reader can refer to following reviews.[587,588]

The COX pathway is also the major pathway for arachidonic acid metabolism in the kidney.[582,583] In both animals and humans, two separate COX enzymes have been identified that are encoded by two separate genes: COX-1 (589) and COX-2 (590). The human COX-1 enzyme is constitutively present in the renal vasculature (arterial and arteriolar endothelial cells, mesangial cells),[583,587,591–593] glomerular epithelial cells,[594] renal interstitial cells,[587,595] along most segments of the tubule, although in markedly varying concentrations,[596–598] and in the medullary and papillary collecting ducts in humans, monkeys, dogs, rabbits, and rats.[587] The COX-2 enzyme, first thought to be only inducible in inflammatory responses, was found to be constitutive in the kidney.[599] Its expression is consistently focal and limited to the MD of the juxtaglomerular apparatus, epithelial cells of the thick ascending limb, and papillary interstitial cells of rats, rabbits, and dogs. In mice, COX-2 expression varied with developmental stages, with high levels of expression in the MD and thick ascending limbs of fetal kidneys and minimal expression upon renal maturation, suggesting a putative role for COX-2 in nephrogenesis.[600] In the adult human kidney, expression of the COX-2 protein has been observed in endothelial and smooth muscle cells of arteries and veins, and intraglomerularly in podocytes, but not in MD cells.[587] It is noteworthy that the distribution of prostanoid synthases within the kidney remains incompletely characterized.[601]

Physiology of Prostaglandins in the Kidneys The rate of PG production is dependent on the release of free arachidonic acid from tissue stores by phospholipase A_2 (PLA_2). Arachidonate tissue stores vary with dietary intake of essential fatty acids and can be depleted when intake is deficient.[602] Fish oil diets (rich in omega-3 polyunsaturated fatty acids) will compete for the arachidonate oxidation process and inhibit formation of active products.[603] Table 8.5 lists several modulators of the key steps involved in PG synthesis. Although under basal conditions both COX-1 and COX-2 contribute to prostanoid production in the kidney, some stimuli have been shown to initiate a more selective response. Evidence indicates that Ang II, through AT_1 receptors, increases MD COX-2 expression.[604,605] In addition, conditions associated with activation of the renin-angiotensin system, such as a low-salt diet or diuretic administration, all significantly increase MD COX-2 expression.[606,607] Recently, pressure was also shown to be an important promoter of renal COX-2 expression in renal medullary interstitial cells subjected to mechanical stress in vitro as well as in rats subjected to ureteral obstruction.[608] In contrast to COX-2, cortical expression of COX-1 is independent from Ang II but relies on hemodynamic changes.[604] Several renal pathophysiologic states such as glomerulonephritis, in addition to ureteral obstruction, are associated with increased prostanoid production.[609–611]

Prostanoids are rapidly degraded, which limits their effects to the immediate vicinity of their site of synthesis and accounts for their autocrine or paracrine function. They mediate diverse actions, in part related to their site of synthesis and the cells on which they act (Tables 8.6 and 8.7). Their principal physiologic role is mediation and/or modulation of hormone action at these locations.[583,587,592,612,613] Thus, cortical production by arterioles and glomeruli is related to regulation of RBF, GFR, and renin release. Other cortical sites of PG production affect ammoniagenesis[614] and calcium

8.5 Modulators of Prostaglandin Synthesis[a]

Modulator	Site of Action

AVP, arginine vasopressin; PAF, platelet-activating factor; TNF-α, tumor necrosis factor-α; PDGF, platelet-derived growth factor; EGF, epidermal growth factor; NSAIDs, nonsteroidal anti-inflammatory drugs; PLA, phospholipase A; COX, cyclooxygenase; TX, thromboxane.

and phosphate transport.[615] Medullary PG production is directed to regulating vasa recta blood flow, tubular sodium and chloride transport, and the response of the collecting duct to vasopressin. Inhibition of COX activity in the absence of exogenous administration or endogenous release of hormones such as Ang II, NE, or vasopressin has little effect on renal functional parameters.[616] Once their local release is enhanced, COX products may themselves stimulate the local generation of other hormones. Under pathophysiologic conditions, such as inflammatory injury, local release of prostanoids may mediate some of the functional derangements that characterize these conditions.[609–611]

Prostanoids act through specific and distinct receptors.[617,618] These receptors are members of the G protein-coupled family of receptors. In the kidney, they mainly include the E-prostanoid (EP), F-prostanoid (FP), I-prostanoid (IP), and T-prostanoid (TP) receptors, which respectively interact with PGE_2, $PGF_{2\alpha}$, PGI_2, or TxA_2 (Fig. 8.1). Multiple subtypes of each of these prostanoid receptors may exist, as in the case with the PGE_2 receptor (EP receptor), thus explaining the apparently contrasting effects mediated by PGE_2 on smooth muscle and collecting duct permeability to water.[619] The differential sensitivity of tissues to several structural PGE analogs has led to the identification of at least four distinct EP receptors: the two vasodilator receptors, EP_2 and EP_4, and the two vasoconstrictor receptors, EP_1 and EP_3.[620] EP_1 receptors signal mainly by IP_3-mediated increased intracellular Ca^{2+}.[621–623] In contrast, the vasodilator receptors EP_2 and EP_4, signal through increased cAMP.[624–626] EP_3 receptors constrict smooth muscle, probably by inhibiting cAMP generation via a pertussis toxin-sensitive, G_i-coupled mechanism.[627,628] In mesangial cells, the $PGF_{2\alpha}$ receptor (FP receptor) seems to be coupled to increased intracellular Ca^{2+}. At higher concentrations, $PGF_{2\alpha}$ also stimulates EP receptors.[629,630] The TXA_2 receptor (TP receptor) appears to signal via phosphatidylinositol hydrolysis, leading to increased intracellular Ca^{2+}.[631] There is pharmacologic evidence for existence of TP receptors in the glomerulus.[629] The PGI_2 receptor (IP receptor) signals via stimulation of cAMP generation.[632,633] PGI_2 has been demonstrated to play an important vasodilator role in the glomerular microvasculature, where the effects of PGI_2 and PGE_2 to stimulate cAMP generation were distinct and additive.[634] Thus, because multiple PGs can be synthesized through the COX pathway and because these PGs can interact with different receptors, their pathophysiologic effects are further diversified and depend on which prostanoid is produced and which receptor is available locally.

Renal Hemodynamics There are some species differences in the renal actions of PGs, and this must be taken into account when extrapolating data from animals to humans. Although acute inhibition of PG synthesis does not change arterial pressure in normal circumstances, it does produce both an increase in renal vascular resistance and a decrease in sodium and water excretion.[635–637] In general, PGE_2 and PGI_2 are vasodilators in most species, whereas TXA_2, $PGF_{2\alpha}$, and PGE_2 (in certain circumstances) are vasoconstrictors.[584,638,639] The contribution of these vasoactive properties of COX products to the regulation of renal vascular tone under normal physiologic conditions is probably minimal.[640–645]

In contrast, the local release of vasodilator PGs (PGE_2 and PGI_2) in response to renal vasoconstrictors plays an important role in maintaining RBF and GFR. There is compelling evidence indicating that mesangial cell synthesis and release of PGE_2 and PGI_2 modulate the constrictor actions of Ang II, NE, and AVP.[583,584,587,629,646] Activation of the renin-angiotensin and sympathetic nervous systems leading to enhanced release of angiotensin, catecholamines, and AVP occurs in conditions, such as hemorrhage, volume depletion, general anesthesia, cirrhosis, and cardiac failure. While serving to maintain the systemic blood pressure, these hormones constrict mesangial cells and glomerular

8.7 Renal Actions of the Different Prostanoids

Mediator	**Main Source**	**Primary Effects**
PGE_2	Tubular epithelial cells Interstitial cells	Renal vasodilation Relaxation of mesangial cells Modulation of glomerular capillary ultrafiltration coefficient Stimulates renin release from juxtaglomerular apparatus Antagonizes hydroosmotic effect of ADH in collecting tubular epithelial cells Inhibits sodium chloride reabsorption Mediates renal response to loop diuretics
PGI_2	Vascular and glomerular endothelial cells	Renal vasodilation Relaxation of mesangial cells Stimulates renin release from juxtaglomerular apparatus
$PGF_{2\alpha}$	Mesangial cells	Contracts smooth muscle Glomeruli
TXA_2	Glomeruli	Contracts smooth muscle Contracts mesangial cells

ADH, antidiuretic hormone; TXA, thromboxane A; PGE, prostaglandin E; PGI, prostaglandin I; PGF, prostaglandin F.

arterioles. Fortunately, their enhancement of renal PG release locally opposes their constrictor effects. The vasodilatory action of PGs on the afferent arteriole serves to maintain renal perfusion, whereas their relaxant effects on mesangial cells maintains the effective surface area for filtration.[638] Inhibition of PG generation in these circumstances is associated with a dramatic fall in RBF and GFR.[645–648] Vasodilator PGs, in particular PGI_2, may also counteract the vasoconstrictor responses to calcium in human subjects.[638] In addition to modulating the effects of vasoconstrictors, endogenous PGs mediate the actions of some vasodilator agents. These include a role for PGI_2 in mediating the vasorelaxant actions of dopamine[650] and magnesium[651] in humans.

Finally, PGs synthesized from the MD can trigger renin release,[652] which leads to increased Ang II levels. Ang II preferentially constricts the glomerular efferent arteriole, thus increasing intraglomerular pressure and, ultimately, maintaining GFR in volume-contracted conditions.[653] This response is further reinforced by the PGE_2-induced afferent vasodilation. In contrast, TXA_2 exerts a negative effect on renin release.[654] However, inhibition of COX activity reduces plasma renin activity, suggesting that the predominant influence of prostanoids is stimulatory. PG-mediated renin release is independent of β-adrenergic mechanisms.[655] It has been recently reported that a decrease in extracellular tonicity leads to renin release through a mechanism involving aquaporin 1–mediated water influx in juxtaglomerular cells and PG-dependent formation of cAMP and activation of PKA.[645]

Solute Excretion Infusion of arachidonic acid or the COX products PGE_2 or PGI_2 directly into the renal artery results in natriuresis.[656,657] Natriuresis is largely a direct tubular phenomenon originating in the distal nephron.[657] PGE_2 has mild or no effects on sodium transport in the proximal tubule and most segments of the ascending limb of Henle, with the exception of the medullary thick ascending limb in some species.[658] This lack of effect is in keeping with both the low rates of PG production and the low density of PG receptors in these nephron segments.[597,598] Under normal circumstances, inhibition of COX does not result in alteration of sodium delivery out of the loop of Henle to the early distal tubule.[659] PGE_2, however, has significant effects on sodium transport in the collecting duct, where it inhibits transepithelial sodium transport.[656,658] In fact, in most mammalian species, the collecting ducts are the major nephron segments responsible for PG synthesis[597,598] and, along with the MTAL, express the majority of receptors for PGE_2 in the kidney.[660,661]

There is evidence that PGE_2 exerts its inhibitory effect on rabbit CCD sodium transport by at least two mechanisms. The first involves inhibiting principal cell basolateral Na^+-K^+-ATPase activity[662–664] and the second by directly decreasing the open probability of the apical amiloride-sensitive sodium channels.[665,666] PGE_2 utilizes multiple signal transduction pathways in the CCD. These include increase in intracellular Ca^{2+}, activation of PKC, and modulation of cAMP levels.[584] The inhibitory effects of PGE_2 on sodium transport in the thick ascending limb probably involve inhibition of adenyl cyclase.[667] Through G_i-coupled EP_3 receptor expressed in the thick ascending limb,[668,669] PGE_2 also blocks the phosphaturic action of PTH in the proximal tubule.[670] Recent evidence obtained from a randomized, placebo-controlled, crossover study in healthy humans suggest that PGs may modulate sodium excretion through ENaC regulation in the distal nephron.[671] Natriuresis may also be regulated by renal medullary COX-derived prostanoids acting in a paracrine manner. The prostanoid receptors regulating renal medullary blood flow through the descending vasa recta seem to be EP2, EP4, and/or IP receptors.[672] The importance of EP2 and IP receptors has been confirmed to be associated with salt-sensitive hypertension in animal models of EP2 and IP receptor deficiency.[673,674] Expression of EP3 in the renal medulla was shown to be induced by hypertonicity, suggesting a role for this receptor as well in natriuresis and protection of the renal medulla. EP3 activation leads to inhibition of Na^+-K^+-$2Cl^-$ transporter and aquaporin 2.[675]

Sodium loading is associated with an increase in urinary PG excretion, yet PGs are not important in the regulation of sodium balance in normal euvolemic subjects. However, in circumstances associated with sodium retention and compromised renal function, PGs play a significant role. In fact, high-salt diet increases renal medullary COX-2 and microsomal prostaglandin E synthase-1 (mPGES-1) expression to maintain blood pressure homeostasis.[676–678] Inhibition of PG synthesis or blocking their effects in such conditions is associated with sodium retention.[647,679,680] Administration of furosemide is associated with increased PG excretion, which is, in part, mediated by a direct action on tubular cells.[681,682] Administration of NSAIDs diminishes the natriuretic action of furosemide and other loop diuretics, suggesting a role for PGs in mediating the action of these agents. This cannot be the sole mechanism, however, for the natriuretic response to diuretics outlasts the increase in PG excretion.

Water Excretion PGs, especially PGE_2, affect water transport in the collecting duct in many ways. PGs may indirectly regulate water excretion by a reduction of the corticomedullary osmotic gradient via inhibition of solute transport in the thick ascending limbs or by increase in renal medullary blood flow. In fact, during physiologic stress, PGE_2 dilates descending vasa recta, thereby buffering the constrictor effects of Ang II, AVP, and catecholamines, which is vital to prevent hypoxic damage to renal medullary cells.[683] Moreover, PGs of the E series blunt the hydraulic conductivity response of the collecting duct to AVP.[684,685] In fact, in vivo infusions of arachidonic acid or PGE_2 induce water diuresis, whereas inhibition of PG synthesis potentiates the urinary hyperosmolality caused by AVP.[686] However, in the absence of vasopressin, basolateral PGE_2 actually increases osmotic water reabsorption.[687,688] These effects on water conductivity in the collecting ducts have been explained by changes in cAMP accumulation. AVP mediates the increase in water conductivity in the collecting duct through increased cAMP generation.

Studies on the effect of PGE_2 on cAMP metabolism in this nephron segment demonstrated that PGE_2 could both stimulate basal cAMP generation and suppress AVP-stimulated cAMP generation.[689,690] The inhibitory effects of PGE_2 on AVP-stimulated cAMP generation and water conductivity in the collecting duct are probably mediated through the EP_3 receptor, as discussed previously.[675,690,691] In addition to affecting water flow via modulation of cAMP levels, PGE_2 has been shown to inhibit AVP-induced water conductivity by activation of PKC and elevation of intracellular calcium.[619,692]

Application of basolateral PGE_2 probably increases water absorption in the collecting duct by stimulating cAMP production.[687,688] The EP_4 receptor, which is found on the epithelial cells of the ureter, bladder, and collecting duct, is coupled to the G_s-stimulated cAMP signaling pathway.[625,693] This suggests that an EP_4 receptor mediates cAMP-stimulated water absorption in the collecting duct. Recently, PGE_2 was shown to mediate lithium-induced polyuria by downregulating the expression of aquaporin 2 and the Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) in the medulla but not in the renal cortex.[694]

Another facet of the PGE_2-AVP interaction is that AVP acutely stimulates endogenous PGE_2 production by the collecting duct. This effect has been demonstrated in rats[695,696] and the current consensus is that it also occurs in humans.[696,697] It also suggests that PGE_2 participates in a negative feedback loop, whereby endogenous PGE_2 production dampens the action of AVP. In agreement with a functional role for the increase in urinary PGE_2 production seen during AVP infusions are numerous observations of enhanced renal concentrating ability in animals or humans pretreated with inhibitors of PG production.[698,699] Given that the concentration of AVP needed to stimulate PGE_2 production is 10 to 100 times the concentration needed to maximally stimulate water conductivity, it is controversial whether AVP plays a physiologic role in PGE_2 generation.[700] At these concentrations, AVP has been shown to acutely increase intracellular calcium and activate PKC, via activation of phospholipase C.[700,701]

Other Effects on Renal Function The tubuloglomerular feedback (TGF) response is modulated by multiple autacoids and hormones including ATP, Ang II, NO, and PGs, including PGE_2, PGI_2, and TxA_2.[702,703] Under basal conditions, MD COX-2 directly modulates TGF response, particularly through TXA_2,[702] with little contribution of COX-1, as well as via inhibition of nNOS-dependent NO.[704] When subjected to low-dose chronic Ang II, the increase in TGF response is mediated by the local release of vasoconstrictive COX-1 PGs.[705] These studies suggest that: (1) both COX isoforms regulate TGF but (2) their contribution differs in various settings.

Clinical Pathophysiologic Role of Prostaglandins in the Kidneys

PGs, through their vasodilator effects, play a salutary role in maintaining RBF and GFR in several prerenal conditions such as hemorrhage, septic shock, cirrhosis, and low cardiac output states. Studies in patients with congestive heart failure have confirmed that enhanced PG synthesis is crucial in protecting kidneys from the effects of elevated vasoconstrictor levels in these patients.[706] Renal artery stenosis is another condition associated with increased renal PG secretion[707] that may locally act to enhance renal perfusion. Administration of COX inhibitors in these settings with renal hypoperfusion is associated with adverse effects on RBF and GFR.[708]

With regard to intrinsic renal diseases, COX products have been implicated in modulating or mediating renal injury (or both). Single nephron GFRs increase significantly after renal ablation and are associated with increased glomerular synthesis and urinary excretion of prostanoids by the remaining nephron.[709,710] In this model of renal ablation, increased expression of COX-2 has been described and inhibition of COX-2 was associated with amelioration of the renal functional changes associated with renal ablation.[709,710] Similar results were observed with omega-3 fatty acid[711] or flax oil[712] supplementation after renal ablation. Selective inhibition of TXA_2 synthesis is associated with an increase in GFR, lessening of proteinuria, and preservation of renal histology.[713,714] In addition, COX-2 inhibition was also found to slow progression in the rat model of polycystic kidney disease.[715] Dietary soy protein was recently shown to decrease production of prostanoids and expression of COX in a model of polycystic kidney disease and to be associated with reduced disease progression.[716]

Enhanced TXA_2 production has been implicated in the pathophysiology of the intense vasoconstriction that characterizes the obstructed kidney[717,718] and in mediating the decrease in RBF and GFR that occurs in the early phase of nephrotoxic serum nephritis.[609,610,719,720] In patients with lupus nephritis, an inverse relation between TXA_2 biosynthesis and GFR has been proposed.[721,722] In this setting, renal function improved after short-term therapy with a TX receptor antagonist, but not with aspirin.[721,723] In addition, administration of TXA_2 synthesis inhibitors or receptor antagonists has been associated with improved renal function in animals with allograft rejection and cyclosporine toxicity.[638] Although basal COX-2 levels are important for podocyte survival, overexpression of COX-2 in podocytes leads to increased albuminuria and glomerular injury, partly through activation of the thromboxane receptor.[724,725] Jia et al. also recently showed that cisplatin-induced renal injury is mediated by activation of the COX-2/mPGES-1 pathway, which may offer a new therapeutic target for management of the adverse effect of cisplatin chemotherapy.[726]

Ischemia/reperfusion injury has been shown to be worsened by COX-2 inhibitors or in COX-2 knockout mice, suggesting that PGs protect the kidney against acute renal injury.[727] Recent studies show that EP4 and EP2 receptor agonists improve renal function and/or increase survival rate of a rat model of acute renal failure, supporting a protective role of EP2 and EP4 receptors in preventing the progression of kidney failure.[728] Lithium treatment was also shown to improve outcome of renal ischemia/reperfusion

injury through NO and/or COX pathways and represents a promising therapeutic approach to boost renal viability and function after ischemia/reperfusion injury in the setting of transplantation.[729] However, other groups reported a beneficial effect of COX-2 inhibitors that could be acting through immune modulation.[730,731] These opposite findings could be partly explained by differences in the experimental models.

The role of COX products in mediating diabetic nephropathy remains controversial. Vasodilator PGs may contribute to the hyperfiltration that occurs in early stages of diabetic nephropathy, whereas TXA_2 may play a role in the subsequent development of albuminuria and basement membrane changes.[732,733] MD COX-2 expression is increased in models of hyperfiltration, such as high-protein diet and diabetes. COX-2 inhibition decreases hyperfiltration and proteinuria, and inhibits development of glomerular sclerosis in experimental diabetes.[734,735] Interestingly, inhibition of COX-2 in patients with type 1 diabetes mellitus reduces, but does not correct, hyperfiltration in subjects whose baseline GFR was $\geq$135 mL/min^{-1}/1.73 m^{-2}.[736] However, in response to COX-2 inhibition, women with type 1 diabetes mellitus exhibited a significant renal hyperfiltration response suggesting that women have a greater dependence on vasodilatory PGs than men.[737] A role for decreased PGI_2 synthesis in type IV renal tubular acidosis associated with diabetes mellitus has also been suggested.[738] The increased renal production of TXA_2 and PGI_2 in type 2 diabetes has also been suggested as a role for these compounds in the pathogenesis of diabetic nephropathy.[733,739,740] Recently, the lipocalin-type PGD2 synthase (L-PGDS) knockout mouse was shown to develop structural changes associated with diabetic nephropathy, such as glomerular hypertrophy, fibrosis, and basement membrane thickening.[741] Urinary excretion of L-PGDS, found at elevated levels in type 2 diabetic patients, correlates with the progression of diabetic nephropathy and reflects the underlying early increase in glomerular damage.[742]

Diminished vasodilator renal PG synthesis has also been implicated in the pathogenesis of the severe sodium retention that occurs in patients with the hepatorenal syndrome.[743] Pregnancy is associated with increased glomerular synthesis and urinary excretion of PGE_2, $PGF_{2\alpha}$, and PGI_2.[744] Augmented renal vasodilator PG production does not appear to regulate GFR and RBF in normal pregnancy; however, diminished synthesis of PGI_2 has been demonstrated in human and animal models with pregnancy-induced hypertension.[745–747] A beneficial effect of reducing TXA_2 generation, while preserving PGI_2 synthesis, by low-dose (60 to 100 mg per day) aspirin therapy has been proposed in patients at risk for pregnancy-induced hypertension.[748,749] In patients with hypertension, COX inhibition by NSAIDs is associated with increased salt retention and resistance to the diuretic action of thiazides and furosemide.[750,751] Short-term use of some NSAIDs was found to increase the mean arterial pressure of hypertensive patients.[752,753] On the other hand, attempts to treat hypertension with PG analogs have generally been disappointing.[754,755]

Finally, chronic inhibition of COX by regular use of NSAIDs leads to gastrointestinal toxicity and may increase the risk of chronic renal disease, especially in older patients and patients with heart disease.[756–758] Selective COX-2 inhibitors have been developed and have been shown to spare gastric PG production. These nontraditional COX-2 selective anti-inflammatory agents might have represented a significant advance for the treatment of acute and chronic inflammatory disorders[759–761]; however, the safety of their use has been placed into question after two large prospective cohorts in elderly patients showed an increased risk of cardiovascular events in patients on selective COX-2 inhibitors versus those on NSAIDs.[762,763] Clinical studies have also demonstrated that selective COX-2 inhibitors can even reduce GFR and RBF in physiologically stressed volunteers or patients.[764,765]

In summary, prostanoids exert diverse and complex functions in the kidney under physiologic and pathologic conditions. Further understanding of pathways involving and regulating COX, prostanoid synthases, and prostanoid receptors should provide targets for pharmacologic treatments of renal disease.

LIPOXYGENASE PRODUCTS

Biosynthesis and Metabolism

Lipoxygenases (LOs) comprise a family of enzymes capable of mediating selective lipid oxidation.[766] Enzymatic lipoxygenation of arachidonic acid leads to the generation of leukotrienes (LTs), lipoxins (LXs), and hydroxyeicosatetraenoic acids (HETEs). Formation of these compounds is initiated by 5-, 12-, or 15-lipoxygenase, whereby a hydroperoxy group is introduced onto arachidonic acid at carbon-5, carbon-12, or carbon-15, respectively, to yield the corresponding 5-, 12-, or 15-hydroperoxytetraenoic acid (HPETE). HPETEs are unstable compounds that are transformed into the corresponding 5-, 12-, and 15-HETE, which, in turn, undergo enzymatic modification leading to the generation of the various LTs and LXs. The 5-lipoxygenase pathway is a major route of arachidonic acid metabolism in the polymorphonuclear cells and macrophages leading to the formation of 5-HETE and LTs.[767–769] 5-Lipoxygenase requires activation by a cell membrane-bound protein called the 5-lipoxygenase-activating protein (FLAP).[770] The 15-lipoxygenase enzyme catalyzes the production of 15-HETE and initiates another major pathway of arachidonic acid metabolism in leukocytes. In activated neutrophils and macrophages, sequential lipoxygenation of arachidonic acid at carbons-15 and -5 yields trihydroxy derivatives, the LXs.

Renal Actions of Lipoxygenase Products

In the rat, 5-LOX FLAP + 12-LOX mRNA are present in the glomerulus as leukotriene B_4 (LTB_4) and leukotriene D_4 (LTD_4) receptors.[771] 15-LOX is localized to the distal nephron only.[771] Products of lipoxygenase are classically proinflammatory;

however, lipoxins, 15-HPETE, and 15-HETE exhibit anti-inflammatory activity.[674]

The LTs are potent proinflammatory molecules. LTB_4 has minimal spasmogenic properties, but is the most potent chemotactic substance yet described for polymorphonuclear cells, and promotes their activation and adhesion to the endothelium.[767] It has no significant effects on renal hemodynamics in normal animals, but amplifies glomerular inflammation and proteinuria in animals with glomerulonephritic injury.[773] The peptidyl LTs contract vascular, pulmonary, and gastrointestinal smooth muscle and increase vascular permeability to macromolecules.[767] LTC_4 and LTD_4 exert potent effects on glomerular hemodynamics. In rats, systemic administration of LTC_4 leads to reduction in RBF and GFR.[774] Similarly, infusion of either LTC_4 or LTD_4 in the isolated perfused kidney results in dramatic increase in renal vascular resistance and reduction in GFR.[775] LTD_4 mediates these effects by causing a significant increase in efferent arteriolar resistance, leading to a fall in glomerular plasma flow rate (Q_A), and a rise in glomerular capillary hydraulic pressure (P_{GC}). In addition, it markedly reduces the glomerular capillary ultrafiltration coefficient (K_f) and, therefore, its overall effect is to decrease single nephron GFR.[776] LTC_4 and LTD_4 contract mesangial cells[777,778] and LTD_4 stimulates neutrophil adhesion to these cells.[779] In both rats and humans, specific mesangial cell LTD_4 receptors have been identified. Intracellular signaling for LTD_4 in these cells involves receptor-activated phosphatidylinositol diphosphate (PIP_2) hydrolysis, release of inositol phosphates, and increased intracellular calcium concentrations.[780,781]

LXA_4 attenuates LTB_4-induced neutrophil chemotaxis and inhibits natural killer cell cytotoxicity.[767,769] The effects of LXA_4 are mediated primarily by functional high-affinity LXA_4 receptors.[782] In rat glomerular mesangial cells, LXA_4 competes with LTD_4 at a common receptor whereby LXA_4 mediates partial agonist–antagonist effects.[783] Different LXs display distinct effects on renal hemodynamics.[769,784,785] In rats, LXA_4 causes a selective decrease in afferent arteriolar resistance, thereby increasing RBF, glomerular capillary pressure, and GFR. The LXA_4-induced increase in GFR, however, is partially offset by its mild effect in decreasing K.[783,785] The vasodilator actions of LXA_4 are mediated by prostaglandins.

Role of Lipoxygenase Products in Kidney Disease

LTs are increasingly recognized as major mediators of glomerular hemodynamic and structural deterioration during the early phases of experimentally induced glomerulonephritis.[784,786,787]

Mesangial cell (MC) proliferation is a central event in the pathogenesis of glomerulonephritis. LTD_4-induced proliferation of mesangial cells is modulated by LXA_4.

Increased glomerular generation of LTB_4 and peptidyl-LTs has been demonstrated in several models of glomerular injury.[784,786,787] LTB_4 probably worsens glomerular injury by augmenting leukocyte recruitment and activation and the peptidyl LTs, by depressing K_f and GFR.[773–779] Selective blockade of the 5-lipoxygenase pathway, in the course of glomerular injury, is associated with significant amelioration of the deterioration of renal hemodynamic and structural parameters.[788,789] In addition, dietary deprivation of essential fatty acids, which results in arachidonic acid and eicosanoid deficiency, confers protection against the histopathologic and the functional consequences of immune-initiated injury in the glomerulus.[790] In hemodialysis patients, 5-LOX activity and expression are significantly increased in peripheral blood monocytes, and can be markedly suppressed by polyunsaturated fatty acid supplementation.[1] In human glomerulonephritis, 5-lipoxygenase and 5-LO-activating protein (FLAP) mRNA expression have been detected in kidney biopsy specimens from patients with immunoglobulin A (IgA) nephropathy and mesangial proliferative glomerulonephritis and were associated with a clinically worse renal status.[791] Urinary LTE_4 levels are also elevated in patients with active SLE.[792] A pathophysiologic role for LTs has also been described in experimental acute allograft rejection,[793] cyclosporine toxicity, and acute ureteral obstruction.[787] LXA_4 and 15-S-HETE are also generated during experimental glomerular injury and may exert salutary effects on glomerular function by antagonizing the proinflammatory actions of LTs.[784,794–797] In animals with experimental glomerulonephritis, 5-lipoxygenase inhibition results in marked reduction in proteinuria and preservation of GFR.[786,798] The binding of 5-lipoxygenase to FLAP is a prerequisite for subsequent formation of leukotrienes from arachidonic acid.[799] The use of a FLAP antagonist has been shown to reduce proteinuria and restore glomerular size selectivity in human glomerulonephritis.[800] 12/15-lipoxygenase (12/15-LO) expression is increased in high glucose (HG)-stimulated MC and in experimental diabetic nephropathy.[801–803]

ENDOTHELIN

Endothelin (ET), originally isolated from porcine aortic endothelial cells, is an extremely potent and long-lasting vasoconstrictor.[804] Initially, ET's effect on vascular tone regulation was the focus of research. Later, other actions—such as ET effects on cell growth and proliferation, ion transport, eicosanoid synthesis, renin and ANP release, fibrosis, and inflammation—emerged as important factors linking ET to diseases.[771,805,806] The kidney is an important site of ET production and expresses a high density of ET receptors.[807] Endothelin may, therefore, act in an autocrine and paracrine manner to influence renal hemodynamics, tubular function, and mesangial cell biology.

Biochemistry, Synthesis, and Receptor Biology

The term endothelin refers to a family of homologous 21-amino acid vasoconstrictor peptides found in three distinct isoforms: ET-1, ET-2, and ET-3. In humans, ET isoforms

are encoded by three separate genes located on chromosomes 6, 1, and 20, respectively.[808,809] The initial ET peptide translation product is a large (approximately 200 amino acids) isopeptide-specific prohormone named preproendothelin. Posttranslational processing of this prohormone to mature ET requires two steps. The first involves its proteolytic cleavage by dibasic pair-specific endopeptidases on Lys-Arg and Arg-Arg pairs, which respectively flank the N- and C-terminals of the preproendothelin molecule, to yield an intermediate 38- or 39-amino acid proET polypeptide. The subsequent step is accomplished by proteolytic cleavage of proET between Trp^{21} and Val^{22} by a putative endothelin-converting enzyme (ECE).[810] All ET isopeptides have a hairpin loop configuration structure imparted by two intrachain disulfide bonds bridging amino acid residues 1 through 15 and 3 through 11, the reduction of which leads to a twofold loss of biologic activity.[811] The two endothelin isoforms ET-2 and ET-3 differ from ET-1 in 2 and 6 amino acid residues, respectively. The three ET isoforms are highly homologous in their amino acid sequences and tertiary structure to certain scorpion and snake venoms, the sarafotoxins, which suggests common genetic evolutionary origins.[812] Although all isoforms of ET are potent vasoconstrictors, there are significant cell- and tissue-specific differences in the secretion of, and biologic responses to, different isoforms.[813,814]

ECEs are metalloproteases that belong to the M13 group of proteins, a family including several proteins such as neutral endopeptidases, X-converting enzyme, ECEs, and others.[815] Three major ECE isoforms have been identified to date and named ECE-1, ECE-2, and ECE-3, of which ECE-1 and ECE-2 are the most prominent.[820] The ECEs differ from each other regarding cell/tissue distribution, localization, pH of optimal activity, and substrate specificity.[815] Four variants of ECE-1 have been reported in humans (ECE-1a, ECE-1b, ECE-1c, and ECE-1d), and two ECE-2 variants (ECE-2a and ECE-2b).[809] Both ECE-1 and ECE-2 cleave big ET-1 more efficiently than either big ET-2 or big ET-3. ECE-1 is expressed ubiquitously with highest expression in endothelium, lung, ovary, testis, and adrenal medulla, whereas ECE-2 is expressed in neural tissues. ECE-3, which selectively cleaves ET-3, has been found in the bovine iris.[816] ECE-1 was located at the cell surface and on intracellular vesicles.[817] ECE-1 also hydrolyzes BK, substance P, and insulin.[809] Not all the enzymes responsible for the final step of posttranslational processing of ET-1 have been identified. Current evidence suggests that other proteases may be involved in the final processing of ET, because mice lacking ECE-1 and ECE-2 can still produce mature ET-1.[818] In addition, alternative, ECE-independent pathways have been suggested possibly involving tissue chymases and non-ECE metalloproteinases.[819] Recently, several inhibitors specific for the ET-converting enzyme have been reported.[820]

Initial studies identified ET on the basis of its release from large-vessel endothelial cells. Since then, ET immunoreactivity has been detected in the kidney, spleen, skeletal muscle, and lung.[821] In the kidney, the arcuate arteries, veins, glomerular arterioles, and capillaries are a rich source of ET.[20] In the glomerulus, there is evidence for ET secretion by mesangial, endothelial, and epithelial cells.[823] In the rest of the nephron, the internal medullary collecting duct (IMCD) has been demonstrated to be a major site of ET-1 and ET-3 production.[823–825]

Normally, blood vessels produce very little ET, and the normal circulating level of ET is extremely low.[24] Secretion of ET by endothelial cells is controlled at the level of transcription and these cells do not store ET for future release.[810,827] Thus ET-1 probably acts primarily as a paracrine/autocrine mediator and not as a circulating hormone.[809] ET peptide secretion is upregulated by various humoral mediators, such as thrombin, BK, insulin, Ang II, AVP, endotoxin, IL-1, TGF-β, and tumor necrosis factor (TNF).[828] These mediators may be responsible for the increase in ET observed in various pathophysiologic states. Hypoxia is also an important stimulus for ET production.[829] In the kidney, increasing osmolarity serves as a stimulus for tubular production of ET.[830] On the other hand, NO, ANP, and prostacyclin exert inhibitory influences on ET synthesis and release.[831] In summary, mesangial cells' ET-1 release is under complex regulation, with vasoconstrictor, profibrotic, inflammatory, and proliferative agents augmenting its release, whereas vasorelaxant agents tend to inhibit its production.[832]

Endothelins exert their actions through two major receptor subtypes known as ET_A and ET_B receptors. These belong to the superfamily of G-protein coupled receptors and have been identified in a variety of tissues.[833] A third type of ET receptors, ET_C, has been cloned from Xenopus laevis.[834] Both ET_A and ET_B receptors have widespread distribution and are abundantly expressed in the kidneys. The ET_A receptor is believed to be involved in vasoconstrictive and proliferative responses to ET-1 and binds endothelins with the following affinity: ET-1 > ET-2 > ET-3.[809] ET_B receptor, on the other hand, is a nonisofrom selective receptor and recognizes all three ET isoforms with equal affinity. Its activation induces transient vasodilation. The recently cloned ET_C receptor binds preferentially ET-3 and its stimulation causes NO release.[823,833,834] Both ET_A and ET_B receptors are expressed on vascular smooth muscle.

The kidney expresses abundant mRNA transcripts for ET_A and ET_B receptors.[823,833,835] Expression of ET receptors is especially prominent in the renal artery, glomerular arterioles, endothelium, mesangium, vasa recta bundles, and collecting duct.[771,823,833] Both receptor subtypes are expressed in the glomerulus. Vascular smooth muscle cells of the arcuate arteries and the renal medullary interstitial cells display ET_A receptors. Epithelial cells of the cortical, inner medullary, and outer medullary collecting ducts have ET_B receptors.[823]

ET receptor activation leads to diverse cellular responses involving a chain of receptor-mediated amplification of effectors. At the ET_A receptor, these responses include the phospholipase pathway (PLC) leading to the formation of inositol triphosphate and diacylglycerol and to the release of

stored calcium into the cytosol. This causes cellular contraction and vasoconstriction. ET-mediated effects persist after dissociation of ET from its receptor, probably because of persistently high intracellular calcium or prolonged activation of signaling pathways.[815] Endothelial cells can express ET_B receptors linked to formation of NO and prostacyclin and mediate endothelium-dependent vasorelaxation.[836] In nephron segments and other renal structures, ET mediates its effects via a multiplicity of intracellular signal-transduction pathways that involve phospholipase activation, tyrosine phosphorylation of proteins, and elevation of intracellular free calcium.[837]

Biologic Effects of Endothelin in the Kidney

Endothelin effects on the kidney are broadly divided into vascular and tubular. Endothelin is a potent renal vasoconstrictor, as much as 30-fold more potent in this regard than Ang II.[771,804,805,836,837] Indeed, the renal vasculature is more sensitive than other vascular beds to the vasoconstrictive effects of ET-1.[838] In the isolated perfused kidney, ET-1 administration reduces GFR and causes a dose-dependent increase in renal vascular resistance. In whole animals, systemic ET infusion induces a decline in cortical blood flow, GFR, and urine volume[771,805]; however, some studies have shown differential regulation of blood flow between the cortex and the medulla with exogenous ET-1 infusion, showing cortical vasoconstriction and NO-dependent medullary vasodilation.[839,840] The direct effects of ET-1 on preglomerular and postglomerular resistances are quantitatively similar at lower doses, so the glomerular transcapillary hydraulic pressure and GFR are maintained.[841] However, at higher doses, a greater increase in preglomerular resistance occurs that, in addition to a decrease in glomerular capillary ultrafiltration coefficient (K_f), leads to a decline in GFR.[841,842] Dihydropyridines inhibit ET-mediated vasoconstriction exclusively in the afferent arterioles.[841] Renal hemodynamics may also be influenced by indirect effects of ET, such as modulation of arachidonic acid metabolism and renin release.[842] Local generation of prostaglandins (PGs), such as $PGF_{2\alpha}$, may mediate some of the vasoconstrictor effects of ET.[843] ET-1 directly inhibits renin release, but the net renin secretory response in vivo varies with the ET-1 dose, as well as with the state of activation of intrarenal baroreceptors and the MD-mediated pathway.[842] In humans, similar effects have been shown on renal vasculature, with renal vasoconstriction and reduction in RBF and GFR, whereas no studies addressed the effect of ET-1 on intrarenal distribution of blood flow.[838]

At the tubular level, ET-1 seems to play an important role in volume regulation. Despite compromise of RBF and GFR, infusion of nonpressor doses of ET in animals is associated with an increase in urinary flow and Na^+ excretion.[771,805] In addition, studies in the isolated perfused kidney have shown that ET increases Na^+ excretion despite a dramatic decline in GFR.[805] These effects on Na^+ and water balance are largely due to the ability of ET to reduce Na^+-K^+-ATPase activity and reversibly inhibit AVP-stimulated cAMP generation and water transport in the IMCD.[805,844] In addition, a natriuretic role for ET-1 is demonstrated in animals through ET_B receptors engaging NO and leading to inhibition of chloride transport in the MTAL of Henle's loop.[845] Furthermore, ET effect on epithelial amiloride-sensitive sodium channel is dose-dependent including activation and inhibition through both ET_B-mediated and non–ET_B-mediated effects.[846,847] The high concentration of ET receptors in the human inner medulla[835] and the recent observations suggesting ET production by human IMCD cells[825] justify the assumption that a similar physiologic role for intrarenal ET may also be operative in humans. ET also affects Na^+ balance indirectly by stimulating release of ANP.[848]

ET is well known to induce contraction of MCs in culture and results of micropuncture experiments demonstrate that ET-1 directly reduces the coefficient of ultrafiltration.[849] ET is also recognized as a growth factor with mitogenic effects on MCs in culture, inducing changes in MC phenotype and gene expression.[771,805,833] Abundant evidence points to a pivotal role for ET-1 in the biology and, particularly, the pathology of the renal mesangium. The peptide is produced by MC and can, in turn, act on MCs to elicit proliferation, hypertrophy, contraction, and/or extracellular matrix accumulation. These effects are mediated in large part through activation of ET_A and particularly involve PKC and MAPK. Excessive ET-1 production by, and action on, MCs is of pathogenic importance in glomerular damage in animal models of glomerulonephritis (GN), diabetes, and hypertension (Fig. 8.11).[832]

Studies with ET receptor antagonists demonstrated that, in the animal kidney, ET-1-induced reductions in total RBF are mediated by ET_A receptor, whereas selective medullary vasodilation is mediated by ET_B receptor.[850,851] In humans the situation is less clear. Antagonism studies have suggested that ET-1 effects through ET_A receptors may not be major contributors to the maintenance of renal vascular tone in health, whereas ET-1 vasodilatory effects through ET_B receptors are important.[852]

Endothelins in Kidney Disease

Endothelins have been implicated in a variety of diseases including cardiovascular (CV) and renal diseases, neoplasia, wound healing, and others. ET-1 has been implicated in the pathophysiology of congestive heart failure, showing cardiac pro-arrhythmic effects and promoting fibrogenesis and ventricular remodeling.[853,854] Despite its central role in CV disease pathogenesis, antagonism did not show any clear beneficial effect.[815]

The role of ET-1 in the pathogenesis of hypertension has been evoked by several studies showing a cross-talk between all pressor and vasoconstrictor systems including ET, the renin-angiotensin system, and the sympathetic nervous system.[815] Collectively, study results suggest that dysregulation of the endothelin system contributes to multisystem complications of hypertension.[855–857]

At the renal level, various diseases were associated with a dysfunctional endothelin system, including progression

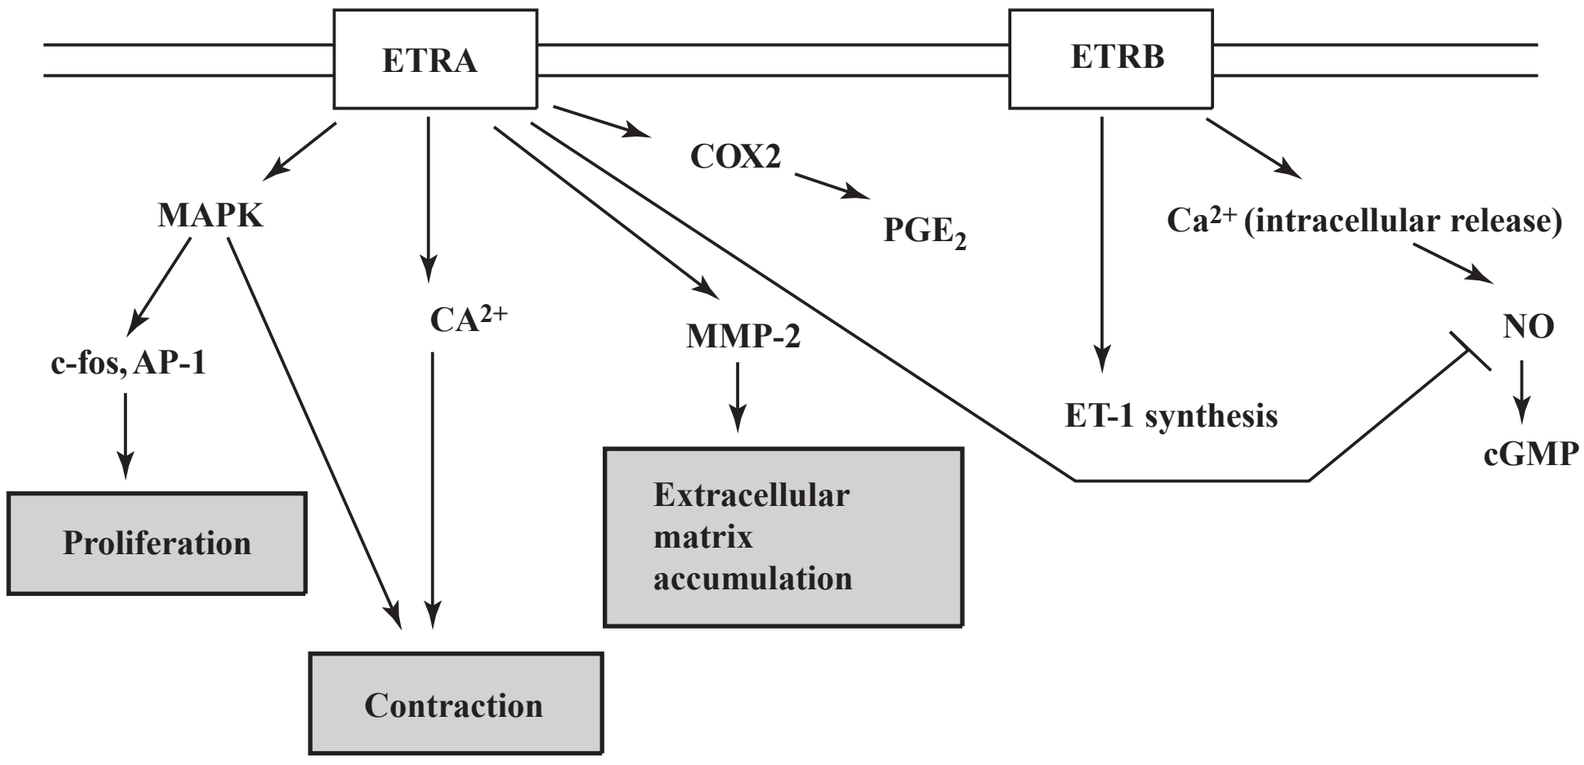

FIGURE 8.11 Schematic representation of biologic effects mediated by endothelin receptor A (ETRA) and endothelin receptor B (ETRB) in mesangial cells. The net effect of ETRA activation is mesangial cell contraction, extracellular matrix accumulation, and proliferation. The net effect of activation of ETRB tends to be vasorelaxant as well as causing autostimulation of ET-1 production. *AP-1*, activator protein-1; *MMP-2*, matrix metalloproteinase-2. (From Sorokin A, Kohan DE. Physiology and pathology of endothelin-1 in renal mesangium. *Am J Physiol Renal Physiol.* 2003;285:579, with permission.)

of chronic kidney disease, hypertension, and proteinuria. Declining renal function is associated with an increase in plasma ET levels.[858] Patients undergoing hemodialysis have higher ET levels than do patients undergoing peritoneal dialysis or uremic patients not yet on renal replacement therapy.[859] Erythropoietin administration, as well as acute volume contraction during hemodialysis, may contribute to the elevation of ET-1 level in patients undergoing hemodialysis.[860] Although the significance of elevated plasma levels of a primarily autocrine or paracrine hormone (ET) remains questionable at present, ET-secreting hemangioendotheliomas have been shown to produce marked hypertension.[861]

A pathophysiologic role for ET has been reported in several conditions affecting the kidney.[805,823,862] Urinary ET-1 excretion increases in patients with several forms of chronic progressive glomerulopathies.[862] MCs' ET-1 production is increased in rat models of immune complex GN, nephrotoxic serum nephritis, and mesangial proliferative GN. In addition, MC ET-1 production is augmented in human SLE and urinary ET-1 excretion is proportional to the severity of human mesangial proliferative GN.[832]

Although there is no direct evidence in vivo that MC ET-1 production is increased in diabetic nephropathy (DN), there are in vitro data suggesting that MC ET-1 synthesis is increased by hyperglycemia.[832] Studies suggest that MC ET-1 production is enhanced in DN and that excessive ET-1 action in the diabetic glomerulus can cause enhanced matrix accumulation, proteinuria, and reduced GFR.[832]

In animals subjected to surgical reduction of renal mass, ET-1 gene expression increases in parallel with proteinuria and glomerulosclerosis.[863] Proteinuria is currently known to be a renal and CV risk factor, and its reduction may confer CV protection.[838] Upregulation of the renal ET system exacerbates proteinuria. Implicated mechanisms include increased glomerular capillary hydrostatic pressure and permeability.[838] Chronic selective ET_A receptor blockade was associated with reduction of microalbuminuria in diabetic patients.[62] Renal ischemia, on the other hand, is a potent stimulus for ET-1 production.[63] ET-1 is upregulated after renal ischemia/reperfusion injury and may contribute to the injury by prolonging vasoconstriction. It is known that ET_A-selective, but not ET_B-selective, antagonist is protective against renal IR injury.[64] ET-1 aggravates cell damage through the activation of Na^+/Ca^{++} exchanger suggesting that Ca^{++} may play a critical role in hypoxia/reoxygenation-induced renal tubular injury.[65] Other renal diseases involving the ET system include: radiocontrast-induced renal injury,[66,823] cyclosporine-mediated nephrotoxicity,[67] immune nephritis, and the rat remnant kidney model.[68] However, data supporting a role for ET antagonists in the treatment of acute or chronic kidney disease in humans are currently lacking.[815]

In summary, ET is a potent vasoconstrictor peptide. In the kidney, it reduces RBF and GFR, contracts mesangial cells, and may function as a paracrine–autocrine factor in modulation of sodium and water balance. It is a potential mediator of growth and proliferative changes within the kidney. It is thought to play a pathophysiologic role in a number of kidney diseases. ET receptor antagonists may prove to be beneficial in certain conditions.

NITRIC OXIDE

NO is a paracrine mediator with a wide spectrum of physiologic actions, including the control of vascular tone, antithrombotic actions, cell cycle regulation, neurotransmission, signal transduction, and inflammation. NO is synthesized during conversion of its physiologic precursor L-arginine

(L-Arg) to L-citrulline.[864,865] This reaction is catalyzed by a family of enzymes known as NO synthases (NOS).[864,866–868] Three NOS isoforms (neuronal [nNOS, NOS1], inducible [iNOS, NOS2], and endothelial [eNOS, NOS3]) have been identified in mammalian tissues. Neuronal nitric oxide synthase (nNOS) was first found in the neuronal cells of the brain, but is also constitutively expressed in the kidney and may be of physiologic importance.[867] iNOS is expressed upon activation of macrophages and other cells. The third isozyme is found in endothelial cells (eNOS) and, like nNOS, is constitutive in nature.[868,869] NO produced from endothelial cells (eNOS-derived) is important as a tonic vasodilator and inhibitor of platelet aggregation and adhesion.

Renal Action of Nitric Oxide

All three NOS isoforms are expressed in the medulla and medullary NO production exceeds that in the cortex.[864] eNOS is found predominantly in renal vasculature, whereas iNOS immunoreactivity has been shown in the preglomerular portion of the afferent arteriole[871] and in glomerular mesangial cells. Isolated rat proximal tubule and inner medullary collecting duct cells express iNOS following stimulation with TNF-α and IFN-γ.[872]

Studies at the Single Nephron Level

NO has been shown to participate in the regulation of renal hemodynamics. The administration of a competitive inhibitor of NO production, L-NMMA, to normal rats causes dramatic glomerular hemodynamic changes, including reduced single nephron plasma flow, augmented afferent and efferent arteriolar resistances, decreased ultrafiltration coefficient, and increased glomerular capillary pressure.[873–876] Chronic oral supplementation with an L-arginine inhibitor in rats caused proteinuria, increased glomerular capillary pressure, and glomerular hemodynamic changes as described previously.[875] These observations suggest that NO might be an important regulator of glomerular capillary pressure and that its dysregulation might be involved in the development of glomerular sclerosis through increases in glomerular capillary pressure.

Dietary supplementation with L-arginine ameliorates the progression of renal disease in rats with subtotal nephrectomy,[876] at least in part because of its inhibitory effects on the development of glomerular hypertension.[877]

Role in Renal Injury

Increasing evidence implicates a role for decreased NO and increased peroxynitrite production in the pathophysiology of reactive oxygen species (ROS)-induced acute kidney injury.[878–880] Furthermore, Ang II promotes the production of O_2 and Ang II synthesis is increased in the kidney when there is a deficiency of NO. Once initiated, these events create a cycle that continues to increase Ang II levels in the glomerular circulation and to raise glomerular capillary pressure.[881] A locally activated renal RAS, in conjunction with increased TGF-1 expression, was shown to be a major feature of renal injury in rats with chronic inhibition of NO synthase.[881] Both exogenous and endogenous NO have protective effects against ischemia/reperfusion-induced renal dysfunction and tissue damage, probably through the suppression of endothelin-1 overproduction in postischemic kidneys.[882]

Therapeutic Implications

Not only do ACE inhibitors decrease Ang II synthesis, they also prevent the degradation of bradykinin, which is an important physiologic molecule involved in the release of NO. With ARBs, blocking the AT_1 receptor favors the synthesis of NO and stimulates factors that allow NO to be biologically more active.[881]

nNOS is abundantly expressed in MD cells, and its expression is stimulated in various high-renin states including salt restriction, administration of loop diuretics, or inhibition of the renin-angiotensin system—some of the same interventions that augment COX-2 expression. Direct evidence in support of MD NOS, presumably nNOS, acting as a positive regulator of renin secretion came from studies in the in vitro perfused juxtaglomerular apparatus (JGA). In this preparation, administration of L-arginine-stimulated renin secretion and NOS blockers almost completely abolished the stimulation of renin secretion by low levels of NaCl.[883] Studies have also demonstrated that tubuloglomerular feedback control of afferent arteriolar resistance is influenced by MD NO production, thereby enhancing autoregulation of RBF, GFR, and renin secretion.[884]

ERYTHROPOIETIN

Erythropoietin (EPO) is a 30.4-kDa glycoprotein hormone that acts on the bone marrow to stimulate red blood cell production.[885] The kidneys produce 85% to 90% of circulating erythropoietin in adults and the liver accounts for the remainder.[885,886] The liver is the major source of erythropoietin in the fetus.[886] In situ hybridization studies performed in anemic or hypoxic animals and erythropoietin-transgenic mice demonstrated that EPO is synthesized by peritubular cells of the renal cortex, particularly at the corticomedullary junction.[886–889] Other tissues were also found to produce EPO (peripheral endothelial cells, vascular smooth muscle cells, neurons, astrocytes, microglia, and cardiomyocytes). EPO receptors (EPO-R), members of the cytokine receptor superfamily, are localized in different parts of the kidney, as well as in the CNS, endothelial cells, solid tumors, liver, and uterus.[890] In erythroid progenitor cells, EPO binds to EPO-R, leading to activation of the JAK2 and downstream signal transduction pathways including STAT5, PI3 kinase, and MAPK.[891] The main stimulus for EPO production and secretion is decreased oxygen supply to renal tissue which most commonly results from anemia or hypoxemia. Decreased oxygen triggers a cascade of reactions mostly mediated by the so-called hypoxia-inducible factors (HIF), which activate a wide set of genes involved in protecting the

kidney from hypoxia including EPO gene.[892] This autocrine/paracrine secretion of EPO helps by decreasing apoptosis and cell necrosis in mesangial and tubular cells subjected to hypoxic (ischemia reflow injury) stress and toxic insult (cisplatinum), suggesting a potential therapeutic use of EPO or EPO analogs in tubular necrosis.[893–895] Extensive evidence indicates that EPO is a pleiotropic cytokine that confers broad tissue-protective properties as part of an innate response to stressors, promotes angiogenesis, and modulates wound healing responses.[896] It seems that SGK1 might contribute to the mediation of EPO effects under ischemic conditions.[897] Conversely, when the kidney is hyperoxygenated, as occurs after red cell transfusion, EPO production is reduced. In addition to modulation by oxygen availability, EPO production is influenced by several cytokines. IL-1 and TNF-α were shown to inhibit EPO mRNA levels and EPO formation in human hepatoma cell cultures and to reduce EPO production in isolated perfused rat kidneys.[898] Secretion of these cytokines by macrophages could contribute to defective EPO production and anemia in infectious or inflammatory diseases. Wang et al. showed that EPO has antioxidative properties in organs affected by diabetes and may prevent incipient microvascular damage in the diabetic retina.[899] Schiffer et al. studied the effects of different EPO molecules on podocyte signaling in vitro and on podocyte survival in an experimental model of diabetic kidney injury. EPO activates pro-survival intracellular pathways in podocytes in vitro, and ameliorates diabetes-induced podocyte loss in vivo.[900]

EPO has the potential to modulate oxygen delivery through regulation of endothelial NO production. In endothelial cell cultures, although short-term exposure to EPO decreases or leaves unchanged eNOS and endothelin-1 expression, the combination of EPO and hypoxia increases EPO-R and eNOS expression, and nitric oxide (NO) and cGMP production, demonstrating a direct effect of EPO on endothelial eNOS and NO production. EPO administration for 14 days in healthy rats increased hematocrit as well as eNOS expression and augmented NO-dependent vasodilatation.[901]

In healthy volunteers, Ang II injection increases EPO secretion in a dose-dependent manner. This effect is neutralized by a selective AT_1 receptor blocker, inferring that the stimulation of EPO by Ang II is probably via AT_1 receptors.[902] It has been postulated that EPO has antinatriuretic action, which could account for the worsening hypertension observed in some patients receiving recombinant EPO. In one study in isolated Wistar rat kidneys, EPO decreased Na excretion, possibly by increasing Ang II production.[904]

Cyanate, a compound that could spontaneously form from urea, reacts with EPO leading to carbamylated EPO, an EPO protein with reduced activity. In renal insufficiency, cyanate can reach levels high enough to reduce the activity of both endogenous and exogenous EPO. This might explain one mechanism of suboptimal responses to recombinant EPO in patients with ESRD on inadequate dialysis. It might also explain the superiority of continuous peritoneal dialysis over hemodialysis in terms of decreasing blood urea nitrogen (BUN) and, at the same time, improving anemia.[903]

INSULIN

Besides inhibiting gluconeogenesis in the proximal tubule, insulin exerts a significant vasodilatory effect on the kidney, thus increasing RPF; this effect appears to be mediated by PGs and partially counteracts the vasoconstrictor effect of Ang II.[905] In contrast, insulin appears to enhance the contractile effect of Ang II on mesangial cells.[906] It also potentiates AVP action in terms of water reabsorption at the collecting ducts by increasing the gene transcription of aquaporin-2 (AQP2).[907] In rats' renal proximal tubule cells, insulin and dopamine receptors interact to regulate renal sodium transport.[908] Studies using primarily cell culture have demonstrated that insulin can directly increase activity of the epithelial sodium channel, the sodium-phosphate cotransporter, the sodium-hydrogen exchanger type III, and Na-K-ATPase.[909]

C-peptide

C-peptide, or connecting peptide, for a long time thought of as an inert by-product of the conversion of proinsulin to insulin, has revealed multiple biologic roles by partially reversing or preventing complications of insulin-dependent diabetes.[910] Physiologic concentrations of C-peptide in diabetic rats activates pathways involved in cellular proliferation, and limits or prevents the glomerular hypertrophy and the mesangial matrix expansion seen in the posthyperfiltration phase of early diabetic nephropathy.[911] In the kidney, C-peptide reduces diabetes-induced glomerular hyperfiltration, albuminuria, and renal hypertrophy. C-peptide may induce constriction of afferent arterioles in diabetic mice thus reducing GFR—one of the renoprotective mechanisms of C-peptide in diabetes.[912] Following in vivo administration of C-peptide to patients with type 1 diabetes (T1DM), microvascular blood flow to tissues and organs, including muscle, skin, and kidney, is consistently augmented and likely relates to stimulatory effects on NO pathways.[913] One month treatment with C-peptide in T1DM patients results in a 6% decrease in GFR, and a 50% decrease in urinary albumin excretion.[914]

C-peptide reduces diabetes-induced hyperfiltration via a net dilation of the efferent arteriole and inhibition of tubular Na reabsorption, both potent regulators of the glomerular net filtration pressure.[915] In several studies, increased renal Na-K-ATPase activity has been linked to hyperfiltration and to the increase in oxygen consumption. Via inhibition of Na-K-ATPase, C-peptide may contribute to a normalization of the basal oxygen consumption of proximal tubules in diabetic animals. C-peptide may also influence oxygenation through effects on NO release. In addition, C-peptide can improve diabetes-reduced erythrocyte deformability. This has the potential to improve capillary blood flow, thus improving oxygen availability in the kidney, and

other affected tissues.[914] In vivo, C-peptide supplementation for 1 month improves body weight in STZ-induced diabetic rats and decreases urinary sodium wasting.[916] TGF-β1, overexpressed in renal cells in diabetes, has been suggested as a major malefactor in the development of morphologic changes in diabetes by stimulating the mesenchymal formation of collagen IV, and eliciting fibrosis in renal tissues. It has been reported that C-peptide has a protective effect on early diabetic glomerular changes in response to TGF-β1 in STZ-diabetic mice. In addition, an inhibitory effect of C-peptide on TGF-β1-induced gene expression has been demonstrated in a mouse podocyte cell line. C-peptide is reported to effectively reverse TGF-β1-induced structural changes in proximal tubular cells and to inhibit TGF-β1-induced gene expression in a mouse podocyte cell line. The mechanism by which this occurs is not fully understood. It has also been reported that C-peptide, via activation of NF-κB regulated survival genes, protects against TNF-α–mediated renal tubular injury.[914]

RENAL DEGRADATION OF HORMONES

Hormones fall in general into four structural groups: peptides and proteins, steroid hormones, amino acid derivatives, and fatty acid derivatives. Peptide hormones such as insulin have generally a short half-life and are extracted by the kidney, which, on average, removes between 16% and 40% of the hormone entering the renal circulation.[917] In exceptional cases, the kinins for example, more than 90% is removed during a single passage. The removal of biologically active and inactive peptides from the renal circulation occurs predominantly by glomerular filtration.

The rate of filtration is influenced by the size, shape, and charge of the molecule. After filtration, peptide hormones are degraded in the proximal tubule via two mechanisms. Larger peptides, such as insulin, require absorption by epithelial cells and degradation in lysosomes or endosomes. Growth hormone, for example, is also absorbed by tubules where it undergoes peritubular degradation.[918] Smaller peptides, such as bradykinin, angiotensin, and ANP, are degraded by hydrolysis on the brush border. Urinary hormone excretion accounts for less than 1% to 2% of the filtered load.[918] In most cases, the liver contributes significantly to peptide hormone metabolism. A few hormones, however, undergo negligible hepatic extraction and the kidneys are their predominant site of degradation.[917] Examples of these hormones are calcitonin, the amino-terminal fragment of PTH, and the C-peptide of proinsulin. Complete removal of insulin is also dependent on intact renal function.[919] Glomerular filtration accounts for approximately 60% of all the insulin removed by the kidney and the remaining is extracted from the peritubular circulation. Uptake and degradation occurs largely by receptor-mediated endocytosis of insulin on the basolateral membrane of tubule epithelial cells.[920,921] The kidneys contribute significantly to disposal of glycoprotein hormones, such as erythropoietin, follicle-stimulating hormone, and luteinizing hormone.[922,923]

Steroid hormones are derivatives of cholesterol and are typically eliminated by inactivating metabolic transformations and excretion in urine or bile. Examples include testosterone, cortisol, and vitamin D. Their half-lives vary considerably between a few minutes and a few hours. With the exception of vitamin D, the kidney plays only a minor role in the metabolsim of steroid hormones.[920]

Two major hormone groups are derivatives of amino acids: thyroid hormones and catecholamines. These were discussed in detail in previous sections of this chapter. Thyroid hormones are inactivated primarily by intracellular deiodinases and catecholamines are rapidly degraded by enzymes such as monoamine oxidase and catechol-O-methyl transferase.

Fatty acid derivatives include mainly eicosanoids and were discussed in other sections of this chapter. These hormones are rapidly inactivated by metabolism and have short half-lives.

CHAPTER 9

Laboratory Evaluation of Kidney Disease

Lesley A. Inker • Richard A. Lafayette • Ashish Upadhyay • Andrew S. Levey

Diseases of the kidney are often "silent" until late in the course of disease, when clinical signs and symptoms of uremia mark the onset of kidney failure. In contrast, laboratory evaluation for kidney disease reveals earlier manifestations and is an essential part of the clinical assessment of health and disease. In this chapter, we begin with a general approach to the laboratory evaluation of acute and chronic kidney disease (CKD). We then focus on glomerular filtration rate (GFR) as an index of overall kidney function, and proteinuria and other abnormalities in the urine sediment as markers of structural damage. In addition, we review all aspects of the routine urinalysis. Tubular functions, including concentration and dilution of the urine, urinary acidification, and reabsorption and secretion of electrolytes and other solutes are described in other chapters, as are production of hormones and metabolism by the kidney and novel biomarkers for specific diseases.

GENERAL APPROACH

Recent guidelines define kidney diseases according to alterations in kidney structure and function and their duration (Fig. 9.1 and Table 9.1).[1,2] Kidney diseases are further classified by severity of reduction in GFR and magnitude of albuminuria and by cause, reflecting the pathogenesis and pathologic abnormalities. The level of GFR is generally accepted as the best overall index of kidney function, and other kidney functions often decline in parallel to GFR in acute and chronic kidney diseases. Albuminuria generally reflects structural damage to the glomerular filtration barrier. Both measures appear to reflect kidney involvement in systemic vascular diseases as well as primary kidney diseases, and recent studies show that the severity of reduced GFR and magnitude of albuminuria are associated with a graded increase in risk for adverse outcomes across a wide variety of settings, including patients with acute and chronic kidney diseases, patients with increased risk from cardiovascular disease, and the general population (Figs. 9.2 and 9.3).[3] Abnormalities in the urine sediment, such as renal tubular cells and cellular casts, signify kidney damage and may provide a clue to the cause of kidney disease, but quantification is not well studied. Abnormalities on imaging studies and pathologic abnormalities are sufficient for diagnosis of acute or chronic kidney disease. A history of kidney transplantation is sufficient for a diagnosis of chronic kidney disease.

Recent guidelines also suggest simplification of initial diagnostic testing for detection and evaluation of acute and chronic kidney diseases. Although the importance of timed urine collections is acknowledged for gold standard measures of GFR and albumin excretion rate, they are impractical for routine general clinical practice. In this chapter, we emphasize initial testing using estimation of GFR from serum levels of endogenous filtration markers, estimation of albumin excretion rate from untimed "spot" urine albumin-to-creatinine ratio, and interpretation of reagent pads on the urine dipstick. Timed urine collections can be considered for more accurate assessment of GFR or albuminuria or further evaluation of abnormalities observed on the urine dipstick.

GLOMERULAR FILTRATION RATE

Glomerular Filtration: Determinants and Measurement

Normal Glomerular Filtration

The human kidney contains approximately 1 million glomeruli.[4,5] This number is determined at birth but is quite variable and a lower nephron number may be associated with development of hypertension and kidney disease in later life.[6,7] Each glomerulus attains an adult size of approximately 150 to 200 μm in diameter, providing a total surface area provided for filtration that approximates 1 square meter.[8] Approximately 180 L per day (or 125 mL per minute) of tubular fluid are produced from the rich renal plasma flow by the process of ultrafiltration. Glomerular filtration, driven by the high hydrostatic pressure across the glomerular capillaries, is facilitated by a hydraulic permeability of the glomerular capillary wall that is one to two orders of magnitude greater than other capillaries.[9]

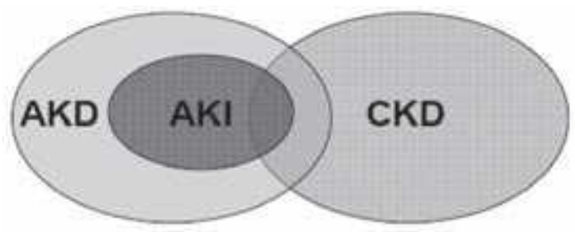

FIGURE 9.1 Conceptual model for integration of acute kidney injury (*AKI*), chronic kidney disease (*CKD*), and acute kidney diseases and disorders (*AKD*). Overlapping ovals show the relationships among AKI, AKD, and CKD. AKI is a subset of AKD. Both AKI and AKD without AKI can be superimposed upon CKD. Individuals without AKI, AKD, or CKD have no known kidney disease or disorder (NKD), not shown here. (Reproduced from Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group. KDIGO Clinical Practice Guideline for Acute Kidney Injury. *Kidney Int Suppl.* 2012;2(1):1–126.)

The glomerular filtration barrier is both size- and charge-dependent. Substances with molecular weights lower than 10,000 daltons cross the glomerular capillary wall as easily as water and electrolytes.[10–12] Micropuncture sampling of glomerular filtrate in amphibians and mammals shows the filtrate to be identical in nonprotein composition to plasma, with electrolyte concentrations conforming to the Gibbs-Donnan relationship.[11,13] As discussed later, plasma proteins are excluded from the filtrate as a consequence of the unique structure of the glomerular capillary wall.

Determinants of the Glomerular Filtration Rate

In principle, the GFR is dependent on the number of nephrons (N) and the single-nephron glomerular filtration rate (SNGFR), as described below:

$$GFR = N \times SNGFR \quad (1)$$

In normal individuals, regulation of GFR occurs via regulation of SNGFR. In patients with kidney disease, in whom the nephron number may be reduced, regulation of SNGFR remains important in modulating GFR. SNGFR is determined by two major factors. The first factor is the net ultrafiltration pressure (P_{UF}), determined by the difference between the net transcapillary hydraulic pressure (ΔP) favoring filtration and the net oncotic pressure ($\Delta\pi$)

9.1 Definitions of Kidney Disease

	Functional Criteria	Structural Criteria
Acute kidney injury (AKI)	Increase in serum creatinine by 50% within 7 days, OR Increase in serum creatinine by 0.3 mg/dl within 2 days, OR Oliguria	No criteria
Chronic kidney disease (CKD)	GFR $<$60 mL/min/1.73 m^2 for $\geq$3 months	Kidney damage for $\geq$3 months, including Albumin excretion rate $>$30 mg/d, OR, Urine sediment abnormalities, OR, Imaging abnormalities, OR Pathologic abnormalities, OR History of kidney transplantation
Acute kidney diseases and disorders (AKD)	AKI, OR GFR $<$60 mL/min/1.73 m^2 $<$3 months, OR Decrease in GFR by $>$35% or increase in serum creatinine by $>$50% for $<$3 months	Kidney damage for $<$3 months, as defined by above
No kidney disease or disorder (NKD)	GFR $>$60 mL/min/1.73 m^2, AND Stable serum creatinine	No kidney damage

Note: AKI and CKD have formal consensus definitions. The definition for AKD is proposed as an operational definition to classify individuals with alterations in kidney function and structure and function who do not meet the definitions for AKI and CKD. NKD indicates no functional or structural alterations that meet the definition for AKI, CKD, or AKD. Clinical judgement is required or individual decision-making regarding the extent of evaluation that is necessary to assess kidney function and structure. Glomerular filtration rate (GFR) may be assessed from estimated or measured GFR. Estimated GFR does not reflect measured GFR in AKI as accurately as in CKD. Albuminuria may be assessed from timed urine collections or "spot" urine albumin-to-creatinine ratio. Novel markers of kidney damage have been proposed, but none have been validated for inclusion in the definitions of AKI or CKD. A history of kidney transplantation is considered a marker of kidney damage for CKD but not AKD.

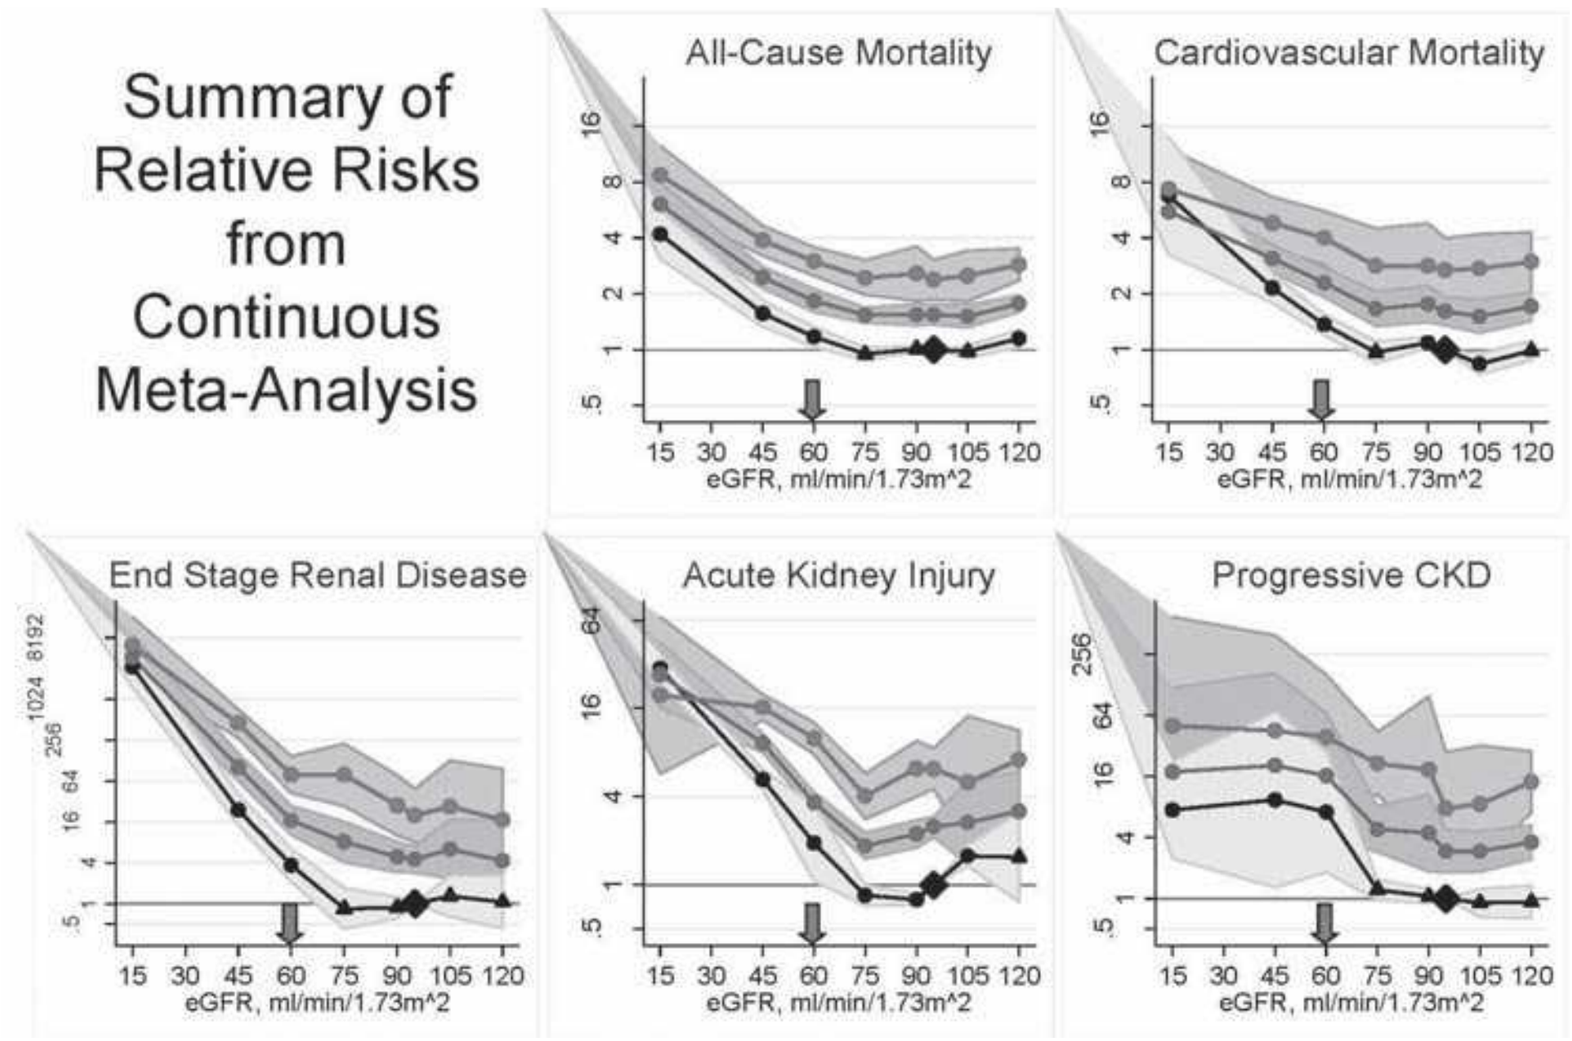

FIGURE 9.2 Summary of KDIGO Controversy Conference continuous meta-analysis (adjusted relative risk [RR]) for general population cohorts with albumin-to-creatinine ratio (ACR). Mortality is reported for general population cohorts assessing albuminuria as urine ACR. Kidney outcomes are reported for general population cohorts assessing albuminuria as either urine ACR or dipstick. Estimated glomerular filtration rate (eGFR) is expressed as a continuous variable. The three lines represent urine ACR of <30 mg per g or dipstick negative and trace (*blue*), urine ACR 30 to 299 mg per g or dipstick 1+ positive (*green*), and urine ACR >300 mg per g or dipstick ≥2+ positive (*red*). All results are adjusted for covariates and compared with reference point of eGFR of 95 mL/min/1.73m^2 and ACR of <30 mg per g or dipstick negative (*diamond*). Each point represents the pooled RR from a meta-analysis. *Solid circles* indicate statistical significance compared with the reference point ($P < 0.05$); *triangles* indicate nonsignificance. *Red arrows* indicate eGFR of 60 mL/min/1.73m^2, threshold value of eGFR for the current definition of chronic kidney disease (CKD). HR, hazards ratio; OR, odds ratio. (Reproduced from Levey AS, de Jong PE, Coresh J, et al. The definition, classification and prognosis of chronic kidney disease: a KDIGO Controversies Conference report. *Kidney Int*. 2011;80:17–28.) (See Color Plate.)

opposing filtration. ΔP is determined by the difference between the glomerular capillary hydraulic pressure (P_{GC}) and that in the earliest proximal tubule (P_T). $\Delta\pi$ is determined by the glomerular oncotic pressure alone as the ultrafiltrate is virtually protein free. The second factor, K_f, describes the surface area and permeability characteristics of the glomerular ultrafiltration barrier. This relationship can be expressed by the equation:

$$\text{SNGFR} = K_f(\Delta P - \Delta\pi) \quad (2)$$

Absent from this equation is the renal plasma flow rate. Alterations in renal plasma flow affect SNGFR largely by affecting $\Delta\pi$. Changes in determinants of SNGFR as plasma traverses the glomerular capillary are demonstrated in Figure 9.4. For a detailed analysis of these determinants and the multiple factors that result in the regulation of glomerular filtration, the reader is directed to Chapter 2.

In acute and chronic kidney disease, decreased GFR can be due either to a decrease in nephron number or SNGFR. Interestingly, in a number of experimental chronic kidney diseases characterized by decreased nephron number, SNGFR is elevated, perhaps reflecting compensation in processes to maintain whole kidney GFR. Moreover, in some diseases, increased SNGFR precedes the decline in nephron number, thereby raising the hypothesis that hyperfiltration in single nephrons may give rise to the development or progression of chronic kidney disease.[14]

Normal Range and Variability of Glomerular Filtration Rate

The GFR cannot be measured directly. Instead, as discussed later, it is assessed from the urinary clearance of an ideal filtration marker, such as inulin. When measured repeatedly in a single individual, under constant conditions and according to a standard protocol, the GFR appears relatively constant. Homer Smith measured the inulin clearance in one "hospitalized but otherwise normal subject" 15 times during 1 year; the range was 113 to 137 mL per minute with a mean of 122 mL per minute.[15] However, variation among individuals is quite large, and normal values show considerable spread. As discussed later, the major causes of variability in healthy individuals are age, gender, and body size. Hence,

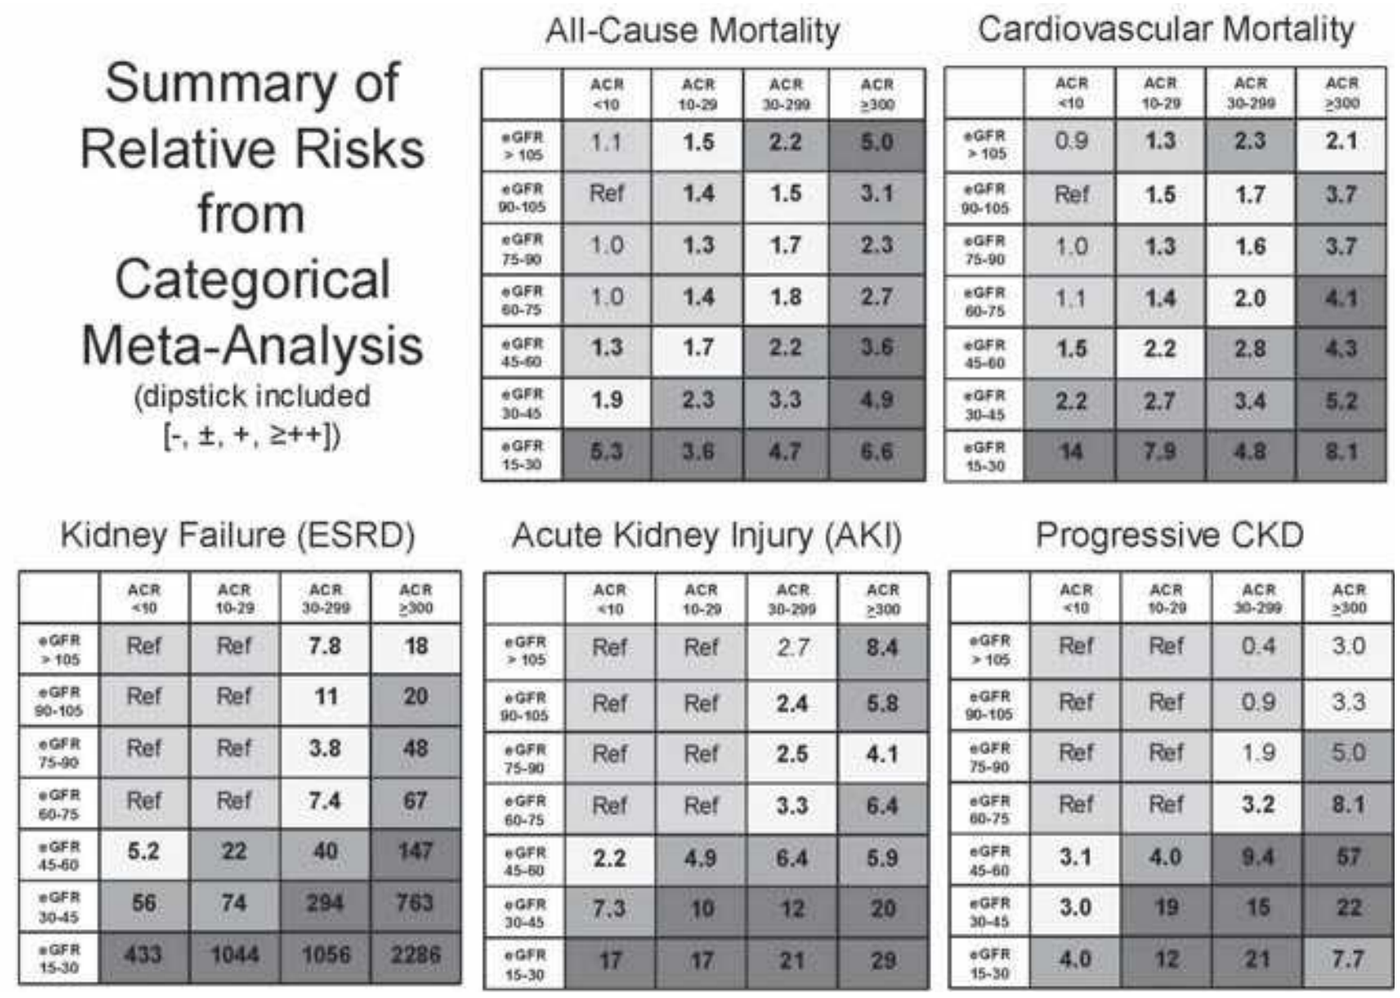

FIGURE 9.3 Summary of KDIGO Controversy Conference categorical meta-analysis (adjusted relative risk [RR]) for general population cohorts with albumin-to-creatinine ratio (ACR). Mortality is reported for general population cohorts assessing albuminuria as urine ACR. Kidney outcomes are reported for general population cohorts assessing albuminuria as either urine ACR or dipstick. Estimated glomerular filtration rate (eGFR) and albuminuria are expressed as categorical variables. All results are adjusted for covariates and compared with the reference cell (*Ref*). Each cell represents a pooled relative risk from a meta-analysis; *bold numbers* indicate statistical significance at $P < .05$. Incidence rates per 1,000 person-years for the reference cells are 7.0 for all-cause mortality, 4.5 for cardiovascular disease mortality, 0.04 for kidney failure, 0.98 for acute kidney injury (AKI), and 2.02 for kidney disease progression. Absolute risk can be computed by multiplying the RRs in each cell by the incidence rate in the reference cell. Colors reflect the ranking of adjusted relative risk. The point estimates for each cell were ranked from 1 to 28 (the lowest RR having rank number 1, and the highest number 28). The categories with rank numbers 1 to 8 are *green*, rank numbers 9 to 14 are *yellow*, the rank numbers 15 to 21 are *orange*, and the rank numbers 22 to 28 are colored *red*. (For the outcome of kidney disease progression, two cells with RR 1.0 are also green, leaving fewer cells as orange.) (Reproduced with permission from Levey AS, de Jong PE, Coresh J, et al. The definition, classification and prognosis of chronic kidney disease: a KDIGO Controversies Conference report. *Kidney Int*. 2011;80:17–28.) (See Color Plate.)

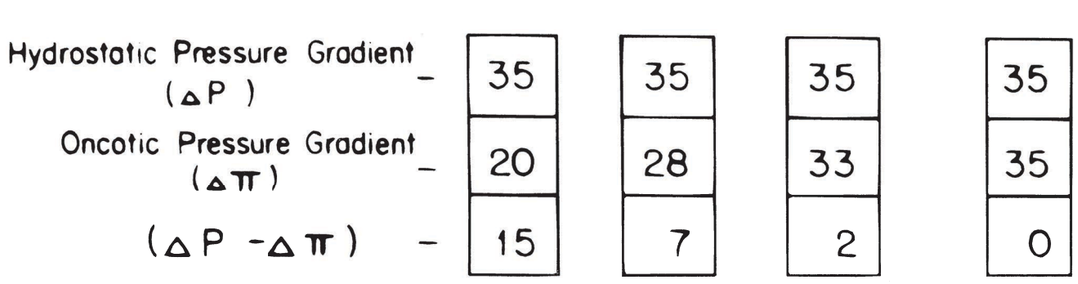

FIGURE 9.4 The changes in hydrostatic and oncotic pressures that occur as plasma traverses the glomerular capillary. As water is filtered without protein, the oncotic pressure gradually rises, thereby decreasing the net pressure favoring filtration. The pressure favoring filtration falls toward zero and filtration stops in this model before the plasma reaches the efferent arteriole. (From Deen WM, Robertson CR, Brenner BM. Glomerular ultrafiltration. *Fed Proc*. 1974;33:14, with permission.)

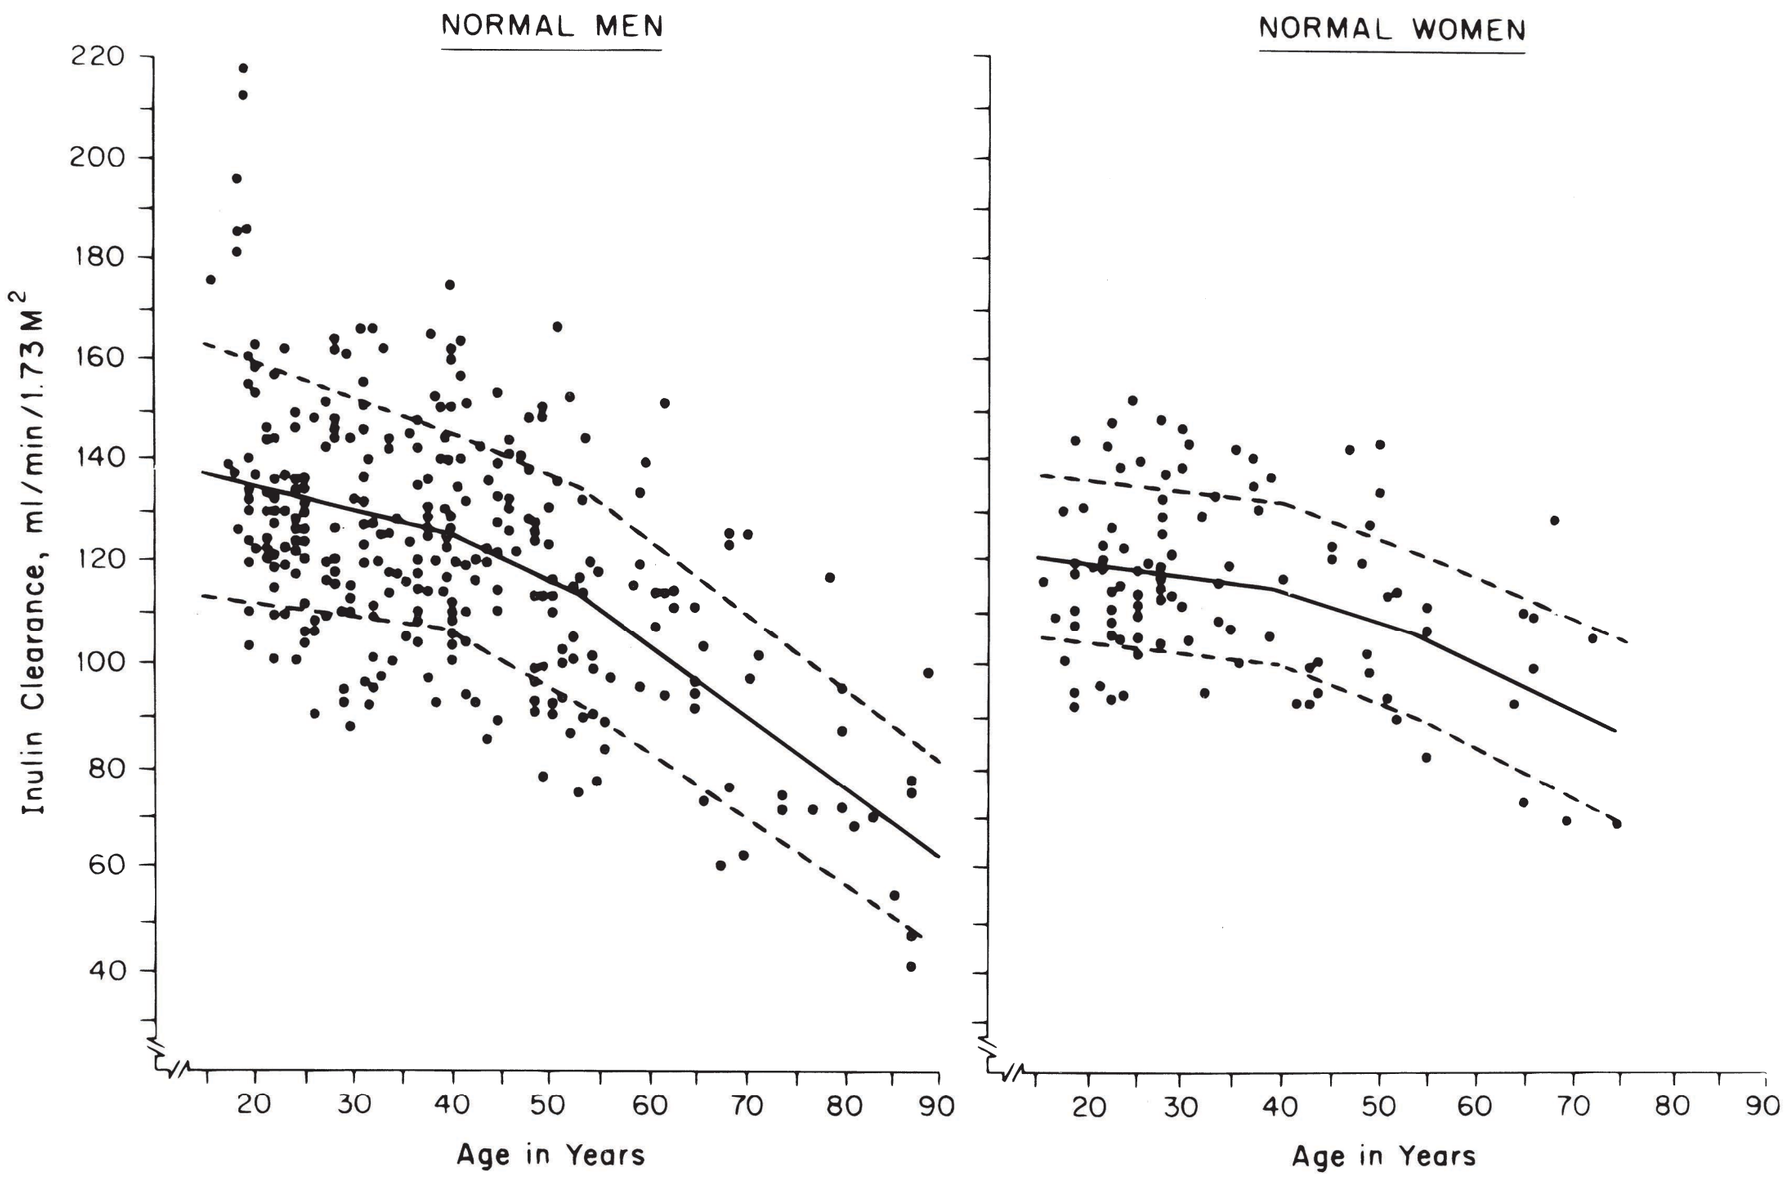

FIGURE 9.5 Normal values for glomerular filtration rate, adjusted for body surface area, in men and women of various ages. (From Wesson LG, ed. *Physiology of the Human Kidney*. New York: Grune & Stratton; 1969, with permission.)

measured values of GFR are typically adjusted for body size (surface area) and are traditionally compared to normative values for age and gender (Fig. 9.5).[16] Even after elimination of these sources of variation, important variability remains. A compilation of inulin clearance measurements in hydrated young adults (adjusted to a standard body surface area of 1.73 m^2) shows the mean value in men to be 131 mL per minute with a coefficient of variation (CV) (defined as the standard deviation divided by the mean) of 18%, and the mean value in women to be 120 mL per minute, with a CV of 14%.[15,16] The following sections discuss causes of normal variation. These same factors also contribute to variation in GFR in patients with kidney disease.

Age, Sex, Body Size, and Ethnicity. The surface area adjustment was first introduced to minimize variability in urea clearance results among normal adults and children.[17–19] Based on the relationship of GFR to glomerular surface area, it is not surprising that the level of GFR is related to kidney size, which in turn, is related to body surface area and metabolic activity.[20] Measured values for GFR are conventionally factored by 1.73 m^2, the mean surface area of men and women 25 years of age. Nonetheless, as described earlier, surface-area adjusted values for GFR are approximately 8% higher in young men than in women of the same age.

Glomerular tuft volume, renal size, and GFR increase during growth and development. The surface area adjustment is not appropriate for newborns, whose adjusted GFR is less than 50% of the value achieved at approximately 1 year of age.[21,22] More recent studies strongly suggest that in newborns, GFR should be expressed in mL/min/kg, with the normal value being 0.6 to 1.6 mL/min/kg. Such an approach reduces the apparent variation in measured GFR more than 10-fold.[23] Beyond age 1 to 2 years, however, GFR values in normal children, adjusted to 1.73 m^2, are the same as those for young adults.

The appropriateness of the surface area correction in obesity remains controversial.[24] Because adipose tissue is less metabolically active than lean body mass, the physiologic matching of GFR to body surface area may not be the same in obese as in lean individuals. There are few data to relate measured GFR to body size, metabolic activity, and risks for development of kidney disease in obesity, leaving many important questions unanswered.[25] Are estimates of body surface area from height and weight as accurate in obese as in lean individuals? Does GFR increase with weight gain in proportion to body surface area? If so, is the resulting hyperfiltration associated with increased risk for development of kidney disease, as hypothesized in other conditions with hyperfiltration, such as diabetes? If so, indexing GFR to body surface area in obesity may obscure detection of an important marker of disease. Cross-sectional and longitudinal studies of measured GFR in obesity, in association with measures of body size and metabolic activity, and markers of kidney damage are necessary to answer these questions.[24]

Most studies of measured GFR in populations without kidney disease have been conducted in North America or

Europe, so data on nonwhite races and other ethnicities is limited. Reports on small to moderate numbers of subjects have suggested a lower average value,[26,27] but these studies are somewhat limited by differences in GFR measurement methods and by incomplete ascertainment of protein intake (see below). A more recent report from a representative population in Pakistan suggests mean values of GFR in young adults only slightly below those in whites, with similar age-related decline.[28]

In older studies, both cross-sectional and longitudinal studies in normal men demonstrate an age-related decline in GFR of approximately 10 mL/min/1.73 m^2 per decade after the age of 30 years.[16,29–31] Recent studies in the general population have not been performed, but studies in kidney donors demonstrated a 4 mL/min/1.73m^2 lower measured GFR per decade up to the age of 45 years and a 7.5 mL/min/1.73m^2 lower measured GFR per decade thereafter.[32] Thus, using the data from the general population, during the 50 years from age 30 to 80, GFR declines by almost 40% from approximately 130 to 80 mL/min/1.73 m^2. Cross-sectional studies in normal women indicate roughly similar results, but comparable longitudinal studies have not been performed and there may be subtle differences related to effects of hormones, pregnancy, and propensity toward illnesses that impact the kidney. This age-related decline in GFR is consistent with the anatomic observation that the number of glomeruli in the normal human kidney declines with age; in the sixth and seventh decades, the number of glomeruli is less than one-half the number present in young adults.[4,33] The cause of age-related decline in GFR is not completely understood, but progressive glomerular sclerosis, independent of traditional kidney disease risk factors, likely contributes to the loss of glomeruli.[34,35] Recent epidemiologic studies demonstrate that this decline in GFR is associated with increased risk for all-cause and cardiovascular disease mortality as well as kidney disease, casting doubt on the traditional interpretation that it is normal.[36]

Pregnancy. Marked increases in GFR occur during pregnancy; elevations to an average as much as 50% occur during the first trimester, and these high levels persist until shortly after term.[37–40] These increments in GFR are associated with an increase in renal plasma flow and relatively constant filtration fraction throughout most of pregnancy, reflecting hemodynamic consequences of widespread vasodilatation. Late in pregnancy, it appears that hyperfiltration becomes dependent on reduced plasma oncotic pressure. This change persists in the very early postpartum period, but the GFR returns to normal in the first 4 to 8 weeks following the end of pregnancy.[40,41]

Interestingly, pregnancy-induced hyperfiltration also occurs in women with preexisting chronic kidney disease.[42] This observation suggests that the physiologic vasodilatation of pregnancy can further augment the single-nephron hyperperfusion and hyperfiltration associated with chronic kidney disease. However, this phenomenon may be restricted to women with only very mild reductions in GFR. Improvement of GFR was not observed in one study of 23 women with chronic kidney disease and pre-pregnancy serum creatinine levels greater than 1.4 mg/dL.[43]

Protein Intake. The effect of protein intake to modulate GFR in experimental animals was recognized 70 to 80 years ago.[44,45] It is now clear that these effects occur in humans, although the magnitude of the effect varies widely among studies.[46] Important causes of variation include the duration of protein feeding (habitual protein intake vs. meat meals or amino acid infusions), the type of protein (animal vs. vegetable or soya protein sources; essential vs. nonessential amino acids), and the filtration marker used to measure GFR (inulin vs. creatinine).

In a classic study, Pullman et al.[47] placed healthy humans on low (0.1 to 0.4 g/kg/day), medium (1.0 to 1.4 g/kg/day), and high (2.6 g/kg/day) protein diets for 2 weeks. Compared to the low protein diet, inulin clearance increased after ingestion of the medium and high protein diets by 9% and 22%, respectively. These changes were accompanied by parallel changes in renal plasma flow, indicating a hemodynamic basis for the changes in GFR. A longer period of habituation may have greater effects on GFR. Similarly, in patients with chronic malnutrition, inulin clearance was 27% to 64% lower than after repletion of nutritional status,[48–51] and returned to near normal values only after 1 month of refeeding. In addition, malnourished patients had smaller kidneys, suggesting that differences in kidney function were due to structural as well as hemodynamic alterations.[48] Increases in GFR and kidney size in association with increased protein intake have been noted in diverse clinical circumstances, such as in patients receiving total parenteral nutrition and in insulin-dependent diabetic patients with poor metabolic control.[52] Some studies suggest a greater response to animal than vegetable protein in habitual diets as well as in response to protein loads.[53–55] A recent study assessing the impact of sustained high protein feeding demonstrated an increase in GFR in young subjects (24 ± 1 years old), but actually a small decrease in GFR in older subjects (70 ± 2 years old).[56]

After a meat meal, GFR, renal plasma flow, and splanchnic blood flow rise within an hour and remain elevated for several hours.[57] In humans, the increment in inulin clearance is about 10%,[58,59] and appears to be less than the increment in creatinine clearance.[46] Nonessential amino acids are more potent than essential amino acids in inducing the postprandial rise in GFR, and branched-chain amino acids appear to have little or no effect.

It had been proposed that protein-induced hyperfiltration represents "renal reserve capacity," which is lost prior to the reduction in baseline GFR associated with kidney disease.[60] However, it has now been shown conclusively that changes in GFR occur in response to changes in habitual protein intake or meat meals in patients with kidney disease and reduced GFR.[59–63] This is consistent

with studies in animals with experimental kidney diseases, which show that changes in protein intake further modulate the determinants of single-nephron GFR. In particular, a high protein diet raises the already increased glomerular plasma flow and transcapillary hydrostatic pressure gradient.[64,65] Thus, protein-induced hyperfiltration augments the hyperperfusion and hyperfiltration of chronic kidney disease.

Diurnal Variation. A normal diurnal variation in filtration rate occurs, with 10% higher values occurring in the afternoon than in the middle of the night.[66] In large part, the diurnal variation is thought to be related to variation in protein intake during the day.[16,60] Possibly, diurnal variation may also be related to transient reductions in GFR associated with exercise. Indeed, a decrease of 40% or more is seen with severe exertion.[16,67,68] However, diurnal variation is also observed in quadriplegics,[69] arguing against physical activity as the sole cause of diurnal variation. Possibly, diurnal variation may also reflect variation in hydration. GFR increases with overhydration and decreases with water restriction. However, the changes are small except when gross disturbances in fluid balance occur.

Antihypertensive Therapy. As a result of powerful mechanisms for autoregulation of renal hemodynamics (Chapter 3), the level of GFR remains relatively constant throughout a wide range of blood pressure. Nonetheless, antihypertensive therapy can be associated with reductions in GFR, due, in part, to the effect of lowering blood pressure and, in part, to specific effects of classes of antihypertensive agents. Indeed, marked reduction in GFR can complicate treatment in patients with severe hypertension and acute or chronic kidney disease,[70] which is an effect thought to be due to the loss or reset of autoregulation due to sclerosis of the renal vasculature from hypertensive injury.[71] In normal individuals and in patients with kidney disease, GFR is transiently reduced by a variety of antihypertensive agents, including diuretics, beta-blockers, central alpha-2 agonists, and peripheral alpha blockers.[72] In contrast, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcium channel blockers, and directly acting vasodilators do not regularly lower GFR in healthy subjects. A large study in patients with chronic kidney disease and well-controlled hypertension showed persistent small (less than 5 mL per minute), but significant, reductions in GFR associated with the use of ACE inhibitors as well as diuretics and beta-blockers.[73] In addition, after controlling for the effect of these classes of antihypertensive agents, a small effect of lowering blood pressure remained. Because the effects of the various classes of medications and of lowering blood pressure appear to be independent, a clinically significant reduction in GFR could occur in patients with chronic kidney disease undergoing treatment with multiple antihypertensive agents.

Measurement of the Glomerular Filtration Rate

Clearance. As mentioned earlier, the GFR is assessed from the clearance of filtration markers, substances excreted by glomerular filtration that can be used to assess the GFR. The "gold standard" for the measurement of GFR is the urinary clearance of inulin. The term clearance was introduced into kidney physiology by Van Slyke and his colleagues in reference to studies of the excretion of urea in 1929.[18] Two years later, Jollife and Smith extended the use of the term to the excretion of creatinine and later to the excretion of many other substances.[74] In the many decades since these pioneering studies, the concept of clearance has maintained its primacy as the cornerstone of our understanding of the measurement of glomerular filtration.

The clearance of a substance is defined as the rate at which it is cleared from the plasma per unit concentration. The clearance of substance "x" (C_x) is given in the following equation:

$$C_x = A_x / P_x \tag{3}$$

where A_x is the amount of x eliminated from the plasma and P_x is the average plasma concentration. Hence, C_x is expressed in units of volume per time. The value for clearance does not represent an actual volume, but a virtual volume of plasma that is completely cleared of the substance per unit of time, without reference to the route of elimination. The value for clearance is related to the efficiency of elimination: the greater the rate of elimination, the higher the clearance.

Relationship of Glomerular Filtration Rate to Urinary Clearance. For a substance that is cleared by urinary excretion, the clearance formula may be rewritten as follows:

$$C_x = U_x \times V / P_x \tag{4}$$

where U_x is the urinary concentration of x and V is the urine flow rate. The term $U_x \times V$ is defined as the urinary excretion rate of x. If substance x is filtered freely across the glomerular capillary walls and excreted only by glomerular filtration, then the rate of filtration is equal to the rate of urinary excretion:

$$GFR \times P_x = U_x \times V \tag{5}$$

where the term $GFR \times P_x$ is defined as the filtered load of x. By substitution into Equation 9.2:

$$C_x = GFR \tag{6}$$

Hence, substance x would be defined as an "ideal filtration marker" whose urinary clearance could be used to measure GFR.

However, if substance x is also reabsorbed or secreted by the renal tubules, then the following equations apply:

$$U_x \times V = GFR \times P_x - TR_x + TS_x \quad (7)$$

$$GFR = (U_x \times V - TR_x + TS_x) / P_x \quad (8)$$

$$GFR = C_x - TR_x / P_x + TS_x / P_x \quad (9)$$

where TR_x and TS_x are the rates of tubular reabsorption and secretion of x, respectively, and TR_x/P_x and TS_x/P_x are the clearances of substance x due to reabsorption (C_{TRx}) and secretion (C_{TSx}), respectively. In this case, the rate of urinary excretion ($U_x \times V$) does not equal the filtered load ($GFR \times P_x$), and clearance does not equal GFR. Therefore, the value for urinary clearance of x (C_x) is determined not only by the rate of glomerular filtration, but also by the mechanism of excretion by the kidney. For substances that are filtered and secreted, clearance exceeds GFR, and for substances that are filtered and reabsorbed, clearance is less than GFR.

Inulin Clearance. The requirements for an ideal filtration marker, as outlined by Smith,[15] include the following:

1. It is freely filtered at the glomerulus. It passes from the glomerular capillary blood into Bowman's space unhindered by its size, charge, or binding to plasma proteins.
2. It is not altered during its passage through the nephron. It is not reabsorbed, secreted, synthesized, or metabolized by the tubules.
3. It is physiologically inert and does not alter the function of the kidney.

Inulin, a 5,200-dalton, inert, uncharged polymer of fructose, meets these criteria, and it remains the standard for experimental and clinical measurement of GFR.[15,75,76] The conclusion that inulin is freely filtered and is neither secreted nor reabsorbed in the normal kidney was originally based on indirect evidence, but a large body of direct micropuncture observations have verified this assumption.[11,77–80] Similar evidence is not available, however, in all experimental kidney diseases. For example, in several models of acute kidney failure with extensive tubular basement membrane damage, leakage of inulin across the tubules is readily demonstrated.[81,82] In such situations, of course, the urinary excretion of inulin is less than the filtered load, and inulin clearance is less than GFR.

Although the measurement of inulin clearance is a highly accurate and reproducible means of estimating GFR, there are several disadvantages that make it impractical for clinical use. First, the classical method includes measurement under fasting conditions in the morning, a continuous intravenous infusion, multiple clearance periods requiring repetitive blood and urine collections over 3 hours, oral water loading to stimulate diuresis, bladder catheterization to assure complete urine collection, and careful timing of blood sampling at the midpoint of the urine collection. Period-to-period variability in GFR (intratest variation; expressed as CV) is approximately 10%. Intratest variation may reflect incomplete bladder emptying and is often used to judge the quality of a urinary clearance study.[15] However, one recent study has shown that the precision of GFR determinations is only weakly affected by intratest variability,[83] probably because averaging over several clearance periods minimizes error due to incomplete bladder emptying. In a study in normal individuals using the classical method of inulin clearance, the CV for repeated measurements within an individual (intertest CV) was 7.5%.[84] These estimates of measurement error are probably lower than would be observed in most clinical settings. Second, inulin is difficult to dissolve in aqueous solutions, difficult to measure, and is in short supply. Because of these disadvantages, clinical assessment of GFR generally utilizes other filtration markers and clearance methods.

Urinary Clearance of Endogenous Filtration Markers. In principle, the simplest alternative to inulin clearance would be the urinary clearance of an endogenous filtration marker. The advantage of this method is that clearance can be computed from urine collections and blood sampling under usual clinical conditions without the need for administration of an exogenous marker. Indeed, this method is widely used for measuring creatinine clearance, as discussed later. The most common method is to collect a 24-hour urine collection and a single serum measurement, assuming a steady state. The urine collection is performed at home. At the onset of the collection period, the patient is instructed to empty the bladder and discard the urine. During the collection period, all subsequent urine is saved. At the end of the period, the patient is asked to void completely and to add this last specimen to the urine collection. Shortly thereafter, the blood sample is obtained.

Unfortunately, the accuracy of this method is limited because neither creatinine nor any other known endogenous filtration marker meets all the criteria for an ideal filtration marker and because timed urine collections under usual clinical conditions are notoriously inaccurate. Errors in timing or completeness can result from misunderstanding by the patient or personnel of the instructions, such as omitting urine specimens during the interval or incompletely emptying the bladder at the start or end of the collection period. At first glance, it might appear that the use of short urine collection intervals, such as 1-hour, carried out under close supervision by trained personnel might overcome these difficulties. However, using a shorter collection period, the small errors due to incomplete bladder emptying would have a greater impact on the estimate of the urine volume and hence the urine flow rate. Indeed, the 1-hour technique has been largely abandoned because the extra effort and personnel required do not significantly improve the accuracy as compared to the 24-hour

clearance.[85] However, averaging the results of three to four 30-minute collection periods does significantly improve the accuracy, probably due to cancellation of errors from incomplete bladder emptying.[86]

A similar method can be used to compute clearance for patients who are not in a steady state balance by obtaining additional blood samples during the urine collection to estimate the average serum concentration. The most common strategies are to collect blood at the mid-point of the urine collection, or at the beginning and end of the urine collection, and to average the serum concentrations.

Alternative Clearance Methods and Exogenous Filtration Markers. All alternative clearance methods have been designed to facilitate GFR measurement; however, all have limitations that should be understood for proper interpretation. Table 9.2 summarizes the strengths and limitations of these alternative clearance methods and markers, as well as the gold standard method.[75,87–89]

Changes to the clearance method include substitution of bolus intravenous or subcutaneous injection for a constant intravenous infusion and use of plasma clearance techniques to eliminate the need for urine collection. With a bolus injection, the pattern of decline in serum levels is more accurately modeled as an exponential rather than linear of decline.[83] In the bolus subcutaneous technique, the marker substance (e.g., ^{125}I-iothalamate, ^{51}Cr-EDTA) can be given with a small dose of aqueous epinephrine to slow its release into the circulation, providing fairly constant plasma levels.[90,91] More recently subcutaneous continuous infusions have been used.[92]

Plasma clearance is computed from Equation 9.3 using either the entire area or a one-compartment or two-compartment model of the plasma disappearance plot.[93–95] There are several caveats. First, a relatively long time (3 to 5 hours) is required to accurately determine the declining plasma concentration of the marker, with longer times for people with reduced GFR. Second, filtration markers utilized for this method must meet an additional criterion of rapid equilibration with the extracellular volume, and inulin is therefore not appropriate for use.[96] Third, for some markers, simultaneous assessment of plasma and urinary clearance of a filtration marker typically yields a higher level for plasma clearance, presumably due to extrarenal excretion of the marker.[97,98] This underestimation is more apparent at a lower GFR. Fourth, plasma clearance overestimates GFR in patients with moderate to severe edema probably because of the larger than expected volume of distribution and lower than expected plasma levels of the marker.[99]

Alternative exogenous markers include radioisotope-linked markers ^{125}I-iothalamate, ^{51}Cr-ethylene diamine tetraacetic acid (EDTA), and its analogue, ^{99m}Tc-diethylene triamine pentaacetic acid (DTPA), that can be readily and inexpensively measured using radioactive counters; and nonradioactive markers iohexol and iothalamate that can be measured by X-ray fluorescence and high performance liquid chromatography (HPLC) methods. The advantage of the latter two is the avoidance of radiation exposure; however, the assay methods are more expensive and generally performed in specialized laboratories. All other filtration markers deviate from ideal behavior. Overall, there is suggestion by some but not all studies that iothalamate clearance results in a higher GFR than inulin clearance, presumably due to secretion of iothalamate by the tubules. Other studies suggest that iohexol clearance may underestimate inulin clearance. DTPA readily dissociates from its radioactive tracer, allowing binding of the tracer to plasma proteins leading to retention of the tracer and underestimation of GFR.

GFR can also by measured by counting of a radioactive exogenous filtration marker over the kidneys and bladder. This technique can be combined with renal imaging, usually using ^{99m}Tc-DTPA, and is useful for determination of split kidney function.[88,100] Several studies indicate poor correlation of ^{99m}Tc-DTPA dynamic renal imaging with simultaneous urinary or plasma clearance, reflecting both bias and imprecision, and lesser accuracy than estimated GFR.[101–103] Currently, magnetic resonance imaging (MRI) is being investigated for measurement of GFR. Many protocols are in use which will require consolidation before introduction into clinical practice.[104,105]

Because of these limitations, all values for measured GFR contain an element of error, which differentiates them from true GFR. As such there is variability in the literature as to how each of these markers and methods compare to the gold standard method.

Estimation of the Glomerular Filtration Rate

Relationship of Glomerular Filtration Rate to the Plasma Solute Concentration

The plasma level of a solute (P_x) is determined by its generation (G_x) from cells and diet, extrarenal elimination (E_x) by gut and liver, and urinary excretion ($U_x \times V$) by the kidney (Fig. 9.6).[106] Physiologic processes other than GFR that affect the plasma level of a solute (P_x) are termed "non-GFR determinants." The following discussion relates concepts of plasma levels of filtration markers, their non-GFR determinants, and the physiologic basis for GFR estimating equations.

An important concept for this discussion is the steady state of solute balance. A steady state with regard to substance x is achieved when the rate of generation in body fluids (either from endogenous production or exogenous intake) is constant and equal to its rate of elimination from body fluids (either from excretion or metabolism). Therefore, in the steady state, the plasma concentration of substance x is constant:

$$G_x - E_x = U_x \times V \quad (10)$$

where G_x and E_x are the rates of generation and extra-renal elimination of x. If the substance is excreted only in the

9.2 Strengths and Limitations of Glomerular Filtration Rate Measurement Methods and Markers

Approach	Strengths	Limitations
Methods		
Urinary Clearance		
Bladder catheter and continuous intravenous infusion of marker	■ Gold standard method	■ Invasive
Spontaneous bladder emptying	■ Patient comfort ■ Less invasive	■ Possibility of incomplete bladder emptying ■ Low flow rates in people with low levels of GFR
Bolus administration of marker	■ Shorter duration	■ Rapidly declining plasma levels at high levels of GFR ■ Longer equilibration time in extracellular volume expansion
24-hour urinary collection		■ Cumbersome ■ Prone to error
Plasma clearance	■ No urine collection required ■ Potential for increased precision	■ Overestimation of GFR in extracellular volume expansion ■ Inaccurate values with one-sample technique, particularly at lower GFR levels ■ Longer duration of plasma sampling required for low GFR
Nuclear imaging	■ No urine collection or repeated blood samples required ■ Relatively short duration	■ Less accurate
Markers*		
Inulin	■ Gold standard ■ No side effects	■ Expensive ■ Difficult to dissolve and maintain into solution ■ Short supply
Creatinine	■ Endogenous marker, no need for administration ■ Assay available in all clinical laboratories	■ Secretion which can vary among and within individuals
Iothalamate	■ Inexpensive ■ Long half-life	■ Probable tubular secretion ■ Requirement for storage, administration, and disposal of radioactive substances when iothalamate-125 used as tracer ■ Use of nonradioactive iothalamate requires expensive assay ■ Cannot be used in patients with allergies to iodine
Iohexol	■ Not radioactive ■ Inexpensive ■ Sensitive assay allows for low dose	■ Possible tubular reabsorption or protein binding ■ Use of low doses requires expensive assay ■ Cannot be used in patients with allergies to iodine ■ Nephrotoxicity and risk for allergic reactions at high doses

(continued)

9.2 Strengths and Limitations of Glomerular Filtration Rate Measurement Methods and Markers (continued)

Approach	Strengths	Limitations
EDTA	■ Widely available in Europe	■ Probable tubular reabsorption ■ Requirement for storage, administration, and disposal of radioactive substances when ^{51}Cr is used as tracer
DTPA	■ Widely available in the United States ■ New sensitive and easy to use assay for gadolinium	■ Requirement for storage, administration, and disposal of radioactive substances when ^{99m}Tc used as tracer ■ Requires standardization for ^{99m}Tc ■ Dissociation and protein binding of ^{99m}Tc ■ Concern for NSF when gadolinium is used as the tracer

^{51}Cr, chromium-51; ^{99m}Tc, technetium-99m; DTPA, diethylene triamine pentaacetic acid; EDTA, Ethylenediaminetetraacetic acid; GFR, glomerular filtration rate; NSF, nephrogenic systemic fibrosis.

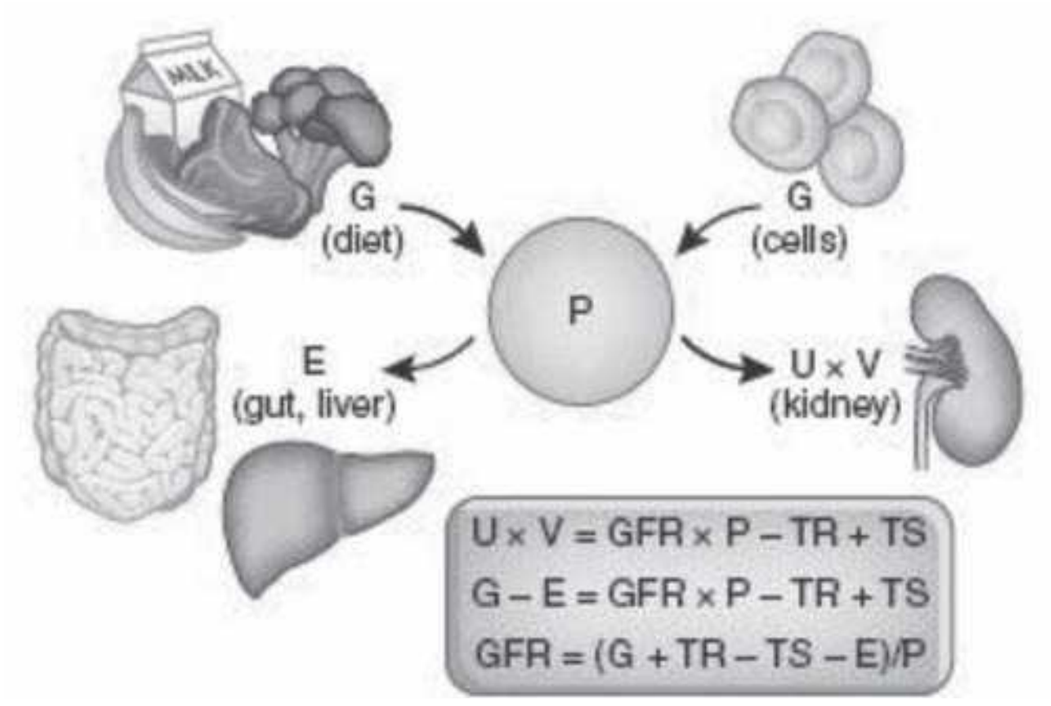

FIGURE 9.6 Determinants of the serum level of endogenous filtration markers. The plasma level (P) of an endogenous filtration marker is determined by its generation (G) from cells and diet, extrarenal elimination (E) by gut and liver, and urinary excretion (UV) by the kidney. Urinary excretion is the sum of filtered load (GFR × P), tubular secretion (TS), and reabsorption (TR). In the steady state, urinary excretion equals generation and extrarenal elimination. By substitution and rearrangement, GFR can be expressed as the ratio of the non-GFR determinants (G, TS, TR, and E) to the plasma level. (Reproduced from Stevens LA, Levey AS. Measured GFR as a confirmatory test for estimated GFR. *J Am Soc Nephrol.* 2009;20(11):2305–2313.)

urine, in the steady state, the rate of generation can be assessed from the urinary excretion rate.

$$G_x = U_x \times V \quad (11)$$

By rearrangement of Equations 9.7 and 9.10 and solving for P_x, we obtain the following:

$$P_x = (G_x - TR_x + TS_x - E_x) / GFR \quad (12)$$

Hence, P_x is inversely related to GFR, and directly related to its non-GFR determinants.

$$GFR = (G_x - TR_x + TS_x - E_x) / P_x \quad (13)$$

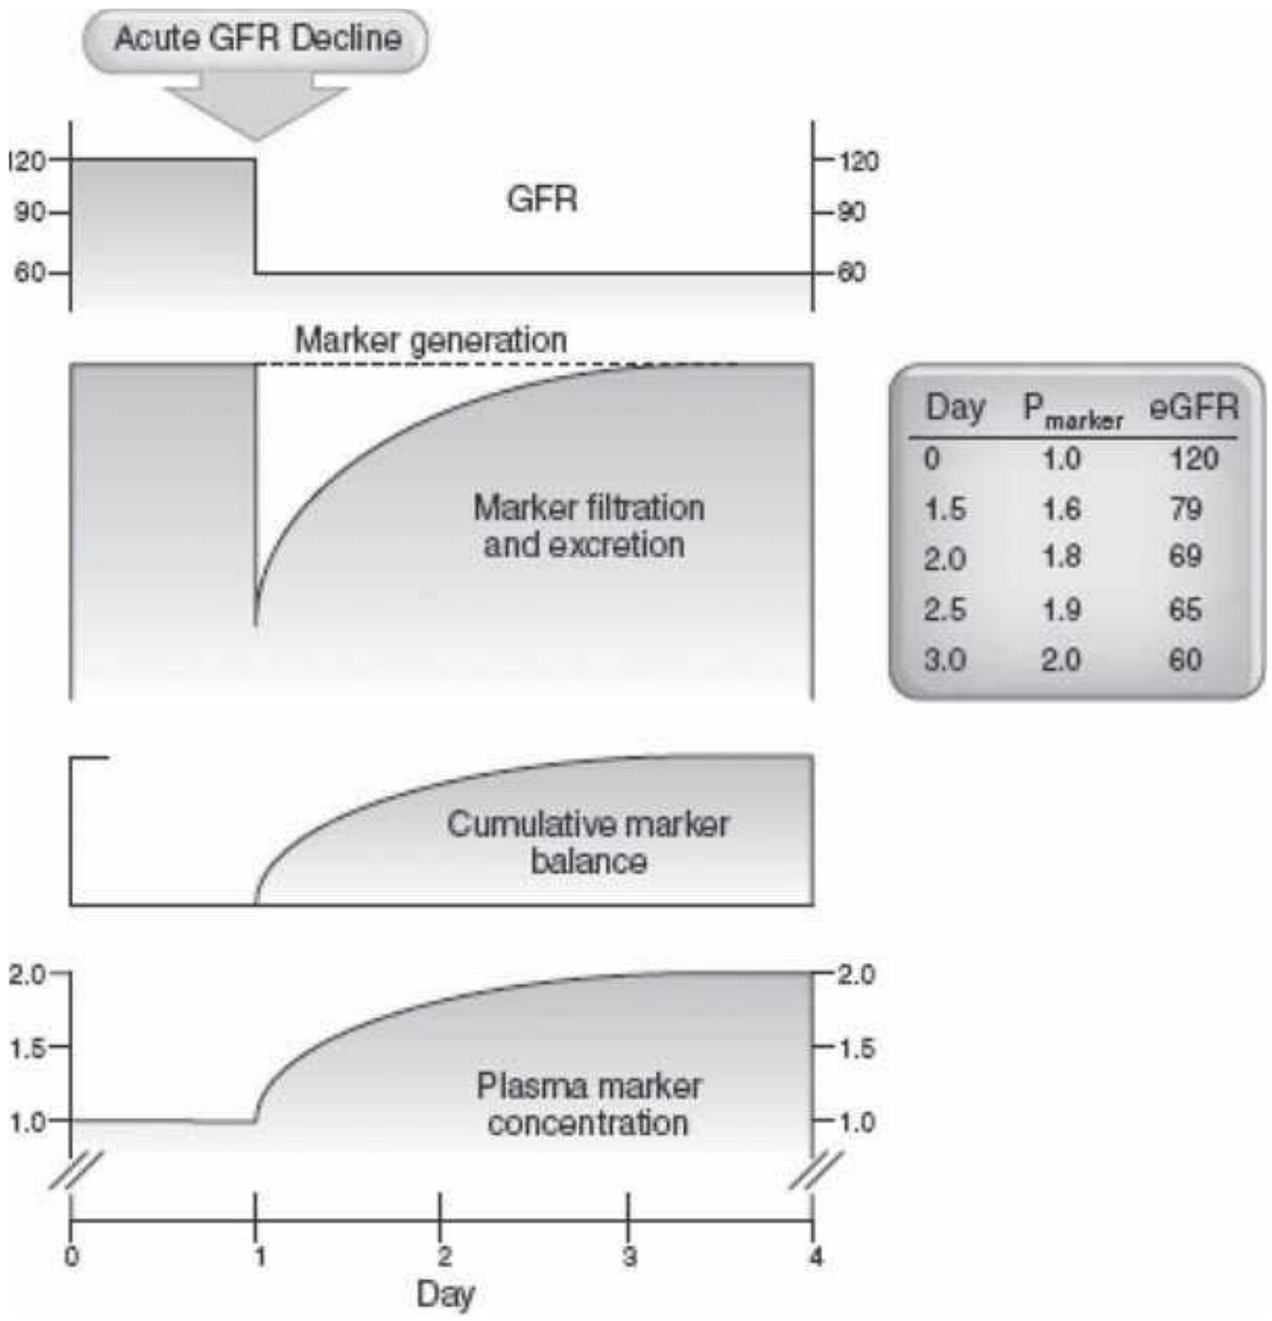
For a substance that is eliminated entirely by glomerular filtration, this relationship simplifies to the following.

$$GFR = G_x / P_x \quad (14)$$

If the rate of generation is constant across individuals and over time, the level of GFR can be estimated by the plasma level and proportionality constant.

$$GFR = k / P_x \quad (15)$$

Figure 9.7 shows the hypothetical change in levels of a filtration marker GFR after an acute change in GFR.[106,107] After an acute GFR decline, generation of the marker is unchanged, but filtration and excretion are reduced, resulting in retention of the marker (a rising positive balance) and a rising plasma level (non–steady state). Although GFR remains reduced, the rise in plasma level leads to an increase



Day	P_{marker}	eGFR
0	1.0	120
1.5	1.6	79
2.0	1.8	69
2.5	1.9	65
3.0	2.0	60

FIGURE 9.7 Effect of an acute glomerular filtration rate (GFR) decline on generation, filtration, excretion, balance, and serum level of endogenous filtration markers. GFR is expressed in units of milliliter per minute per 1.73 m^2. Tubular secretion and reabsorption and extrarenal elimination are assumed to be zero. (Reproduced with permission from Stevens LA, Levey AS. Measured GFR as a confirmatory test for estimated GFR. *J Am Soc Nephrol.* 2009;20(11):2305–2313. Modified from Kassirer JP. Clinical evaluation of kidney function—glomerular function. *N Engl J Med.* 1971;285:385–389.)

in filtered load ($GFR \times P_x$) until it equals generation (G_x). At that time, cumulative balance and the plasma level plateau at a new steady state. In this example, a halving of GFR is associated with a doubling of the plasma concentration of the marker.

Physiologic Basis of Glomerular Filtration Rate Estimating Equations

This section discusses general principles of GFR estimating equations. Specific estimating equations for GFR are discussed in more detail later in the chapter. Estimating GFR from the plasma level of endogenous filtration markers has the advantages of eliminating the need for infusion of an exogenous filtration marker and urine collections. Unfortunately, the plasma levels of all endogenous filtration markers are influenced by physiologic processes other than GFR, these processes are generally not measured in clinical practice, and clinical conditions affecting these physiologic processes are not known for all filtration markers.

Estimating equations for GFR are regression equations that estimate measured GFR from plasma levels of endogenous filtration markers and demographic and clinical variables as observed surrogates for the unmeasured physiologic processes (non-GFR determinants).[108] By definition, an estimating equation provides a more accurate estimate of measured GFR than the plasma concentration alone. For example, the equation below shows the hypothetical relationship of numerical values for demographic and clinical variables X, Y, and Z to generation of the filtration marker (G_x).

$$G_x \sim X + Y + Z \tag{16}$$

Therefore, by substitution into Equation 9.14

$$eGFR = (bX + cY + dZ) / aP_x + \varepsilon \tag{17}$$

where eGFR is estimated GFR and a, b, c, and d are regression coefficients relating P_x and other variables to measured GFR, and ε is the error based on uncertainty due to measurement, biologic variability, and statistical techniques used to derive the coefficients. Estimating equations for GFR are often expressed on the logarithmic scale and, therefore, have the appearance of

$$\log eGFR = aP_x + bX + cY + dZ + \varepsilon \tag{18}$$

$$eGFR = [P_x]^a \times X^b \times Y^c \times Z^d \times \varepsilon \tag{19}$$

where a is a negative coefficient to account for the inverse relationship between GFR and the plasma level of the filtration marker.

GFR estimating equations are derived in the steady state; hence, GFR estimates are more accurate in the steady state than in the non–steady state. In the non–steady state (Fig. 9.7), the rate and direction of change in the level of the

filtration marker and eGFR are affected by the magnitude of change in GFR, but also by the non-GFR determinants and the volume of distribution of the filtration marker.[109] Hence, the plasma level of the filtration marker reflects the magnitude and direction of the change in GFR but does not accurately reflect the level of GFR. After a fall in GFR, the decline in eGFR is less than the decline in GFR, and eGFR thus exceeds GFR. Conversely, after a rise in GFR, the rise in eGFR is less than the rise in GFR, and eGFR is thus less than GFR. As the plasma level approaches the new steady state, eGFR approaches GFR and the level of the filtration marker varies inversely with GFR.

Development and Validation of Glomerular Filtration Rate Estimating Equations

Development and validation of GFR estimating equations should be undertaken with appropriate attention to epidemiologic and statistical techniques. In general, a large sample size (n > 500 subjects) with a wide range of GFR is required for developing a GFR estimating equation. It is important to include both men and women across a wide age range and from a variety of racial and ethnic groups for international use. Validation should be undertaken in a separate population, selected according to similar criteria and with similar clinical and demographic characteristics to the development population. GFR should be measured in both populations using either inulin or an exogenous filtration marker and clearance method validated against inulin clearance. Plasma or serum concentrations of the endogenous filtration markers should be measured using assays calibrated to reference standard. The development process should proceed according to a protocol for introduction and selection of important covariates that are hypothesized to reflect non-GFR determinants of the filtration markers. The validation process should systematically evaluate bias, precision, and accuracy in the overall validation population and in clinically relevant subgroups (Table 9.3).[110] Bias reflects a systematic difference in performance, generally due to differences between the development and validation population in measurement methods for GFR, assays for filtration markers, or selection of study subjects. Imprecision reflects random error, and is generally greater at higher GFR values, due to greater GFR measurement error and greater variation in non-GFR determinants, than at lower GFR. In principle, the use of multiple filtration markers can improve precision by cancelling errors due to variation in non-GFR determinants.

Creatinine as a Filtration Marker

Creatinine is the most frequently measured endogenous filtration marker in routine clinical practice. It has been estimated that serum creatinine is measured more than 280 million times per year in the United States.[111] The classical assay was first introduced more than 125 years ago by Jaffé.[112] The normal level of GFR is sufficient to maintain a low concentration of creatinine in serum, approximately 0.7 to 0.9 mg per dl in healthy young people. Reference ranges cited by clinical laboratories vary because of variation in serum creatinine assays. More importantly, reference ranges are difficult to interpret because of variation among individuals in non-GFR determinants (Table 9.4)[113]; serum creatinine may not rise above the upper limit of the reference range unless GFR is less than 60 mL/min/1.73 m^2. Recent interest in more accurate GFR estimation has led to worldwide standardization of serum creatinine assays and reporting of estimated GFR when serum creatinine is measured.[114] Using eGFR overcomes some of these limitations, but imprecision remains, especially at higher GFR.

9.3 Metrics for Evaluation of Glomerular Filtration Rate Estimating Equations

Criteria	Metric	Definition
Bias	Median difference	mGFR − eGFR
	Median percent difference	(mGFR − eGFR)/mGFR * 100
Precision	IQR difference	Interquartile range of (mGFR − eGFR)
	IQR % difference	Interquartile range of [(mGFR − eGFR)/m GFR] * 100
Accuracy	Median absolute difference	Median of the absolute value of eGFR − mGFR
	P_{30}	Percent of estimates within 30% of measured GFR
	RMSE	Square root of mean $(\log mGFR - \log eGFR)^2$

*Measures of accuracy assess precision when bias is 0 (development datasets).
IQR, interquartile range; eGFR, estimated glomerular filtration rate; mGFR, measured glomerular filtration rate; RMSE, root-mean-square deviation.

9.4 Clinical Conditions that Cause Errors in the Estimation of GFR from Measurement of Creatinine Clearance or Serum Creatinine

Condition	Effect on C_{cr}	Effect on P_{cr}	Comment
Plasma Ketosis	None	Increase	Interference with the picric acid assay for creatinine
Medications			
Certain cephalosporins or flucytosine	None	Increase	Interference with the picric acid and iminohydrolase assays for creatinine, respectively
Cimetidine or trimethoprim	Decrease	Increase	Inhibition of tubular secretion of creatinine
Dietary Protein			
Ingesting cooked meat	Increase	Increase	Transient increase in GFR and creatinine generation
Restriction of dietary protein	Decrease	Decrease	Sustained decrease in GFR and creatinine generation
Muscle Change			
Vigorous prolonged exercise	Decrease	Increase	Transient decrease in GFR and increase in muscle creatinine generation
Muscle wasting	None	Decrease	Decrease in muscle creatinine generation
Muscle growth	None	Decrease	Increase in muscle creatinine generation
Kidney Disease[a]	Increase	Decrease	Decrease in GFR, but stimulation of tubular secretion of creatinine, and possible decrease in creatinine generation

[a]Effects on C_{cr} and P_{cr} relative to effects on GFR (i.e., C_{cr} is higher than expected and P_{cr} is lower than expected for the reduction in GFR; see text).
C_{cr}, creatinine clearance; P_{cr}, serum creatinine; GFR, glomerular filtration rate.

Kidney Handling of Creatinine

Creatinine is small (molecular weight 113 daltons, molecular radius 0.3 nm) and not bound to plasma proteins; hence, it passes freely through the glomerular capillary wall into the Bowman's space. However, it is also secreted by the tubules, probably by the same pathway used for other organic cations.[115] Therefore, creatinine is excreted not only by glomerular filtration, but also by tubular secretion.

$$U_{cr} \times V = GFR \times S_{cr} + TS_{cr} \quad (20)$$

where Scr is serum creatinine concentration (virtually identical to plasma concentration) and TScr is the rate of tubular secretion. Consequently, it is not an ideal filtration marker. The true relationship between creatinine clearance and GFR is as follows

$$C_{cr} = GFR + TS_{cr} / S_{cr} \quad (21)$$

where TS_{cr} / P_{cr} is the clearance of creatinine due to tubular secretion (C_{TScr}). Thus, at all levels of GFR, creatinine clearance exceeds GFR by an amount equal to the clearance of creatinine due to tubular secretion.

Tubular Secretion of Creatinine. Creatinine secretion was recognized long ago,[116] and has been reemphasized in the modern era.[117] It was not initially recognized as a limitation to the estimation of GFR from creatinine clearance; the major reason was related to the method of measurement of serum creatinine used in the past. As discussed later, the classical method, the Jaffé reaction, used a colorimetric reaction that detects both creatinine and a number of noncreatinine chromogens in serum, but not in urine. Thus, the serum "chromogen creatinine" exceeded the true serum creatinine measured by more accurate methods, and using the "chromogen creatinine" to calculate creatinine clearance led to a systematic underestimation of the true value. On the other hand, because of tubular secretion, the true creatinine clearance exceeded GFR. The net result was that estimated creatinine clearance deviated little from GFR in normal individuals. With the introduction of more accurate methods to measure serum creatinine, the discrepancy between creatinine clearance and GFR became more apparent.

Using older assays, the level of serum creatinine in the low range is overestimated, and average creatinine secretion in normal individuals accounted for 5% to 10% of the excreted creatinine. Hence, creatinine clearance exceeded GFR by approximately 10 mL/min/1.73 m^2. However, with the newer assays, normal serum levels are lower, so creatinine secretion can exceed GFR by much larger amounts. The magnitude of this overestimation has not been well quantified. Most studies find proportionately greater creatinine secretion in patients with reduced GFR, which leads to a clear disparity between creatinine clearance and GFR.[118] Moreover, the magnitude of creatinine secretion is variable among individuals and over time. Only some of the factors responsible for this variability are known. The level of GFR appears to be a major determinant.[117] The mean difference between C_{cr} and GFR (the clearance due to tubular secretion) within the range of GFR from 40 to 80 mL/min/1.73 m^2 is approximately 35 mL/min/1.73 m^2 and lower at lower GFR.

Other factors determining the magnitude of creatinine secretion are the type of kidney disease and the quantity of dietary protein intake. Patients with polycystic kidney disease and tubulointerstitial diseases have lower mean values for creatinine clearance due to secretion than patients with glomerular diseases and other diseases,[61] perhaps reflecting more serious tubular injury and limitation of tubular secretion. On the other hand, higher protein intake is associated with higher mean values for creatinine clearance due to secretion,[61] perhaps due to stimulation of secretion due to protein ingestion. This finding may account for the greater effect of protein loads on creatinine clearance compared to GFR.[46]

Several commonly used medications, including cimetidine and trimethoprim,[119] competitively inhibit creatinine secretion, thereby reducing creatinine clearance and raising the serum creatinine concentration, despite no effect on GFR. Clinically, it can be difficult to distinguish a rise in serum creatinine due to drug-induced inhibition of creatinine secretion from a decline in GFR. A clue to inhibition of creatinine secretion is that urea clearance and blood urea nitrogen concentration are unchanged.

Some investigators have proposed using cimetidine to inhibit creatinine secretion during creatinine clearance measurements, thereby permitting a more accurate assessment of GFR.[120,121] However, complete inhibition of creatinine secretion may require prolonged high dose cimetidine therapy.[122] Variable inhibition of tubular secretion by cimetidine makes interpretation of the test difficult.

Tubular Reabsorption of Creatinine. To a limited extent, creatinine may also be reabsorbed by the tubules. Studies in normal animals and humans with very low urine flow rates,[123–125] and in patients with decompensated congestive heart failure or uncontrolled diabetes mellitus[126–130] have demonstrated a ratio of clearances of creatinine and inulin <1.0. Reabsorption of creatinine may be due to its passive back-diffusion from the lumen to blood because of the high tubular creatinine concentration that occurs during low urine flow. Based on the clearance ratios observed in these studies, the maximum effect of creatinine reabsorption probably would be a 5% to 10% decrease in creatinine clearance.

Creatinine Metabolism

Generation. Creatinine is distributed throughout total body water. It is generated in muscle from the nonenzymatic conversion of creatine and phosphocreatine (Fig. 9.8).[131] Approximately 98% of the total creatine pool is contained in muscle and about 1.6% to 1.7% per day is converted to creatinine.[131] For example, in an individual with a total creatine pool of 100 g, creatinine generation would be 1.6 to 1.7 g per day. Thus, creatinine generation is proportional to muscle mass, which can be estimated from age, gender, and body size (Fig. 9.9).[132] Based on five reports containing data on 1,100 healthy individuals and patients without renal or hepatic disease, Walser derived the following equations to estimate urine creatinine excretion[133]:

$$eU_{cr} \times V = 28.2 - 0.172 \times \text{age (men)} \quad (22)$$

$$eU_{cr} \times V = 21.9 - 0.115 \times \text{age (women)} \quad (23)$$

where creatinine excretion (given in mg/kg/day) is assumed to equal creatinine generation and age is given in years. These equations do not take into account racial and ethnic differences in muscle mass. African American men and women have higher muscle mass and, consequently, higher creatinine excretion than their European American counterparts.[134–138]

Recently, Ix and colleagues derived equations in a pooled dataset of six studies of 2,466 black and white subjects with and without kidney disease and diabetes.[139] These equations were more accurate than those proposed by Walser and may be more generalizable.

$$\begin{aligned} eU_{cr} \times V = {} & 879.89 + 12.51 \times \text{weight (kg)} \\ & - 6.19 \times \text{age} + 34.51 \text{ (if black)} \\ & - 379.42 \text{ (if female)} \end{aligned} \quad (24)$$

$$\begin{aligned} eU_{cr} \times V = {} & 1115.89 + 11.97 \times \text{weight (kg)} \\ & - 5.83 \times \text{age} - 60.18 \\ & \times \text{phosphorus (mg/dl)} + 52.82 \\ & \text{(if black)} - 368.75 \text{ (if female)} \end{aligned} \quad (25)$$

The relationship of creatinine generation to age, gender, and body weight is affected by muscle mass and diet. Muscle wasting is associated with a decreased creatine pool, which leads to decreased creatinine generation and excretion.[140–143] However, some muscle diseases are associated with increased creatine turnover,[141] which in principle could transiently

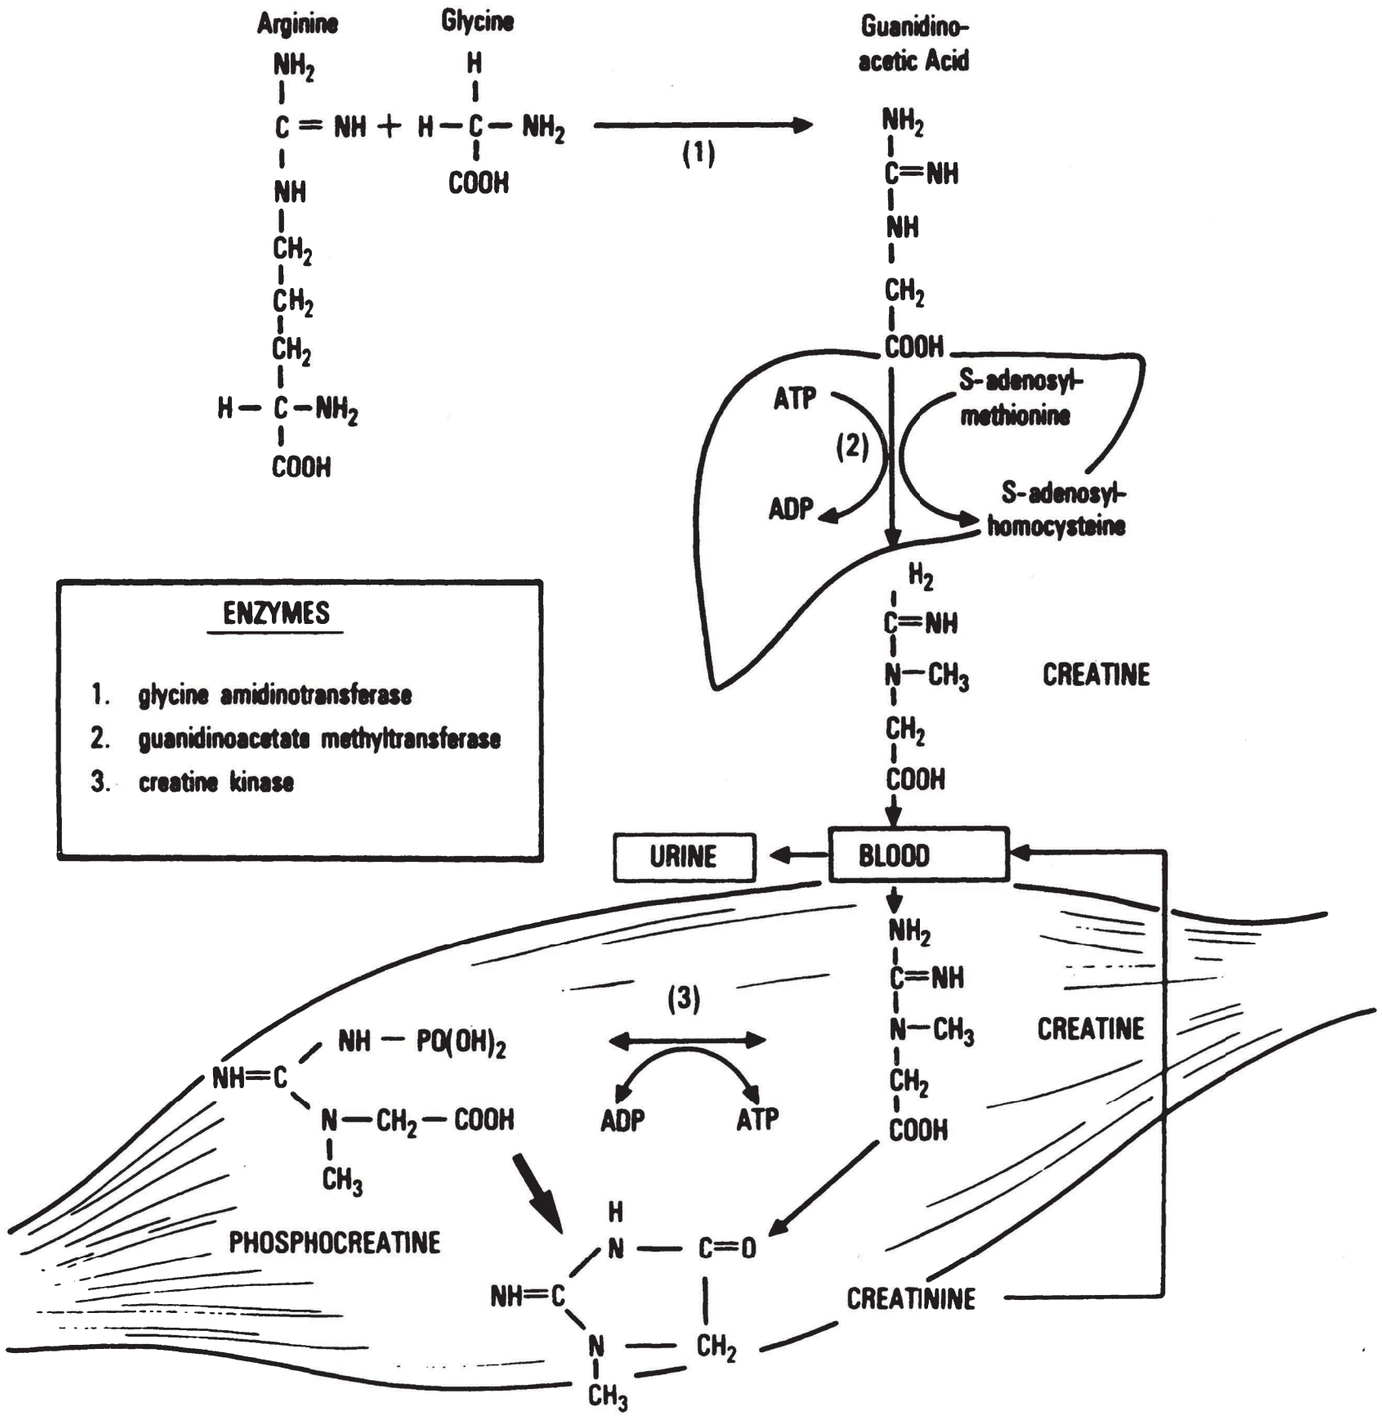

FIGURE 9.8 Pathways of creatinine metabolism. (From Heymsfield SB, Arteaga C, McManus C, et al. Measurement of muscle mass in humans: validity of the 24-hour urinary creatinine method. *Am J Clin Nutr.* 1983;37:478, with permission.)

increase creatinine generation and excretion. Reduction in dietary protein causes a decrease in the creatine pool by 5% to 15%, which is probably due to the reduction of the availability of creatine precursors, arginine, and glycine.[131,144] Of greater importance is the effect of creatine in the diet. Creatine is contained largely in meat; uncooked lean beef contains about 3.5 to 5 mg of creatine per g.[145,146] Elimination of creatine from the diet decreases urinary creatinine excretion by as much as 30%.[144,147,148] Conversely, ingesting a creatine supplement increases the size of the creatine pool and increases creatinine excretion.[144,149–151] Meat intake also affects creatinine generation and excretion independent of its effect on the creatine pool. During cooking, a variable amount (18% to 65%) of the creatine in meat is converted to creatinine, which is absorbed from the gastrointestinal tract. Therefore, following ingestion of cooked meat, there is a sudden transient increase in the serum creatinine concentration and urinary creatinine excretion. These findings are not observed when a similar quantity of uncooked meat is ingested.[152,153]

Extrarenal Elimination. Extrarenal loss of creatinine is not detectable in normal individuals, but may account for up to 68% of daily creatinine generation in patients with severe decrease in GFR. One likely, but still not established, mechanism is degradation of creatinine within the intestinal lumen by microorganisms due to induction of the enzyme creatininase.[154–158]

Thus, in patients with kidney disease, creatinine excretion underestimates creatinine generation:

$$U_{cr} \times V = G_{cr} - E_{cr} \quad (26)$$

where E_{cr} is the rate of elimination of creatinine by extrarenal routes.

Measurement of Creatinine

Creatinine can be measured easily in serum, plasma, and urine and a variety of methods are used by clinical laboratories. The National Kidney Disease Education Program (NKDEP) and the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) have recently completed standardization of serum creatinine assays to minimize differences in clinical laboratories and facilitate more accurate reporting of estimated GFR.[114,159] The reference standard for creatinine assay is isotope dilution mass spectrometry (IDMS) using either gas or liquid chromatography.[114,160,161] All instruments can now be calibrated to standardized serum creatinine using secondary reference materials and proficiency testing programs.[162] Calibration does not eliminate the problem of interference by specific substances in serum with specific assays.[161]

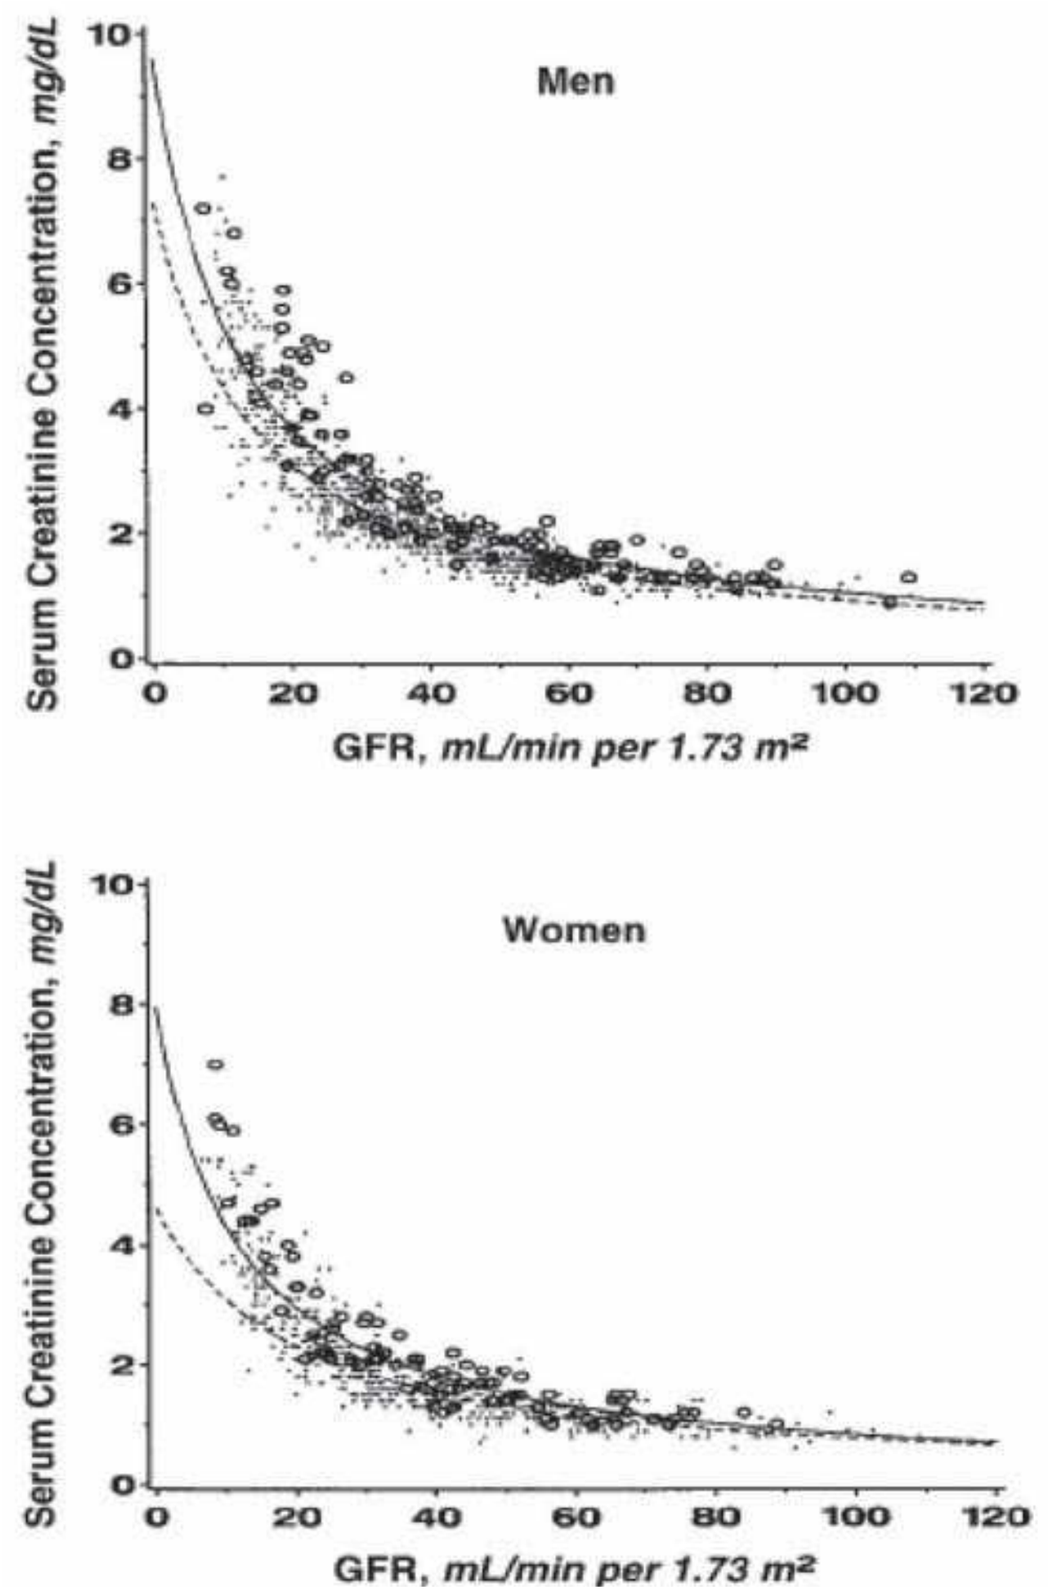

FIGURE 9.9 Relationship of serum creatinine concentration to measured glomerular filtration rate (GFR) in the Modification of Diet in Renal Disease Study. GFR was measured as the urinary clearance of ^{125}I-iothalamate. Serum creatinine concentration was measured using a Beckman Astra CX3 analyzer and a kinetic alkaline picrate assay.[33,47] Regression lines were computed from the relationship of reciprocal of serum creatinine versus GFR. When GFR is 60 mL/min/1.73 m^2, the 95% confidence interval for the serum creatinine concentration is 1.4 to 1.8 mg per dl for white men (n = 802) and 1.3 to 1.5 for African American men (n = 113) (*left panel*), and 1.1 to 1.4 mg per dl (97.2 and 123.8 μmol per L) for white women (n = 502) and 1.0 to 1.2 mg per dl (88.4 and 106.1 μmol per L) for African American women (n = 84) (*right panel*). These levels are close to the upper limit of the reference range. Confidence intervals for serum creatinine levels are wider at lower levels of GFR. (Reproduced with permission from Stevens LA, Coresh J, Greene T, et al. Assessing kidney function—measured and estimated glomerular filtration rate. *N Engl J Med*. 2006;354(23):2473–2483.)

The classic method uses the Jaffé reaction in which creatinine reacts directly with picrate ion under alkaline conditions to form a red-orange complex that is easily detected and quantified.[163] However, in normal subjects, up to 20% of the color reaction in serum or plasma is due to substances other than creatinine. Two classes of positive interferences have been described: substances such as glucose, ascorbate, and uric acid, which slowly reduce the alkaline picrate, and substances such as acetoacetate, pyruvate, other ketoacids, fluorescein, furosemide, hemoglobin, paraquat and diquat, and serum proteins which react with alkaline picrate to form colored complexes. The error in measurement can be greater, however, in diabetic ketoacidosis due to the increased concentration of acetoacetate, and in patients taking certain cephalosporins which can contribute to the colorimetric reaction. Very high serum bilirubin levels can cause falsely lower creatinine levels. In patients with kidney disease, noncreatinine chromogens are not retained to the same degree as creatinine. Consequently, the overestimation of serum creatinine and the corresponding underestimation of creatinine clearance are reduced. In general, noncreatinine chromogens are not present in sufficient concentration in urine to interfere with creatinine measurement. Hence, measurement of creatinine clearance in normal individuals using the Jaffé reaction results in values that are approximately 20% lower than the true value.

The kinetic alkaline picrate method takes advantage of the differential rate of color development for noncreatinine chromogens compared to creatinine. It significantly reduces, but does not eliminate, both types of positive interferences described earlier. A survey by the College of American Pathologists (CAP) in 2004 found that assays based on the alkaline picrate method were the most widely used in clinical laboratories in the United States.[162]

To circumvent interferences in the alkaline picrate reaction, other methods have been developed which are increasingly used by clinical laboratories. Enzymatic methods include the creatinine iminohydrolase and creatininase-creatinase-sarcosine oxidase methods. The antifungal agent, flucytosine, interferes with the creatinine iminohydrolase method, whereas bilirubin, dopamine, dobutamine, ascorbic acid, and sarcosine may interfere with the creatinase-creatininase methods. HPLC is a fairly sensitive and analytically specific method for measuring serum creatinine, but technically more difficult than enzymatic methods. Enzymatic and HPLC methods usually provide values that are 10% to 20% lower than kinetic alkaline picrate methods and are closer to the reference standard.

Serum Creatinine as an Index of Kidney Function

Based on substitutions and rearrangements of Equations 9.20 and 9.24, the relationship between GFR and serum creatinine is as follows:

$$GFR = (G_{cr} - E_{cr} - TS_{cr}) / S_{cr} \quad (27)$$

Estimating equations have been developed to estimate creatinine clearance[164–170] and GFR.[171–174] Most use age, sex, and body size as surrogates for creatinine generation. According to the June 2008 Chemistry Survey of the College of American Pathologists (CAP), 77% of clinical laboratories report eGFR when serum creatinine is measured.[114]

Due to its relative ease of use, one of the first estimating equations to be widely used is the Cockcroft and Gault formula.[164]

$$eC_{cr} = [140 - \text{age} \times \text{body weight}] \times 0.85 \text{ (if female)} / [S_{cr} \times 72] \quad (28)$$

where C_{cr} is expressed in mL per minute, age is expressed in years, body weight is expressed in kg, and S_{cr} is expressed in mg per dl. The formula was derived in 236 men (mean measured creatinine clearance of 73 mL per minute) in 1973. The formula for women was based on the assumption that creatinine generation is 15% less in women than in men. The Cockcroft and Gault formula was extensively validated before standardization of creatinine assays, but cannot be re-expressed for use with standardized creatinine assays. Use of standardized serum creatinine values in the Cockcroft and Gault equation leads to overestimates of creatinine clearance. Because measured creatinine clearance exceeds measured GFR, these overestimations may be particularly misleading.

Recent studies have developed equations to estimate GFR rather than creatinine clearance. The most commonly used equation is the Modification of Diet in Renal Disease (MDRD) Study.[132,175]

$$\text{eGFR} = 186 \times S_{cr} \text{ (mg per dl)}^{-1.154} \times \text{age (years)}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)} \quad (29)$$

where eGFR is expressed in mL/min/1.73 m^2, S_{cr} is expressed in mg per dl, and age in years. The MDRD Study equation has now been re-expressed for standardized serum creatinine as

$$\text{eGFR} = 175 \times \text{standardized } S_{cr} \text{ (mg per dl)}^{-1.154} \times \text{age (years)}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)} \quad (30)$$

The MDRD Study equation was developed in 1,628 patients with chronic kidney disease (mean GFR of 40 mL/min/1.73 m^2) who were predominantly white and had predominantly nondiabetic kidney disease. The equation was reported in 1999 and has been validated in African Americans with hypertensive nephrosclerosis, diabetic kidney disease, and kidney transplant recipients.[176] Inclusion of the race term significantly improved the prediction, which is likely because of the larger muscle mass in African Americans compared to whites. The MDRD Study equation is more accurate than the Cockcroft-Gault equation as well as measured urinary creatinine clearance. Its main disadvantage is a systemic underestimation of measured GFR and imprecision at higher values. Because of this, NKDEP recommends that eGFR >60 mL/min/1.73 m^2 using this equation not be reported as a numeric value.

In 2009, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) reported a more accurate equation using a large diverse dataset pooled from multiple studies. The development dataset included 8,254 individuals from 10 studies with a mean measured GFR of 68 mL/min/1.73 m^2. The validation dataset included 3,859 individuals from 16 additional studies with measured GFR.[177]

$$\text{eGFR} = 141 \times \min(\text{standardized } S_{cr}/\kappa, 1)^{\alpha} \times \max(\text{standardized } S_{cr}/\kappa, 1)^{1.209} \times 0.993^{\text{age}} \times 1.1018 \text{ (if female)} \times 1.159 \text{ (if black)} \quad (31)$$

where eGFR is expressed in mL/min/1.73 m^2, standardized serum creatinine is expressed as mg per dl, age is expressed in years, κ is 0.7 for females and 0.9 for males, α is −0.329 for females and −0.411 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates maximum of S_{cr}/κ or 1. The CKD-EPI equation uses the same variables as the MDRD Study equation, but includes a nonlinear term for serum creatinine that substantially reduces bias at higher GFR, enabling numeric eGFR reports throughout the range (Fig. 9.10). The main disadvantage is imprecision in the high range for eGFR. Most but not all studies confirm the greater accuracy of the CKD-EPI equation compared to the MDRD Study equation.[178–184] In addition, because of lesser bias, use of the CKD-EPI equation leads to lower prevalence estimates of decreased GFR in cross-sectional studies and more steep risk relationships of eGFR to adverse outcomes in longitudinal studies.[111]

Modifications to the MDRD Study and CKD-EPI equations have been proposed to account for racial, ethnic, and regional differences in diet and muscle mass.[185–187] Where these modifications lead to more accurate GFR estimations, it may be reasonable to substitute them for the MDRD Study and CKD-EPI equations, but it is not clear from the current literature whether these modifications truly reflect population differences in non-GFR determinants or methodologic differences, such as GFR measurement, serum creatinine assay, or subject selection.

Currently, most clinical laboratories report eGFR using the MDRD Study. In April 2011, large commercial clinical laboratories in the United States began to use the CKD-EPI equation and it is likely that it will be used more widely in the future. Only a small number of clinical laboratories in the United States report estimated creatinine clearance using the Cockcroft and Gault equation. However, since 1979, the U.S. Food and Drug Administration (FDA) has recommended the Cockcroft and Gault equation for pharmacokinetic studies used for drug development and labeling. For these reasons, drug dosing recommendations by pharmacists are generally based on estimated creatinine clearance computed using the Cockcroft and Gault rather than the MDRD Study or CKD-EPI

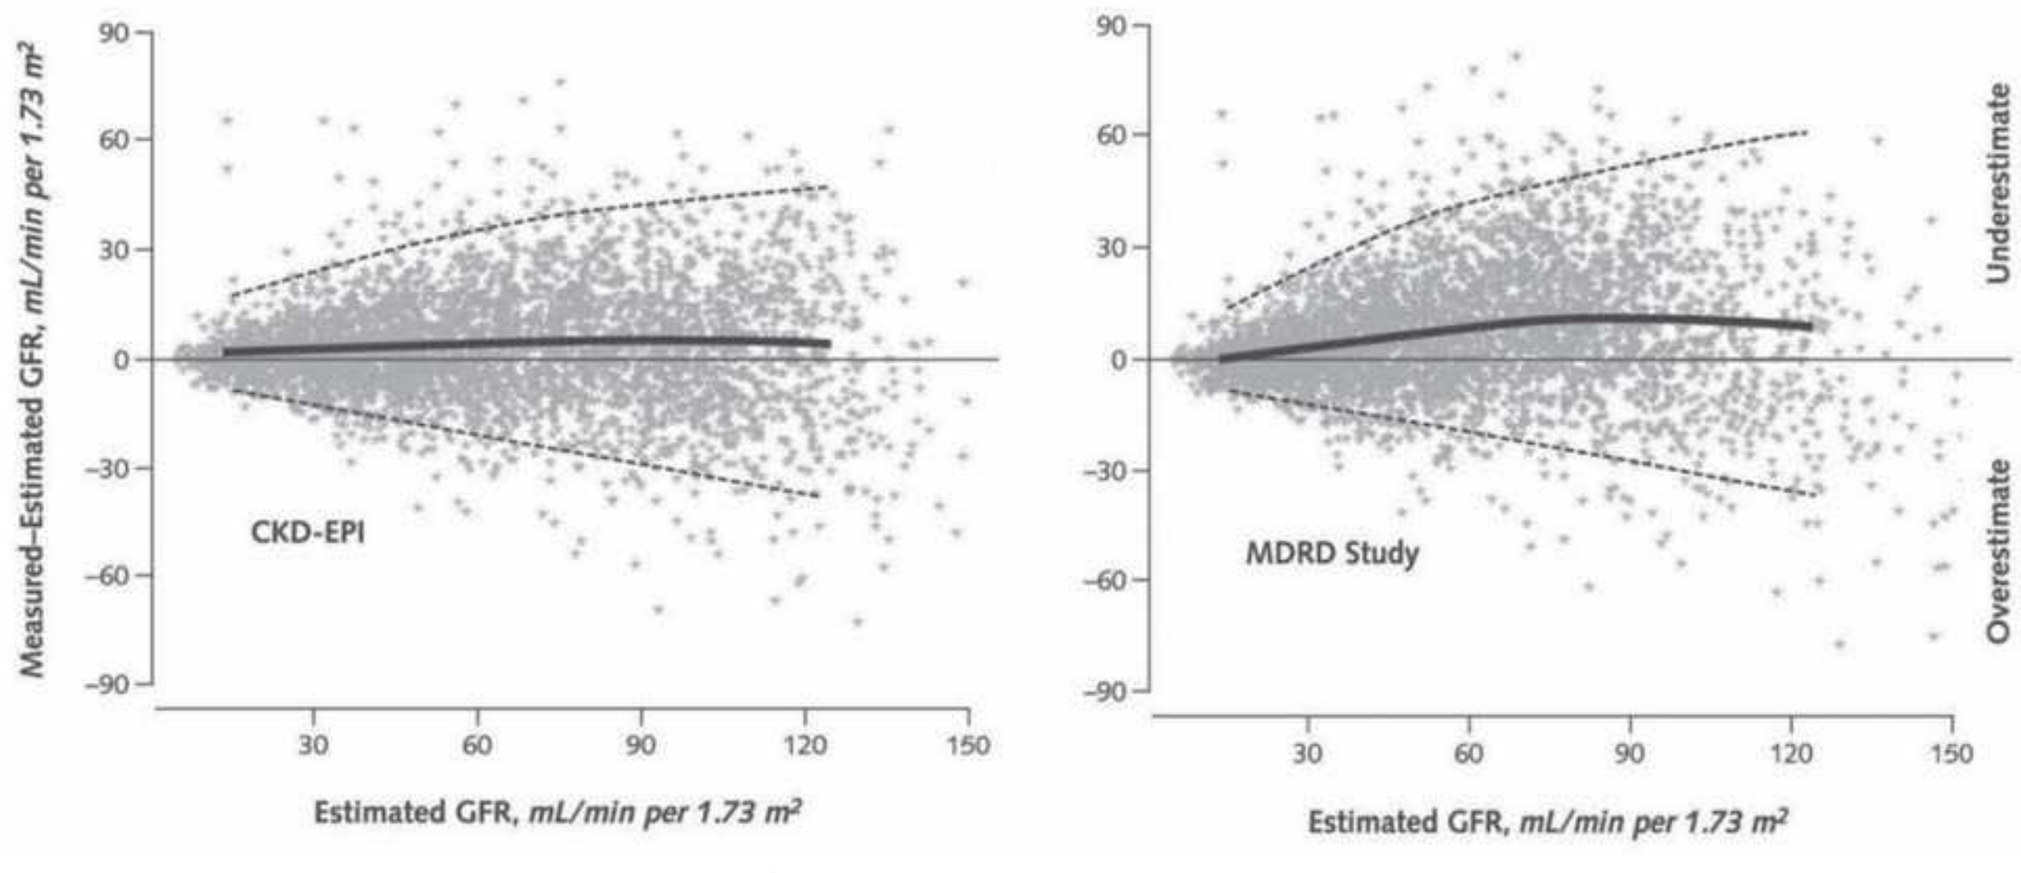

FIGURE 9.10 Comparison of performance of Modification of Diet in Renal Disease (MDRD) Study and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations by estimated glomerular filtration rate (GFR) in the external validation dataset. *Left*. Measured versus estimated GFR. *Right*. Difference between measured and estimated versus estimated GFR. Shown are smoothed regression line and 95% confidence interval (computed using the lowest smoothing function in R), using quantile regression, excluding lowest and highest 2.5% of estimated GFR values. To convert GFR from mL/min/1.73 m^2 to mL/s/m^2, multiply by 0.0167. (Reproduced with permission from Levey AS, Stevens LA, Schmid CH, et al. A new equation to estimate glomerular filtration rate. *Ann Intern Med*. 2009;150(9):604–612.)

equations.[188] One study shows a relatively high concordance in drug dosing recommendation using all three of the equations compared to measured GFR, and the NKDEP suggests using GFR estimates reported by clinical laboratories for drug dosing.[189,190] Further guidance by the FDA is needed.

In summary, there are limitations to the use of estimating equations based on the physiologic, analytical, and statistical principles described earlier.[106,108] Tables 9.4 and 9.5 list clinical situations in which estimating equations may not be accurate and clearance measurements may be indicated as a confirmatory test.[106]

9.5 Clinical Situations in Which Estimating Equations for Creatinine Clearance or Glomerular Filtration Rate Measurements May Not be Accurate and Clearance Measurements May be Recommended

- Extremes of age and body size
- Severe malnutrition or obesity
- Diseases of skeletal muscle
- Paraplegia or quadriplegia
- Vegetarian diet
- Rapidly changing kidney function
- Pregnancy
- Prior to dosing drugs with significant toxicity that are excreted by the kidneys

Urea as a Filtration Marker

A relationship between serum urea and kidney function was recognized long before the development of the concept of clearance of or techniques to assess GFR.[191] The factors influencing both the production of urea and its renal excretion, however, are considerably more complex and variable than those for creatinine (Table 9.6).[113] In the United States, urea is traditionally assayed as urea nitrogen. The usual concentration of serum urea nitrogen (for historical reasons, often referred to as the blood urea nitrogen, or BUN) in healthy young people is in the range of 8 to 12 mg per dl, but the reference ranges in clinical laboratories are wider to take into account variation among individuals. The urea clearance is rarely used today as a measure of kidney function, and the serum urea nitrogen concentration has been replaced largely by the serum creatinine concentration as an index of GFR in routine clinical practice. Nonetheless, measurement of the BUN remains useful both as a diagnostic aid in distinguishing among the various causes of acute decline in GFR and as a rough correlate of uremic symptoms in kidney failure. To understand the utility and shortcomings of BUN measurements, a brief summary of the kidney handling and metabolism of urea is presented subsequently.

Kidney Handling of Urea

Urea (molecular weight 60 daltons) is filtered freely by the glomerulus and reabsorbed in both the proximal and distal

9.6 Clinical Conditions that Cause Errors in the Estimation of Glomerular Filtration Rate from Measurement of Urea Clearance or Blood Urea Nitrogen

Condition	Effect on C_{urea}	Effect on BUN	Comment
Extracellular Volume			
Dehydration	Decrease	Increase	Increased urea reabsorption
Reduced renal perfusion (volume depletion, congestive heart failure)	Decrease	Increase	Reduced GFR, increased urea reabsorption, increased urea generation
Overhydration	Increase	Decrease	Reduced urea reabsorption
Increased renal perfusion (volume expansion, pregnancy, syndrome of inappropriate ADH secretion)	Increase	Decrease	Increased GFR, reduced urea reabsorption
Dietary Protein or Catabolism			
Restriction of dietary protein	Decrease	Decrease	Sustained decrease in GFR and reduced urea generation
Increased dietary protein	Increase	Increase	Sustained increase in GFR and increased urea generation
Accelerated catabolism (fever, trauma, GI bleeding, cell lysis, therapy with tetracycline or corticosteroids)	None	Increase	Increased urea generation
Liver Disease	Decrease[a]	Decrease[a]	Decreased GFR, decreased urea reabsorption, decreased urea generation
Kidney Disease	None[a]	Decrease[a]	Decreased GFR, no change in urea reabsorption, decreased urea generation (if dietary protein is restricted)

[a]Effects on C_{urea} and BUN relative to effects on GFR (i.e., C_{urea} is lower than expected for the reduction in GFR).
ADH, antidiuretic hormone; BUN, blood (serum) urea nitrogen; C_{urea}, urea clearance; GFR, glomerular filtration rate; GI, gastrointestinal.

nephron. Hence, urea excretion ($U_{UN} \times V$) is determined by both the filtered load and tubular reabsorption (TR_{UN})

$$U_{UN} \times V = GFR \times BUN - TR_{UN} \quad (32)$$

Consequently, clearance of urea (or urea nitrogen, C_{UN}) is less than GFR

$$C_{UN} = GFR - TR_{UN} / BUN \quad (33)$$

A large fraction of the filtered load of urea is reabsorbed in the proximal convoluted tubule. In the medullary collecting duct, urea reabsorption is linked closely to water reabsorption. In the absence of antidiuretic hormone (diuresis), the medullary collecting duct is relatively impermeable to urea; thus, urea reabsorption is minimal. Conversely, in the presence of antidiuretic hormone (antidiuresis), permeability rises and urea reabsorption increases. In normal individuals, the ratio of urea clearance to GFR varies from as high as 0.65 during diuresis to as low as 0.35 during antidiuresis.

In patients with GFR less than 20 mL/min/1.73 m^2, the ratio of urea clearance to GFR is higher (0.7 to 0.9) and is not influenced greatly by the state of diuresis. Thus, urea clearance is approximately 5 mL per minute less than GFR. By coincidence, at this level of GFR, the difference between the values of GFR and urea clearance is similar to the difference between the values of creatinine clearance and GFR. Hence, the average of the clearances of urea and creatinine approximates the level of GFR.[172,173] This coincidence provides a relatively simple method to assess GFR in advanced renal disease. A single blood sample and 24-hour urine collection may be analyzed for creatinine and urea nitrogen

and the values for clearance may be averaged. However, the kidney handling of urea and creatinine is influenced by different physiologic and pathologic processes and may vary independently, causing deviations from this approximation.

Urea Metabolism

The metabolism of urea, its relationship to dietary protein intake, and the effect of renal insufficiency on protein metabolism are discussed in detail in Chapter 72. Briefly, urea is the end product of protein catabolism and is synthesized primarily by the liver. Approximately one quarter of synthesized urea is metabolized in the intestine to carbon dioxide and ammonia; thus, the ammonia that is generated returns to the liver and is reconverted to urea.

Dietary protein intake is the principal determinant of urea generation and may be estimated as follows:

$$EPI = 6.25 \times G_{UN} \quad (34)$$

where EPI is estimated protein intake, G_{UN} is urea generation, and both are measured in g per day.[192] Usual protein intake in the United States is approximately 100 g per day,[193–195] corresponding to a usual value for urea nitrogen generation of approximately 15 g per day.

In the steady state, urea generation can be estimated from the measurements of urea excretion, as shown below:

$$G_{UN} = U_{UN} \times V + 0.031 \times \text{weight} \quad (35)$$

where G_{UN} and $U_{UN} \times V$ are measured in g per day, weight is measured in kg, and 0.031 g/kg/day is a predicted value for nitrogen losses other than urine urea nitrogen.[196] For a 70-kg individual with a dietary protein intake of 100 g per day, urea excretion and other nitrogen losses would be approximately 13 and 2 g per day, respectively.

Measurement of Urea

The urease method assays the release of ammonia in serum or urine after reaction with the enzyme urease.[197] The presence of ammonium in reagents or use of ammonium heparin as an anticoagulant may falsely elevate the BUN, as can the drugs chloral hydrate, chlorbutanol, and guanethidine.[198] Urea is also subject to degradation by bacterial urease. Bacterial growth in urine samples can be inhibited by refrigerating the sample until measurement or by adding an acid to the collection container to maintain urine pH <4.0.

Blood Urea Nitrogen as an Index of Kidney Function and Protein Intake

In the steady state, the BUN level reflects the levels of urea clearance and generation.

$$BUN = G_{UN} / C_{UN} = U_{UN} \times V / C_{UN} \quad (36)$$

Consequently, many factors influence the level of BUN (Table 9.6). Nonetheless, the BUN can be a useful tool in some clinical circumstances.

As mentioned earlier, the state of diuresis has a large effect on urea reabsorption and a small effect on GFR, but does not affect creatinine secretion. Hence, the state of diuresis affects urea clearance more than creatinine clearance, and is reflected in the ratio of BUN to serum creatinine. The normal ratio of BUN to serum creatinine is approximately 10:1. In principle, a reduction in GFR without a change in the state of diuresis would not alter the ratio. However, conditions causing antidiuresis (dehydration or decreased kidney perfusion) would decrease GFR and increase urea reabsorption, thus raising the BUN-to-creatinine ratio. Consequently, the BUN-to-creatinine ratio is a useful aid in the differential diagnosis of acute GFR decline. Conversely, overhydration or increased renal perfusion would raise GFR and decrease urea reabsorption, thus lowering the serum creatinine and the BUN-to-creatinine ratio.

Also important is the well-recognized relationship of the level of renal function, the BUN level, and clinical features of uremia. A useful "rule" is that a BUN level greater than 100 mg per dl is associated with a higher risk of complications in both acute and chronic kidney failure and may indicate the need to initiate dialysis.[199,200] In both acute and chronic kidney disease, restriction of dietary protein intake to 40 to 50 g per day would reduce urea nitrogen excretion to approximately 4.5 g per day. Consequently, the BUN level might rise to only 40 to 60 mg per dl, despite severe reduction in GFR. Although protein restriction may temporarily ameliorate some of the uremic symptoms, severe reduction in GFR is associated with development of uremic symptoms despite only moderate elevation in BUN.

Urea generation and the BUN are also influenced by factors other than protein intake.[192] An increase is observed after the administration of corticosteroids, diuretics, or tetracyclines; after the absorption of blood from the gut; and in infection, renal failure, trauma, congestive heart failure, and sodium depletion. Decreases in urea generation and BUN may occur in severe malnutrition and liver disease. These conditions may also affect the BUN and the BUN-to-creatinine ratio.

Cystatin C as a Filtration Marker

Cystatin C has been proposed as an endogenous filtration marker. Assays for cystatin C are available in some countries in Europe but are not yet available in the United States. Research studies show that serum levels in healthy young adults are approximately 0.8 mg per L.[201] Studies in human subjects demonstrate a good correlation of serum cystatin C levels with GFR; typically better than that of serum creatinine levels alone, but equivalent or worse than serum creatinine adjusted for age, sex, and race.[202,203] A summary of issues related to its kidney handling, metabolism, measurement, and use as an index of GFR is presented subsequently. Table 9.7 lists the factors that influence the level of cystatin C.

9.7 Clinical Conditions that Cause Errors in the Estimation of Glomerular Filteation Rate from Measurement of Cystatin C

Condition	Effect on Cystatin C	Comment
Demographics		
Age	Decrease	
Male sex	Increase	
Race	No change	When tested in blacks vs. whites; finding has not been validated and requires testing in other racial groups
Cell turnover		
Inflammation	Increase	Seen in inflammatory conditions as indicated by WBC, CRP
Corticosteroids	Increase	
Hyperthyroid	Increase	
Hypothyroid	Decrease	
Diabetes	Increase	
Fat Mass	Increase	
Kidney Disease	Increase	Decreased GFR, suspect may be decrease in extrarenal elimination of cystatin C at low levels of GFR

CRP, C-reactive protein; GFR, glomerular filtration rate; WBC, white blood cell.

Kidney Handling of Cystatin C

Based on its small size (13 kD) and limited direct measurements in the rat, it appears that cystatin C is freely filtered.[204–211] It is then reabsorbed and catabolized by the renal tubules.[204–206] Urinary cystatin C is a marker of kidney damage; it is found in the urine of patients with tubulointerstitial kidney disease,[212] in particular in patients with acute kidney disease, and some glomerular diseases,[213] presumably due to impaired catabolism.[207,208] There is no evidence for tubular secretion,[210] whereas there is indirect evidence for extra-renal elimination of cystatin C in animal studies.[204,211] Direct evaluation of kidney handling in humans has not yet been performed.

Cystatin C Metabolism

Cystatin C is a nonglycosylated basic protein—its mRNA is found in every human tissue.[214] Molecular analysis of its promoter suggests that cystatin C is encoded on a "housekeeping" gene.[214,215] Indirect evidence suggests that there is variability in the generation rate, in particular with states associated with higher or lower cell turnover, such as hyperthyroid or hypothyroid states,[216] or steroid use.[217–220] Epidemiologic studies have suggested that non-GFR determinants of cystatin C—age, sex, body mass index, diabetes, white blood cell count, albumin, and C-reactive protein—were significantly related to higher levels of cystatin C,[202,221] whereas other studies have not shown a relationship to inflammation[222] or diet.[223]

Measurement of Cystatin C

There are several commercially available autoanalyzers to assay cystatin C. At present, methods use nephelometric, turbidimetric, or enzyme-linked immunosorbent assay (ELISA) methods. Despite high precision and reproducibility of the assays, there are large differences among them.[224–226] One study has compared two turbidimetric and one nephelometric cystatin C assay and showed large variation when the assays are used with patient samples, but not when control samples were used, suggesting interference of the assays with substances found in patient samples.[225] Other studies have shown large within and between laboratory variations even for the same assay.[225,227] Variations in the assay would lead to inaccurate GFR estimates. Recently, the International Federation of Clinical Chemists (IFCC) made available a reference material for cystatin C that will allow for standardization of the assays across platforms.[228] At present, the reference materials are not yet FDA approved, and so likely standardization of the commercial platforms will not be uniform in the United States until at least 2015.

Cystatin C as an Index of Kidney Function

Based on these considerations the relationship of GFR to serum levels of cystatin would be as follows:

$$GFR = G_{cys} / S_{cys} \quad (37)$$

Several factors could influence the level of cystatin C independent from the GFR, leading to errors in estimation of GFR (Table 9.7).

Multiple studies have compared serum cystatin C and creatinine as filtration markers in the general population,[182] in those with CKD,[202,229,230] and in special populations with reduced muscle mass[203,231–234] where cystatin C is hypothesized to have a particular advantage and results are mixed. In general, when the two analytes are compared alone, cystatin C appears to be a better filtration marker. When compared

to GFR estimates based on serum creatinine adjusted for age, sex, and race, there is no clear advantage of cystatin C. These results do not suggest that cystatin C should replace creatinine or that there are specific populations in which cystatin C should be used. In combination, creatinine and cystatin C result in a more precise estimate of GFR than either marker alone.[202,235–240] In acute GFR decline, studies in animals and in humans demonstrate that cystatin C increases prior to serum creatinine, and has been interpreted as a more sensitive marker; however, few studies have compared changes in cystatin C to changes in measured GFR.[241]

In contrast to the data on cystatin C as a marker of GFR, the data on cystatin C as a prognostic marker show that it provides consistently better information than creatinine or creatinine-based estimating equations.[241] It is not known whether this improvement is because cystatin C is indeed a better marker of kidney function in these study populations or because non-GFR determinants of cystatin C are also associated with adverse outcomes, as described previously.

PROTEINURIA

The plasma filtered by the kidneys each day contains approximately 11,000 to 14,000 g of protein, yet the final urine is virtually protein-free due to selectivity of glomerular filtration. This conservation of essential proteins is necessary for oncotic regulation, for immune protection, for normal coagulation, and for a host of other vital processes.

An increased protein excretion rate (proteinuria) is usually due to kidney disease, and most kidney diseases are associated with some degree of proteinuria. Proteinuria does not generally cause clinical signs or symptoms. An exception is the nephrotic syndrome, characterized by loss of proteinuria sufficient to cause hypoalbuminemia, edema, and hypercholesterolemia (usually >3.5 g per day). The detection and evaluation of lesser quantities of proteinuria has gained additional significance years as multiple studies have demonstrated its diagnostic and prognostic importance. It has long been known that the degree of proteinuria is a risk factor for kidney disease progression. It has now been shown that the presence of even mildly increased amounts of protein in the urine serves as an independent risk marker for cardiovascular disease and death, independent of other risk factors such as diabetes, hypertension, or advancing age. Recent experimental and clinical studies also suggest an important role for proteinuria in the pathogenesis of the progression of kidney disease.[242] The physiology of protein handling by the kidney and the pathophysiology of proteinuria are extensively covered elsewhere in this book.

This section considers (1) mechanisms by which the kidney handles proteins, (2) methods to measure urine protein, (3) patterns of proteinuria, and (4) clinical interpretation of proteinuria. For several reasons, clinical terminology is slowly changing to focus on albuminuria rather than proteinuria. Albumin is the principal component of urinary protein in most kidney diseases. Recent recommendations for measurement of urine proteins emphasize quantification of albuminuria rather than total protein[1,243,244]; recent epidemiologic data demonstrate a strong graded relationship of the quantity of urine albumin with both kidney and cardiovascular disease risk[36,245–247]; and a recent international conference suggested classification of kidney disease by albuminuria in addition to GFR.[3] In this chapter we will refer to proteinuria when discussing general concepts and will refer either to total protein, albumin, or other specific proteins when discussing measurements, patterns, and interpretation of proteinuria.

Protein Handling by the Kidney

In healthy individuals, the daily urinary protein excretion averages 40 to 80 mg, and the upper limit of normal ranges from 75 to 150 mg. Urine protein is a mixture of plasma proteins that cross the filtration barrier and other proteins that originate in the tubules and lower urinary tract. Of the total, albumin constitutes 30% to 40%, immunoglobulin G (IgG) 5% to 10%, light chains 5%, and IgA 3%. Tamm-Horsfall protein (THP), also known as uromodulin, is a glycoprotein not found in plasma[248,249] and is the most abundant protein in normal human urine and constitutes the remainder.[250] Large molecules, such as IgD and IgM, normally are not detected in the urine.[248,251]

The handling of plasma proteins by the kidney is complex, but consists of two major components: the permeability of the glomerular filter to plasma proteins and the tubular metabolism of filtered proteins. For a detailed review of these mechanisms, the reader is referred to Chapters 72 and 73.

Urine Proteins of Plasma Origin

Low Molecular Weight Proteins. Low molecular weight proteins (less than 25,000 daltons or radius less than 2.3 nm) are extensively filtered by the glomeruli, taken up by the tubules, and subsequently handled by proximal tubular degradation.[252] Biologically important low molecular weight proteins handled by the kidney include enzymes (lysozyme and ribonuclease), immunoglobulins (light chains and beta-2 microglobulin), fibrin-fibrinogen degradation products, and hormones (insulin, growth hormone, and parathyroid hormone). The tubular concentration of these proteins ranges from 50% to 90% of their plasma concentrations (Table 9.8). Low molecular weight proteins are small enough that their charge plays only a minor role in their filtration.

Despite the significant amount of low molecular weight protein that is filtered, only minimal quantities appear in the urine. The proteins are taken up in the proximal tubule and hydrolyzed into amino acids by the vacuolar-lysosomal system. Small amounts of these proteins are actually reabsorbed intact.[253–255] The tubular capacity for some of these low molecular weight proteins is significantly greater than the filtered load. For example, when purified lysozyme was given in an isolated perfused rat kidney, lysozyme did not appear in the urine until the filtered load was increased

9.8 Handling of Plasma Proteins by the Kidney

Protein	Molecular weight (daltons)	Approximate Stokes-Einstein radius (nm)	Approximate ratio of glomerular filtrate to plasma concentrations
Inulin (for reference)	5,200	1.4	1.0
Insulin	6,000	1.6	0.9
Lysozyme	14,600	1.9	0.75
Myoglobulin	16,900	1.9	0.75
Parathyroid hormone (cow)	9,000	2.1	0.65
Growth hormone (rat)	20,000	2.1	0.6–0.7
Light chains	44,000	2.8	0.09[a]
Amylase	48,000	2.9	0.02
Albumin	69,000	3.6	0.02
Gamma globulin	160,000	5.5	0.0
Ferritin	480,000	6.1	0.02

[a]Can be as high as 0.45 if light-chain monomers predominate over dimers in plasma.
From Kanwar YS. Biology of disease: biophysiology of glomerular filtration and proteinuria. Lab Invest. 1984;51:7. Maack T, Johnson B, Kau ST, et al. Renal filtration, transport, and metabolism of low-molecular-weight proteins: a review. Kidney Int. 1979;16:251.

nearly threefold.[253] Through the process of filtration, tubular absorption, and excretion, the kidney accounts for between 30% and 80% of the metabolic clearance of low molecular weight proteins.[253]

Immunoglobulin light chains are handled in a similar manner. The monomer (molecular weight 22,000 daltons) is filtered freely and then degraded by the tubules with small amounts appearing in the urine. In contrast, the dimer (molecular weight 44,000 daltons, radius 2.8 nm) is restricted with only approximately 10% filtered. Horseradish peroxidase, a neutral tracer molecule of similar weight and size to light chains, is handled in a similar manner.[256,257]

Albumin is the principal plasma protein and has a molecular weight of 69,000 and radius of 3.6 nm. Under normal situations, any significant amount of albumin is prevented from entering the urine space by the glomerular permselectivity barrier. However, under certain conditions such as reduced glomerular plasma flow, albumin passes into the urine, demonstrating that size selectivity alone is not sufficient to restrict the filtration of albumin. Rather, it appears that the negative charge on the various structures of the glomerular barrier contributes significantly to restricting the filtration of albumin. Of these structures, the negative charge on the basement membrane has been considered the major obstacle to albumin crossing the glomerular capillary wall.[257–263]

Changes in filtered albumin sufficient to account for heavy proteinuria have been documented by micropuncture studies in experimental nephrotic syndrome and by indirect studies in humans. In rats with aminonucleoside nephrosis, the increase in filtered albumin accounts entirely for the increase in protein excretion.[264,265] In fact, in animals with either aminonucleoside nephritis or nephrotoxic nephritis, the proximal tubular albumin concentration is increased 8- to 12-fold.[265,266] These animals may excrete 100 to 400 times as much albumin as controls.[265,266] In humans, clearance studies have provided indirect evidence of increased filtration of protein; in patients with nephrotic syndrome, the minimal protein concentration in the glomerular filtrate (calculated by correcting the urine protein concentration by the fraction of water reabsorbed) far exceeds the concentration of filtered protein observed in the proximal tubular fluid in normal animals.[267] Furthermore, urine albumin excretion is linearly related to plasma albumin concentration when the latter is increased by infusion.[267,268] Such a relationship is characteristic of substances excreted mainly by glomerular filtration.[15]

Although increased filtration of protein appears to be the major factor leading to proteinuria, the specific defects in the capillary wall that are responsible for the protein loss are not completely defined. New information regarding the

major role of the podocyte and its slit diaphragm in many proteinuric diseases has become available from multiple studies.[269–272]

Filtered albumin is also absorbed and catabolized by the proximal tubule with little or no reabsorption of intact albumin. As in the case of low molecular weight proteins, there is excess capacity above normal, but this pathway is saturable.[273] This explanation of albumin handling by the kidney has been challenged lately, with the suggestion that albumin is, in fact, highly filterable and not impeded by charge, but handled largely by tubular reabsorption.[274] Rebuttals against this theory have been effective, including new insights regarding the importance of the podocyte slit diaphragm in genetic causes of proteinuria and the molecular mechanisms of albumin transport in the proximal tubule. Presently glomerular size and charge selectivity are still considered the main barriers to albuminuria.[275,276] For a detailed discussion regarding the pathophysiology of glomerular proteinuria, the reader is directed to Chapter 45.

Large Plasma Proteins. Large molecular weight plasma proteins are restrained from crossing the glomerular barrier. Proteins such as globulins (molecular weight 160,000 daltons, radius, 5.5 nm) are undoubtedly restricted by the basement membrane, but the contribution of the endothelial fenestrae is uncertain. A tiny fractional clearance of large plasma weight proteins has been established and animal studies suggest that this is due to the presence of rare, very large pores in the glomerular ultrafiltration barrier.[277] Changes in glomerular plasma flow do not alter the restriction of these molecules from the urine space.

Proteins in Urine Not of Plasma Origin

The major protein in normal human urine that has no counterpart in plasma is THP, a glycoprotein with a molecular weight of 7 million.[250,278,279] It is excreted in amounts of 20 to 100 mg per day.[280,281] Immunofluorescent staining techniques in human kidneys have demonstrated that THP is confined to the cells lining the thick ascending limb of Henle's loop and the most proximal part of the distal convoluted tubule, which strongly suggests that these cells are the source of the THP in the urine.[282,283] THP is the major protein component of urinary casts.[282,284] Excretion of this protein increases only slightly in patients with nephrotic syndrome, and its excretion rate does not appear to be related quantitatively either to the number of casts or to the degree of proteinuria.[284] In vitro studies indicate that the addition of albumin to THP-containing solutions leads to precipitation of THP,[284] which suggests that increased albumin excretion may lead to precipitation of THP in the tubules causing cast formation. The structure and function of this unusual glycoprotein has been extensively reviewed.[250] Mutations in the gene coding for THP are associated with rare hereditary tubulointerstitial kidney diseases, and in large populations, genetic variation is associated with CKD.[285,286]

In addition to THP, many other discrete proteins unrelated to plasma proteins have been identified in trace amounts in urine.[278] These proteins presumably originate in the lower urinary tract and prostate gland. Endothelin, the potent endogenous vasoconstrictor peptide, is produced by renal epithelial cell lines in vitro, appears in human urine, and may serve as a nonspecific marker of kidney damage.[287] In fact, intense efforts are underway to identify urinary proteins that may signal acute or chronic kidney damage.[288]

Measurement of Urine Protein

Urine protein excretion is routinely measured to detect, evaluate, and manage kidney disease. Historically, total urine protein was considered the preferred measure of proteinuria because of the simplicity of the assays. However, due to lack of a gold standard for total urine protein, and due to the evidence that albumin excretion rises substantially before total urine protein becomes abnormal, there has been a shift of emphasis to measurement of albuminuria. Nonetheless, total urine protein is still widely measured using a variety of methods (Table 9.9).[289]

The simplest and most widely used methods are semiquantitative tests done on random urine samples. Although these tests are extremely useful in screening for proteinuria, they detect an abnormal concentration of total urine protein, not an abnormal excretion rate. Therefore, they might be positive in patients with low urine volume even if the excretion rate is normal, and they may be negative in patients with high urine volume even if the excretion rate is elevated. For more definitive evaluation and management of patients with proteinuria, quantitative protein analysis must be undertaken in timed urine collections. A number of different methods are available for assay of specific proteins.[290] Semiautomated, two-dimensional, electrophoretic systems, which employ ultrathin gels, combined with silver staining, allow the detection of a host of specific urinary proteins on a routine basis.[291,292] These techniques also improve the characterization of urinary proteins with molecular weights less than 70,000.[293] Specific immunoassays are available for detection of individual proteins within the urine, as described subsequently for albumin. Additionally, broad descriptions of patterns of urinary protein excretion have become possible by proteomic techniques.[294]

Semiquantitative Tests for Total Urine Protein

Semiquantitative tests for urinary protein involve either precipitation of protein or protein-induced color changes of an indicator dye on a dipstick. The precipitation tests may be performed by adding either 5% sulfosalicylic acid or concentrated nitric acid to an aliquot of urine or by heating the urine and adding glacial acetic acid.[289] With these methods, the quantity of precipitate is graded from 0 (no precipitate) to 4+ (heavy gelatinous precipitate). Urine samples with a protein concentration as low as 5 to 10 mg per dl will give a positive reaction with the acetic acid precipitation test,

9.9 Definitions of Proteinuria and Albuminuria

	Urine Collection Method	Name (units)	Interpretation of Results: Normal to High Normal	High	Very High
Albumin	24-hour collection	AER (mg/day)	<30	30–300	>300
	Spot urine albumin-to-creatinine ratio	ACR (mg/g)	<30	30–300	>300
Total Protein	24-hour collection	PER (mg/day)	<150	150–499	>500
	Spot urine	PCR (mg/mmol, mg/g)	<150	150–499	>500
	Spot urine	Protein dipstick	negative to trace	trace to 1+	>1+

To convert from mg/g creatinine to mg/mmol of creatinine multiply by 0.113.
ACR; albumin/creatinine ratio; AER, albumin excretion rate; PCR, protein/creatinine ratio; PER, protein excretion rate.

but radiopaque contrast materials, tolbutamide, or large amounts of penicillin, nafcillin, or oxacillin may produce a false-positive reaction.[289,295,296]

The dipstick test for protein (also see Urinalysis section) utilizes a paper strip impregnated with a pH indicator dye (tetrabromophenol blue) buffered to maintain the pH in the paper at 3.0. The test is based on the capacity of proteins to change the color of tetrabromophenol, and is more sensitive to albumin than other proteins.[289] The degree of color change is roughly proportional to the amount of protein present, with the color varying from yellow, with low protein concentrations, to blue, with high protein concentrations. A color comparison chart is provided with the dipstick that contains a scale of protein concentrations as well as a 0 to 3 or 4+ rating. It should be noted that the correlation between color change and actual protein concentration is only approximate. In one study, for example, comparison with quantitative methods indicated agreement only 60% to 70% of the time.[297] The use of the dipstick test is further restricted by the finding of substantial interobserver variation between technicians in interpretation of the results,[298,299] which can be improved by semiautomated and automated reading devices.[300] Additionally, different brands of dipsticks may have different performance characteristics.

The dipstick method has the advantage that it is not affected by urine turbidity, radiopaque material, or drugs.[289,296] It can give a false-positive value in highly buffered alkaline urine, but such samples are encountered rarely. The major fault of the dipstick test is its insensitivity. Although dipstick tests can detect protein concentrations as low as 6 to 15 mg per dl,[298] it is only protein concentrations of 30 mg per dl and above that are detected with certainty. Below this level, the test is negative or trace positive in over half the samples tested.[297,301] In a patient excreting 300 mg of protein per day in a total volume of 1,500 mL, the protein concentration is only 20 mg per dl, and this concentration may not be detected using the dipstick method. Also, the test is insensitive to light chains and can give a negative reaction even when the excretion of this protein is moderately high.[302–304] In selected populations, dipstick screening for proteinuria carries a high risk for false-positive and -negative results with a sensitivity of less than 67% and specificity of 74%.[305]

Quantitative Tests for Total Urine Protein

As discussed previously, the major limitation to tests for total urine protein is the absence of an absolute gold standard due to the presence of many different types of protein in the urine in health and disease. Thus, it is not possible to entirely standardize measurements across laboratories or to determine precise cut-off values for the definition of normal or various diseases. Despite this limitation, a large number of tests are available.

Excretion in Timed Collection. Quantitative methods for measuring protein excretion have been traditionally based on precipitation of protein, usually accomplished using trichloroacetic acid or sulfosalicylic acid. Presently, these methods have been largely replaced by precipitation with other agents, such as benzethonium chloride or benzalkonium chloride, or by colorimetric methods employing automated dye binding assays, using pyrogallol red or pyrocatechol violet dyes.[306,307]

In the precipitation methods, the denaturing substance is added to an aliquot of urine, and the turbidity, measured with a photometer or nephelometer, is compared to standards prepared by the addition of known amounts of

protein to urine. The dye binding assays use a photometer to measure absorbance at a given wavelength of color.[308] These methods remain only roughly quantitative, however, because they have a CV as large as 20%.[289,309] Light chains (Bence Jones protein), however, are effectively measured by these methods, although the precision of measurement is poor compared to pheresis and ELISA. Relative insensitivity to globulins has been reduced by the use of TCA or other precipitating agents, but still is an issue.[309] Iodinated contrast material can falsely elevate the turbidity regardless of agent, and it is best to wait 24 hours after contrast to determine protein excretion rates.[310] With all of these tests, the protein concentration is multiplied by the total volume of the sample and result reported in milligrams or grams per unit of time (usually 24 hours).

Excretion in an Untimed Collection ("Spot Urine Sample"). Twenty-four-hour protein excretion can be easily approximated by measurement of both protein and creatinine in a random urine specimen. Because the excretion of both creatinine and protein is fairly stable throughout the day, if the daily creatinine excretion is known, the ratio of the concentrations of protein and creatinine in a random urine specimen provides an estimate of the daily protein excretion (Fig. 9.11).[311–313] In most circumstances, however, urine creatinine excretion is not known, but is assumed to be 1.0 g per day. However, as discussed before, in the steady state, creatinine excretion is a reflection of creatinine generation, which is affected by age, sex, race, and body size and changes in GFR. Thus, the protein-to-creatinine ratio may differ substantially from protein excretion rate, especially in the non–steady state. Nonetheless, within populations, correlations of protein-creatinine ratio with protein excretion rate are moderate to high and associations of protein-creatinine ratio with disease outcomes are strong. Consequently, this test is now widely used as a first quantitative test, with confirmation using a timed urine collection if necessary.

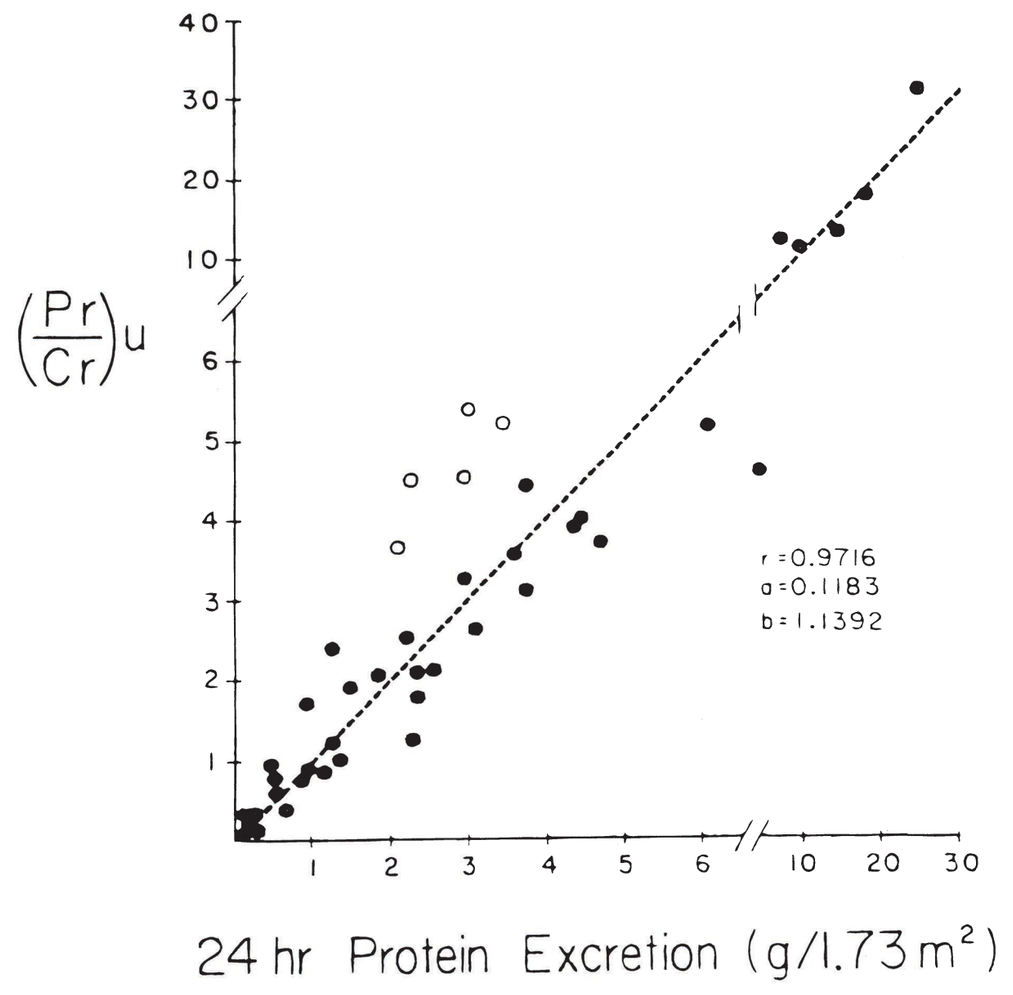

FIGURE 9.11 Ratio of urinary protein to creatinine concentration (Pr/Cr) of random single voided urine samples expressed as a function of protein excretion per 24 hours per 1.73 m^2. (From Ginsberg JM, Chang BS, Matarese RA, et al. Use of single voided urine samples to estimate quantitative proteinuria. *N Engl J Med.* 1983;309:1543, with permission.)

Recently, dipsticks have become more widely available as an alternative method to measure the urine protein-to-creatinine ratio with initial results suggesting excellent reasonable correlation with standard measures for screening.[314,315]

It has also been demonstrated that the protein-osmolality ratio in a random urine sample may reliably predict protein excretion rates. This ratio was successful in screening for abnormal proteinuria in normal and proteinuric populations with a sensitivity of 96% and a specificity of 93%, superior to routine dipstick performance and equal to the protein-creatinine ratio.[316] Adequate validation studies have not been performed to date, and this test cannot yet be recommended in place of the protein-creatinine ratio.

Clinical practice guidelines by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) recommend measurement of total urine protein in adults using spot urine protein-to-creatinine ratios and expressing the results as total protein in milligrams per creatinine in gram. The normal value varies with the laboratory, but is approximately <200 mg per g (Table 9.9).

Tests for Specific Proteins

Albumin. Specific radioimmunoassay is the standard test for detecting and quantitating albumin concentrations, although turbidimetric assays can be used with similar precision.[317] HPLC techniques allow for even more accurate and early detection of abnormal albumin excretion rates but are not widely available and also have limitations in reproducibility.[318] Many different screening tests are also available as qualitative screens with varying ability to detect albuminuria in the normal and above normal range.[319–322]

Albumin excretion in timed urine samples is considered the gold standard for classification of albuminuria. Given the wide variability in urinary albumin excretion at the low range, several urine samples should be tested to classify albumin as high.[323] The albumin-to-creatinine ratio in a spot urine sample is widely used as a first test for albuminuria, with high correlation with albumin excretion rate,[324,325] but is subject to the same limitations as the protein-to-creatinine ratio. Moreover, spot samples for albumin concentration or for albumin-to-creatinine ratio are associated with a strong graded relationship with adverse outcomes in the general population and populations at increased risk for cardiovascular and kidney diseases, with increased risk detectable at levels greater than 10 mg per g.[3,247,326] Some but not all

recent studies suggest optimal prediction of outcome with albumin-to-creatinine ratio (tested in first morning samples) rather than other measures of proteinuria.[327,328] NKF KDOQI, Kidney Disease: Improving Global Outcomes (KDIGO), and National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) National Kidney Disease Education Program (NKDEP) all recommend spot urine albumin-to-creatinine ratio for detecting and following chronic kidney disease in adults (Table 9.9).[1,243,329–331]

Dipsticks are also available to measure the albumin-to-creatinine ratio[332] but validation studies remain mixed in terms of their sensitivity and specificity,[333] although performance of these dipsticks are improved by adjustment for specific gravity.[334] Presently, they may be most useful for screening high-risk populations with quantification better served by laboratory testing.

Immunoglobulin Light Chains. Identification of immunoglobulin fragments in the urine is useful in establishing the diagnosis of multiple myeloma and other monoclonal gammopathies. Light chains are often sought by the traditional Bence Jones test, a method that depends on the unusual solubility characteristics of these proteins. When the urine is heated to 45°C to 55°C, light chains precipitate, particularly when the pH is brought to 4.9 by the addition of an acetate buffer.[335] When the urine is then brought to a boil, the precipitated light chains redissolve partially or completely. This test is difficult to carry out properly and can be rather insensitive. It is positive only when the concentration of light chains exceeds 800 to 1,600 mg per L,[336,337] and even in the presence of such concentrations, it may still be falsely negative.[304,336,338] As noted earlier, the semiquantitative dipstick test also may be negative when light chains are present in the urine due to the insensitivity of the indicator dye to globulins.[302,303] By far the most sensitive tests for detection of light chains and other immunoglobulin fragments are routine electrophoresis and immunoelectrophoresis. In the presence of light chains, routine electrophoresis discloses a monoclonal peak, and immunoelectrophoresis (of concentrated urine) makes it possible to accurately identify the specific protein, even at low concentrations.

Patterns of Proteinuria

Proteinuria can be classified according to its pathophysiology into three major groups: glomerular proteinuria, tubular proteinuria, and overproduction proteinuria.

Glomerular Proteinuria

Glomerular proteinuria is defined as proteinuria due to increased permselectivity of the glomerular filtration barrier to plasma proteins. Therefore, the hallmark of glomerular proteinuria is albuminuria (Fig. 9.12). Albuminuria may be a transient phenomenon in normal individuals without kidney disease. However, persistent albuminuria (albumin-creatinine ratio >30 mg per g for 3 or more months)

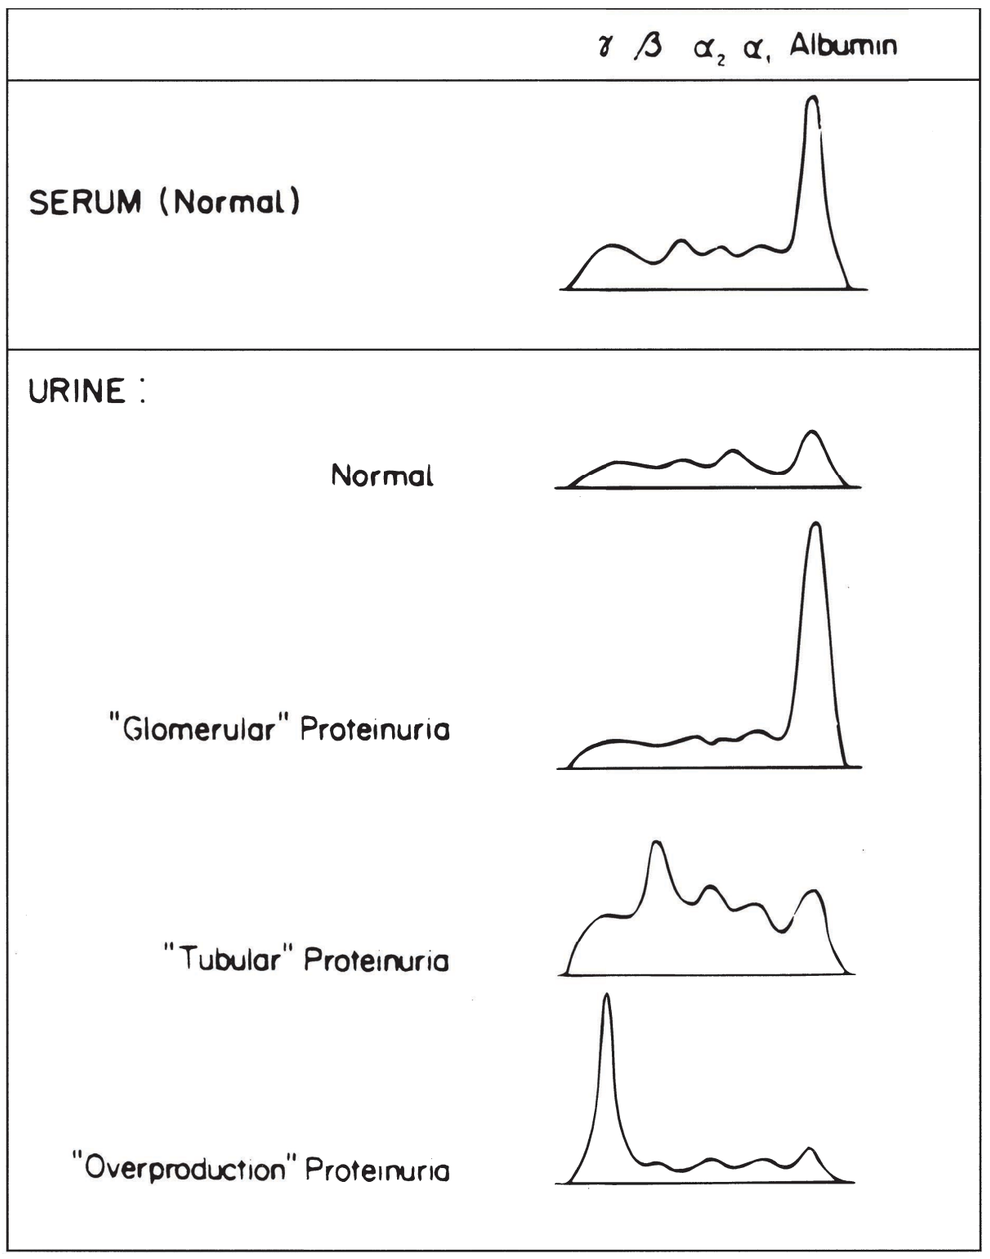

FIGURE 9.12 Electrophoretic patterns of normal serum, normal urine, and urine with three types of abnormal protein excretion. The electrophoresis pattern shown for overproduction proteinuria is taken from a patient with multiple myeloma.

indicates the presence of kidney disease, even when kidney function is normal, when the urine sediment contains no abnormalities, and when the patient has no signs or symptoms of kidney disease.[339–341] Indeed, albuminuria occurs in the great majority of kidney diseases. Whether the primary site of injury is the glomerulus or the tubulointerstitial compartment, albumin makes up 60% to 90% of the urinary protein (Fig. 9.12). The excretion of low molecular weight proteins usually remains minimal.[342,343]

The persistent excretion of small amounts of albumin has been termed microalbuminuria. The term has been defined variably, but usually refers to an albumin excretion rate of 30 to 300 mg per day, which is above the normal values of 5 to 20 mg per day, but less than that detected by tests for total urine protein (i.e., 200–300 mg per day). Albumin excretion greater than 300 mg per day is sometimes referred to as macroalbuminuria or clinical proteinuria, because it can sometimes be detected by the usual dipstick. Despite their widespread usage, these terms should probably be abandoned, because they are technically incorrect or imprecise. Neither microalbuminuria nor macroalbuminuria refer to the size of urinary albumin fragments, and clinical proteinuria does not convey a specific meaning. It has now been proposed to classify albuminuria using the albumin-to-creatinine ratio as normal (<10 mg per g), high normal (10–29 mg per g),

high (30–299 mg per g), very high (300–1,999 mg per g), or nephrotic (>2,200 mg per g).[344]

An albumin excretion rate between 300 and 2200 mg per day, corresponding to a total protein excretion rate between 500 mg and 3,500 mg per day can be seen in many types of CKD, whereas excretion rates greater than this amount are almost invariably the result of glomerular disease. Persistent excretion of ≥2.2 g per day of albumin or ≥3.5 g per day of total protein usually leads to the nephrotic syndrome.[345] Clinical and laboratory evaluation can identify the cause of CKD in many patients with the nephrotic syndrome, but the various histologic subtypes can be definitively identified only by kidney biopsy.

Functional Albuminuria. A transient increase in albumin excretion occurs in a variety of physiologic and experimental settings in the absence of kidney disease. Protein excretion is increased twofold to threefold during and immediately following heavy exercise,[346–348] and the increase is accounted for largely by plasma protein components.[249,349,350] Minor abnormalities in the urine sediment can accompany the proteinuria, but both the proteinuria and the sediment abnormalities usually disappear within hours after the completion of exercise. Similar increases in protein excretion can be induced by fever,[351] severe emotional stress,[352] infusions of norepinephrine or angiotensin,[353,354] and prolonged assumption of the lordotic position.[355] In addition, mild to moderate proteinuria often is observed in patients with congestive heart failure.[356]

Orthostatic Albuminuria. In patients with CKD, proteinuria typically increases in the upright position to levels above those present in the recumbent position. This orthostatic change in excretion appears to have no special diagnostic or prognostic importance. The finding of proteinuria (mainly albumin) only in the upright position is known as orthostatic or postural proteinuria.[357,358] In this condition, total daily excretion usually does not exceed 1 g. Postural proteinuria occurs in the healing phase of many glomerular diseases and also in the absence of kidney disease. In the latter group, minor histologic abnormalities are found on kidney biopsy in approximately one half of the patients.[359] Kidney biopsy in patients with postural proteinuria typically discloses few morphologic abnormalities either on light or electron microscopy,[359–361] although in two reports both immunoglobulins and complement were identified in a substantial fraction of such patients on immunofluorescence microscopy.[362,363] The significance of this finding is uncertain.

To test for postural proteinuria, the patient is instructed to collect a urine sample in the upright position, while carrying out his other usual daily activities. A 16-hour collection can begin in the morning and end just before the patient goes to bed. On retiring, the patient begins an 8-hour recumbent urine collection, including voiding at the time of arising. The amount of protein in both samples is extrapolated to 24 hours. Patients with postural proteinuria have an increased excretion in the specimen collected in the upright position and a normal excretion in the specimen collected when recumbent. If protein excretion is increased in both specimens, the patient has persistent rather than postural proteinuria.

Long-term follow-up studies strongly suggest that postural proteinuria is a benign condition.[358,364] After 10 years of follow-up in one study, it was found that over half of the patients no longer had proteinuria, somewhat less than half continued to have postural proteinuria, and only a small minority developed persistent proteinuria.[365] Decreased GFR was not observed, and hypertension was a rare occurrence. After 20 years of follow-up of many of the same patients, all those examined had normal kidney function, the prevalence of hypertension was no different from that in the general population, and only one third had proteinuria. In half of the proteinuric group, the pattern of protein excretion was still the postural variety.[366] Thus, the prognosis of patients with postural proteinuria appears to be excellent, and patients with this condition should be reassured about the benign nature of the disorder.

Protein Selectivity. Proteinuria can be classified into either a selective or a nonselective pattern, based on a comparison of the clearance of larger molecular weight proteins, such as globulins, with the clearance of albumin.[290,291,367] Investigators have sought to gauge the severity of the glomerular leak by measuring the relative clearance rates of proteins of various sizes.[268,368,369] In patients with proteinuria secondary to a wide variety of CKDs, the clearance rates of large molecules, such as IgG, range from less than 10% to greater than 60% of the clearance rate of albumin or transferrin, a protein similar in size to albumin. Patients with a clearance ratio of IgG/albumin (or transferrin) of less than 0.10 are considered to have only a modest increase in glomerular permeability and are defined as having a "highly selective" pattern of protein excretion. Conversely, patients in whom the clearance ratio is 0.5 or greater are considered to have a relatively porous filter and are defined as having a poorly selective pattern.

Studies of the pattern of protein excretion have shown that the majority of patients with proteinuria have a nonselective pattern.[368,369] Among patients with the idiopathic nephrotic syndrome, however, two populations emerge. One group has selective proteinuria and, in most cases, has minimal change in the disease. The second group has nonselective proteinuria and usually has one of the more severe histologic varieties, such as membranous nephropathy or membranoproliferative glomerulonephritis. Because of this correlation and the frequency of the minimal change lesion among patients with the idiopathic nephrotic syndrome, selectivity studies could have some value in predicting the presence of the minimal change lesion. However, the technical difficulties involved in carrying out the protein analyses, the failure of the test to distinguish among the many subgroups of nephrotic syndrome, and the low risk of kidney biopsy relative to its diagnostic yield have made measurements of selectivity superfluous in the study of the nephrotic patient.

Tubular Proteinuria

A pattern of abnormal protein excretion in which low molecular weight proteins predominate is found in patients with a diverse group of kidney diseases characterized by primary tubular injury. This includes hereditary tubular disorders, such as Fanconi syndrome and Wilson disease,[370] chronic potassium depletion, acute renal failure due to acute tubular necrosis, Balkan nephropathy,[371] and cadmium poisoning.[372,373] The low molecular weight proteins excreted by these patients are the plasma constituents described earlier that are present in only minute amounts in the urine of normal individuals.[374] As many as 20 of these proteins have been identified. A typical pattern seen in these patients is shown in Figure 9.12. The magnitude of tubular proteinuria exceeds 150 mg per day and rarely is greater than 2 g per day.[375–377]

As described previously, the urinary clearance rates of these low molecular weight proteins in normal individuals and in patients with glomerular disease are very low despite the fact that these proteins are filtered readily, suggesting that when the tubules are intact, extensive tubular reabsorption and degradation of these substances occurs.[254,370] By contrast, in patients with primary tubular diseases, the clearance rates of these proteins are markedly increased. In fact, in these patients, the clearance rate correlates closely with the predicted filtration rates of these proteins (estimated from molecular size) if the assumption is made that no tubular uptake occurs.[370] On the basis of these observations, it appears that tubular proteinuria is due to impaired tubular reabsorption of low molecular weight proteins rather than to increased glomerular permeability.[343,370]

Among the low molecular weight proteins excreted in excess in tubular and interstitial diseases are N-acetyl-beta-D-glucosaminidase (NAG), beta-2 microglobulin (B2M), neutral endopeptidase, and lysozyme (muramidase), an enzyme with a molecular weight of 14,600. The finding of increased amounts of these proteins has received attention as a diagnostic aid in identifying tubular and interstitial disease as well as serving as an early marker of acute kidney injury (AKI).[378–381] The cause for increased excretion of these low molecular weight proteins is thought to be ineffective reabsorption and catabolism by the injured, dysfunctional tubules.[382] Lysozyme excretion is increased in patients with tubular damage secondary to infection, transplant rejection, nephrotoxic agents, and Fanconi syndrome. Unfortunately, the diagnostic utility of this determination is limited because many patients with interstitial and tubular disease do not have lysozymuria and because increased excretion of lysozyme occurs in some patients with glomerular diseases.[379] The largest increase in lysozyme excretion occurs in patients with leukemia, presumably secondary to increased production of this protein (see Overproduction Proteinuria).

The interpretation of increased excretion of light chains poses a problem similar to that encountered in patients with lysozymuria—namely, to distinguish between increased excretion secondary to tubular disease on the one hand or to overproduction of the protein on the other. In the case of light chains, a slight increase in excretion and a finding of a mixture of both kappa and lambda fragments points to a primary tubular defect, whereas high levels of excretion (greater than 500 mg per day) and the presence of only a single type of light chain points to accelerated synthesis.[383,384]

Overproduction Proteinuria

When the plasma concentration of a filterable protein is increased beyond the capacity of the tubules to reabsorb it, it then appears in the urine. Enhanced excretion of light chains, heavy chains, and other fragments of immunoglobulins occurs predominantly in the monoclonal gammopathies, including multiple myeloma, macroglobulinemia, heavy-chain disease, and idiopathic light-chain proteinuria (Fig. 9.12). Overproduction with increased filtration rather than a primary tubular defect appears to account for the increased excretion of these substances. Both light-chain and heavy-chain fragments of immunoglobulins are excreted in minute amounts in the urine of normal individuals.[352,385] Normally, only 3 mg or so of light chains are excreted daily and the ratio of kappa to lambda light chains is approximately 3 to 1.[386–388] Approximately 25% are present as monomers and the remainder as dimers, even though light chains are normally synthesized as monomers.[386,389,390]

Because light chains are small in size and a substantial amount is filtered, it follows that an increase in their delivery into the glomerular filtrate will result in increased excretion unless tubular reabsorption is concomitantly increased. In fact, the clearance of light chains in patients with multiple myeloma is quite high and is inversely related to molecular size—a finding consistent with the view that tubular reabsorption is readily saturated.[391] In these patients, light chains have clearances ranging from one tenth to one half that of creatinine, depending on the size of the specific protein destined for excretion (Table 9.8). Light-chain proteinuria is most often found in patients with multiple myeloma and, in this disease, some patients have a daily excretion greater than 15 g. Although a mild increase in albumin excretion is common in patients with monoclonal gammopathies, the excretion of light chains usually predominates, unless the glomerular lesion of renal amyloidosis (or light-chain deposition disease) supervenes. Increased excretion of lysozyme in acute leukemia,[392] amylase in pancreatitis, myoglobin in muscle injury, and hemoglobin following hemolysis are other examples of overproduction proteinuria. The quantity of urine proteins can serve as an index of clinical disease. In the case of light chains, the quantity of light-chain excretion is a reflection of tumor burden and is used clinically as a biomarker of remission and relapse after treatment.

Overproduction proteinuria can have important clinical consequences. Patients with light-chain proteinuria can develop acute or chronic kidney failure, and others manifest the Fanconi syndrome,[393,394] distal renal tubular acidosis,[384] nephrogenic diabetes insipidus, or various combinations of these disorders.[383,384] The association between light-chain

proteinuria and tubular nephropathies has led to the speculation that light chains are toxic to renal tubular cells.[384,393,394] Because some patients with increased excretion of light chains have no abnormalities of tubular function, the specific factors producing tubular dysfunction remain to be defined.[383] Similarly, the lysozymuria associated with leukemia has been implicated as a cause of renal potassium wasting seen in some patients.[395] However, in view of studies demonstrating potassium wasting in some leukemic patients in the absence of lysozymuria, this thesis must be considered unproven.[396,397] It should be noted that lysozymuria also occurs in experimental glomerulonephritis and that its excretion is in direct proportion to the magnitude of the albuminuria.[398]

The Interpretation of Proteinuria

Proteinuria is central to the detection, evaluation, and management of CKD (Table 9.10). The pattern of proteinuria can be assessed by first determining whether the urine protein contains albumin. A positive dipstick test is strongly suggestive of albuminuria, which, when substantial, most likely indicates glomerular proteinuria. Quantification of albumin excretion provides a clue to diagnosis, prognosis, and response to therapy. A negative dipstick test in the presence of elevated total urine protein excretion suggests nonalbumin protein due to tubular proteinuria or overload proteinuria. Electrophoresis or other tests should be performed to detect light chains or other low molecular weight proteins when suspected.

NKF KDOQI guidelines on CKD define persistent proteinuria for 3 months as a marker of kidney damage, which is sufficient for the detection of CKD, even in the absence of other markers of kidney damage or decreased GFR. Persistent albumin excretion (>30 mg per day, roughly equivalent to an albumin-creatinine ratio >30 mg per g) is widely acknowledged to be the earliest sign of diabetic nephropathy. Persistent albuminuria in this range is generally required for the diagnosis of diabetic nephropathy, and precedes the decline in GFR in most patients.[399] The literature indicates that albuminuria in this range is one of the earliest markers of kidney damage in hypertension, but does not occur in all patients prior to the reduction in GFR.[400,401] However, there is a substantial heterogeneity in the presentation of these diseases, likely due to the substantial coexistence of type 2 diabetes and hypertension. In these diseases and others, it seems likely that albuminuria is associated with systemic endothelial dysfunction in addition to altered glomerular permselectivity, which may relate to its increased risk for cardiovascular disease. Using this definition of albuminuria as a marker of kidney damage has enabled studies of the prevalence of earlier stages of CKD, regardless of specific cause, in large populations.[402]

A large number of clinical practice guidelines now suggest routine testing for urine albumin-to-creatinine ratio. The National Kidney Foundation recommends testing for albuminuria in all individuals at increased risk for CKD, including those with hypertension, diabetes, a family history of kidney disease, or advancing age.[1] The American Diabetes Association also endorses routine testing for albuminuria in all diabetic subjects as part of their evidence-based guidelines.[403] Furthermore, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) recommended routine urinalysis in the evaluation of all patients with hypertension with the option of measuring urine albumin excretion as well.[404] Increasingly, guidelines focus on the urine albumin-to-creatinine ratio as the screening test of choice, and the optimal way to quantitate proteinuria in CKD.

9.10 Importance of Proteinuria in Chronic Kidney Disease

Interpretation	Explanation
Marker of kidney damage	Spot urine albumin-to-creatinine ratio >30 mg/g or spot urine total protein-to-creatinine ratio >150 mg/g for ≥3 months defines CKD
Clue to the type (diagnosis) of CKD	Spot urine total protein-to-creatinine ratio >500–1000 mg/g suggests diabetic kidney disease, glomerular diseases, or transplant glomerulopathy
Risk factor for adverse outcomes	Higher proteinuria predicts faster progression of kidney disease and increased risk of CVD
Effect modifier for interventions	Strict blood pressure control and ACE inhibitors are more effective in slowing kidney disease progression in patients with higher baseline proteinuria
Hypothesized surrogate outcomes and target for interventions	If validated, then lowering proteinuria would be a goal of therapy

ACE, angiotensin-converting enzyme; CKD, chronic kidney disease; CVD, cardiovascular disease.

Initial and repeated measurement of protein excretion is a valuable guide in following the course of patients with kidney disease. Several studies have established that the magnitude of proteinuria is directly correlated with the risk of progressive decline in kidney function, regardless of the cause or type of kidney disease.[405–407] This is also true, independent of the level of GFR.[408]

Secondary analysis of recent clinical trials demonstrates that the beneficial effects of lowering blood pressure and inhibition of the renin-angiotensin system are greater in patients with higher levels of proteinuria at the beginning of therapy.[409–413] Consequently, the magnitude of proteinuria is central to the new guidelines for the management of hypertension in chronic kidney disease.[400] For patients with persistent albumin-to-creatinine ratio >30 mg per g, the guidelines recommend a lower target blood pressure (<130/80 mm Hg) and initial antihypertensive therapy using an ACE inhibitor or ARB. Furthermore, evidence has mounted to demonstrate that the degree of reduction in proteinuria serves as an important guide to the prognosis of patients treated with ACE inhibitor or ARB therapy. Studies demonstrate that the better the antiproteinuric response to therapy, the better the outcome.[409,414,415] This may lead to the selection of agents and dosing based on the antiproteinuric response. This strategy would need to be tested in a prospective fashion, in various kidney diseases, before being broadly adopted, as adverse effects of higher dose or combination agents may outweigh their benefits.[416]

URINALYSIS

Urine examination has been used in medicine for more than 6,000 years.[417] Ancient Hindu, Babylonian, and Egyptian physicians are known to have used urine for diagnosing illnesses, and the connection between sweet urine and diabetes was made as early as 600 BC.[417] Early western physicians like Hippocrates (460–355 BC) and Galen (129–200 AD) have written about the associations between different urinary characteristics and disease states.[417] During medieval times (500–1500 AD), urinalysis established its place as an unrivalled diagnostic tool and was also widely used by unscrupulous profiteers to prognosticate future events.[418]

The modern urinalysis techniques took a foothold in the 19th century with the use of microscopy; description of casts; discovery of chemical analysis methods for urine, glucose, bile acid, protein, and blood; and the development of urinary test strips.[419,420] Dipsticks became commercially available in 1956 and, since the early 21st century, the manual reading of dipsticks is increasingly being replaced by sophisticated semiautomatic or automatic strip readers with both chemical and sediment analysis capabilities.[300] In spite of advances in microscopy, chemical analysis, and automation, direct examination of urine by physicians provides invaluable diagnostic information and remains indispensable for evaluating patients who are suspected of having acute or CKD.

Urinalysis entails macroscopic, dipstick, and microscopic examinations of the urine. The standards for urinalysis have not yet been uniformly applied and there is a wide inter-operator variability in the interpretation of both macroscopic and microscopic findings.[298,299,421–423] A number of organizations have recently developed guidelines to make laboratory urinalysis more uniform, but most nephrologists perform this procedure in their office outside of laboratory purview.[424,425]

Urine Collection

Urine specimens can be obtained by voiding into a container, urethral catheterization, or suprapubic needle aspiration of the bladder. Voiding into a container is the most commonly used method. Urethral catheterization is usually reserved for patients who are unable to void due to urinary obstruction, incontinence, or impaired consciousness. Suprapubic needle aspiration of the bladder is mostly done in infants and is only used in older children or adults if urine cannot be obtained by any other means. Regardless of the method used, every effort should be made to avoid specimen contamination with the contents of skin, urethra, or vagina. Urethral catheterization and suprapubic aspiration should be done using a sterile technique to prevent introduction of infection into the bladder.

A clean catch sample is essential for accurate assessment. Patients should be instructed to wash their hands before sample collection. Men should retract the foreskin and wash or use sterile wipes to clean the external genitalia. For uncircumcised men, the foreskin should be held back during the entire collection time. Women should separate the labia and clean the area around the urethral meatus with sterile wipes going from front to back. The same procedures are used for children. For infants and very young children, external genitalia are cleaned and dried using wipes and towels, and a sterile urine collection bag is placed over the area using adhesives to adhere to the skin. A mid-stream clean catch sample is preferred as this is least likely to be contaminated. The specimen should be examined as soon as possible after the collection as the chemical composition of urine changes and formed elements degenerate over time. Highly concentrated and acidic urine favor cellular preservation. Refrigeration is acceptable but leukocytes break down rapidly and cell counts performed after 2 to 4 hours may be questionable even with refrigeration.[426] Microbiologic investigations should be done within 2 hours and if more than 2 hours of delay is expected then the sample should be refrigerated at 4°C.[424]

The first morning urine is traditionally considered to be the standard specimen for urinalysis as it best correlates with a 24-hour urine sample.[1] The first morning specimen is least likely to be affected by prior food or fluid intake, movement, and also allows for preservation of formed elements as it is usually most concentrated and acidic.[424] A random urine sample is an acceptable alternative to the first morning urine in an acute setting, and when the collection, storage, and timely transportation of the first morning specimen is difficult.

Macroscopic Examination

Normal urine color is determined by the concentration of the pigment urochrome. Urochrome is the product of hemoglobin metabolism in the liver. Urine is pale yellow when it is dilute and dark yellow or amber colored when it is concentrated. Occasionally, the precipitation of phosphate crystals in alkaline urine and urate crystals in acidic urine may give rise to cloudy urine in the absence of any disease. The appearance of urine changes in certain disease states, and with the ingestion of certain foods or drugs.[300] Cloudy urine may be seen in urinary tract infection or in the presence of significant pyuria. Foamy urine suggests moderate to heavy proteinuria. Reddish urine indicates hematuria, hemoglobinuria, myoglobinuria, or the intake of rifampin, phenytoin, phenazopyridine, or beet-root. Yellow-brown urine may be seen in hyperbilirubinemia, or following the ingestion of chloroquine, nitrofurantoin, senna, or rhubarb. White milky urine suggests chyluria, and dark or black urine may be seen in alkaptonuria, porphyria, or malignant melanoma.

Urine odor usually does not have much clinical significance. A pungent odor may indicate bacterial ammonia production. Sweet or fruity odor suggests ketonuria. Certain rare hereditary metabolic diseases may give rise to strong unusual urine odor: maple-syrup urine disease, maple syrup odor; phenylketonuria, musty or mousy odor; isovaleric academia, sweaty feet odor; hypermethioninemia, rancid butter or fishy smell; Oasthouse urine disease, brewery odor; tyrosinemia, cabbagelike or fishy odor; trimethylaminuria, stale fish odor; and hawkinsinuria, swimming pool odor.[427]

Dipstick Examination

Use of a single- or multiple-test reagent strip, commonly called a dipstick, allows for a rapid and convenient chemical screening of urine specimens. The dipstick method uses a paper or plastic strip embedded with pads that contain reagents for different chemical reactions. Reactions in these pads result in color change when a particular analyte is present in the urine. The degree of color change in each pad is then compared against the range of colors on brand-specific color charts to get a semiquantitative result for the analyte in question.

Although the dipstick method is simple to perform, certain precautions need to be taken to obtain accurate and reliable results.[300] Reagent strips should not be exposed to the extremes of temperature and must be stored in a dry place away from direct sunlight. Only the container provided by the manufacturer should be used for storage as these containers are light-sealed and have desiccants to prevent moisture. While performing the test, the reagent strip should be dipped in urine in one continuous motion and the excess urine needs to be removed by touching the edge of the strip to the urine container as mixing or dilution of reagents gives rise to false results. The color change in reagent pads takes time and reading should be done only after the manufacturer specified wait time. Strips usually have a control pad and the color change in that pad must always be compared with the standard before interpreting reactions in other pads.

Dipsticks commonly include tests for specific gravity, pH, blood, protein, glucose, ketones, bilirubin, urobilinogen, nitrites, and leukocytes. The composition of reagents and detection limits vary with different brands and manufacturers. Table 9.11 lists chemical reactions, detection limits, and conditions associated with false-positive and false-negative results for a typical dipstick. Dipstick results provide important diagnostic clues and abnormal dipstick findings usually lead to further evaluation with confirmatory tests (Table 9.12).

Dipstick reactions perform variably when compared to confirmatory tests. The dipstick specific gravity reaction detects ion concentration rather than particle mass, thus the dipstick will show a lower value for urine specific gravity than hygrometry or refractometry when nonionized molecules like glucose and radiocontrast dye are present.[428,429] The dipstick specific gravity, however, correlates fairly well with urine osmolality in most situations. Specific gravity is the relative mass of the urine compared to water, and thus reflects the total number of particles in solution and their size and density, whereas osmolality reflects only the number of particles. Therefore, a solution of glucose (molecular weight = 180 daltons) equal in osmolality to a solution of urea (molecular weight = 60 daltons) has a higher specific gravity (Fig. 9.13). For total protein, dipsticks have low sensitivity and variable specificity and positively charged proteins like immunoglobulin light chains may escape detection even when concentrations are high.[300] Dipsticks perform poorly as a screening tool for diabetes as fasting urine glucose testing has sensitivity of only 17% even though specificity can be as high as 98%.[430] Similarly, dipsticks cannot be used solely to estimate the level of ketosis as beta-hydroxybutyrate, the most abundant serum ketone during ketosis, is not detected by dipstick. Dipsticks perform well for white blood cells (WBCs) and are usually positive when more than five WBCs are present per high power field (HPF).[431,432] Dipsticks are also reliable for detecting red blood cells (RBCs) with the sensitivity and specificity of 80% to 95% and 95% to 99% for more than three RBCs per HPF, respectively.[433–435] For the detection of urinary infection, negative dipstick results for leukocytes and nitrites are likely sufficient to exclude microscopic and culture abnormalities.[432,436–438] It has been shown that 95% of urines with negative dipstick results for protein, glucose, ketones, blood, leukocytes, and nitrites have normal microscopic examination and, in most cases, microscopy can be reserved for only those with abnormal dipstick results.[432,439] Discolored urines and urine samples of patients with urinary tract symptoms or kidney disease, however, are best examined microscopically as the dipstick examination alone may not pick up all potentially relevant abnormalities.[436]

Microscopic Examination

Microscopic examination of the urine is primarily performed to identify cells, casts, crystals, and microorganisms. The examination can be a qualitative or semiquantitative procedure.

9.11 Urine Dipstick Testing

Test	Reaction in Dipstick Pad	Detection Limit[a]	Associated with False-positive Results	Conditions Associated with False-negative Results
Specific gravity	Urinary cations compete with H+ bound to polyionic polymer causing a release of free H+ that alters pH of a pH-sensitive dye	1.000–1.030	Heavy proteinuria Acidic urine	Alkaline urine
pH	H+ reacts with methyl red and bromthymol blue	pH 5.0–9.0	Prolonged storage (falsely alkaline) Formaldehyde (falsely acidic)	—
Protein	Proteins (primarily albumin) alter pH of a pH-sensitive dye (commonly tetrabromophenol blue)	≥18–32 mg/dl (albumin)	Concentrated urine Alkaline urine Phenazopyridine Polyvinylpyrrolidone (blood substitute) Chlorhexidine	Dilute urine Acidic urine
Blood	Hemoglobin or myoglobin oxidizes ortho-toluidine and organic peroxidase	≥5–20 RBC/μl	Oxidizing detergents Dilute urine Alkaline urine Hemoglobinuria Myoglobinuria Bacteria with pseudo-peroxidase activity (Enterobacteriaceae, staphylococci, streptococci)	Ascorbic acid Formalin preservative Acidic urine
Glucose	Glucose is oxidized by glucose oxidase to gluconic acid and hydrogen peroxide. Hydrogen peroxide then reacts with chromogen.	≥30–40 mg/dl	Oxidizing detergents	Ascorbic acid Keto-acids Aspirin Bacteria Concentrated urine
Ketone	Acetoacetate and acetone reacts with nitroprusside reagent	≥5–15 mg/dl (acetoacetic acid) ≥70 mg/dl (acetone)	Ascorbic acid Phenazopyridine Levodopa Mesna Free sulfhydryl group (N-acetylcysteine, captopril)	Improper storage
Bilirubin	Conjugated bilirubin reacts with aniline dye	≥0.5–1.0 mg/dl	Fecal contamination Chlorpromazine Phenazopyridine	Ascorbic acid

(continued)

9.11 Urine Dipstick Testing (continued)

Test	Reaction in Dipstick Pad	Detection Limit[a]	Associated with False-positive Results	Conditions Associated with False-negative Results
Urobilinogen	Urobilinogen reacts with dimethylaminobenz-aldehyde (Ehrlich's reaction)	≥0.4–2.0 mg/dl	Sulfonamides Phenazopyridine Procaine Alkaline urine	Prolonged storage
Nitrite	Bacteria with nitrate reductase activity reduces urinary nitrates to nitrites. Nitrites react with p-arsanilic acid, forming a diazonium compound.	≥0.05–0.10 mg/dl (typically >10 organisms/mL)	Phenazopyridine	Prolonged storage Short bladder incubation (<4 hours) Ascorbic acid Low vegetable diet Bacteria without nitrate reductase activity (Enterococcus, Neisseria, Mycobacterium)
Leukocyte esterase	Pyrrole amino acid esters are cleaved forming free pyrrole that reacts with diazonium compound.	>25–35 WBC/μl	Vaginal contamination Beets Formaldehyde Imipenem Meropenem Clavulanic acid	Concentrated urine Ascorbic acid Glycosuria Heavy proteinuria Cephalexin Gentamicin Tetracycline Nitrofurantoin

Philadelphia, PA: Lippincott Williams & Wilkins; 2007.

Preparation of the urine sediment and examination methods are of the utmost importance. About 10 mL of fresh or properly stored urine is centrifuged in a conical tube at approximately 2,000 revolutions per minute for at least 5 minutes. The supernatant is carefully decanted and the pellet is resuspended in a small amount of urine that remains in the tube by gentle agitation. A pipette is then used to transfer a drop of this resuspended pellet onto the microscope slide. A coverslip is gently placed on top of the urine before transferring the slide to the microscope. The sediment is usually examined unstained. Papanicolaou stain may be used to enhance details, and Wright's or Hansel's stain is used in special circumstances to identify eosinophils.

Microscopic examination of the urine is most commonly performed using a bright field microscope. Polarized light is used to identify some crystals and fat droplets, and phase-contrast microscopy is occasionally used when detailed examination of cell membranes is required.[439,440] The use of interference contrast microscopy, scanning electron microscopy, and transmission electron microscopy have also been reported but there use is mostly limited to research settings.[441–443] The examination is first done under low magnification (×100) to identify formed elements. Higher magnification (×400) is important to differentiate the types of casts, cells, crystals, or other abnormalities. Laboratories provide quantification by counting and averaging the

9.12 Clinical Significance and Confirmatory Tests for Urine Dipstick Results

Test	Clinical Significance	Confirmatory Test
Specific gravity	1.000–1.005: Excess water intake, diabetes insipidus 1.010 (Isosthenuric urine): Acute tubular necrosis, severe CKD >1.030: Volume depletion, glycosuria, extrinsic osmotic agent	Refractometry or hygrometry Urine osmolality
pH	<5.0: Metabolic acidosis of nonrenal cause, volume depletion, hyperaldosteronism, high protein diet >6.0–6.5: Type I renal tubular acidosis, low protein diet, infection with urea-splitting organisms (e.g., >Proteus)	pH-electrode under oil emulsification
Protein	Persistently positive in CKD with elevated albuminuria	Further quantification and qualification using a timed or spot urine sample (see Measurement of Urine Protein)
Blood	Spot staining: Hematuria Diffuse staining: Marked hematuria, hemoglobinuria, myoglobinuria	Urine microscopy
Glucose	Positive in proximal tubular dysfunction, or when serum glucose concentration is more than renal glucose threshold (180 mg/dl)	Serum glucose (diabetes); Urine amino-acid, phosphorus and uric acid (proximal tubular dysfunction)
Ketone	Positive in diabetic ketoacidosis, alcoholic ketoacidosis, starvation, and severe volume depletion	Serum keto acids
Bilirubin	Positive in conjugated hyperbilirubinemia Positive bilirubin and negative urobilinogen may indicate intestinal obstruction with conjugated hyperbilirubinemia	Serum bilirubin and liver enzymes, abdominal imaging if obstruction is suspected
Urobilinogen	Positive in conjugated hyperbilirubinemia	Serum bilirubin and liver enzymes
Nitrite	Positive in urinary infection with nitrate reducing bacteria	Urine culture
Leukocyte esterase	Positive in interstitial nephritis and urinary infection	Urine microscopy and urine culture

CKD, chronic kidney disease.

number of elements seen in at least 10 fields in different areas of the sample.[424] The number of casts is usually reported as a number of each type seen per low power field (LPF). The number of cells, crystals, or bacteria is usually reported as a number of each type seen per high power field (HPF). In the office setting, however, physicians use a variety of nonspecific terms like occasional, few, rare, frequent, many, and numerous to quantify formed elements.

Cells

Red Blood Cells. RBCs in the urine originate either from the kidney parenchyma or the urinary tract. Occasionally they may be seen in the absence of kidney or urologic diseases, especially when specimens are obtained during fever, menstruation, or following exercise.[444–446] The upper limit of normal for the number of RBCs in the urine is unclear. Addis was the first to report that healthy people may excrete

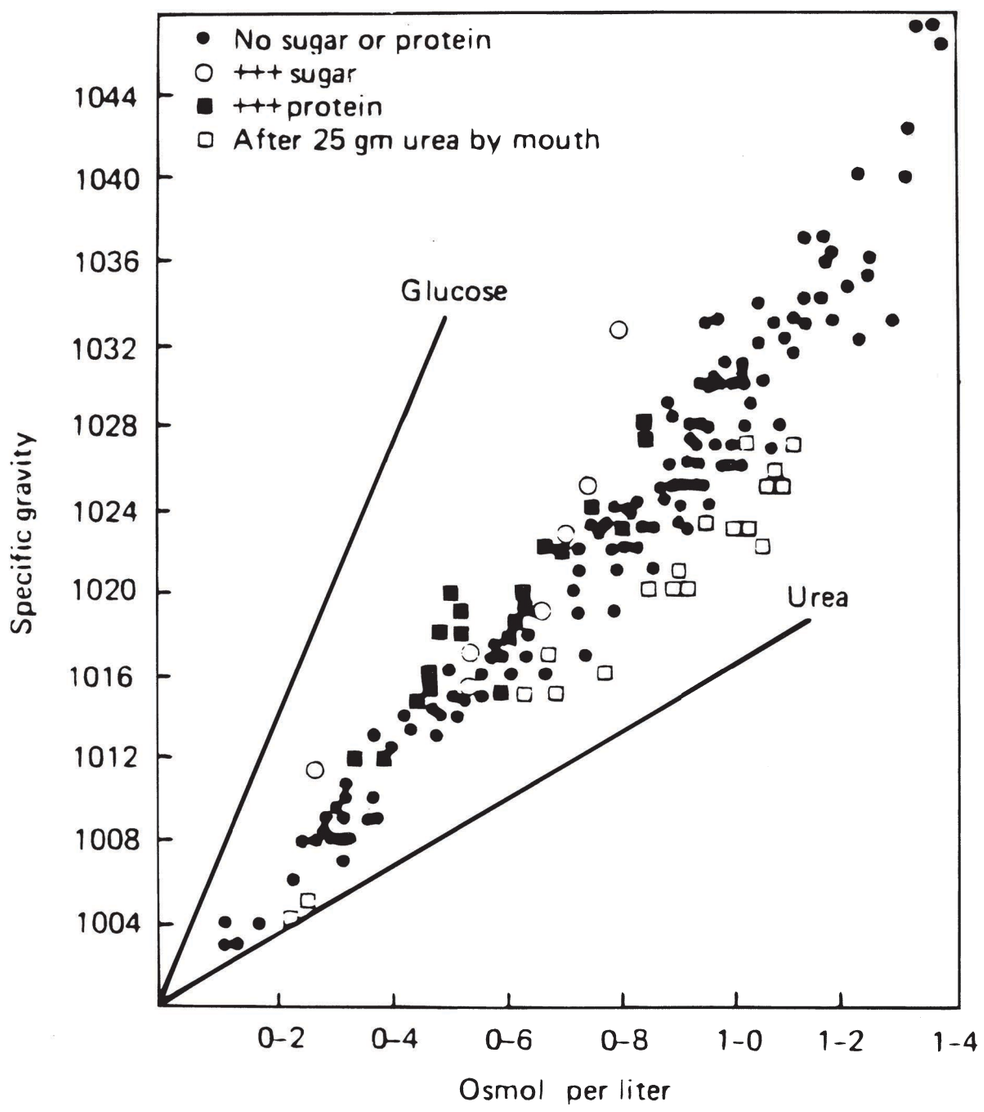

FIGURE 9.13 Relationship between specific gravity and osmolality of the urine. Different urine samples are shown as follows: *small filled circles*, with no sugar or protein; *large open circles*, 3+ sugar; *small filled squares*, 3+ protein; *large open squares*, after 25 g of urea by mouth. The lines show the relation between specific gravity and osmolality for glucose and urea solution. (From Miles BE, Paton A, de Wardener HE. Maximum urine concentration. *Br Med J.* 1954;2:901, with permission.)

up to 425,000 RBCs in urine in a 12-hour period.[444] Subsequent investigators have reported excretion rates in healthy individuals that range from 5,000 to 8,000 RBCs per mL of urine.[447,448] One study revealed that RBCs in healthy individuals typically exhibit a dysmorphic pattern (speculated, crenated, or with cell membrane blebs or folding), suggesting that RBCs enter the urine through the glomeruli.[449] It is believed that RBCs lose their typical biconcave structures as they pass through glomerular basement membrane and get exposed to osmolality changes in renal tubules.[450,451] The presence of more than two to five RBCs per HPF in the urine on two or more occasions is considered by most to warrant further evaluation.[447,452]

The differential diagnosis of hematuria is broad and it is useful to differentiate between hematuria of glomerular origin and nonglomerular origin. The presence of RBC casts or heavy proteinuria points toward glomerular causes for hematuria. Similarly, the presence of a high number of dysmorphic RBCs (particularly acanthocytes) suggests glomerular hematuria (Figs. 9.14 and 9.15).[453,454] Dysmorphic RBCs are best visualized using a phase-contrast microscope.[455,456] The number of dysmorphic RBCs depends on the type of glomerular disease and is considerably higher in proliferative than in nonproliferative glomerular processes.[457]

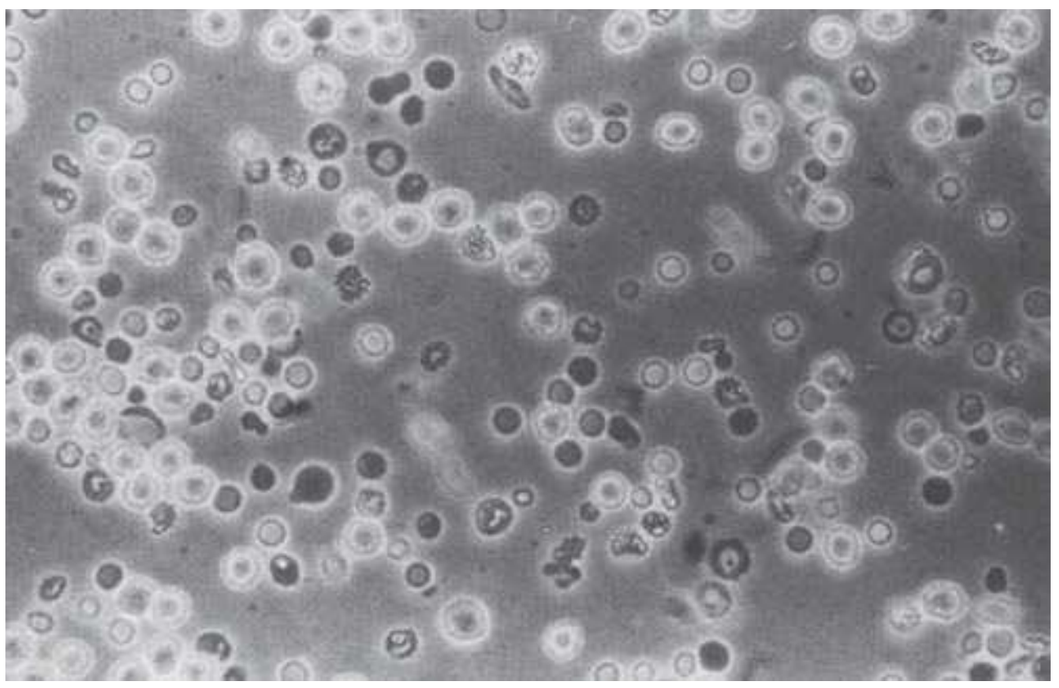

FIGURE 9.14 Urine from a patient with immunoglobulin A glomerulonephritis. Monomorphic and dysmorphic red blood cells are seen. The coexistence of a nonglomerular source of bleeding needs to be considered in such a case, but this "mixed" pattern may be seen in glomerulonephritis in a setting of marked hematuria.

Manual detection of dysmorphic RBCs has a high interobserver variability,[458] and a meta-analysis of 21 studies reported that the average sensitivity and specificity of this technique in detecting glomerular disease in referral centers is between 86% and 90% and 93% and 97%, respectively.[459] Automated red cell volume analysis and urinary flow cytometry have been evaluated as an alternative to the manual examination. The sensitivity and specificity of these techniques in distinguishing between glomerular and nonglomerular hematuria ranges from 98% to 100% and 80% to 91%, respectively, for red cell volume analysis, and 90% to 100% and 87% to 93%, respectively, for urinary flow cytometry.[459,460]

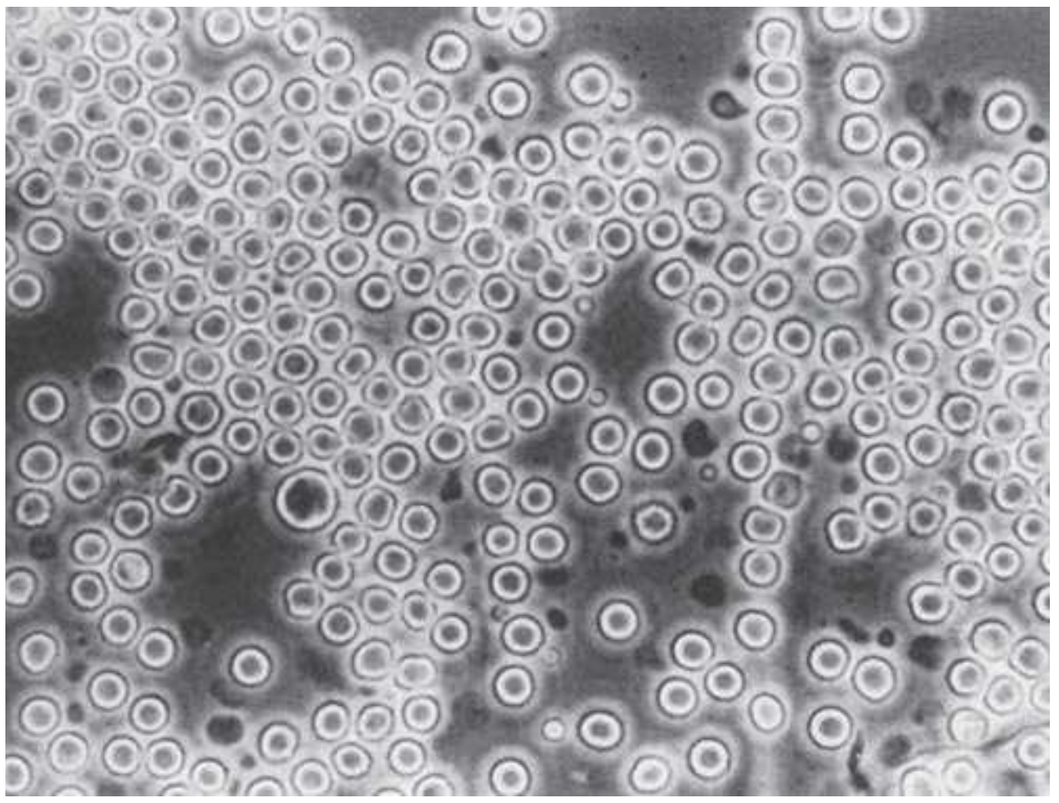

FIGURE 9.15 Monomorphic red blood cells seen in nonglomerular hematuria. Tumors, stones, menstrual contamination, lower urinary tract infection, or contamination of urine sample with blood may give this picture.

White Blood Cells. Small number of WBCs can be seen in urine in the absence of any disease.[461] The presence of five or more WBCs per HPF is usually considered abnormal and requires further evaluation.[462,463] Pyuria, or the presence of WBCs in the urine, implies inflammation in or around the kidneys or urinary tract. The most common cause of pyuria is urinary tract infection.[464] In addition, pyuria may also be seen in interstitial nephritis, glomerulonephritis, acute allograft rejection, and during conditions such as gastroenteritis or acute appendicitis that cause inflammation around the urinary tract. The presence of casts or heavy proteinuria suggests kidney involvement.

Neutrophils are the predominant WBCs found in the urine. They are easy to identify due to the presence of granular cytoplasm and multilobed nuclei (Fig. 9.16). Urine lymphocytes may be seen in acute allograft rejection but their detection requires special staining that is not widely used in clinical practice.[465,466] Urine eosinophils are known to be associated with allergic interstitial nephritis and can be identified using either Hansel's or Wright's stain.[467] Hansel's stain is preferred as it is much more sensitive than the standard Wright's stain.[468] Urine eosinophils are reported either qualitatively or as a percentage of total cells in the sediment. Greater than 1% is considered positive and the predictive value for acute interstitial nephritis increases with higher percentage.[467] For more than 1% urine eosinophils, the sensitivity and specificity for acute interstitial nephritis have been reported as 63% and 93%, respectively.[468] More recent data, however, suggests that sensitivity may be much lower and range between 25% and 40%.[469,470] These inconsistent data have raised doubts about the utility of testing for urine eosinophils.[470] It is advisable that clinicians consider urine eosinophil count as only one of the many diagnostic clues for allergic interstitial nephritis and interpret the results in the context of the patient's clinical presentation, drug exposure history, and other urinalysis and laboratory findings.

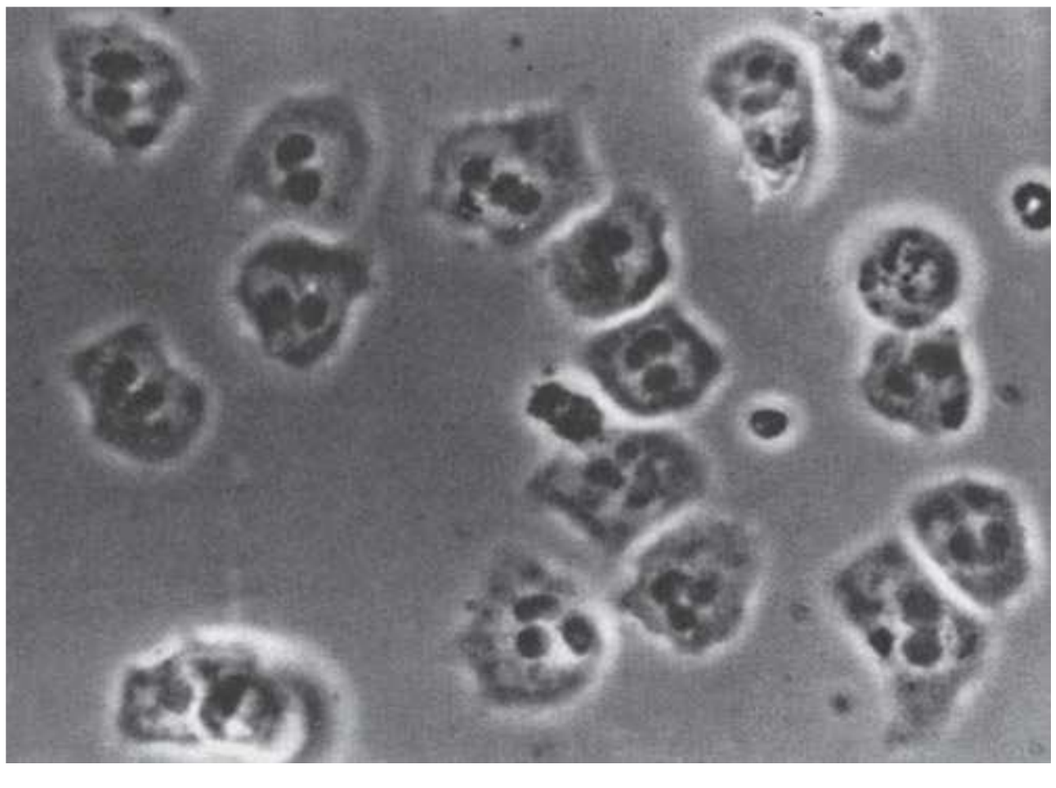

FIGURE 9.16 The multilobed nuclei of the leukocytes, clearly seen on phase-contrast microscopy.

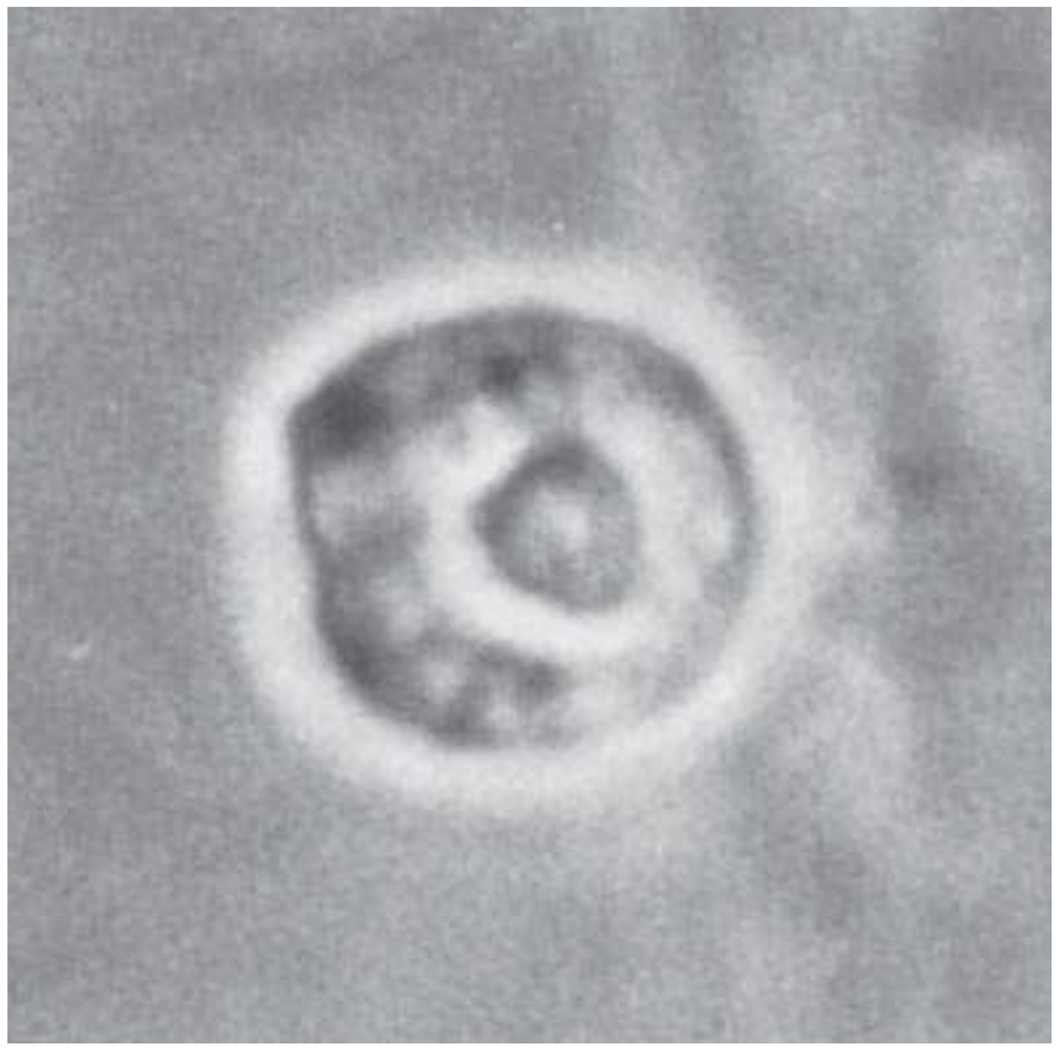

FIGURE 9.17 Renal tubular epithelial cell with a single nucleus, clearly seen on phase-contrast microscopy.

Epithelial Cells. Small numbers of epithelial cells may be present in normal urine. Renal tubular epithelial cells originate at the level of nephrons. They are mononuclear and are larger than neutrophils (Fig. 9.17). Higher numbers of tubular cells indicate tubular damage from conditions like acute tubular necrosis, interstitial nephritis, and allograft rejection. Transitional epithelial cells are derived from renal pelvis, ureters, or bladder. A higher number of transitional epithelial cells is associated with urinary tract infections, tumors, and stones. Squamous epithelial cells are of urethral or vaginal origin. They are large, flat cells with small nuclei. A higher number of squamous epithelial cells indicates urine contamination with the contents of skin, urethra, or vagina.

Casts

Casts are cylindrical structures formed when Tamm-Horsfall glycoprotein (uromodulin) secreted by the epithelial cells of the thick ascending limb of loop of Henle precipitates and takes the shape of renal tubules.[250] Casts are formed in distal tubules and collecting ducts as these are the areas where precipitation is most likely to occur. High tubular fluid concentration, low urinary flow rate, high sodium concentration, heavy proteinuria, and acidic milieu favor cast formation. Trapping of cells, other proteins, and fat within the cast matrix give rise to different types of casts with variable clinical significance (Table 9.13).

Hyaline Casts. Hyaline casts are colorless and are composed of THP alone. They may be seen in the absence of any kidney disease, especially during periods of volume depletion, diuretic use, fever, exercise, or stress.[250,471,472] Hyaline casts are usually seen with other types of cells or casts during disease states.

9.13 Clinical Significance of Cells and Casts in Urine Sediment

Clinical entity	Urinalysis finding									
	Hyaline casts	RBC	RBC Casts	WBC	WBC casts	Tubular cells	RTE casts	Granular casts	Fat[a]	Waxy casts
No kidney or urinary tract disease	+/−	−	−	−	−	−	−	−	−	−
Urinary tract disease not involving kidney	+/−	+/−	−	+	−	−	−	−	−	−
Cystic kidney diseases, urinary tract or kidney neoplasms	+/−	+	−	+/−	−	−	−	−	−	−

[a]Free fat, oval fat bodies, fatty casts.
RBC, red blood cell; WBC, white blood cell; RTE, renal tubular epithelial cells.

Granular Casts. Granular casts are formed when proteins or cellular debris are trapped in the Tamm-Horsfall matrix.[473] In fine granular casts, granules are predominantly composed of filtered proteins and appear small and regular. In coarse granular casts, granules are predominantly composed of degenerated cells and appear large and irregular. A few fine granular casts may be seen in the absence of any kidney disease, but the presence of more than a few fine granular casts or of coarse granular casts indicates kidney disease.

Granular casts are usually nonspecific and can be seen in many different glomerular or tubular disorders. A special type of granular cast, called deeply pigmented or muddy-brown cast, is considered to be the characteristic urine sediment finding of acute tubular necrosis.

Red Blood Cell Casts. RBC casts are formed when RBCs leak into the tubules through damaged glomerular or tubular basement membrane gets trapped in the Tamm-Horsfall matrix.[443] RBC casts are considered pathognomonic for glomerular disease, and many RBC casts suggest glomerular inflammation associated with a proliferative glomerulonephritis. RBC casts can occasionally be seen in other parenchymal diseases like pyelonephritis and renal infarction. A careful examination of the sediment is essential when glomerular hematuria is suspected as RBC casts may be very sparse and contain only few cells. The cells within the casts may also show varying degrees of disruption and degeneration (Fig. 9.18) making it difficult to distinguish from more common coarsely granular casts.

White Blood Cell Casts. WBC casts are formed when WBCs leak into the tubules through damaged tubular or glomerular basement membrane and are trapped in the Tamm-Horsfall matrix.[443] The presence of WBC casts suggests tubulointerstitial inflammation, either from infection in the case of pyelonephritis or from toxins or drugs in the case of interstitial nephritis. Rarely, WBC casts may also be seen in acute glomerulonephritis.

Renal Tubular Epithelial Cell Casts. Renal tubular epithelial cell casts are formed when tubular cells slough from the tubular basement membrane and are trapped in the Tamm-Horsfall matrix. These casts are markers of tubular injury and most commonly are seen in acute tubular necrosis or interstitial nephritis.

Pigment Casts. Hemoglobin, myoglobin, bilirubin, and, rarely, melanin may form casts. Hemoglobin casts have a characteristic brownish hue and are coarsely granular in appearance. These casts are formed either from the degradation of RBC casts, or from free hemoglobinuria in patients with intravascular hemolysis. Myoglobin casts appear similar to hemoglobin casts and are associated with rhabdomyolysis. Bilirubin casts are yellow-brown in color and may be seen in patients with hyperbilirubinemia. Melanin casts are extremely rare and may be seen in patients with melanemia and melanotic tumors. They are coarsely granular and have dark brown or black color.

Broad and Waxy Casts. Broad casts are usually colorless and four to five times wider than typical hyaline casts. They are formed in tubules that are dilated as a result of atrophy and fibrosis of surrounding interstitium. Waxy casts (Fig. 9.19) are similar to broad casts in size, highly refractile, smooth, and waxy in appearance. Broad casts and waxy casts are seen in people with advanced kidney disease, and may reflect dilated and hypertrophic tubules in this condition.

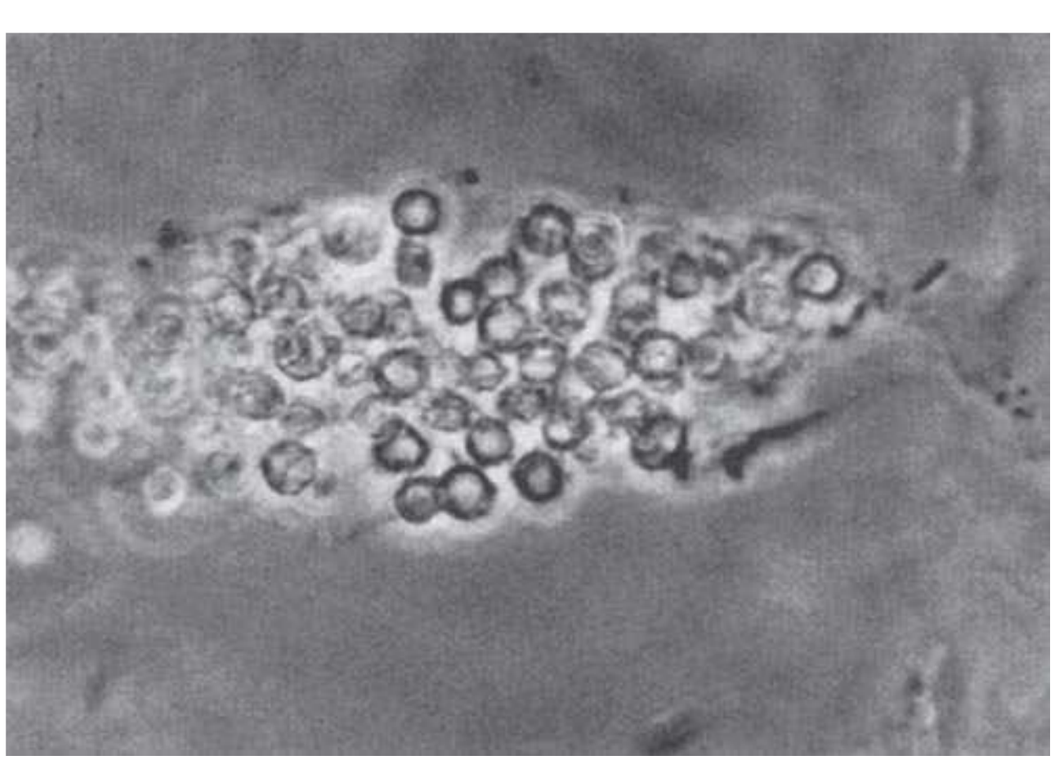

FIGURE 9.18 A red blood cell cast. Much of the hemoglobin from cells has already disappeared.

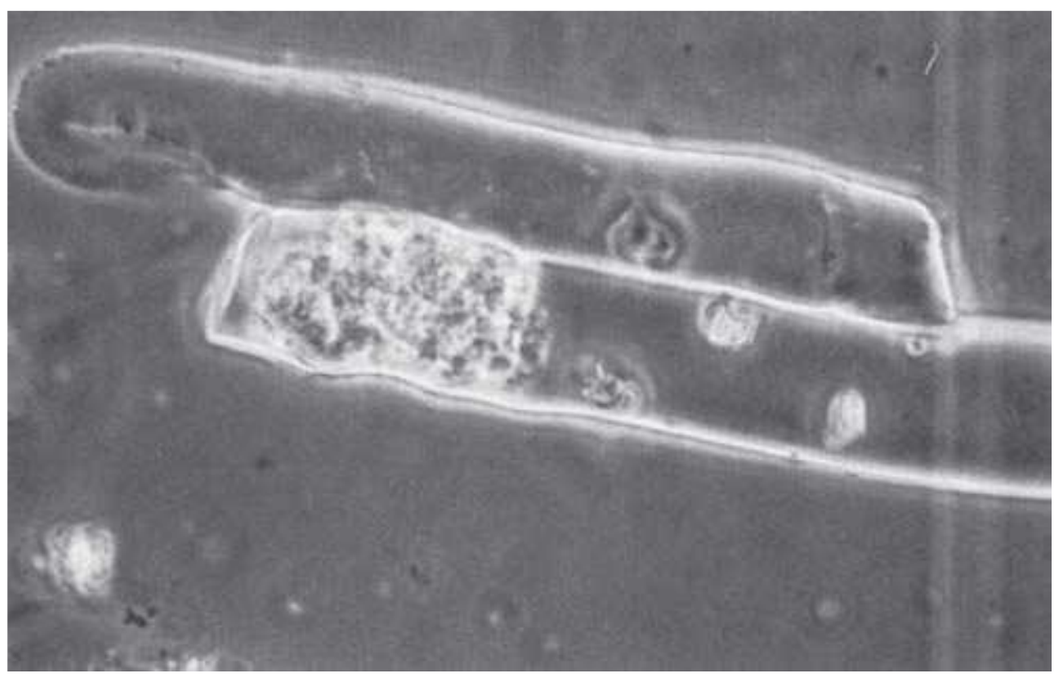

FIGURE 9.19 A waxy cast with sharply defined edges. A clump of disintegrating cells is seen at one end.

Urine Fat and Fatty Casts. Urine fat may be observed in the form of free fat globules, oval fat bodies, or fatty casts. Free fat globules are spherical in shape, yellowish in color, variable in size, and may exist in isolation or as fat clusters. When fat globules are taken up by tubular cells or macrophages, then they are described as oval fat bodies. When fat globules are trapped within the Tomm-Horsfall matrix then they are called fatty casts. Fat globules with cholesterol or cholesterol esters are anisotropic and have a characteristic "Maltese cross" appearance under polarized light (Fig. 9.20). Neutral fats like triglycerides are isotropic, do not polarize, and are identified using special stains like Sudan III or oil red O dye.

Urine fat is typically associated with heavy proteinuria and nephrotic syndrome.[474] It may also be

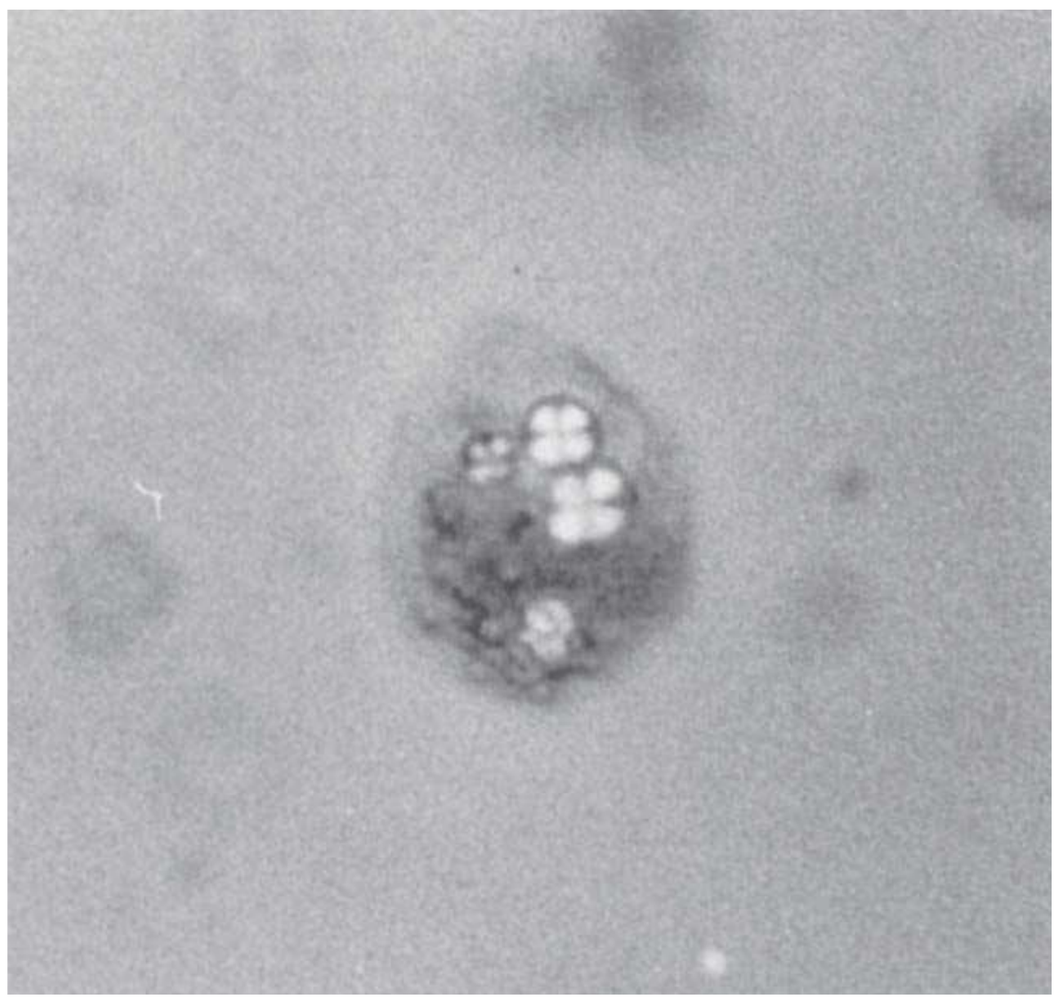

FIGURE 9.20 An oval fat body viewed under polarized light with a classic "Maltese cross" appearance.

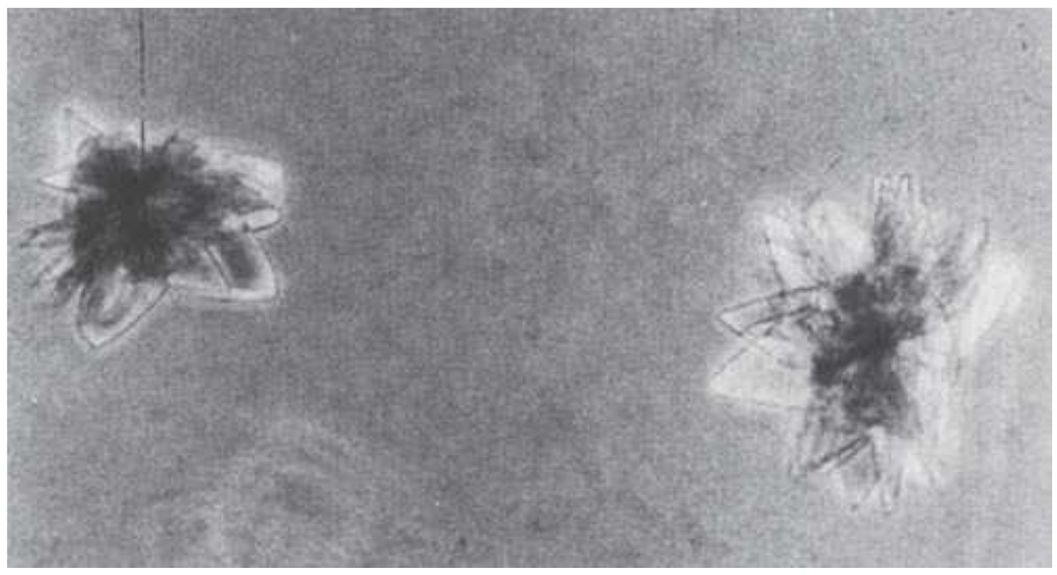

FIGURE 9.21 Uric acid crystals.

seen in polycystic kidney disease and fat embolization syndromes.[475,476]

Crystals

Crystals are common urine sediment findings that are of limited clinical importance in most settings. The identification of crystals, however, can provide important diagnostic clues while evaluating patients with nephrolithiasis, metabolic disorders, or toxin- or drug-induced AKI. Urine pH, crystal morphology, and examination under polarizing light helps to differentiate between different types of urinary crystals (Figs. 9.21 to 9.24). The characteristics of urinary crystals and their associated clinical conditions are described in Table 9.14.

Microorganisms

Bacteria, fungi, protozoa, and parasites may be seen in unstained urine either as a result of contamination or infection. The presence of WBCs suggests infection, and kidney involvement should be suspected if WBC casts or casts embedded with microorganisms are present. Estimation of

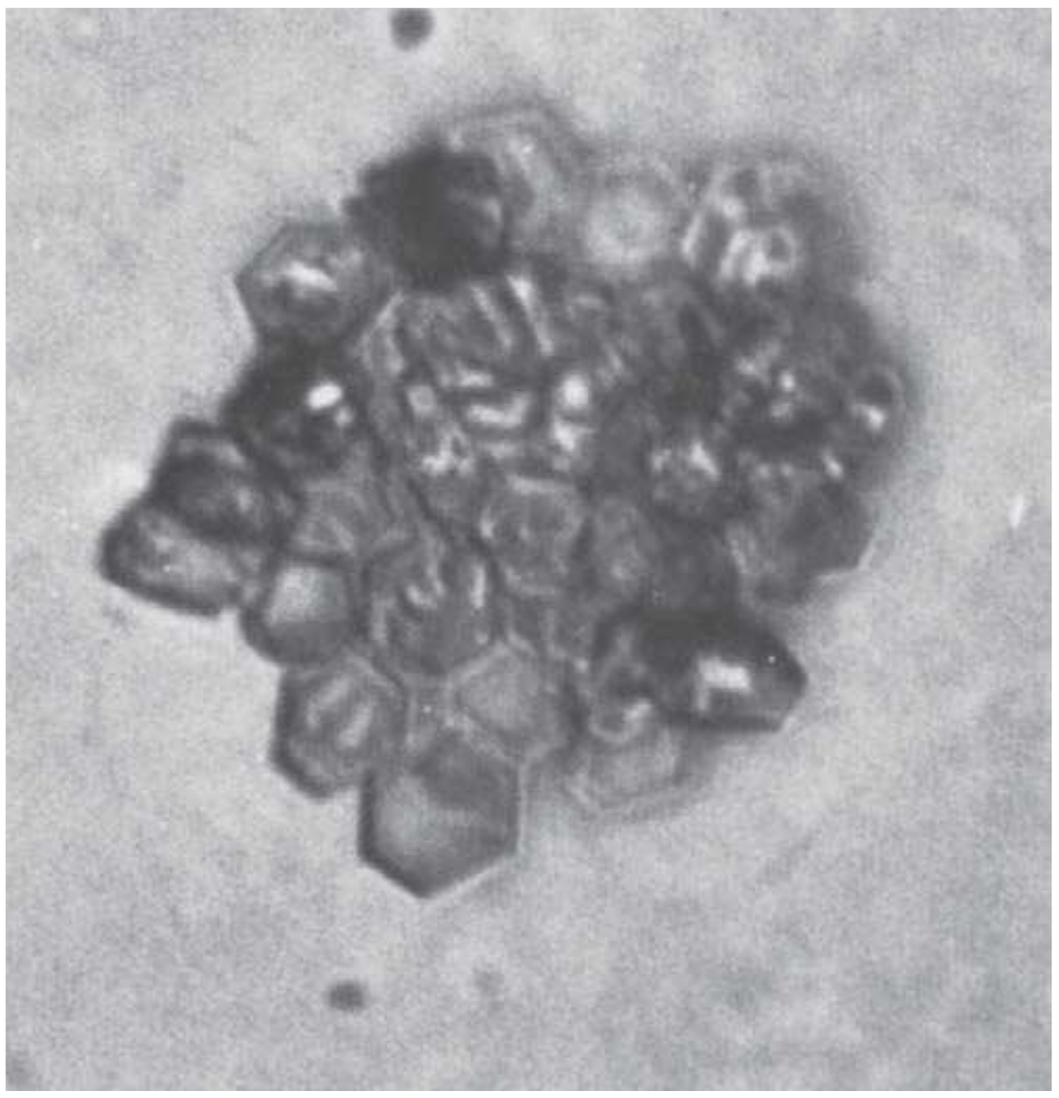

FIGURE 9.23 A conglomeration of cystine crystals from a patient with cystine stones. The typical benzene rings can be seen along the edges.

bacterial count is usually done after Gram staining of the uncentrifuged urine sample. Fungal elements like Candida may be seen both in its yeast and hyphal forms. Trichomonas vaginalis is the most common protozoan found in the urine and has a teardrop shape with motile flagellum. Schistosoma haematobium may be seen in urine in areas of Africa and the Middle East where schistosomiasis is endemic.

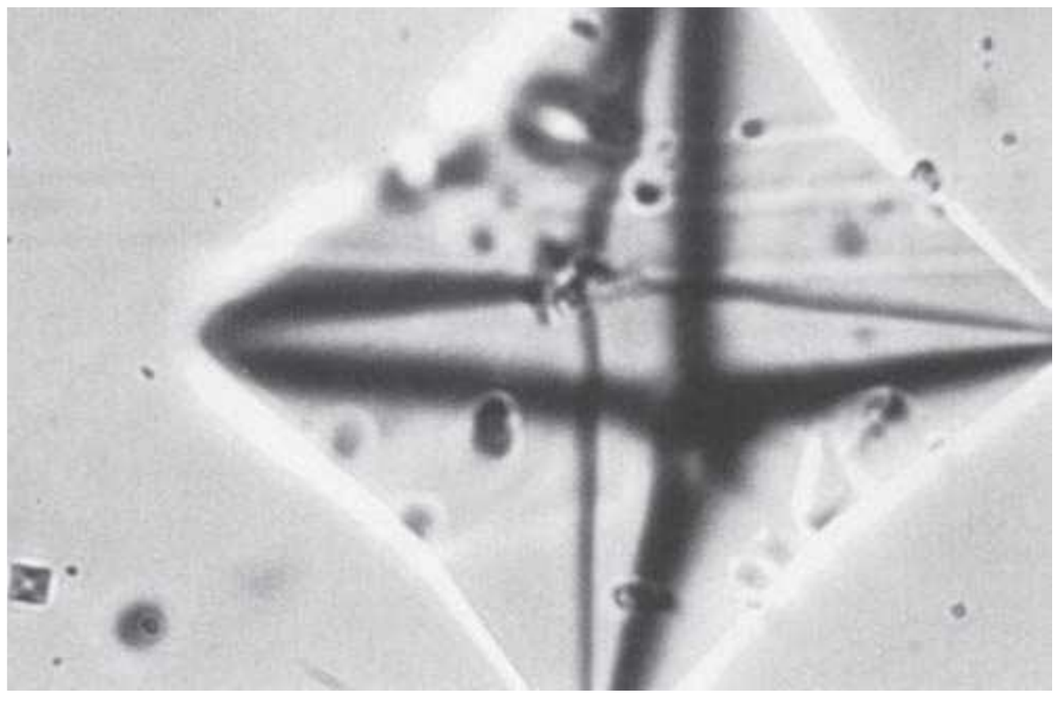

FIGURE 9.22 A very large calcium oxalate crystal. Its large size is obvious when this crystal is compared with the small calcium oxalate crystal (*bottom left corner*).

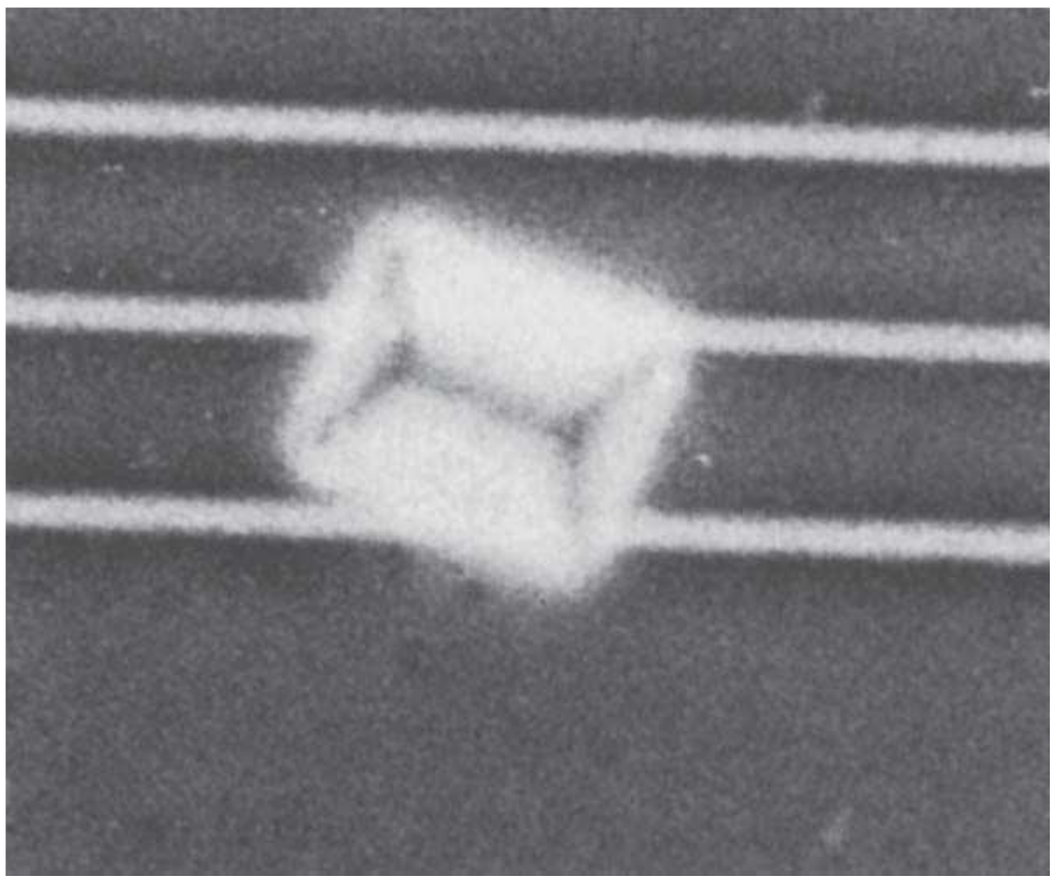

FIGURE 9.24 A triple phosphate crystal with a typical "coffin-lid" appearance, commonly seen in association with infection.

9.14 Urinary Crystals

Type	Description			Associated Clinical Condition
	Shape	Favorable pH	Polarizing Ability (Yes/No)	
Uric acid	Pleomorphic (amorphous, rhomboid prisms, rosettes, needles)	Acidic	Yes	Normal urine, nephrolithiasis (rarely)
Sodium urate	Amorphous	Acidic	Yes	Normal urine, nephrolithiasis (rarely)
Bihydrated calcium oxalate (Weddellite)	Bipyramidal or envelop	Acidic	No	Normal urine, nephrolithiasis (rarely)
Monohydrated calcium oxalate (Whewellite)	Dumb-bell, oval, or biconcave	Acidic	Yes	Nephrolithiasis (rarely), ethylene glycol intoxication
Amorphous phosphate	Amorphous	Alkaline	No	Normal urine, nephrolithiasis (rarely)
Calcium phosphate (hydroxyl-apatite or brushite)	Pleomorphic (prism, starlike, needle)	Alkaline	Yes	Nephrolithiasis (rarely), hyperparathyroidism (rarely), hypercalciuria (rarely)
Magnesium-ammonium-phosphate (triple phosphate or struvite)	Coffin lid or pyramid	Alkaline	Yes	Normal urine, urinary tract infection by urea-splitting bacteria
Calcium carbonate (Calcite)	Dumb-bell, small sphere with radial striations	Alkaline	Yes	Normal urine
Cystine	Hexagonal plate	Acidic	Yes	Cystinosis
Leucine and tyrosine	Yellow sphere (leucine), and brown needles (tyrosine)	Acidic	Yes	Severe liver disease, tyrosinosis, maple syrup disease
Cholesterol	Thin rectangular plate with a square notch corner	Non-pH dependent	Yes (slightly)	Heavy proteinuria
Bilirubin	Needle, red-brown sphere	Non-pH dependent		Conjugated hyperbilirubinemia
Ammonium biurate	Yellow-brown sphere with stria and spicules (thorny apple)	Alkaline	Yes	Normal urine, severe liver disease or portosystemic shunting (rarely)

(continued)

9.14 Urinary Crystals (continued)

	Description			
Type	**Shape**	**Favorable pH**	**Polarizing Ability (Yes/No)**	**Associated Clinical Condition**
Sulfadiazine	Pleomorphic, rosette	Acidic	Yes	Drug use or overdose
Sulfamethoxazole	Sphere, plate, rosette	Acidic	Yes	Drug overdose
Amoxicillin	Broom brush or sheave	Acid	Yes	Drug overdose
Ciprofloxacin	Pleomorphic (needle, sheave, star, fan, butterfly)	Alkaline	Yes	Drug use or overdose
Acyclovir	Needle	Acidic	Yes	Drug use or overdose
Indinavir	Platelike, fan-shaped, starburst	Acidic (may be seen in physiologic pH)	Yes	Drug use, may cause nephrolithiasis
Contrast agent	Platelike		Yes (slightly)	Contrast use
